The axilla is regarded topographically as the hair-bearing hollow below the shoulder, the anterior wall of which is made up of the fibers of the pectoralis major and minor muscles and whose posterior wall consists of the subscapularis, teres major, and tendon of the latissimus dorsi muscle. It is defined by an anterior axillary fold, which is formed by the lateral border of the pectoralis major muscle; a posterior axillary fold, which is formed by the lateral border of the latissimus dorsi muscle; and a medial border, which is formed by the serratus anterior muscle on the chest wall. The axilla is, of course, the location of the major depot of lymphatic drainage from the breast parenchyma. It is within the hollow of the axilla that lymph nodes are clinically palpated and surgically extirpated.

How are the breast and axilla separated from surrounding structures?

The fascial envelope of the breast consists of a fragile superficial layer that is continuous with the superficial abdominal fascia of Camper below and the superficial cervical fascia above. It is separated from the skin by a layer of subcutaneous fat of variable thickness. This fascial plane is relatively avascular, separating as it does the subdermal veins and arteries from larger vessels coursing over the superficial breast. Where the breast overlies the pectoralis major, the fascia is essentially

indistinct from the superficial fascia of the muscle, although a loose areolar plane, the retromammary space, separates the two. The deep fascia of the pectoralis major, like the superficial fascia of the breast, is continuous with the abdominal fascia below and the axillary fascia superiorly and laterally. It fuses with the sternum medially and the clavicle superiorly.

Another deep fascial layer, the clavipectoral fascia—a fusion of layers that are attached to the clavicle, the subclavius muscle, the pectoralis minor, and suspensory ligaments of the axilla, which are attached to the axillary fascia—is of particular surgical importance. Also known as the *costocoracoid fascia*, the *deep pectoral fascia*, or the *clavicoaxillary aponeurosis*, it encompasses the pectoralis minor muscle and attaches to and surrounds the subclavius muscle beneath the clavicle. Its most medial extent is a thickening referred to as *Halsted's ligament*, which traverses the tiny space separating the medial clavicle and the first rib where the subclavian vessels submerge. Laterally, the clavipectoral fascia unites with the anterior layer of the pectoralis major fascia and inferiorly with the axillary fascia, which forms the hollow of the axilla (Fig. 24–3). The fusion of the clavipectoral fascia and the pectoralis major fascia covers the serratus anterior muscle, whereas the axillary fascia continues laterally as the fascia of the latissimus dorsi. The surgical significance of the clavipectoral fascia derives from the access to the vascular and lymphatic anatomy of the axilla that its division allows for the surgeon.

The breast is essentially a subcutaneous structure with a significant component of fat. Its support comes largely from the fibrous bands linking the skin with the deep fascia over the underlying muscles, particularly the pectoralis major. These suspensory ligaments of Cooper are intact in young and nulliparous women but may become stretched and weakened with age, in obesity, or after multiple pregnancies. Although this may lead to an apparent distortion of the topographic

landmarks in many patients, breast tissue continues to be confined to its normal anatomical landmarks.

How does topographic anatomy relate to the planning of incisions?

Topographic anatomy is relevant not only to the accurate clinical assessment of patients but also to planning surgical approaches to breast disease. The major topographic considerations in surgery for breast cancer relate to the appropriate placement of incisions in both the breast and axilla to provide optimal access and exposure of surrounding structures in order to allow appropriate extirpation of disease while at the same time achieving a satisfactory aesthetic result. In the past, incisions in the breast for cancer were largely limited to diagnostic biopsies, not definitive excisions. Their placement was considered almost exclusively in relation to the location of subsequent mastectomy scars, with little regard for cosmetic results or for appropriate surgery for cancer when breast conservation was planned, and certainly no regard for the use of adjuvant radiation therapy in conjunction with such breast-conserving surgery. The aesthetic consequences of where an incision in the breast was placed were invariably considered in the context of excisions for benign lesions. In this regard, periareolar incisions were used as often as possible. When this was not feasible, surgeons were directed to follow the direction of Langer's lines, originally described in the 19th century as the directions of least skin tension.⁵ These were represented in diagrams emanating circumferentially from the central areolar edge. Incisions placed along Langer's lines were considered particularly appropriate in younger premenopausal patients without breast ptosis for whom the surgical excision of benign lesions, such as fibroadenomas, is common. They came to be regarded as the appropriate lines along which incisions should be placed in the breast to minimize the tension that might be exerted on the skin, thereby optimizing the resulting scar. Conversely, radially placed incisions were regarded as inappropriate for the excision of benign lesions.

In planning incisions for carcinomas already diagnosed by needle biopsy, however, other considerations become relevant. Although periareolar incisions and incisions along Langer's lines may be optimal, lines of least skin tension with the patient in an upright position may not always correspond to Langer's lines, particularly in the peripheral extensions of the medial and lateral breast. Certainly in older patients, the lines of least tension are likely to correspond to the more transversely oriented direction of collagen fibers described by Kraissl.⁷ In certain instances, even radially placed incisions may be optimal, particularly if an elliptical skin resection with underlying breast parenchyma is required. For example, incisions placed medially along lines of skin tensions are often in a radial alignment. For centrally placed lesions, periareolar or para-areolar incisions conforming to Langer's lines may well be appropriate. However, in the inferior breast, a radial incision may exert less downward traction on the nipple-areolar complex, particularly when skin is elliptically removed along with underlying breast tissue, whereas incisions near or at the inframammary crease or high in the upper breast are best placed in a curvilinear transverse direction. Likewise, in the upper outer quadrant or tail of the breast near the axilla, a circumferential incision, along which both Langer's lines

and lines of resting skin tension coincide, may be optimal (Fig. 24-4).

As breast conservation has become increasingly used for ductal carcinoma in situ (DCIS), broader areas of extirpation may be required. In many instances, they are more optimally placed in radial directions, to both encompass the often radial, lobar distribution of disease and minimize distortion of nipple-areola symmetry with the contralateral breast that may result from a wide excision of breast parenchyma and overlying skin with resultant significant traction on the central breast. In planning incisions, it is often best to consider the direction of placement with the patient in an upright position, whereby the pectoralis major exerts traction on the breast and overlying skin to create lines of tension. This does not occur when the patient is supine and the breast is distorted by lateral and posterior gravitational pull. For carcinomas medial and lateral to the nipple-areolar complex in particular, major ductal segments may be better encompassed by transversely placed incisions, particularly when ellipses of skin, along with underlying parenchyma, are required, thereby preventing inversion of skin at the incision site. In all instances of segmental excisions for cancer, therefore, planning must consider the issues of encompassing the disease and maintaining breast symmetry as well as the issue of placement of the cutaneous scar.

In the axilla, incisions are optimally placed in lines of minimal skin tension. Natural skin lines can be demonstrated throughout the axilla, particularly below the hair-bearing

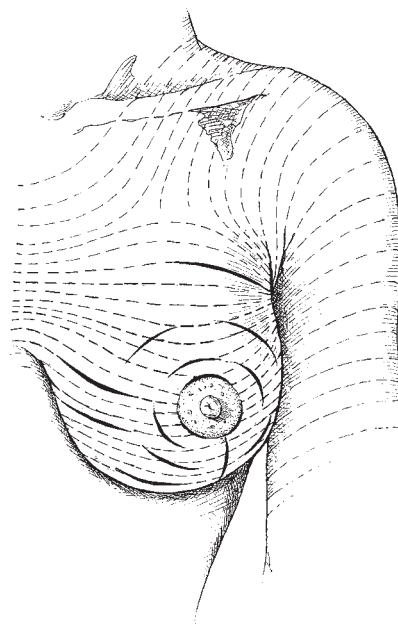

Figure 24-4 Skin incisions for breast cancer excisions, particularly in the older or ptotic breast, are best placed along lines of minimal skin tension. This is especially so in the medial breast. Inferiorly located lesions may even be best excised through radial incisions to avoid traction and distortion of the nipple-areolar complex, particularly when skin or significant segments of underlying breast parenchyma are included in the excision. In the central breast, periareolar or para-areolar incisions, conforming to Langer's lines, are appropriate.

area, where they provide excellent anatomic access and are largely unnoticeable within the confines of the axillary hollow (Fig. 24–5).

SURGICAL ANATOMY OF THE BREAST AND AXILLA

What is the arterial supply to the breast?

The breast receives its blood supply from the internal mammary artery; the highest (supreme) and lateral thoracic arteries; the pectoral branch of the thoracoacromial artery; the intercostal arteries in the third, fourth, and fifth intercostal spaces; and branches of the subscapularis and thoracodorsal

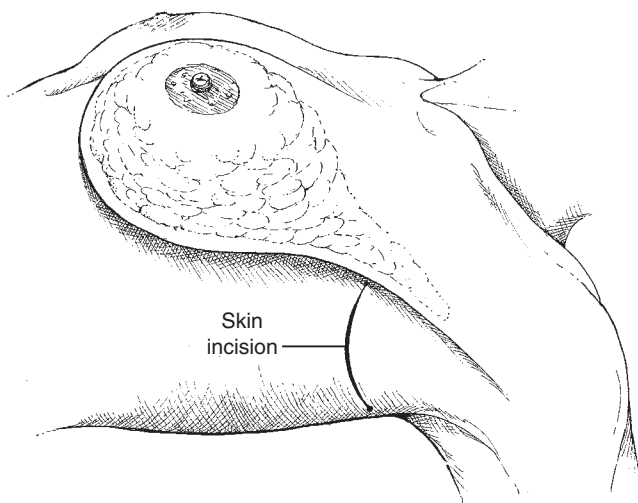

Figure 24–5 Skin incision placement in the axilla.

arteries. The perforating branches of the internal mammary artery supply the greatest source of blood to the breast through the fourth and fifth anterior intercostal branches, as well as through branches in the upper sixth intercostal spaces, all of which perforate the pectoralis major muscle (Fig. 24–6). The lateral thoracic artery of the axillary artery emerges lateral to the pectoralis minor muscle and then supplies the serratus anterior, pectoralis major and minor, and subscapularis muscles, giving off lateral mammary branches as well to the breast.

Although the major blood supply to the breast comes from the internal mammary and lateral thoracic arteries, branches to the breast may arise from the highest (supreme) thoracic artery, which arises at the highest point in the traversal of the axillary artery before it submerges beneath the subclavius muscle; from the thoracoacromial artery, which branches into the pectoral artery, supplying branches to both the pectoralis major and minor muscles; and from the subscapularis artery, which becomes the thoracodorsal artery and which may give branches to the breast. The intercostal perforating arteries of the fourth, fifth, and sixth intercostal spaces provide additional arterial blood to the central and lateral breast. The extensive anastomotic connections between these sources of arterial blood, particularly the internal mammary and lateral thoracic arteries, provide the breast with a rich arterial network. This allows great latitude in planning operative approaches and incisions in the treatment of breast cancer, provided there is careful adherence to basic surgical principles.

What is the venous drainage of the breast?

Venous drainage parallels the arterial supply to the breast. Medially, the perforating branches enter the internal mammary vein, which then joins the brachiocephalic vein. Laterally, the axillary vein, which lies medial to the axillary artery, receives one or two pectoral branches from the breast.

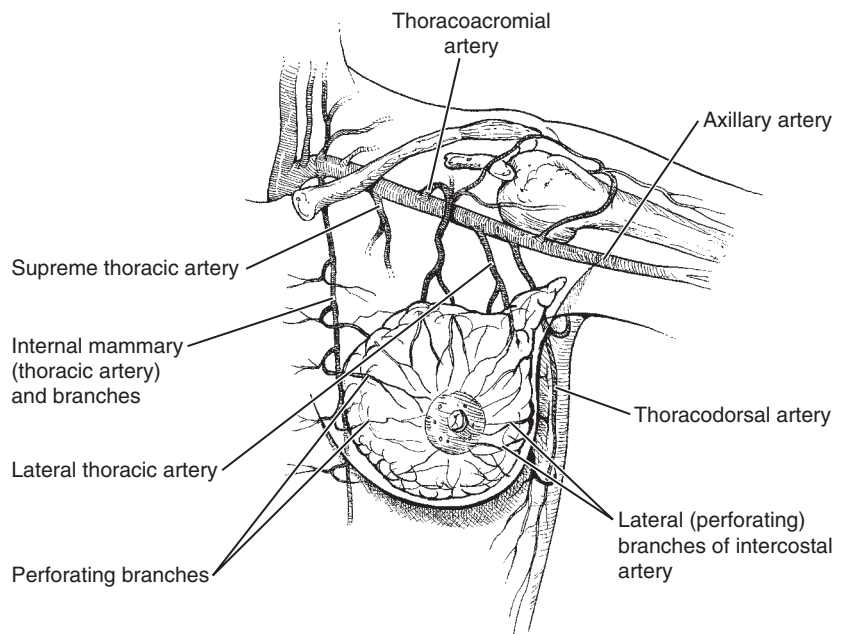

Figure 24–6 Arterial supply to the breast.

It is not uncommon to encounter a bifurcate axillary vein. To avoid division of the lower branch, or even both branches, it is obviously important to recognize this anomaly as being equivalent to a single axillary vein and not to mistake it for a branch or branches off the trunk of the major axillary vein. When its path continues proximal to the first rib, the axillary vein becomes the subclavian vein.

The intercostal veins communicate anteriorly with the internal mammary veins and thereby with the brachiocephalic vein and posteriorly with the vertebral veins, which enter the azygos veins and ultimately the superior vena cava. Venous drainage through the internal mammary vein and branches of the axillary vein has been cited as the route that leads to dissemination of breast cancer to the lungs and more distal systemic sites, whereas drainage through the intercostal veins, which communicate with the vertebral venous system, has likewise been cited as leading to dissemination to the vertebrae.⁸

How is the lymphatic drainage of the breast defined?

As discussed in Chapter 21, lymphatic anatomy and its relation to the spread of breast cancer has long been a focus of intense study. In recent decades, the principles that determine lymphatic flow have been reassessed as previous concepts on the centrifugal lymphatic dissemination of cancer by direct permeation have been largely disproved, and most recently, mapping of the lymphatics has become a widespread practice in the highly selective management of regional lymph nodes.

The lymphatics of the skin begin in a subepithelial plexus located in the papillary dermis, from which they communicate with a subdermal plexus. In the central breast, these cutaneous and subcutaneous lymphatics merge with the subareolar plexus of Sappey, which also receives lymphatic

vessels from the nipple and areola. This subareolar plexus communicates with the lymphatics of the lactiferous ducts, which in turn flow to the peribular and deep subcutaneous lymphatic plexus. Recent studies provide supportive evidence that the skin of the breast and the parenchyma of the breast share the same lymphatic drainage network.⁹

Lymph flows toward the regional lymph nodes and parallels the direction of blood flow in the major veins. The concept that lymphatic flow from the parenchyma of the breast moves centripetally toward the subareolar plexus has been largely refuted.¹⁰ Lymphatic flow is unidirectional to regional lymph nodes, and the rich anastomotic connections between lymphatics enable areas of obstruction to be bypassed and thereby allow lymph to flow unimpeded through the other valveless lymphatics toward the regional lymph nodes. Early radioisotope studies using colloidal gold (¹⁹⁸Au) estimated that 97% of lymphatic flow is toward the axilla and the remainder to the internal mammary nodes.¹¹ Recent studies by Kern on both dye and radioisotope migration following subareolar injection have demonstrated that one or at most two major lymphatic channels carry the dye or isotope to the axilla.^{12,13} Clearly, the lymphatic drainage pattern of the breast to the axilla is a unified system terminating in a very focal lymphatic channel or channels and anatomically focal lymph nodes.

How is the lymph node drainage of the breast defined?

The lymph node drainage of the breast has been subdivided by various methods for surgical, pathologic, and prognostic purposes. The classic reviews of Haagensen¹⁴ and others, drawing on the studies of Poirier and Cunéo¹⁵ as modified by Rouvière,¹⁶ divided the lymph nodes anatomically into six groups (Fig. 24–7). The largest of these is the central group of

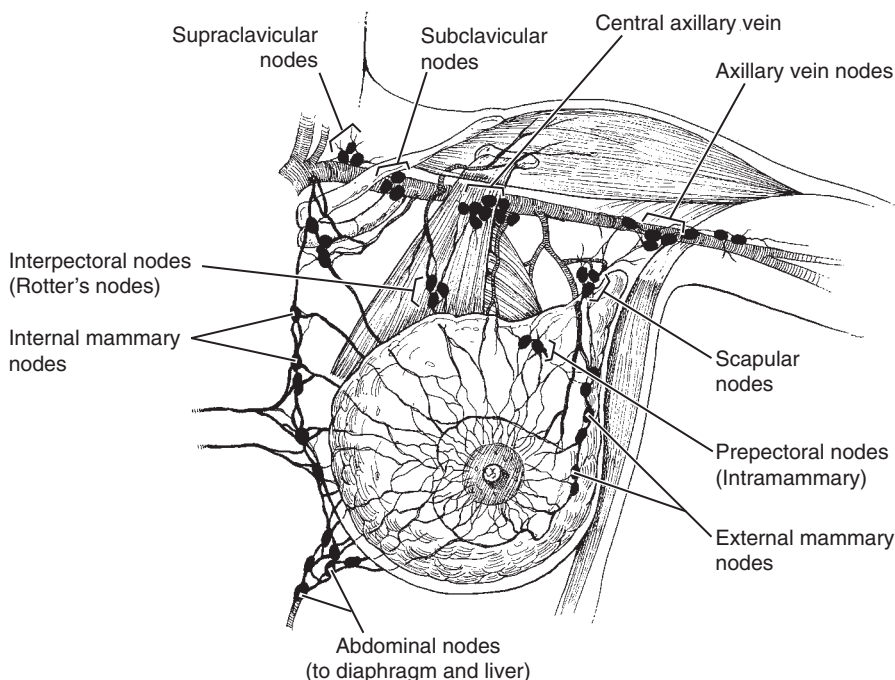

Figure 24–7 Anatomic distribution of venous circulation and lymph nodes draining the breast.

nodes located in the lateral hollow of the axilla and easily palpated against the chest wall. The second largest group is the axillary vein nodes lying on the caudal and ventral surfaces of the lateral axillary vein. The other groups are the scapular nodes along the thoracodorsal branches of the subscapular vessels, also in the lateral axilla; the external mammary nodes lying beneath the lateral edge of the pectoralis major muscle along the medial border of the axilla and following the lateral thoracic artery on the chest wall from the second to sixth ribs; the subclavicular nodes lying on the caudal and ventral surfaces of the medial axillary vein beneath the subclavius muscle; and the interpectoral nodes, also known as *Rotter's nodes*, located between the pectoralis major and minor muscles. In addition, a prepectoral lymph node or nodes may occasionally be found high in the upper outer quadrant of the breast, simulating a well-defined lesion on mammography. Intercostal lymph nodes may also be located along the posterior thoracic cavity within the intercostal spaces and may receive lymphatic drainage from the breast.

The internal mammary lymph nodes have historically been of particular surgical interest because their location sets them apart from traditional en bloc resections to encompass breast cancer. These nodes receive lymphatic flow from vessels that accompany the perforating blood vessels piercing the pectoralis major and intercostal muscles. These nodes also receive lymphatic vessels from the liver, diaphragm, rectus sheath, and upper rectus abdominis muscle.

The internal mammary nodes lie close to the internal mammary vessels in extrapleural fat in the first six intercostal spaces. Studies have demonstrated that the greatest concentration of nodes is in the first three intercostal spaces.¹⁰ Although internal mammary lymph nodes have traditionally been regarded as receiving lymphatic drainage from the medial and central portions of the breast, studies have demonstrated that lymphatic drainage from any quadrant may go to the internal

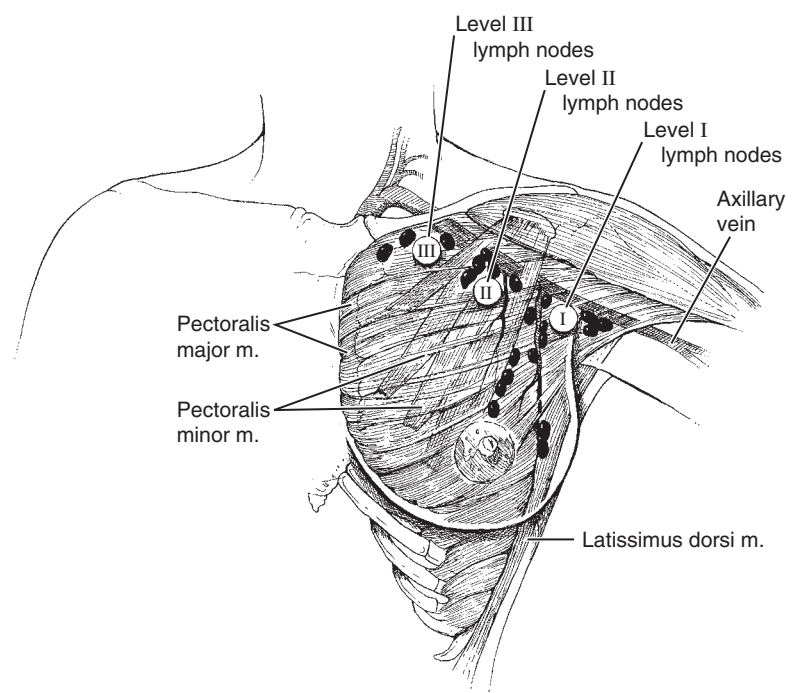

mammary lymph nodes¹⁷ and, as noted, does so in less than 3% of instances in which patterns of lymphatic drainage have been studied.¹¹

Rarer sites of lymphatic drainage, usually as a second-echelon site when direct nodal drainage sites are occluded, are the intercostal lymph nodes of the posterior chest wall near the termination of the ribs, the anteriorly located diaphragmatic nodes beneath the lower sternum at the xiphoid, and contralateral internal mammary nodes.

How are axillary lymph nodes defined for pathologic orientation?

For the purpose of pathologic analysis, axillary lymph nodes have been divided by anatomic levels reflecting the traditional concept that nodal metastases extend sequentially from lateral to medial¹⁸ (Fig. 24–8). The greatest number of lymph nodes are contained in what has been referred to as level I, the grouping of nodes located below the axillary vein and between the lateral border of the pectoralis minor muscle and the anterior border of the latissimus dorsi muscle. Included in this group are the lower external or lateral mammary nodes, which follow the course of the lateral thoracic artery on the chest wall from the second to sixth rib. The level II lymph nodes are those that lie behind the pectoralis minor muscle, and the level III nodes are those nodes that lie below the axillary vein from the medial border of the pectoralis minor muscle to the submergence of the axillary vein below the subclavius muscle at the costoclavicular (Halsted's) ligament. When identifiable, Rotter's interpectoral nodes are apart from these divisions but may be dissected with the pectoralis minor fascial attachments and incorporated into the axillary nodal contents when an axillary dissection is performed. If excised, however, it is often as a separate specimen.

Figure 24–8 Schematic division of axillary lymph nodes.

What is the sentinel lymph node?

The most recent efforts to define the lymphatic drainage pattern of breast cancer have resulted in the concept of the sentinel lymph node. The sentinel node is that lymph node to which lymphatic drainage from the location of the cancer in the breast is directed. It is the node most likely to contain a metastasis if nodal dissemination has occurred. The concept originally evolved from an appreciation that areas of skin have patterns of drainage to specific lymph nodes within the regional nodal basin to which lymphatic vessels are directed, as first described by Cabanas for the treatment of penile cancer,¹⁹ and most convincingly defined by the pioneer studies of Morton and colleagues, in the treatment of cutaneous melanoma, using vital blue or isosulfan blue dyes.²⁰ Subsequent applications to the breast using both dye and radioisotopes in conjunction with a gamma probe as lymphatic mapping agents confirmed the validity of the concept for mapping the potential specific location of lymph node metastases from breast cancer.^{21,22}

What is the neural innervation of the breast?

The innervation to the skin and parenchyma of the breast occurs by way of the medial and lateral intercostal nerves, although a portion of the superior breast, as well as the upper chest wall, comes from branches of the supraclavicular nerve, which originates as a branch of the cervical plexus. Innervation to the nipple is from the lateral and medial branches of the fourth intercostal nerve. The lateral portions of the breast and chest wall receive sensory innervation from the lateral branches of the third through sixth intercostal nerves, whereas the medial aspect of the breast and sternal area receives its innervation from the medial branches.

What anatomically related neural structures are encountered in the axilla?

Several major nerves require identification during surgical procedures that include dissection of axillary lymph nodes (Fig. 24–9). Neuromuscular branches that are related anatomically to the axilla and underlying chest wall muscles include, most significantly, the brachial plexus, the divisions of which lie above and posterior to the axillary vein. In the lateral axilla, the brachial plexus has three divisions, or cords, which surround the axillary artery. Appreciation of the location of the brachial plexus is obviously basic to the surgical anatomy of the axilla, but in addition, it cautions the surgeon against undue stretching during efforts at positioning the arm to create exposure of the axillary contents. Rapid, forceful, or prolonged movement of the arm, superiorly and posteriorly in particular, may create excessive tension on the brachial plexus, creating brachial plexitis, a potential source of significant morbidity and even paralysis.

Traversing the axillary contents is a branch of the second intercostal nerve identified as the intercostobrachial nerve, which supplies sensory fibers to the medial aspect of the upper arm, axillary skin, and upper lateral breast. It arises as the lateral cutaneous branch of the ventral primary ramus of T2. It

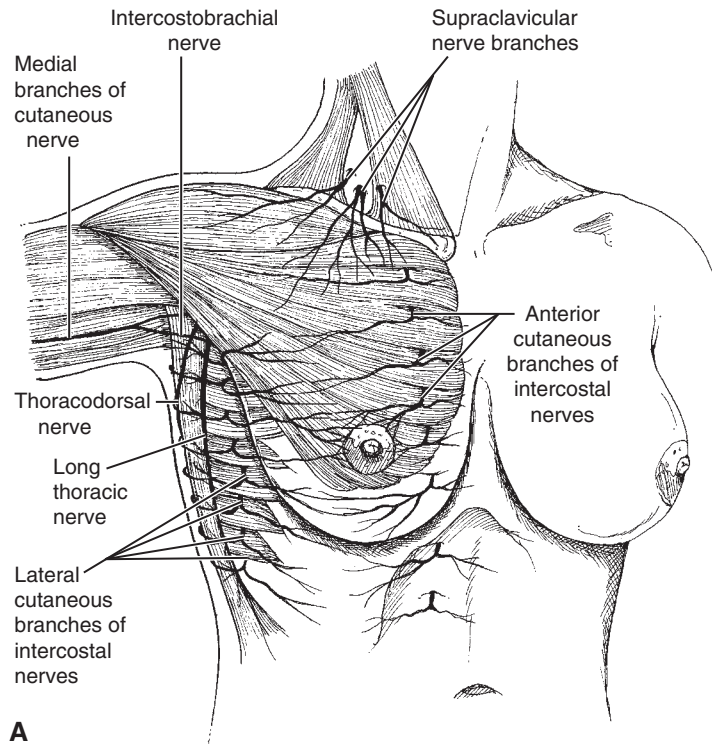

pierces the external intercostal muscle of the second intercostal space lateral to the lateral border of the pectoralis minor muscle and then the serratus anterior, before crossing through the lymphoadipose tissue of the axilla over the border of the latissimus dorsi muscle toward the medial upper arm. In its course through the posterior axilla, it joins with a filament of the medial brachial cutaneous nerve, the smallest branch of the medial cord of the brachial plexus. An additional contact has been described with the posterior brachial cutaneous branch of the radial nerve.²³ The size of the intercostobrachial nerve and the extent of its distribution appear to vary inversely with the size and distribution of the medial brachial cutaneous nerve. Anastomoses between the intercostobrachial and the lateral cutaneous branches of T1 and T3 have often been described. The anastomosis between intercostobrachial and medial brachial cutaneous nerves is rather constant and may be represented by two or more filaments connecting them. Anastomosis with branches of T1 and T3 and the posterior brachial cutaneous branch of the radial nerve appear to be occasional or inconstant findings. The intercostobrachial nerve may give off two or more branches as it traverses the axillary fat.

The medial brachial cutaneous nerve is the smallest branch of the medial cord of the brachial plexus. It is formed from fibers arising from cord segments C8 and T1 or from T1 alone. Descending through the axilla, it pierces the brachial fascia at about the middle of the arm. It innervates the skin and subcutaneous tissues of the posterior aspect of the lower third of the arm as far as the olecranon. The nerve may occasionally arise as a branch of the medial antebrachial cutaneous nerve, which also arises from C8 and T1. It may receive fibers from T2 or T3, or both, or it may be absent. Because the medial brachial cutaneous nerve frequently has direct contacts and varies inversely in size with the intercostobrachial nerve, it should be considered as often sensory to the axilla as well.

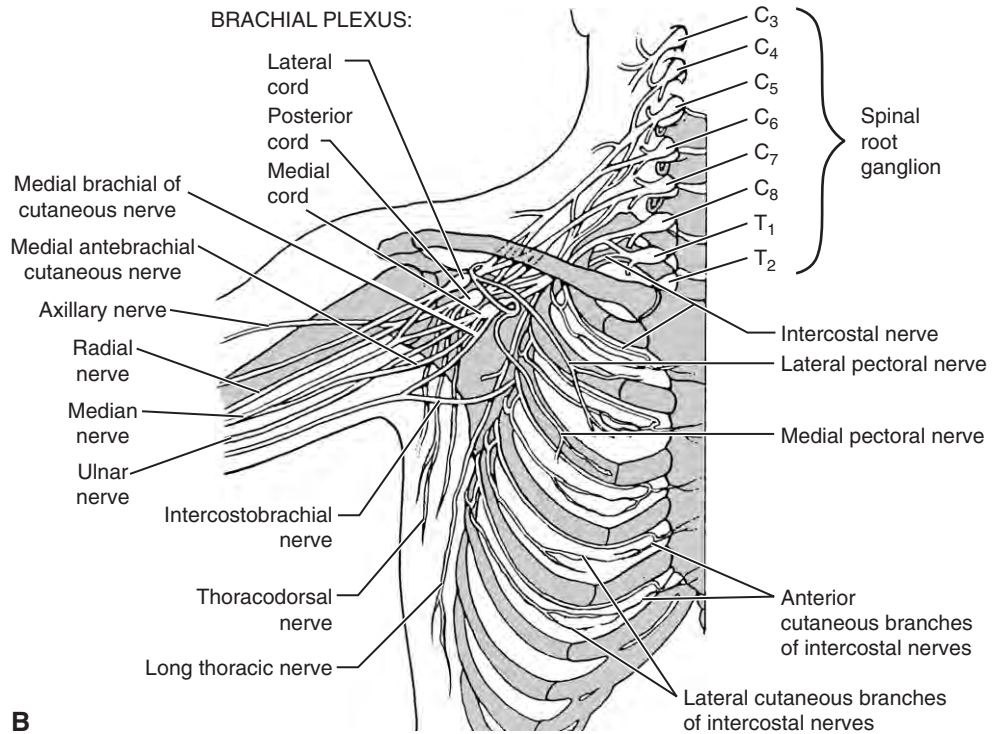

A second intercostobrachial nerve often arises from the lateral cutaneous branch of T3. It supplies the axilla and medial side of the arm.²⁴ The first intercostal nerve provides a lateral cutaneous branch, which supplies the skin of the axilla and may communicate with the intercostobrachial nerve and the medial brachial cutaneous nerve as well. Denervation or division of the intercostobrachial nerve will lead to numbness of the skin in the upper medial arm and axilla. The anesthesia that is produced is often interpreted by the patient as a sense of swelling in the upper medial arm. Paresthesias will be of varying degrees, distribution, and duration owing to the richness of the sensory nerve supply to the axilla and upper arm.²⁵

The pectoral nerves are particularly relevant to the surgical treatment of breast cancer that requires axillary dissection. These nerves innervate the pectoral muscles, and denervation can lead to atrophy and a loss of muscle mass that can compromise the aesthetic benefits of breast conservation. Likewise, reconstructive procedures after mastectomy clearly benefit from an intact pectoralis major and the resulting normal chest wall and axillary contour as a foundation.

The lateral pectoral nerve arises medial to the pectoralis minor muscle, its designation as a lateral nerve deriving from its origin in the lateral cord of the brachial plexus. It can be clearly delineated when the pectoralis minor is divided, emerging medial to the muscle before it branches out to innervate the lower portion of the pectoralis major muscle. The medial pectoral nerve emerges lateral to the pectoralis

A

B

Figure 24-9 A and B, Neurologic structures of the chest wall and axilla.

minor muscle, the medial designation likewise deriving from its origin in the medial cord of the brachial plexus. It innervates the pectoralis minor muscle, but a branch also innervates fibers in the lateral border of the pectoralis major muscle. This branch is often accompanied by a small artery and vein. Its preservation ensures conservation of the lateral pectoralis major muscle.

The two additional nerves of importance in breast cancer surgery are the thoracodorsal nerve, or nerve to the latissimus dorsi muscle, and the long thoracic nerve. The thoracodorsal nerve lies on the subscapularis muscle accompanied by the thoracodorsal artery and vein. Preservation of the entire thoracodorsal neurovascular bundle maintains the viability of the latissimus dorsi muscle, which may be required for reconstructive purposes, as detailed in Chapter 25. Division of the nerve paralyzes the latissimus dorsi muscle and functionally weakens internal rotation and abduction of the arm, whereas no noticeable clinical deformity may result. Patients may complain of a limitation of backward rotation when attempting to touch the scapular region of the back. Of greater functional significance is the long thoracic nerve, which is formed over the most superior component of the serratus anterior from nerves arising in the fifth, sixth, and seventh roots of the brachial plexus. The long thoracic nerve lies superficial and lateral to the surface of the serratus anterior muscle, gradually moving medially to submerge below the fascia of the muscle at the fourth or fifth intracostal space. Division of this nerve creates a deformity that is commonly referred to as a “winged scapula” owing to paralysis of the serratus anterior muscle. This may be a source of significant cosmetic and functional morbidity. During efforts to raise or use the arm for pulling, the scapula, without tension exerted on it by a functioning serratus anterior, will no longer be drawn forward but will instead awkwardly rise outward.

PREOPERATIVE CONSIDERATIONS

What is the best timing for definitive breast cancer surgery?

The window of time between diagnosis and definitive surgery for breast cancer has widened as surgeons and patients in the last decades have expanded the opportunities for careful discussion and consideration of options in therapy. Initially there had been no evidence that two-staged procedures—with excision of the primary lesion preceding, by days or weeks, wider excisions, mastectomy, or axillary nodal procedures—adversely affected outcome, but with the availability of diagnostic strategies by needle biopsy instead of surgical biopsy, even this issue has been largely obviated. However, for lesions that are clinically occult and only detected mammographically, and for which needle biopsy is inconclusive either for a malignant diagnosis or to establish an entirely noninvasive or low-grade invasive diagnosis, or for lesions that are poorly defined by palpation, mammographically, or by additional radiographic criteria, excision as an initial procedure to allow full histopathologic assessment is often desirable. This information is essential before considering therapeutic options, in particular the appropriateness of breast conservation and

axillary staging. Furthermore, when a decision has been made by the patient and physicians that mastectomy is appropriate, reconstruction is often discussed and consultation with a reconstructive plastic surgeon encouraged.²⁶

If the patient elects to have breast reconstruction, it is best performed at the same time as mastectomy. There is no evidence that this adversely affects the ability to detect recurrent disease.²⁷ Immediate reconstruction also may broaden the choice of reconstructive techniques, allow greater flexibility in reconstruction technique, optimize the aesthetic results, and eliminate an additional procedure also requiring general anesthesia. There is ample evidence as well that immediate reconstruction provides a positive psychological balance to the negative impact of mastectomy.^{28,29} All of these decisions on surgical therapy are best made in a reasoned rather than a rushed and emotionally charged setting, which may be the case when an inappropriate emphasis is placed on the importance of making an immediate decision on treatment.

The identification of patients at risk for developing negative psychological sequelae after breast cancer surgery allows the employment of appropriate psychosocial support during the decision-making process before definitive therapy. Patients with an antecedent psychiatric history, those with little or no family or social support, those with a history of substance abuse, those who express excessive anxiety, fear, or depression, and certainly those expressing suicidal thinking should be helped and encouraged to seek appropriate consultation.^{30,31} As discussed in Chapter 38, this information must often be sought by the initial consulting surgeons and physicians.

The influence of the menstrual cycle has entered the discussion of treatment because some studies purport to demonstrate that performance of surgery at certain times in the menstrual cycle may be an independent prognostic variable. Concern theoretically hinges on enhanced metastatic potential during phases of unopposed estrogen stimulation. Immune function may be reduced during this follicular phase of the cycle, whereas the increase in progesterone during the luteal phase (days 15 to 36) may down-regulate estrogen receptors and alter normal cell—and presumably cancer cell—proliferation. The first such report by Hrushesky and associates³² suggested that surgery during the week before or just after menstruation was associated with increased survival, compared with surgery at other times in the menstrual cycle. Senie and associates^{33,34} reported an improvement in survival for patients with nodal metastases if surgery was performed in the luteal phase, compared with the follicular phase, of the menstrual cycle. Other studies supported this observation for patients with metastases.^{35–38} However, Spratt and associates³⁹ obtained a statistically significant improvement in survival when surgery was performed between days 7 and 20 of the menstrual cycle, although only 40 cases were reviewed. These were retrospective analyses, and since then, there have also been reports that were either inconclusive or failed to demonstrate any effect of the timing of surgery in the menstrual cycle on patient outcome.^{40–48}

A prospective analysis of patients operated on at different times in the menstrual cycle and adjusted for multiple prognostic factors would be required to arrive at a reliable resolution of the issue of the timing of surgery in relation to menstruation. It would clearly require large numbers of patients. Ongoing studies may help resolve some of the conflicting conclusions and concerns expressed to date.^{49,50} As the

surgical treatment of breast cancer at the present time may be fragmented by multiple procedures that include needle biopsy, segmental excision, sentinel lymphadenectomy, axillary dissection, segmental re-excision, or mastectomy and reconstruction, the timing of surgical procedures based on the menstrual cycle may be logistically formidable. One study purporting to show a survival benefit from surgery performed in the progestogenic phase (days 0 to 2 and 13 to 35) found no such benefit if definitive surgery was performed in a single procedure.⁵¹ Adjusting surgery to fit into a specific menstrual time frame requires a very clear definition of potential benefits from appropriately controlled studies that objectively assess the precise timing within the menstrual cycle and the uniformity of surgical treatment, staging, and adjuvant therapies.

SURGICAL BIOPSY

Heightened public awareness of breast cancer and mammographic screening, and a proliferation of radiographic techniques with increasing applicability to diagnosis, particularly sonography, have led to a tremendous increase in breast biopsies. More than 20 million women have mammography or sonography annually in the United States,⁵² leading to more than 1 million breast biopsies for nonpalpable breast abnormalities.⁵² For palpable lesions, as well as radiographically detected nonpalpable lesions, percutaneous needle biopsy, as discussed in Chapter 17, has become the preferred diagnostic approach for most breast lesions. Needle biopsy techniques fulfill the need for an expeditious diagnosis of the formidable numbers of detected findings with minimal invasiveness.

The two principal indications for breast biopsy are a dominant, palpable mass that is not a simple cyst on aspiration, or a suspicious lesion detected radiographically. Treatment of breast cancer requires an unequivocal cytologic or histologic diagnosis, and this can be accomplished by needle biopsy for palpable lesions as well as for most nonpalpable lesions with the appropriate use of radioguidance. The availability of needle biopsy has greatly expanded the indications for biopsy for many vaguely perceived dominant findings even in the absence of radiographic correlation. There are instances, however, in which surgical biopsy is indicated because of an inability to use needle biopsy techniques or because of inadequacies in the histologic material provided by needle biopsy techniques. Even when clinical impression, radiographic criteria, and fine-needle aspiration are used to assess a solid breast mass, physicians must be sensitive to the vagaries of clinical and radiographic criteria and the pitfall of hypocellular fine-needle aspiration biopsy results' leading to a failure to diagnose cancer.⁵³

What are the indications for surgical breast biopsy?

Surgical biopsies are required if the location of the radiographic findings precludes or complicates needle biopsy, when the histologic material obtained by needle biopsy is inadequate for definitive diagnosis, and when physical findings warrant biopsy but there is no defined radiographic

abnormality and needle biopsy has failed to establish a diagnosis concordant with the physical findings.

Excision with preoperative wire localization and specimen radiographic confirmation may be required for lesions in the immediate retroareolar region of the breast or posteriorly near the underlying chest wall. Inadequate compression of the breast in these locations and the associated technical limitations of core biopsy or vacuum-assisted core biopsy as a result often preclude the use of such needle biopsy techniques in these instances. Likewise, very faint clusters of microcalcifications may make stereotactic imaging and specimen radiographic correlation uncertain and therefore necessitate surgical excision for diagnosis.

Patients may also require surgical biopsy as a result of inadequate histologic sampling following core needle biopsy. Certain diagnoses require complete excision of the target lesion. Most important in this regard is the diagnosis of atypical ductal hyperplasia on large core needle biopsies that are most often performed for clustered microcalcifications, but occasionally for mass lesions. Numerous studies have shown in 13% to 50% of cases an upgrade from atypical ductal hyperplasia to DCIS and, rarely, to invasive cancer, when needle biopsy diagnosis is followed by surgical excisional biopsy.^{54–58} The rates of upgrade from atypical ductal hyperplasia may well decrease as large core vacuum-assisted devices become standard for needle biopsy of clustered microcalcifications. Indications for surgical excision in these instances may be further altered in the future.^{59,60} Certainly, patients demonstrating mild or focal atypia and those of advanced age may be appropriately managed with radiographic and clinical follow-up, whereas those with marked atypical ductal hyperplasia, particularly with a broader lesion less optimally sampled or with a past history or significant family history of breast cancer, are more safely assessed with surgical excision.

Other groups of lesions diagnosed by core needle biopsy for which surgical excision has been recommended are atypical lobular hyperplasias and lobular carcinomas in situ (LCIS). They are invariably diagnosed as incidental histologic findings on core biopsy for high-risk radiographic findings, and these diagnoses will likely become more frequent as vacuum-assisted techniques increase the tissue volume retrieved on core needle biopsy. The yield of subsequent carcinoma following core biopsy–diagnosed uncomplicated LCIS has been in the 5% to 10% range.⁶¹ Decision making is often complicated by the coexistent mammographic lesion for which the core biopsy was performed as well as by other coexistent histologic findings.^{62–67} Certainly, women at high risk, particularly with a personal history of breast cancer, and those with coexistent histologic findings that may put them at risk or with associated mammographic findings, might be prudently managed by surgical excision. Whether other patients diagnosed on core needle biopsy can be approached in the same way as patients with coincidentally diagnosed atypical lobular hyperplasia or LCIS on surgical excision remains unresolved.

Papillary lesions diagnosed by core biopsy represent another group for which excision has been recommended. Experience to date has been limited to almost anecdotal instances of carcinoma diagnosed by surgical excision after the diagnosis of a benign papillary lesion.^{64,68,69} If there is a significant residual lesion or a discordance with a suspicious radiologic appearance, or if atypia is present, excision would seem prudent. With increasing sampling from

vacuum-assisted core biopsies, this may become a less problematic issue.

Radial scars represent another group that, if diagnosed by core needle biopsy, is prudently followed by complete excision. The mammographic appearance may be indistinguishable from an infiltrating carcinoma.⁷⁰ The histologic features may be variable, with features of ductal hyperplasia with or without atypia, papillomatosis, and adenosis, leading to its other designation as a complex sclerosing lesion. Because of its histologic heterogeneity and the potential that DCIS may be a component of the entire lesion, as well as its significance as a potential marker lesion for increased risk for breast cancer, excision at the present time is prudent.^{71,72}

Finally, surgical biopsy may be indicated for suspected Paget's disease of the nipple, skin changes suggestive of inflammatory carcinoma, and bloody or serous nipple discharge, all in the absence of any associated radiographic findings.

What is the appropriate biopsy for Paget's disease?

The changes noted in the nipple or nipple-areolar complex with Paget's disease may include erythema, scaling, crusting, or weeping, which may progress to ulceration with an underlying palpable mass. When the nipple-areolar changes are noted, Paget's disease must be suspected and a biopsy performed in conjunction with mammographic assessment for an underlying neoplasm. The biopsy should optimally include a full-thickness wedge of the nipple-areolar complex from an area demonstrating the clinical changes, including underlying ductal tissue. Histology of the crust on the nipple surface, touch preparations, or scrape cytology may fail to demonstrate the diagnostic Paget cells present in the basal epidermal layers.

What is the appropriate biopsy for inflammatory carcinoma?

In the presence of skin changes that suggest an inflammatory cancer, a sample of involved skin should be included for histologic study. Underlying breast tissue should be included as well. The diagnosis of inflammatory carcinoma is most often clinically suspected in the absence of any dominant palpable or radiographic breast density and is histologically established by the finding of dermal and subdermal lymphatic permeation by tumor emboli. Skin thickening may be evident mammographically, corresponding to areas of erythema and peau d'orange, and parenchymal thickening may be seen mammographically as well. As the skin changes reflect dermal lymphatic dilation and hypervascularity, not necessarily corresponding to the presence of carcinoma, areas of dermal tumor permeation may not always be evident on small punch biopsy or surgical skin biopsy specimens. Therefore, a more generous excision of skin may be required in the absence of any breast parenchymal changes, but from an area where the cutaneous evidence of disease is apparent. A high index of suspicion by clinical criteria and an assiduous effort to establish the diagnosis of primary inflammatory carcinoma histologically are required in the absence of any palpable or

radiographic breast changes other than diffuse firmness or a vague diffuse mammographic density.

BREAST-CONSERVING SURGERY

What is the proper term for breast-conserving procedures?

Many terms have been applied to breast-conserving procedures for cancer. These include *lumpectomy*, *wide excision*, *tylectomy*, *segmentectomy*, *segmental excision of the breast*, *segmental mastectomy*, *partial mastectomy*, *tumorectomy*, and *quadrantectomy*. These terms may have different implications for the surgeon and patient. The absence of a uniform nomenclature reflects in turn the absence of a uniform anatomic definition of breast-conserving approaches to cancer. Even the term *quadrantectomy*, which implied removing an entire quarter of the breast, but originating from a desire to excise major lobular components, clearly lacked anatomic precision.

The major goal of breast-conserving surgery at the present time is to appropriately excise the entire lesion along with surrounding breast tissue, the margins of which are free of cancer histologically. The extent of resection surrounding the lesion to optimally achieve margins free of malignant change has not been defined and has great variability depending on the architectural and histologic characteristics of the specific tumor. For this reason, the generic phrases *segmental excision* and *partial mastectomy* would seem more appropriate. The former is likely preferable, as any phrase that includes *mastectomy* may be confusing to a patient desirous of breast conservation.

What is the goal of breast-conserving surgery?

Implicit in all breast-conserving procedures is the recognition that an effort will be made to balance the highest priority of complete excision of the cancer and tumor-free margins with the achievement of an excellent aesthetic result—the major reason for the patient to elect breast conservation. To achieve the proper balance, numerous variables must be considered, among which are tumor size, location, breast size, and the histopathology of the lesion. The failure to arrive at a precise descriptive title for such procedures is therefore understandable, given the potential spectrum in the extent of surgery that might be regarded as appropriate for any given tumor, based on these considerations. Furthermore, with few exceptions, radiation therapy is used as an adjunct to primary local treatment. Although radiation therapy may provide some additional latitude in planning the extent of surgery, it does not abrogate the major goals of surgical treatment. Efforts to avoid additional surgery for patients with close or positive margins using aggressive local radiotherapy as well as systemic adjuvant strategies have been associated with significant breast recurrences.

Recurrence-free survival following breast-conserving treatment therefore may depend on many factors, but available data support tumor-free margins as the benchmark for successful breast-conserving therapy.⁷³⁻⁷⁷ The optimal extent of

excision to achieve histologically clear margins may be further complicated by the limitations and lack of uniformity in histologic margin assessment from one pathologist to the next.^{78,79} A specimen with tumor cells detected focally at a single site may be described as “positive,” whereas one in which there is extensive gross tumor less than 1 mm away from histologically free margins in multiple areas may be described as “negative.” These situations may have different implications for the adequacy of resection and are very different from an incomplete excision, which leaves gross tumor in the breast. The generic use of the terms *positive margins* and *negative margins* undoubtedly gives rise to conflicting views in the literature on the true importance of margin involvement. It is clear, however, that patients with margins histologically clear of invasive or in situ cancer have a lower incidence of recurrence after breast-conserving surgery and radiotherapy.^{80–86} In a study by Frazier and associates⁸⁷ of patients having mastectomy or re-excision after a previous segmental excision, 52.5% of those who initially had involved margins had residual tumor, but, significantly, 26.3% of those who had been evaluated as having clear margins had residual tumor as well. A retrospective study by Smitt and associates⁸¹ of 289 patients with 303 stage I and II invasive carcinomas of the breast treated by breast conservation and radiation found the achievement of negative margins either initially or with re-excision to be the most important predictor of local control. The probability of local control in patients with negative margins was 98% at 10 years, whereas it decreased to 82% in patients with non-negative margin status.⁸¹ Similarly, a study by Mansfield and associates⁸⁸ of 1070 patients treated by breast conservation and radiation, when assessed by multivariate analysis, found positive margin status to be a significant risk factor for local recurrence. In a study from the Joint Center for Radiation Therapy in Boston, of 343 patients with stage I or II breast cancer having radiation therapy as part of breast-conserving treatment with a median follow-up of 10.8 years, 7% with negative or close margins treated with 60 Gy or greater to the tumor bed had a breast recurrence, compared with 14% with focally positive margins and 27% with more extensive margin involvement.⁸⁹ No difference was noted in patients with close margins of 1 mm compared with wider margins (greater than 1 mm). Although the extent of tumor-free breast tissue around a lesion is presently undefined, wider margins in several series have clearly been inversely related to recurrence.^{90,91}

The relationship of positive surgical margins to systemic recurrence is less clear. Nevertheless, positive surgical margins are associated with, if not necessarily causative of, systemic relapse in several studies.^{81–86,92–95} Certainly, efforts to minimize breast disease recurrence would appear self-recommending, and the most significant variable in achieving this goal is tumor-free margins of resection. Even advocates of boost radiation to the tumor bed to optimize tumor control in the preserved breast endorse the advisability of achieving tumor-free excision margins.⁹⁶ Although lesser margins are more likely to provide security for a well-defined, low-grade lesion than for a high-grade invasive lobular or ductal carcinoma surrounded by foci of intraductal carcinoma, for neither lesion has the appropriate margin been clearly defined. Furthermore, the contraction of surrounding tissue that may follow excision can create discordance in the objective assessment of the true extent of margins from the operating room to the pathology laboratory.

Until the issue of the appropriate extent of tumor-free margins is better resolved, an effort by the surgeon to achieve margins of 1 cm around the reference lesion would appear to provide confidence that histologically free margins, despite the inherent limitations of such histologic assessment, are an accurate reflection of the architectural configuration of the reference carcinoma to surrounding tissue. Adjustments in the extent of segmental excision of the breast can be made based on the palpable and radiographic characteristics of the tumor, the location of the lesion, the size and consistency of the breast, the histologic characteristics of the tumor, and the age of the patient. Objective data to provide reproducible guidelines on the appropriate extent of tumor-free margins are likely in the future. As will be discussed, there are several appropriate technical considerations for the surgeon and pathologist, as well as the radiologist, particularly with nonpalpable lesions, that have an impact on achieving complete tumor excision with histologically free margins. In most instances, this should be achievable without adversely affecting the aesthetic goals inherent in breast-conserving treatment.

BREAST CONSERVATION FOR IN SITU CANCER

As detailed in Chapters 21, 22, and 23, surgical approaches to breast cancer have undergone very significant changes in the last decades. This is true for invasive as well as for in situ carcinoma. LCIS, which had long been a source of controversy, in particular underwent reassessment. Such changes were, of course, stimulated both by the increasing support for breast conservation in the treatment of operable breast cancer and by the significant increased incidence of the diagnosis of DCIS, a result of widespread mammographic screening efforts at early detection.

For the treatment of LCIS, as detailed in Chapter 23, the most broadly acceptable approach is that originally proposed by Haagensen,¹⁴ which is nonoperative observation, recognizing that LCIS represents a risk factor for the development of cancer in either breast but is not an obligate precursor lesion for invasive cancer in the reference breast. The reassessment of surgery for DCIS has certainly been more complex. For most of the time that DCIS was recognized as a separate pathologic entity, mastectomy was the standard form of therapy. It remained the gold standard, with disease-free survival approaching 100%. Even mastectomy, however, may be associated with local recurrence and mortality resulting from invasive disease undetected at the time of initial surgery or from residual breast tissue that has the potential for developing invasive cancer.^{97,98} The incidence, however, is no more than 1% to 3%.⁹⁹

Before the last 2 decades, there was no advocacy for treating DCIS by observation following excision, as there was for LCIS. Limited series of patients inadvertently given a benign misdiagnosis following biopsy were untreated for what was subsequently shown to be noncomedo DCIS, with breast recurrences in the 25% to 36% range.^{100–102} Such experiences tend to inhibit enthusiasm for observation as a therapeutic option. Furthermore, as reconstruction became a widely accepted adjunct to mastectomy, it became particularly

applicable to patients with DCIS, who represent a group with a very low risk for regional recurrence and, more recently, an optimal presentation for skin-sparing mastectomy incisions that further facilitate the aesthetic benefits of reconstruction using prosthetic implants or autologous tissue flaps. In earlier reports that considered treatment options, however, there was a lack of reference to the various histologic subtypes of DCIS,¹⁰³ let alone an appreciation of the focal presentation of disease in most patients. Because all DCIS was broadly categorized as one homogeneous group, there was uncertainty as to the appropriateness of breast conservation. Furthermore, patients in earlier series tended to have larger, sometimes palpable forms of the disease.^{104,105} Such lesions would more often be associated with areas of microscopic or frank invasion, even if histologically undetected.⁹⁶

Predictably, the equivalent results for breast conservation compared with mastectomy for stage I invasive cancer of the breast led to an interest in treating noninvasive cancer with breast conservation. The issue, of course, was whether the almost 100% survival with mastectomy could be matched by breast conservation, and, as with patients with stages I and II invasive cancers, to what extent patients should be selected. The answers hinged on several issues, among them the architectural pattern and pathologic characteristics of the noninvasive cancer, the effectiveness and appropriateness of adjuvant radiotherapy, and the impact of these variables on breast cancer recurrence and the natural history of the disease. Other related issues were, and continue to be, the extent of the excision and the ability to diagnose and successfully treat breast cancer recurrence.

What is the impact of multicentricity and multifocality on breast-conserving surgery for ductal carcinoma in situ?

DCIS had been associated with a higher incidence of multicentricity (i.e., DCIS in other quadrants of the breast) than are invasive lesions. As smaller foci of DCIS have been diagnosed, the incidence of multicentricity has been reassessed. The incidence of multicentricity in series that adhere to its definition as carcinoma in other quadrants is about one third.^{98,106} Lagios (see Chapter 8) suggested that multicentricity be defined as a second, separate focus of DCIS at a distance of at least 5 cm from the primary focus. A major reason for reassessment of both the true incidence and the clinical significance of multicentricity is the observation that most recurrences after breast-conserving therapy for DCIS are in the immediate vicinity of the original cancer.¹⁰⁷⁻¹¹¹ In the experience of Silverstein, 97 of 109 local recurrences (89%) were at or near the site of original surgery.¹¹¹ The clinical significance of possible occult multicentricity is therefore subject to debate, particularly because studies have failed to demonstrate any impact of these occult foci on survival. The pattern of breast recurrences after breast-conserving treatment of DCIS within the same quadrant as the primary lesion implicates what might more appropriately be regarded as “residual” disease, rather than multicentricity, in treatment failure.¹¹²

The issue of multifocality of DCIS in the same quadrant of the breast has similarly come under re-evaluation. In the studies by Holland and colleagues,¹¹³ mastectomy specimens were

serially sectioned at distances of 5 mm and radiographically imaged. Each suspicious finding was examined histologically along with an extensive sampling of the quadrant of the reference lesion as well as the other quadrants and the central nipple and subareolar region. The correlative radiologic-pathologic study of more than 150 such carefully evaluated specimens found that even with extensive lesions there was a unifocal pattern and suggested, as emphasized by Silverstein,¹¹¹ that presumed multifocality may represent an artifactual pattern resulting from inadequate histologic sampling of an arborizing pattern of distribution. This would lead to artificial skip areas as portrayed on two-dimensional histologic slides. The clear implication of a unifocal concept of the distribution of DCIS is that even what is inappropriately presumed to be multifocal disease may be encompassed by appropriately planned surgery. The possibilities for breast conservation with careful adherence to surgical principles to achieve appropriate tumor-free margins are certainly broadened by such a conceptual reassessment. The final determinant will be the long-term results of expanded efforts at breast conservation for DCIS.

What is the frequency of recurrence after breast conservation for ductal carcinoma in situ?

In series of patients in which breast-conserving treatment has been applied to the treatment of DCIS by wide local excision alone, recurrence rates averaging 26% with follow-up intervals exceeding 5 years have been documented.¹¹⁴⁻¹²⁰ Significantly, about half of these recurrences are invasive. Local recurrence rates have been greatest when the original lesion was palpable^{120,121} and when pathologic confirmation of clear margins had not been assured.^{96,122} Such lesions would be expected to be of higher nuclear and architectural grade, to demonstrate comedonecrosis, and even to have areas of microinvasion or frank invasion that might elude histologic detection. Furthermore, recurrences have occurred as late as 10 years after treatment. This suggests that at greatest risk for recurrence might be not only patients with larger lesions, but also young women, with their longer life expectancy, the application of potentially less stringent criteria for volume of excised breast or breadth of margins in an attempt to achieve optimal cosmesis, their inherently more aggressive histologic and biologic characteristics, and a different hormonal milieu.^{123,124} Recent efforts at predicting the biologic behavior of DCIS using molecular markers may introduce additional significant variables into therapeutic decision making.¹²⁵ Still unresolved is the issue of the need for radiotherapy with excision and breast conservation. Certainly, patients with smaller lesions (<10 mm diameter), particularly those lesions incidentally noted on excision specimens for predominantly benign entities (and these are most often low-grade lesions), might appear to be those treated safely by excision alone with no radiotherapy. Several investigators have focused attention on criteria to select patients who might be safely treated without breast irradiation.^{126,127} These efforts are detailed in Chapter 23. What is clear from a surgical perspective is the importance of achieving tumor-free margins independent of the issue of whether radiotherapy is used as an

adjunct to breast conservation treatment for DCIS.¹²⁸ The difficulty in always defining the limits of ductal carcinoma, the extent of which may not always correspond to and which is often broader than the mammographic region of such microcalcifications, as well as the technical limits of histologic criteria for assessing margins, represents the major surgical challenge in treating DCIS.^{126,129}

Is radiotherapy needed for the treatment of ductal carcinoma in situ when breast conservation is desired?

With the increasing appreciation of the histologic heterogeneity of DCIS and with the increasing ability to detect very small foci of DCIS mammographically, as well as situations in which foci of DCIS are detected incidentally in biopsy specimens obtained for a clinically benign lesion, the incidence of microinvasion and multicentricity is certainly low. As detailed in Chapters 8 and 23, recurrences seem to predominate in cases of larger lesions with high-grade histologic features, certainly when there is a question regarding involvement of the margins.

The addition of radiation therapy to segmental excision for DCIS results in high rates of local control. In series of patients with follow-up exceeding 5 years, breast recurrence rates average 11%.^{112,130–137} The most comprehensive prospective randomized study of excision and radiation therapy for DCIS to date was Protocol B-17 of the National Surgical Adjuvant Breast Project (NSABP), which randomized 818 women with DCIS to undergo either excision alone or excision with radiation. The addition of radiation therapy after 8 years of follow-up reduced the incidence of local noninvasive breast recurrence by 15% (recurrence was 27% for excision alone vs. 12% for excision and radiotherapy).^{74,138} The recurrences were more significant for invasive recurrences (10.5% vs. 3%) than for noninvasive recurrences (10% vs. 7.5%) when excision alone was compared with excision plus radiotherapy. A study by the European Organization for Cancer Research (EORTC) also randomized 1010 patients to either excision alone or excision and radiotherapy for DCIS up to 5 cm in size. After 4 years of follow-up, recurrence was higher in the excision-alone group than in the excision plus radiotherapy group (16% vs. 9%).¹³⁹ Thus, in the NSABP B-17 trial, radiotherapy reduced local recurrence by 59%; in the EORTC trial, by 38%.

The results of these randomized trials have led to a general recommendation for the use of radiotherapy after complete excision of DCIS. However, this tends to blur the distinctions in various subtypes of DCIS, in the varying breadth of architectural distribution, breast configuration, extent of excision, age, and other potentially relevant clinical variables. Furthermore, the impact of radiotherapy on the subsequent treatment of recurrence relevant to breast conservation or reconstruction and the potential long-term sequelae of radiotherapy have led clinical investigators to question a blanket recommendation and consider more selective approaches to the application of radiotherapy, as discussed in Chapter 23. Perhaps most compellingly, there remain no data in prospective randomized trials demonstrating an impact of breast recurrence on survival.

How should mammographically detected ductal carcinoma in situ be approached surgically?

The most common indicator of DCIS is the mammographically detected cluster of microcalcifications, which is almost always nonpalpable unless it is extensive and may, in fact, contain areas of microinvasion or frank invasion. Because the pattern of clustered microcalcifications may be varied and not reliably predictive of a benign or malignant diagnosis, as discussed in Chapter 15, an expeditious histologic diagnosis is appropriate. Diagnostic options are stereotactic fine-needle aspiration or core biopsy, vacuum-assisted core biopsy, or surgical biopsy with preoperative needle localization and specimen radiographic control. The optimal diagnostic strategy has yet to be assessed in a prospective controlled study. Certainly, if the mammographic finding is broad (occupying a segment exceeding 3 cm) and highly suggestive of carcinoma of the breast by the Breast Imaging Reporting and Data System (BIRADS V), a stereotactic core biopsy may be used to establish the diagnosis of intraductal carcinoma. If the patient were to then elect treatment by breast conservation, appropriate excision could be planned; if the breadth of the mammographic findings warranted mastectomy, this could be performed with optimal reconstruction if so elected by the patient, allowing for skin conservation and the best selection of reconstructive technique.

For faint clusters of microcalcifications not well seen on stereotactic imaging units and for microcalcifications in subareolar locations or locations close to the chest wall that may restrict the application of needle biopsy techniques, a segmental excision to incorporate the cluster with appropriate free margins is the initial diagnostic procedure that would most often translate to an appropriate therapeutic procedure as well, should carcinoma be diagnosed histologically. This requires preoperative needle localization and intraoperative specimen radiographic confirmation.

It has been argued that surgical excision of a cluster of indeterminate microcalcifications is unnecessarily burdensome, invasive, and costly for the approximately 75% of patients whose lesions will prove to be benign. In addition to stereotactic fine-needle and core biopsy, as well as vacuum-assisted core biopsies using the Mammotome (Biopsy Medical Instruments, Irvine, CA), these concerns were addressed by more complete sampling, and even excision has been achieved using needle technologies that extract larger volumes of the target tissue such as the ABBI (U.S. Surgical, Norwalk, CT).^{140–142} Definitive excision of the cluster, if a malignant diagnosis has been established and a clip placed, enables optimal planning of the margins of excision. Because DCIS often extends beyond the confines of the area with the microcalcifications, definitive excision with appropriate attention to margins strengthens the chance for local control with breast conservation. Any ambiguity about the histology, or discordance between a benign needle biopsy diagnosis and suspicious radiographic appearance, should be followed by definitive surgical excision. Definitive excision abrogates repeated-interval radiographic evaluation. With current percutaneous biopsy techniques, patients with benign diagnoses can usually be spared a surgical biopsy, whereas patients with

a malignant diagnosis may be further studied radiographically with magnetic resonance imaging (MRI) if appropriate, and a sound decision on appropriate treatment made in a carefully considered manner and followed by careful surgical planning.

An excision for clustered microcalcifications associated with malignant disease should enable a clear definition of margins. When the cluster of microcalcifications is mammographically subtle and tiny, diagnosis by multiple core biopsies runs the risk of significantly reducing or even completely removing the microcalcifications. Radiographic metallic clip placement is therefore essential because a definitive excision would be compromised or made unfeasible in the absence of any marker calcifications needed for localization.

When is mastectomy appropriate for ductal carcinoma in situ?

Consideration must be given to mastectomy if there is a diffuse pattern of comedonecrosis with significant extension to margins despite a broad excision or re-excision, if the microcalcifications are extensive in other areas of the breast as well, if the histologic pattern of the excised cancer is more diffusely malignant than mammographic patterns would have suggested, and if prior radiotherapy or conditions such as significant collagen-vascular disease contraindicate the use of radiation therapy. The risk for recurrence with breast conservation in these circumstances may be prohibitively high, particularly because available data suggest that half of the recurrences in the involved breast, even with radiation therapy, are invasive. Where involvement of margins is limited or focal, re-excision to achieve tumor-free margins without resorting to mastectomy is appropriate. MRI should be considered when the mammographic and sonographic assessment of extent of disease is uncertain. Although MRI may reveal unappreciated areas of invasive carcinoma, the reliability of assessing DCIS that may extend beyond areas of microcalcifications—the only marker of disease mammographically—remains unresolved. Finally, patient preference may dictate the choice of mastectomy.

When mastectomy is performed for high-grade DCIS that is extensive or multicentric, the possibility of microinvasion, and even lymph node micrometastases, has suggested that when excising the tail of the breast from the lateral axilla, the performance of a limited level I dissection is appropriate. This enables those lymph node micrometastases, most commonly located within the level I group of nodes, to be diagnosed and effectively ablated. Sentinel lymphadenectomy may well alter this approach to axillary lymph nodes for such high-risk DCIS, as will be discussed. Although the incidence of axillary metastases for pure DCIS is 0%, sentinel lymph node biopsy in selected series of patients with DCIS has revealed an incidence of nodal micrometastases of 6% to 13%,^{143–145} highlighting the potential underappreciation of invasion in all instances of pathologically diagnosed DCIS. This would be particularly relevant for patients for whom mastectomy has been chosen because of the architectural extent and high-grade histologic characteristics.¹⁴⁶

Mastectomy for DCIS presents an optimal setting for immediate reconstruction with skin-sparing techniques, as discussed in Chapters 23 and 25. This may particularly

enhance the cosmetic results of autogenous transverse rectus abdominis myocutaneous (TRAM) flap reconstruction.¹⁴⁷

SEGMENTAL EXCISION FOR NONPALPABLE CARCINOMA

The increasing use of stereotactic and sonographically directed biopsy techniques, using either fine-needle aspiration or core biopsy, has increased the number of patients with clinically occult cancers coming to definitive breast-conserving surgery. These patients tend to fall into three radiographically definable groups: (1) patients with a cluster of microcalcifications, (2) those with an area of architectural distortion, and (3) those with a mammographically or sonographically definable mass lesion. When breast conservation has been decided on after clinical and radiographic as well as medical and patient-related considerations, every effort should be made to achieve definitive excision with tumor-free margins in one procedure. In those instances when the decision for an axillary procedure, either sentinel lymphadenectomy or axillary dissection, requires more complete analysis of tumor size and histopathologic characteristics, the segmental excision is performed alone. When a definitive diagnosis of intermediate or high-grade invasive carcinoma has been established by stereotactic or sonographically directed core biopsy, and size is clearly evaluable mammographically or sonographically, sentinel lymphadenectomy or axillary dissection can be performed together with the definitive criteria. However, for noninvasive lesions or small (T1a) and selected T1b low-grade invasive lesions, deferring a possible axillary procedure until its appropriateness can be assessed on the basis of a full consideration of the relevant histopathologic information is advantageous, particularly because the segmental excision may be easily performed for the patient as an ambulatory surgical procedure and almost always using local anesthesia.

What preoperative measures ensure optimal excision of the lesion?

A nonpalpable lesion, or a clip indicating the site of a core biopsied lesion, should always be preoperatively localized using an appropriate hooked wire device. Preoperative localization based exclusively on mammographic views in the craniocaudal and mediolateral positions without such a localizer is unreliable. Distances measured from the nipple to the lesion in the superior to inferior and medial to lateral axes of patients in the sitting position may differ from the distances with the patient in the supine position required for surgical biopsy. In addition, the measured depth from the skin to the lesion may be different in these positions. Misguided excisions performed without preoperative wire localization may fail to include the lesion in the biopsy specimen. Furthermore, when the lesion is excised, the margins around the lesion may be inappropriately asymmetrical, with a margin in one plane excessively beyond the lesion, while a margin in another plane abuts the excised lesion or is grossly involved with a lesion that is incompletely excised.

After the radiologist places the hooked wire localizer by the shortest direct path from the skin to the lesion, as detailed in

Chapter 15, the site of the hooked wire placement in relation to the lesion and to the nipple should be clearly communicated. For example, the location of a nonpalpable lesion in the upper outer quadrant might be described as 5.5 cm lateral and 1.0 cm above the mid-nipple line, with the wire through and the hook 3.0 mm medial to the lesion (Fig. 24–10). For patients with sonographically but not mammographically detected lesions, the same mammographic description should be provided to the surgeon after the sonographically guided placement of the hooked wire. For patients with microcalcifications, particularly those that extend over a distance of several centimeters, framing the area with two or more wire localizers enables greater confidence that the entire breadth of the lesion will be excised.¹⁴⁸ The hooked wire localizers should be taped securely to the patient to minimize dislodgment during transport from the radiology suite to the operating facility.

Concerns about the frequency of positive margins after segmental excisions with preoperative wire localization, as well as patient discomfort and logistical issues and occasional wire displacement, have prompted efforts to seek alternative techniques. These include a variety of approaches, such as radioactive localization using a titanium seed containing ¹²⁵I deployed at the lesion site and identified intraoperatively using a gamma probe, carbon marking, methylene blue marking, and intraoperative ultrasound-guided excision of the hematoma within the core biopsy track or of a gel marker.^{149,150} These techniques are being studied but have not displaced wire localization techniques at the present time.

What anesthesia is appropriate?

Although excisions performed without any axillary procedures are done in an ambulatory surgery setting, it is essential that optimal local anesthesia be employed. One percent lidocaine (0.5% when the need for large volumes is projected) without epinephrine is injected intradermally and into the perioperative field. Care should be taken to maintain a volume of anesthetic below the safety limit (<500 mg or 4.5 mg/kg of lidocaine). A small wheal should be raised first, and the remaining length of the incision injected subcutaneously with anesthetic using a long needle before completing the intradermal infiltration. The addition of 1 mL of 8.5% sodium bicarbonate to each 10 mL of 1% lidocaine without epinephrine neutralizes the pH and creates less of a burning discomfort at the onset of infiltrating the anesthetic. Excessive patient discomfort and anxiety may create an intraoperative environment that hinders the successful excision of the appropriate area with the care necessary to ensure both an optimal cancer operation and aesthetic result and may erode the patient's confidence in the surgeon. A nurse at the head of the table to reassure and engage the patient in conversation is an essential adjunct to the surgeon's own comforting narrative and efforts to maintain a calm ambience of professionalism. Supplemental sedation is advisable for the anxious patient, in whom pain may clearly be accentuated by stress, and for those patients having an excision of a deep lesion in a large breast. It should be recognized that anxiety is common even if

Figure 24–10 Needle localization of nonpalpable carcinoma in the upper outer quadrant of the right breast. Craniocaudal (A) and mediolateral (B) views. Note that the wire is distal to the lesion. The lesion is described as 5.5 cm lateral and 1.0 cm above the mid-nipple line, and the hooked wire is described as 3 mm medial and directly through the lesion to allow optimal placement of the skin incision and excision.

disclaimed by the patient. A discussion in advance about the availability of sedation and anesthesiologist assistance is essential for allowing the patient to express her concerns and optimally prepare for the procedure. Few surgeons have not experienced the personal discomfort of operating on a patient who did not convey her anxiety until it was expressed as pain during the procedure despite receiving what volumetrically was more than appropriate local anesthesia. An intravenous benzodiazepine such as diazepam (Valium) or midazolam (Versed) may be most helpful in patients expressing anxiety in advance to potentiate the analgesic properties of the local anesthetic. Anesthesiology-assisted use of 2,6-diisopropyl phenol (propofol) may very effectively supplement local anesthesia, thereby providing an optimal level of anesthesia, sedation, and a very rapid recovery. All such measures enable a concentrated effort to achieve accurate and complete excision with attention to the issues of intraoperative radiographic and pathologic verification and optimal efforts at achieving tumor-free margins and meticulous hemostasis.

Where is the incision made?

The incision for the definitive excision of a nonpalpable malignant lesion should be placed over the site of the lesion as determined radiographically from the craniocaudal and mediolateral views (Fig. 24–11A and B). Placing the incision at the site of entry of a wire localizer, rather than at the site of the lesion, may require a larger incision and create undue tracking over a lengthy field of normal breast tissue if the wire does not enter directly over the lesion. It may also result in the removal of an excessive amount of breast tissue as well as distortion of the breast contour on subsequent healing. Although circumareolar incisions may be aesthetically optimal, an over-reliance on these incisions, particularly for peripherally located lesions, may produce excessive tracking, make location of the hooked wire localizer at the site of the lesion unnecessarily difficult, and lead to excessive removal of tissue and distortion of the nipple–areolar complex, thereby undermining the desired cosmetic benefit. Improper incision placement may interfere with optimal planning of the field of radiation and may create undue distortion on subsequent radiographic evaluation, impeding subsequent mammographic follow-up. For small focal lesions, incisions should be placed in lines of resting skin tension, as noted previously.

For nonpalpable lesions well within the breast, inclusion of a margin of skin is rarely needed. If the lesion is located more subjacent to the skin, dimpling may be minimized and appropriate anterior tumor-free margins achieved by incorporating a small ellipse of skin in contiguity with the underlying segmental excision. For deeper lesions, the development of skin flaps is unnecessary and may also be aesthetically counterproductive.

For DCIS or for invasive lesions with surrounding microcalcifications, especially occupying a broad area as indicated by the distribution of microcalcifications, a particular effort is indicated in planning the excision to incorporate the breadth of the lesion with appropriate margins of tissue. In such situations, a radial incision more often allows the distribution of DCIS to be encompassed without disrupting the symmetry of the nipple–areolar complex in relation to the opposite breast. Silverstein has emphasized the appropriateness of

such incisions based as well on the studies of Holland and Faverly demonstrating the frequently radial distribution of DCIS.^{113,151–153} This is particularly compatible with achieving good cosmetic results and is often preferable in this regard for lesions in the lower half or emanating from the periareolar region in all areas of the breast.

How is hemostasis achieved?

In the performance of procedures that require wire localization, the overuse of electrocautery to achieve hemostasis in the initial stages of the excision should be avoided. Excessive use of electrocautery can divide the wire localizer during the procedure, destroy epithelial cells nearest the cutting edge, and create coagulation artifacts at the margin of the excised specimen, making the histopathologic assessment of margins or even of the lesion near the margins less reliable. Protein destruction from excessive use of electrocautery may also lead to a dequantification of hormone receptor assays, particularly with small, nonpalpable lesions. The use of electrocautery to achieve meticulous hemostasis should be reserved for the excision bed after the specimen has been removed.

How is the wire localizer handled intraoperatively?

Before the incision is made, the wire protruding outside the skin is cut to a length of about 3 to 4 cm (Fig. 24–11C). In some instances, the wire is inserted over the site of the lesion and therefore traverses the same site as the incision. When the wire entry site is not directly over the biopsy incision site, however, the proximal end of the wire is carefully delivered into the operative field after the incision is made (Fig. 24–11D). This should be done without placing undue traction on the wire and disrupting engagement of the hooked end.

The surgeon should provide appropriate traction on the tissue around the hook end of the localization wire, but not on the wire itself. Inadequate traction may create unnecessary dissection and fragmentation of the biopsy specimen. A traction suture, Lahey clamp, or towel clip is best used for traction, as a crushing clamp may distort or fragment a mammographically subtle, small lesion. The traction suture is placed to incorporate the tissue surrounding the hook end, and proper placement is verified by pulling gently upward, which causes the proximal free end of the wire to move downward (see Fig. 24–11D). When multiple hooked wire localizers are used to frame a lesion, multiple traction sutures are placed. The hooked wires themselves should never be used for traction because they can easily be dislodged, particularly in a breast that is predominantly composed of fat, with little fibroglandular tissue into which the hook end might be securely engaged. It is particularly helpful that the radiologist placing the localization wires traverse the lesion and have the hooked end slightly distal to the lesion to ensure that the lesion will be more easily and thoroughly excised with the wire. Use of multiple wires to frame a lesion that was not clearly defined as a focal density or identified by a localizing clip, such as an area of architectural distortion or a diffuse cluster of microcalcifications, clearly provides further

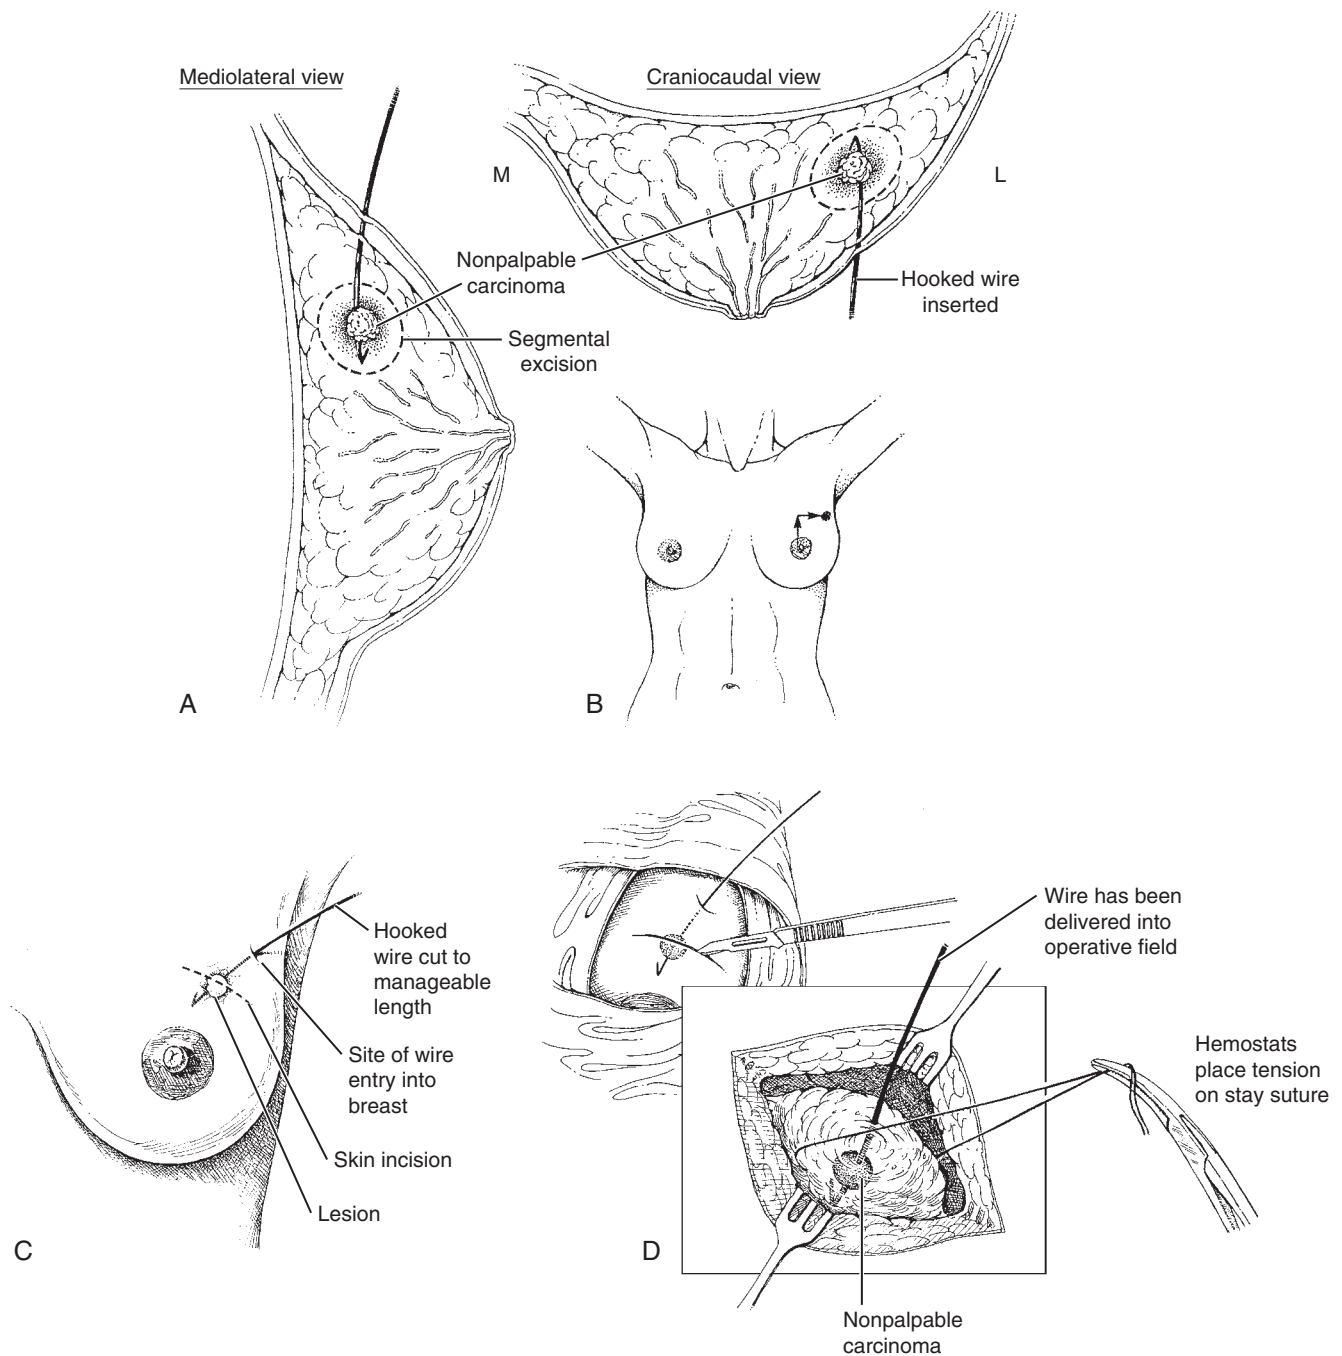

Figure 24-11 A and B, The incision is planned over the site of a lesion in the left breast based on its location in relation to the nipple on mediolateral (*left*) and craniocaudal (*right*) radiographic views. The free end of the wire has been cut to a manageable length (C) and delivered into the operative field (D), and a traction suture has been placed into the breast around the distal hook end to facilitate the complete inclusion of the lesion in the planned excision.

guidance for the surgeon attempting to optimally excise the lesion with proper margins.

How is the specimen handled before being sent to the pathologist?

As the lesion is being excised, at least three marking sutures or clips are placed at the margins of the excision specimen (anteriorly or posteriorly, medially or laterally, superiorly or

inferiorly) (Fig. 24-12). If an ellipse of skin is excised with the specimen, this obviously provides orientation as to the anterior margin. Likewise, if the posterior margin abuts on or is the pectoralis major fascia, this should be noted and communicated to the pathologist. It is essential to obtain specimen radiography of an appropriately oriented specimen to ensure that it matches the mammographic lesion for which the excision is being performed. As the lesion has been optimally evaluated radiographically by compressed spot-magnification views, the specimen should be radiographed with compressed

sion and magnification (Fig. 24–13). This may be particularly valuable in assessing the adequacy of an excision for clustered microcalcifications. If any margins are deemed too close to the lesion on gross inspection or specimen radiography, an additional segment from the excision bed at the site indicated by the orientation markers is best excised. To ensure that the lesion has been completely excised and to maximize the likelihood of free margins on final histopathologic assessment, particularly in the patient with a dense fibroglandular breast where margin involvement may not always be suspected by gross inspection or evaluation of the radiographs, it may be of value to excise an additional segment of the excision bed from any margin that on gross inspection or on specimen mammographic evaluation appears near a specimen margin or margins, and the new margin should be appropriately tagged for identification by the pathologist. Finally, the specimen is immediately conveyed to the pathologist for further assessment before the procedure is completed. It has been suggested that additional specimens be excised from each of the excision

Figure 24–12 As it is excised, the specimen is appropriately tagged for orientation by at least two marking sutures or tags.

bed margins (i.e., superior, inferior, medial, lateral, and posterior), which can then be further assessed to ensure that the margins are free of tumor.¹⁵⁴ Whatever the technique, efforts to achieve tumor-free margins while avoiding unnecessarily excessive excisions of tissue are appropriate and best performed at the time of initial definitive surgery.

How does the pathologist evaluate the specimen?

After specimen radiography has confirmed that the lesion, or clip, is well contained within the excised segment, the specimen is carefully oriented by the pathologist as indicated by the surgically placed marking sutures or clips. Every effort should be made to ensure that the communication in this regard between surgeon and pathologist is clear. The surface is then cleaned of blood with alcohol and blotted dry, and the margins are inked to allow appropriate evaluation on final histopathologic sections. Multicolored gelatin dye systems are most commonly used for color coding and identifying different margins. The dyes are applied with a small paintbrush and blotted dry again.

After the appropriate inking of the margins, the specimen is serially sectioned into 3- to 4-mm parallel slices. A definable lesion may be identified on examination and any specific proximity to a specific margin or margins communicated to the surgeon. Additional specimen radiographs of the sectioned tissue for detection of more subtle lesions, particularly clustered microcalcifications, are also obtained using a tabletop unit (Faxitron X-ray Corp., Wheeling, IL) (Fig. 24–14). The slices on the specimen radiographs are labeled and placed in cassettes.

The potential pitfalls in pathologic margin assessment are evident to anyone viewing the technique, as dye works its way

Figure 24–13 A, Magnification specimen radiography confirms the lesion centrally located in the specimen. B, Magnification specimen radiography confirms a Mammotome clip, the site of diagnosis of ductal carcinoma in situ, and additional microcalcification framed by two hooked wire localizers.

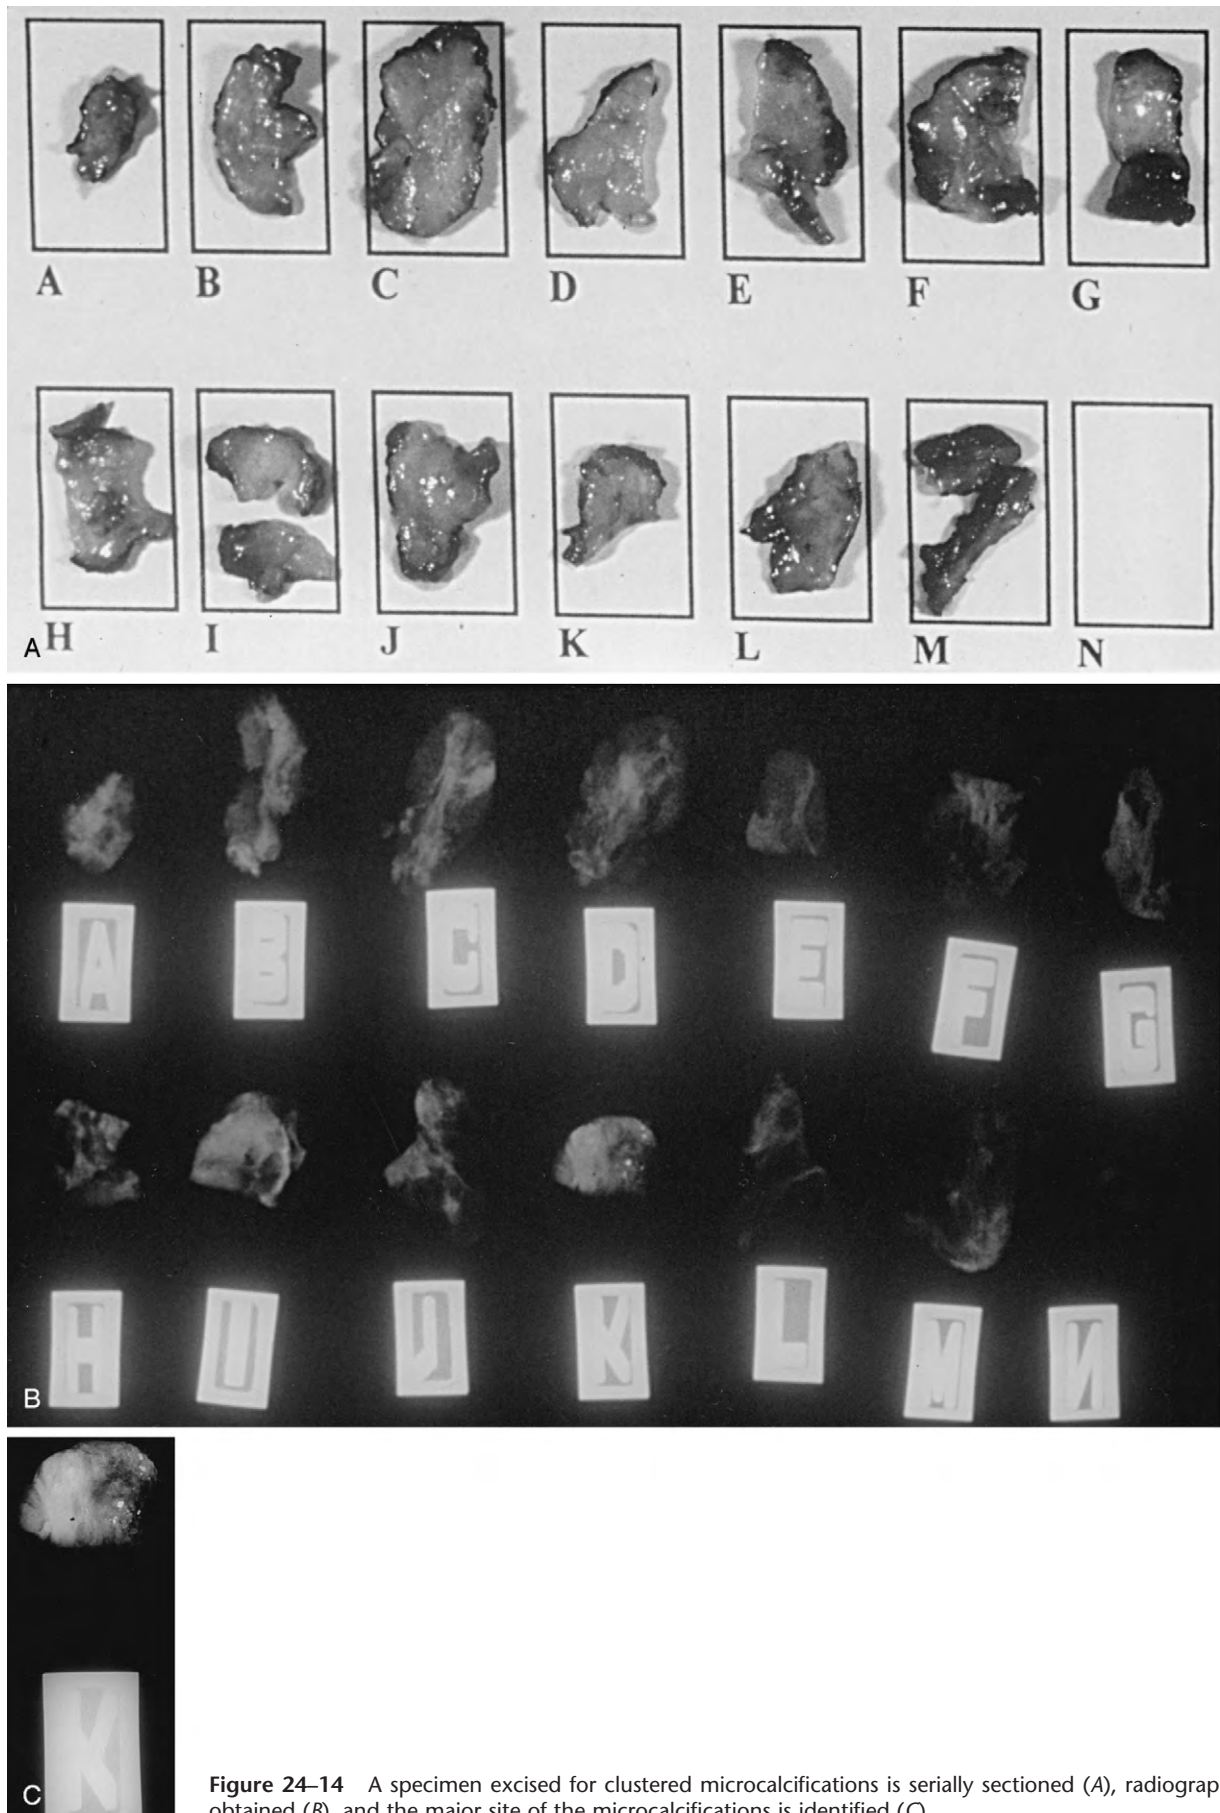

Figure 24-14 A specimen excised for clustered microcalcifications is serially sectioned (A), radiographs are obtained (B), and the major site of the microcalcifications is identified (C).

into crevices and tracks down the cut surfaces created by “bread loafing” of the specimen. Touch preparation cytology of the various margins before inking has been favorably used by several groups^{155,156} but may be limited by the requirement of expertise in cytologic interpretation as well as by the nuances of accurate interpretation even among experienced cytologists, particularly in discriminating atypia from carcinoma. Frozen section analysis has been successfully employed in the assessment of tissues sampled from the tumor bed but has interpretative, as well as even more significant sampling, limitations.¹⁵⁷ Clearly, no definitive and uniformly reliable technique for intraoperative analysis of margins has yet been developed, beyond a diligent assessment of gross and radiographic criteria and efforts to direct the surgery toward optimal excision and additional directed margin re-excision whenever there is suspicion of the close proximity of a lesion. Certainly, having a needle biopsy-proven diagnosis in advance of surgery provides the surgeon with the assurance that efforts at wider excision are justified and allows the best planning for balancing the oncologic and cosmetic requirements of the procedure for a given malignant lesion.

Should frozen section diagnoses be obtained for nonpalpable lesions?

Obtaining frozen section diagnoses of a lesion removed by segmental excision when a preoperative needle biopsy diagnosis has not been obtained or is equivocal and when immediate confirmation of a nonpalpable cancer is desired may not be appropriate. Such frozen section diagnosis or confirmation may compromise the full assessment of histologically subtle or very small (<10 mm) lesions, which are more accurately evaluated on paraffin sections. Freezing of tissue may produce artifacts that compromise assessment after the tissue is embedded in paraffin and may preclude margin evaluation. Higher false-negative rates have been noted when lesions less than 1 cm in diameter were evaluated by frozen section diagnosis than when these lesions were eliminated from frozen section analysis of excision specimens.¹⁵⁸ Although frozen section analysis of nonpalpable lesions may be performed with a low false-negative rate, as reported by Ferreiro and associates,¹⁵⁹ the stereotactic and sonographically controlled core needle biopsy for nonpalpable cancers has largely eliminated the need for frozen section evaluation. Certainly, the accuracy of diagnosing DCIS by frozen section has been questioned in several series.^{160,161} Even for small and low-grade cancers, the source of many equivocal needle biopsy results, frozen section diagnosis may not be completely reliable. Even when the diagnosis of cancer by needle biopsy is secure, definitive excision and full assessment of the size and histopathology of nonpalpable T1a and selected T1b cancers by paraffin section, as previously discussed, best enables an appropriate decision on whether additional surgery, such as sentinel lymphadenectomy, should be performed.

What if the specimen radiograph fails to confirm the presence of the lesion?

If the specimen radiograph does not confirm the presence of the lesion within the excised tissue, there may have been a

technical error or dislodgment of the wire. As noted, dislodgment may occur in a breast composed predominantly of fat, particularly when excessive traction or manipulation has moved the wire during the procedure. When the lesion is not present in the specimen radiograph, the proximity of the hook of the wire within the excised specimen should be assessed in relation to the markers that denote the different margins. If the hook of the wire, presumably the site that would be closest to the retained lesion, is located at a definable margin, further excision at the site corresponding to this margin may successfully remove the lesion with appropriate margins. If specimen radiography of the additional specimen fails to reveal the lesion detected mammographically, the procedure should be terminated. A repeat mammogram to confirm the continued presence of the lesion and repeat needle localization excision should be done at the earliest possible time after the failed excision. With appropriate planning and attention to detail, failure to include the lesion in the specimen should occur very rarely.

As core needle biopsy and, in particular, large-gauge vacuum-assisted core biopsy with clip placement are increasingly employed for diagnosis, all radiographic evidence of the lesion may be removed. This may occur in as many as 50% to 72% of cases, as reported by Burbank and Forcier.^{162,163} A potential problem for excisions targeted at the clip has been migration. In a study by Kass and associates,¹⁶⁴ a calculated clip migration of more than 20 mm from the targeted site occurred in 21.5% of patients. The overzealous application of vacuum-assisted core biopsy certainly may contribute to difficulties in relying exclusively on clip localization. Alternative approaches to clip localization have been and are being assessed, but at the present time, surgeons should be sensitive to this potential problem when intraoperatively assessing the adequacy of excisions. Having some residual intact reference lesion, be it a mass or microcalcification, is helpful in this regard, as long as appropriate sampling of the reference lesion has occurred.

How is a segmental excision for a palpable lesion performed?

Skin incision placement follows the topographic and oncologic principles previously discussed. Although appropriate placement of skin incisions should be directly over the site of the lesion, or radially extending from the periareolar region, some modification, if possible, is appropriate to allow the incision to be centrally placed. This permits concealment by clothing, such as a sweater with a V-neck or a décolleté dress. Some flap development from a more centrally placed incision to a more peripherally located lesion in the upper breast may be cosmetically desirable, so long as it does not create excessive tracking and distortion.

With palpable carcinomas, the aesthetic issues in performing a segmental excision take on added significance. Clearly, the size of the required resection relative to the breast size may influence the basic decision to pursue breast conservation. However, patients may still elect to have breast-conserving treatment even when the resulting reduction in size, particularly of a small breast, creates a noticeable distortion. A later contralateral mastopexy to correct the asymmetry that may follow a segmental excision in the superior half of the breast,

for example, may be helpful in this instance. Segmental excision of centrally located lesions subjacent to the nipple–areolar complex may require its partial or complete removal, but this need not be an absolute contraindication to breast conservation if the patient is fully apprised of the aesthetic and sensory deficit that will result. Certainly, small lesions in the subareolar location without evidence of nipple involvement may be treated by breast conservation as well as preservation of the nipple–areolar complex.¹⁶⁵

The other considerations in segmental excision for palpable cancers are the same as for nonpalpable cancers. With palpable lesions subjacent to the skin, an ellipse of skin en bloc with the parenchymal resection is often desirable because skin depression can result from preservation of skin overlying a wide resection of breast tissue. In situations in which the lesion extends mammographically for distances beyond the apparent confines of the palpable lesion, associated microcalcifications extend for distances beyond the definable palpable or mammographic density, or the palpable findings are vague or diffuse and potentially discordant with the focal carcinoma noted radiographically, needle localization framing is advisable. The correlation of the palpable lesion with the radiographic assessment is also essential in planning the extent of surgery and the type of incision that might be used. A radial incision, including an ellipse of skin, might be appropriate for a carcinoma with associated microcalcifications extending in a segmental distribution, whereas a para-areolar incision might be appropriate for a focal lesion with no associated additional radiographic features in the same location.

A special note should be made regarding the excision of lesions in a patient with a submammary breast augmentation prosthesis. Particular care is obviously indicated to avoid disrupting the prosthesis. This is one circumstance in which electrosurgery can be judiciously used throughout the procedure for both cutting and coagulation because this will not damage the prosthesis, a risk when sharp instruments are used for traction and dissection. The patient, nevertheless, should be apprised of the risk for leakage. It is best as well to avoid entering the fibrous capsule surrounding the prosthesis.

The pitfalls of breast-conserving surgery are listed in Table 24–1.

How is the segmental excision closed?

Following segmental excision and confirmation of the successful inclusion of a nonpalpable cancer by specimen radiography, and assessment of both nonpalpable and palpable cancers for the adequacy of margins, complete inspection and palpation of the excision bed is appropriate. This may reveal a suspicious area of tissue distortion or hardness not detected by clinical palpation or mammography. An additional excision should be performed to allow full assessment of such a finding.

The placement of small hemoclips to delineate the segmental excision bed may be useful in assisting the radiotherapist in planning subsequent radiation portals, particularly if a radiation boost has been determined to be appropriate, as discussed in Chapter 26. Although placement of surgical clips may be helpful anatomically, its influence on local relapse is more difficult to assess.¹⁶⁶ A study by Fein and associates¹⁶⁷ compared 556 patients irradiated after the placement of clips

Table 24–1 Pitfalls of Definitive Surgical Excision of a Cancer in Breast-Conserving Therapy

Nonpalpable Lesions

1. Failure to localize the lesion preoperatively
2. Failure of the radiologist to clearly communicate the precise site of the lesion after needle localization
3. Failure to place the incision over the site of the lesion
4. Excessive reliance on periareolar incisions
5. Overvigorous use of electrocautery before the lesion is excised
6. Failure to provide adequate traction around the lesion
7. Dislodgment of the localizer wire
8. Failure to orient and properly identify the margins of the specimen
9. Excessive or inadequate margins
10. Failure to obtain specimen radiography
11. Failure of communication between the pathologist and surgeon on the adequacy of margins
12. Inappropriate use of frozen-section analysis
13. Failure to achieve meticulous hemostasis

Palpable Lesions

1. Inappropriate incisions, including excessive reliance on periareolar incisions
2. Failure to orient and properly identify the margins of excision
3. Excessive or inadequate margins
4. Failure of communication between the pathologist and surgeon on the adequacy of margins
5. Failure to achieve meticulous hemostasis

with 808 comparably staged patients irradiated without clips. Recurrence rates at 10 years were 5% without clips and 11% with clips, the latter rate most likely resulting from a higher incidence of unknown histologic margins in that group. The use of clips to anatomically delineate the surgical bed for boost irradiation planning should never be intended to compensate for a failure to delineate tumor-free margins, as this delineation is the most important component to decrease the potential for disease relapse in the breast.

When hemostasis has been achieved, the wound is closed. Reapproximation of breast tissue with limited tissue removal is usually not advisable. Attempts to reconstruct underlying breast tissue when the patient is supine on the operating table, with the breast in a laterally pendulous position, may result in particular distortion when the patient assumes the upright position. A few subcutaneous absorbable sutures may be helpful in relieving tension on the skin incision, but more aggressive attempts at reconstructing a small breast defect itself may be inappropriate and even counterproductive to achieving an optimal aesthetic result. However, when a significant segmental excision has been performed through a radial incision with an elliptical excision of skin, undermining the breast on each side of the defect above the pectoralis major and approximating the deep tissues is appropriate to minimize distortion and create a more normal contour.

Drains are rarely indicated, although with large defects they may be used for the first day or two to minimize fluid collection. A simple postoperative aspiration of any serous accumulation in the excision cavity may suffice in most instances when the patient is seen for the first office visit. The wound is closed with a subcuticular suture, and Steri-Strips are applied to the skin (Fig. 24–15). The considerations relative to an axillary procedure are discussed below. Moderate pressure

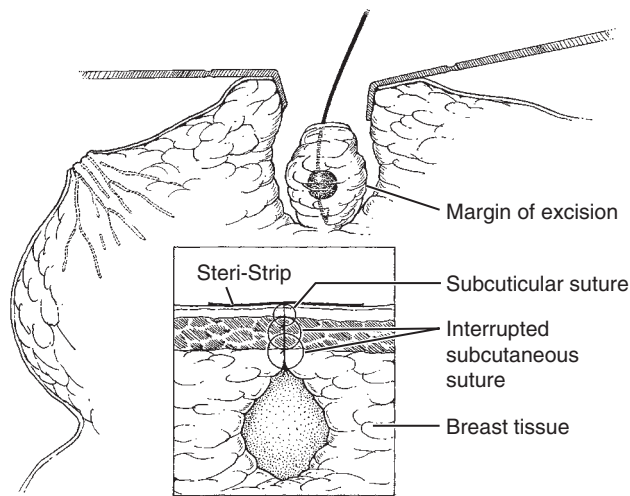

Figure 24-15 Closure of segmental excision.

is applied to the wound with a fluffed gauze dressing, but tape applied under tension to secure the dressing should be avoided because this may cause blistering and even full-thickness loss of skin if the tape is applied with significant stretching. Rather, the patient should be instructed to wear a brassiere postoperatively and certainly for the first evening to provide additional compression of the dressing and support of the surgical wound. A sports bra after the first day and even for weeks afterward is recommended as a further means of achieving comfort during the postoperative phase. Advance purchase of a sports bra that closes with hooks is recommended. Showering is permitted with appropriate wound protection, with a sealing dressing or impermeable cover placed in a bra worn in the shower.

SURGICAL MANAGEMENT OF THE AXILLARY LYMPH NODES

Does axillary dissection confer any survival advantage?

There is no convincing evidence that axillary dissection improves survival. In a meta-analysis of six clinical trials that randomized patients to breast cancer surgery by segmental excision and radiation with or without axillary dissection or to mastectomy with or without axillary dissection, Orr demonstrated an average survival advantage of 5.4% of those groups having axillary dissection.¹⁶⁸ However, these trials were from an era when far fewer patients received adjuvant systemic therapy and few were treated for nonpalpable lesions, an ever-increasing component of the present population of breast cancer patients. The two largest trials included in the analysis were those from the NSABP (B-04)¹⁶⁹ and the Institut Curie.¹⁷⁰ In the NSABP B-04 trial, 25% of patients with positive nodes were free of disease at 10 years, regardless of whether they had been treated by elective dissection or

delayed dissection for clinically detected metastases. In the Institut Curie trial, there was a survival advantage of 4% for patients having axillary dissection. However, there was greater use of both adjuvant systemic therapy and radiation therapy in patients whose elective axillary dissection revealed metastatic disease. If a survival advantage did result from axillary dissection, it would clearly be limited to a small subset of patients. Accrual of clinical evidence that would either demonstrate or disprove a survival advantage for axillary dissection is even more unlikely as the use of adjuvant systemic therapy broadens for patients with invasive cancers and as the percentage of patients diagnosed with nonpalpable T1a and T1b lesions increases.

Is the evaluation of axillary lymph nodes important for staging?

The pathologic assessment of axillary lymph nodes remains the most important prognostic variable for the invasive breast cancer patient. In the absence of any evidence of distant metastases, the status of axillary lymph nodes has maintained its dominant influence, even with the trend toward earlier detection of clinically occult cancers and the proliferation of molecular assays of the primary tumor. No other factors, including size, either alone or in combination, are superior at predicting the potential for relapse.¹⁷¹ Data from the NCI Surveillance and Epidemiology and End Results (SEER) program reporting on 5-year survival in 24,740 patients demonstrated a predictable increased risk for lymph node metastases as tumor size increased but demonstrated as well that size and nodal metastases are independent variables. Even for tumors equal to or greater than 5 cm, survival decreased from 82.2% if node negative to 45% if four or more nodes had metastases.¹⁷² Furthermore, the extent of nodal involvement, the number of metastatic axillary nodes,¹⁷²⁻¹⁷⁴ the size of metastases,^{175,176} and the extension of metastases beyond the capsule¹⁷⁷ have demonstrated impact on survival, as detailed in Chapter 19. As further refinements in the pathologic evaluation of micrometastases evolves, including immunohistochemical staining¹⁷⁸⁻¹⁸² and molecular assays such as polymerase chain reaction (PCR),¹⁸³ the importance of axillary nodal assessment may be enhanced. However, the true prognostic significance of nodal metastases consisting of small emboli of cells in the nodal sinuses, immunohistochemically detected isolated cells, or PCR-positive assays, compared with true micrometastases (<2 mm), has yet to be reproducibly determined. Conversely, the widespread use of adjuvant systemic strategies may limit the importance of such assessment. It is for these reasons that more selective approaches to axillary surgical management have particular appeal.

Can the axilla be staged noninvasively?

No clinical or radiographic techniques have yet been demonstrated to have the sensitivity necessary to accurately stage the axilla. Physical examination can detect gross disease but has an unacceptable rate of false-positive as well as false-negative findings.¹⁸⁴⁻¹⁸⁷ Mammography, ultrasound, power Doppler sonography, MRI, lymphoscintigraphy, and radiolabeled

monoclonal antibody scanning have proved inadequate to date.^{185,185-193} More recently, positron emission tomography (PET) has been evaluated, but this technique can detect only tumors that are about 1.0 cm or larger.¹⁹⁴

Size and the histologic and molecular characteristics of the primary tumor, as well as patient age, have been analyzed as determinants of axillary metastases. The most accurate predictor remains primary tumor size.^{172,195} The incidence of axillary involvement increases with the size of the primary tumor and may even exceed 20% for tumors smaller than 1 cm (T1a and b). In the experience of one of the authors, as noted, the rate of axillary metastasis associated with T1a tumors was 10% using hematoxylin and eosin (H&E) staining alone and 15% using immunohistochemical staining in addition to H&E staining.¹⁹⁶ As data have accrued on the more detailed pathologic analysis of sentinel nodes, the frequency of nodal metastases has increased. When investigators have looked at the incidence of nodal involvement as a function of tumor size as well as lymphatic or vascular invasion, histologic grade, laminin receptor and *c-erb-2* overexpression, patient age, progesterone receptor status, and S-phase fraction,¹⁹⁷⁻¹⁹⁹ they have concluded that analysis of the primary tumor could not replace histologic evaluation of the axillary nodes as an effective staging technique at the present time. Furthermore, the more detailed assessment of axillary nodes may shed increasing light on the biologic significance of micrometastases as well as on the group of patients heretofore considered node negative by traditional histologic analysis of the entire axilla but who experienced recurrence, despite a presumed favorable prognosis.

What is the role of axillary dissection in the treatment of breast cancer?

Axillary dissection has remained a component of the local treatment of invasive breast cancer but has been subjected to increasing scrutiny in recent years. For patients with palpable lymphadenopathy, it remains an essential component of surgical therapy. Of patients without lymphadenopathy, more than 70% will have no histologic evidence of nodal involvement, and this incidence will likely increase as the diagnosis of smaller and biologically more favorable lesions increases.²⁰⁰

The controversy relating to elective axillary dissection in the absence of palpable lymphadenopathy derives from a failure to demonstrate clearly an independent therapeutic value and from the perception that it should be applied only for patients in whom the histologic investigation of axillary nodes would alter adjuvant therapeutic strategies. This perception, however, may oversimplify the prognostic information that may be gained from axillary dissection and also undermine the potential for achieving effective local treatment of axillary metastases with minimal morbidity, thereby preventing axillary recurrence. Until recently, the alternative to elective axillary dissection has been surveillance or radiation. A more selective approach using intraoperative lymphatic mapping and sentinel lymphadenectomy has now gained hold as a means of both staging and directing the potential therapeutic benefits of axillary dissection. A detailed consideration of sentinel lymphadenectomy will follow. Suffice it to say at this point that sentinel lymphadenectomy circumvents the

limitations of surveillance and radiation, which fail to obtain the prognostic information provided by histologic assessment of the axillary lymph nodes, and it directs axillary dissection for those patients most likely to benefit from the procedure. This enables full assessment of the prognostic information the axillary nodes may provide, which is related not only to the presence or absence of axillary micrometastases but also to the extent of such micrometastases. Such information has been well demonstrated to correlate with survival.²⁰¹⁻²⁰³ In this sense, the detailed analysis of sentinel lymph nodes may allow even more specific prognostic information and effective therapeutic strategies.

How effective is axillary dissection in the local control of disease?

The rarity of axillary recurrence following a carefully performed axillary dissection is well established.^{204,205} In the NSABP B-04 study, axillary recurrence was reported in only 1.4% of node-negative patients and in 1.0% of node-positive patients following axillary dissection, whereas 17.8% of patients with clinically negative axillae randomized to not have an axillary dissection developed clinically palpable nodal metastases.²⁰⁶ Series of patients whose axillae were not treated have been reported by Cady and associates,²⁰⁷ who found an axillary failure rate of 16%, and by Baxter and associates,²⁰⁸ who found a 10-year actuarial axillary failure rate of 23%. Radiation is an effective alternative, as reported by Recht and associates,²⁰⁹ who noted an 0.8% incidence of axillary recurrence following axillary radiation in 355 clinically node-negative patients. Wong and associates²¹⁰ reported on 92 patients with no lymphadenopathy treated with radiotherapy that included the level I nodes. A single axillary recurrence in association with a breast recurrence, but no isolated axillary recurrence, was noted.

Radiotherapy can decrease axillary recurrence in the absence of clinically diagnosed axillary metastases, but it does not yield prognostic information that might impact adjuvant therapy.²⁰⁹ Furthermore, as reported in the NSABP B-04 study, the axillary recurrence rate in patients receiving axillary radiation rather than axillary dissection for palpable nodal disease was 12%. An even higher rate of 19% was reported in a series by Osborne and associates²¹¹ from the Royal Marsden Hospital. It has not been feasible to date to segregate the impact that axillary dissection may or may not have on the natural history of breast cancer because any benefit is inextricably linked to the greater use of adjuvant therapy resulting from the information obtained from axillary dissection. Axillary dissection has therefore remained a component of the local treatment of invasive breast cancer, but it has appropriately come under intense scrutiny as the frequency of smaller, often nonpalpable and low-grade cancers has risen as a result of more widespread mammographic screening and as more refined sentinel lymphadenectomy techniques are developed. The issue of complications from axillary dissection will be discussed later in this chapter. While complications depend on a clear definition of the extent of surgery, the issue for our present consideration is whether the detection of axillary metastases might be optimized and axillary dissection limited to only those patients in whom a prognostic and possible therapeutic benefit might be realized.

Is axillary staging always indicated for invasive breast cancer?

Histologic assessment of the axilla in conjunction with breast conservation has generally not been advocated in instances in which the histologic characteristics of the cancer are predominantly intraductal, with only microinvasion, or in instances of invasive cancers that are smaller than 1 cm (T1a and T1b) with well-differentiated characteristics, such as pure tubular or colloid carcinomas, and are hormone receptor positive.²¹²⁻²¹⁴ Likewise, in elderly patients, particularly those with serious intercurrent medical illness, such procedures may not be appropriate.²¹⁵

Greater refinements in some of the indications for axillary staging are being introduced because increased use of mammography has produced an increase in the frequency of clinically occult lesions, many with low-grade histologic characteristics, and more concentrated efforts to pathologically assess for axillary micrometastases have been advanced. Giuliano and associates,²¹⁶ in a study of 259 patients with T1 invasive carcinoma having axillary dissection, found 27% to have axillary metastases. The only factor predictive of axillary metastasis was tumor size, with 10% of T1a (≤ 5 mm), 13% of T1b (5 to 10 mm), and 30% of T1c (10 to 20 mm) tumors having axillary metastasis. Other factors, such as age, hormone receptor status, the presence of DCIS, histology, ploidy, and S-phase assessment, were not significant predictors of nodal involvement.²¹⁶ Nodal metastases were noted in 9.8% of patients with T1a and 19.4% of patients with T1b lesions in a study by White and associates²¹⁷ of 931 axillary dissections, whereas Barth and associates²¹³ analyzed 918 patients with T1 lesions and found that in 117 patients with nonpalpable, non-high-grade cancers smaller than 1 cm without lymphatic or vascular invasion, the incidence of axillary metastases was 3%. Although several investigators have sanctioned the abandonment of axillary dissections for T1a carcinomas in view of the low incidence of axillary metastases,²¹⁸⁻²²² refinements in surgery and pathology have recast the discussion.

Can the axilla be more selectively staged?

Axillary dissection is associated with well-documented morbidity rates, to be considered later in this chapter. If axillary dissection conferred a clear survival advantage this morbidity would be acceptable, but because an increasing percentage of patients treated for breast cancer have small, often clinically occult cancers, the need for axillary dissection has become less compelling. Nevertheless, the significance of prognostic information gained; the possibility of ablating occult nodal metastases, which may offer an unproven but possible therapeutic advantage; and the opportunity to secure local control of disease continue to focus attention on axillary dissection.

The means by which to accurately evaluate for the presence or absence of axillary nodal metastases without axillary dissection evolved from the long-standing study of lymphatic anatomy and from the clinical experiences applying modern technologic advances to this issue. Lymphoscintigraphy using radioisotopes has long been applied to study the direction of lymphatic drainage from ambiguous primary melanoma sites on the trunk and head and neck.²²³ As already noted,

Cabanas²²⁴ introduced the concept that a specific cutaneous site, a penile carcinoma in the case he reported, would drain not just to a specific nodal site but to a specific node. Morton and associates²²⁵ brought this concept into the operating room with great specificity in the treatment of melanoma, convincingly demonstrating that identifiable nodes were the first drainage sites not only of cutaneous lymphatics but also of nodal metastases. For breast cancer, the sentinel node or nodes are therefore those that drain the area of the breast where the primary tumor is located and thus are most likely to contain metastases. The nodal tumor status can thereby be evaluated by the selective assessment of this node or nodes. These sentinel nodes have now become the focus of intense study and clinical application and are leading to a redefinition of axillary surgery for cancer of the breast.

In staging and treatment of melanoma patients by Morton and associates,²²⁶ initial success was achieved in 95% of patients undergoing sentinel lymphadenectomy followed by a completion regional node dissection. The applicability of the technique was subsequently validated in a multicenter study.²²⁷ There were no false-positive results, and the rate of false-negative sentinel nodes, whereby metastases were detected in nonsentinel nodes in the absence of sentinel node metastases, was only 1%. This technique was applied to breast cancer beginning in 1991. After the development of a variety of techniques for lymphatic mapping, the success at identification of the sentinel nodes in breast cancer patients has exceeded 95%, with false-positive rates of 0% and false-negative rates of 0% to 13% in series in which the technique has been followed by a completion axillary dissection.²²⁸⁻²³⁵ Furthermore, three major clinical follow-up studies of patients with sentinel nodes that were negative for metastases and for whom no further dissection was performed, although limited in the duration of follow-up, have no reported instance of an axillary recurrence.²³⁶⁻²³⁸ With refinements in technique as well as the pathologic and even molecular assessment for nodal micrometastases, it is to be expected that false-negative rates will continue to decline. Indeed, the ability to obtain detailed information on the multiple sections of sentinel nodes has been a major incentive toward the rapid, broad study and acceptance of the technique.

How is sentinel lymphadenectomy performed?

Since the introduction of sentinel lymphadenectomy, several successful techniques have been proposed. As these techniques evolved, technologies were introduced using radioisotopes and gamma probe detection, which led to numerous further modifications. The varying designation of the procedure as a sentinel lymph node dissection, sentinel lymph node biopsy, or sentinel lymphadenectomy, often preceded by the phrase "intraoperative lymphatic mapping," reflects the ongoing evolution of the procedure. Differing approaches for the most part hinge on the differing substances used to trace the lymphatic drainage and to identify the sentinel node as well as on the sites of injection of these substances. The most commonly used agents for lymphatic mapping are the dye lymphazurin 1% (isosulfan blue) and the radiocolloid ^{99m}Tc-labeled sulfur colloid in either a filtered or unfiltered form.

Isosulfan blue dye was selected because of its propensity to be taken up and retained by lymphatics in an animal study, as

compared with water-soluble methylene blue dye.²³⁹ Clinical assessment, however, has demonstrated that methylene blue is efficacious for lymphatic mapping and sentinel node identification and may be an appropriate substitute.²⁴⁰ Its smaller particle size compared with unfiltered filtered ^{99m}Tc-labeled sulfur colloid allows more rapid uptake and transit by lymphatics but also greater suffusion into the intravascular compartment. Success has been achieved with both, as well as with isotopes with smaller particle size, such as ^{99m}Tc-human albumin, ^{99m}Tc-dextran, and ^{99m}Tc-antimony sulfur colloid. Radiocolloid lymphatic mapping requires the use of a gamma probe for intraoperative identification of the sentinel nodes. Individual surgeons and centers have used dyes, radioisotopes, or both, with comparable success.

The mapping agent or agents may be injected in peritumoral, subcutaneous, intradermal, or subareolar locations, alone or in varying combinations. Techniques may be dictated by how the diagnosis was made (i.e., needle biopsy that leaves an intact lesion, or excision that leaves no reference lesion), by the proximity of the lesion to the axilla, and by the timing of surgery in relation to injection. All parameters may affect the decision on which agent and technique of introduction to use. A panel of internationally recognized investigators of sentinel lymph node biopsy, at a consensus conference on the role of the procedure, endorsed dual-agent mapping with dye and radiocolloid for surgeons first adopting sentinel lymph node biopsy, while they recognized that use of either agent alone may be appropriate as experience is acquired.²⁴¹ A combined approach is therefore presented and is supported as well by several recent studies demonstrating the improved sentinel node detection rate using dual-agent techniques.^{242–245}

The procedure is initiated by the injection of ^{99m}Tc-sulfur colloid around the lesion or prior excision site. If the lesion is nonpalpable, injection is directed by the localization technique used, either at the site of needle or hooked wire localization, or sonographically if appropriate expertise is available in the nuclear medicine facility. The injection should be scheduled at least 1 hour and optimally 2 hours before the planned procedure. If significantly longer time intervals are predicted, unfiltered ^{99m}Tc-sulfur colloid is preferred as it may be less likely to migrate to second-echelon lymph nodes. ^{99m}Tc-sulfur colloid is available in the United States and Canada but not in Europe, and the use of ^{99m}Tc-labeled colloidal human albumin is employed in most patient series there. In general, 1 to 2 mCi of ^{99m}Tc-sulfur colloid is injected in a total volume of 2 to 6 mL in divided doses of 1 mL around the lesion or excision cavity, including a subdermal injection if the lesion is not deep in the breast. Injection into the excision cavity will not be successful at promoting uptake by the lymphatics. Successful sentinel node identification has been reported with intradermal injection,²⁴⁴ intraparenchymal injection,^{246–248} and subareolar injection.²⁴⁹ Subareolar injection may be particularly useful for lesions high in the upper outer quadrant to eliminate radioactive overlap with the axilla and for nonpalpable lesions in which the precision of peritumoral injection may be uncertain.

Sentinel lymphadenectomy is performed before segmental excision or mastectomy. In the operating room, the patient is positioned as for an axillary dissection, with the arm free and at a right angle to the body on an armboard. The breast and axilla are prepared and draped, with the arm free, and the table is rotated slightly to the contralateral side and in a

reverse Trendelenburg position. Anesthesia is dependent on the surgical plan, such as whether the sentinel lymphadenectomy is to be performed with a breast-conserving operation or a mastectomy, whether completion axillary dissection is planned if a sentinel nodal metastasis is detected, and the patient's preferences, level of anxiety, or body habitus. Although sentinel lymphadenectomy can be performed under local anesthesia, sedation is often desirable, as is general anesthesia in appropriate instances.

Lymphazurin (isosulfan blue dye) is injected around the lesion if it is palpable, around the site of localization if the lesion is not palpable, and around but not into the excision cavity if the lesion has been excised. Subdermal or intradermal injection may be used if the skin site is to be excised. The volume of dye varies with the size of the breast and the location of the carcinoma in relation to the axilla. Lymphatic drainage from lesions in the upper outer quadrant is best mapped with as little as 1 to 3 mL in a small breast to avoid suffusing the axilla and making blue node identification difficult. By contrast, mapping of the lymphatic drainage from an excision cavity in other areas of a large breast may require amounts as high as 5 mL. Injections are made in divided amounts around the lesion or cavity, favoring the axillary side (Fig. 24–16). The breast is then compressed and gently massaged for about 5 minutes to increase the interstitial pressure and improve lymphatic flow, as emphasized in the report by Giuliano and coworkers²²⁸ and the study of Bass and associates.²⁵⁰ The lack of any substantiating data makes it unlikely that massaging an intact tumor and theoretically causing lymphatic dissemination of malignant cells has any adverse clinical relevance. The time from injection to incision is precisely monitored, so that the incision is not made before at least 5 minutes has elapsed, to allow transit of the dye into the lymphatics and to the sentinel node. For medial locations, longer intervals approaching 10 minutes are advisable.

At the outset of the procedure, the appropriately calibrated gamma probe is placed on the field in a sterile sheath. The incision is made just below the hair-bearing area of the axilla in a transverse, slightly curvilinear direction. Invariably, this is the site of highest radioisotope counts as the gamma probe is moved over the skin to determine the location of radioisotope concentration (Fig. 24–17). The incision may be adjusted if highest radioactivity is focused above or below this area. The length of the incision depends on patient size, fat distribution in the axillary fold, and muscular development. Rarely is there a need to extend the incision beyond 4 cm. The incision is carried down through the subcutaneous tissue to the clavicular fascia, which is gently divided. Meticulous hemostasis using electrocautery is essential. No attempt should be made to develop skin flaps. A Weitlaner self-retaining retractor greatly facilitates exposure. When a mastectomy is planned, the axillary incision will be the lateral extension of the incision, a flap in this instance being developed. At this point, the aim is to identify a blue-stained lymphatic channel or channels. The gamma probe may help to direct the dissection to the area in the surgical field with greatest activity, indicating radioisotope concentration in the sentinel node. A small retractor placed at the edge of the pectoralis major for medial retraction also facilitates exposure. Similarly, supporting the forearm superiorly toward the contralateral side and parallel to the patient may allow greater access to the lateral axillary contents. Efforts should be made to avoid inadvertent

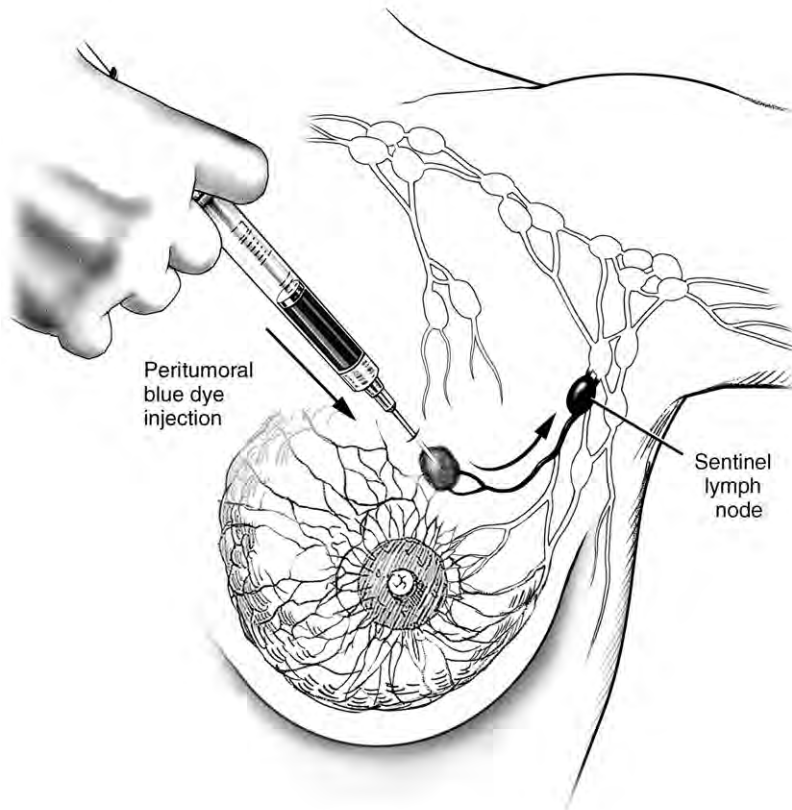

Figure 24-16 Blue dye and/or radioisotope injection at site of cancer.

Figure 24-17 Site of incision for the sentinel lymph node biopsy.

disruption of a blue lymphatic channel because this may result in inadequate staining of the sentinel node and unnecessary blue staining of the soft tissues. After the blue channel or channels are detected by careful dissection with a mosquito clamp and electrocautery, they are traced both proximally and distally to ensure that the first node in the chain is identified. Following identification of a blue node with appropriately high radioisotope counts, great care is exerted in handling the node. A traction suture may be placed adjacent to it, or a noncrushing Babcock clamp may also be used to

deliver the node into the field and allow its complete excision (Fig. 24-18).

After excision of the node or nodes, care must be taken to evaluate the specimen for its color and for its ex vivo radioactive counts. A potential pitfall of the use of radio-colloid and gamma detection of sentinel nodes is “shine-through” of radioactivity, not only from an injection site close to the axilla but also from a node or nodes behind or adjacent to the presumed sentinel node. The excised nodes should have the same ex vivo counts as recorded in vivo (Fig. 24-19). The nodes should be evaluated for radioactive counts away from the operative field. With a larger node, a specific focus of high radioisotopic counts may be identifiable and can be tagged with a suture to direct the pathologist to this potential site of metastatic disease. The site of excision should also be evaluated for residual background radioactivity, with the probe directed not only centrally but also in all directions around the periphery of the field of dissection except toward the site of injection. It has been suggested that nonsentinel node counts should be less than 10% of the sentinel nodes.²⁴² Certainly, if the ex vivo counts over the node are lower than the in vivo counts, if the concentration of the blue dye is uncertain, and if the background counts are not significantly lower than the reference nodes, further dissection is indicated. The proliferation of gamma detection instruments and collimators requires that the surgeon be familiar with the specifications and calibration of the specific instrument being used. Careful recording of the counts, not over-reliance on audible features, is essential. Inspection and palpation of the axilla may reveal a grossly involved node that has failed to concentrate dye or radioisotope, or a blue node that has been overlooked. These should be excised, because a node replaced by metastatic

Figure 24-18 Blue-stained lymphatic channel coursing toward blue-stained lymph node is identified.

Figure 24-19 Sentinel lymph node or nodes, excised, and radioisotope counts confirmed *ex vivo*.

carcinoma may direct lymphatic flow to other nodes and fail to take up dye or isotope.^{251,252} Finally, failure to identify the sentinel nodes should be followed by an axillary dissection, except in those instances in which the probability of nodal metastases is low, there are relative contraindications to the procedure, or the potential for altering prognosis is small. In

Table 24-2 Pitfalls of Sentinel Lymphadenectomy

1. Failure to inject dye intraparenchymally, favoring the axillary side of the intact lesion or segmental incision site.
2. Failure to inject isotope at least 1 to 2 hours prior to commencement of the procedure.
3. Failure to record time of injection of dye and/or isotope and time of commencement of the procedure.
4. Failure to massage the site of dye injection.
5. Failure to place the incision below the hair-bearing area of the axilla to allow extension to an axillary dissection incision, if necessary.
6. Failure to transect tissues directly down to the clavipectoral fascia.
7. Failure to carefully dissect until blue-stained lymphatic channel(s) are identified to avoid their disruption.
8. Failure to achieve meticulous hemostasis.
9. Failure to carefully review gamma probe settings and collimation characteristics.
10. Failure to direct gamma probe away from injection site, particularly to avoid "shine-through" with lesions in the upper outer quadrant.
11. Failure to check *ex vivo* counts of sentinel node(s), away from the operative field, to ensure that they approximate *in vivo* counts.
12. Failure to check background counts at excision site to ensure that there has been a reduction to less than one tenth of the hottest node.
13. Failure to inspect the excision site for any suspiciously enlarged or palpable nodes and failure to excise such nodes regardless of their failure to concentrate dye or radioisotope.

these situations, the more extended procedure may not be justified.

The pitfalls of sentinel lymphadenectomy are listed in Table 24-2.

How is the sentinel node examined?

The sentinel node is immediately conveyed to the pathology lab, where it is inspected. If there is any suspicion of metastatic disease by gross inspection or after the node is bivalved along the longitudinal axis, the sentinel node is examined by frozen section. If the sentinel node demonstrates metastasis on frozen section, a standard level I and II axillary lymph node dissection is performed at the initial surgical procedure. For nodes that are not suspicious by inspection, the issue of intraoperative evaluation is more controversial. There is certainly an advantage to establishing a diagnosis of metastatic carcinoma at the time of initial surgery, particularly in the setting of mastectomy and reconstruction. When breast conservation is planned the issue is not as compelling, given the limited extent of surgery and the frequently ambulatory setting for performing these procedures. This experience had led some to recommend sentinel node biopsy as an initial separate procedure for those having mastectomy and reconstruction.²⁵³

There are potential pitfalls in the routine use of frozen section analysis, including tissue loss, which occurs particularly with a small lymph node, and there are recognized limitations on the accuracy of frozen section diagnosis. When compared

with permanent paraffin section results, frozen section analysis of sentinel nodes may have a false negative rate of 11% to 43%.^{254–263} With more exhaustive intraoperative frozen section analysis this may be reduced, but micrometastases may continue to elude detection.^{264,265}

Another intraoperative approach is the use of touch preparation analysis. Nodes are bisected, and after inspection, imprints are made for cytologic analysis.^{266–269} As with touch preparation assessment of segmental excision margins, touch preparation of lymph nodes depends on available expertise in cytologic analysis, but in experienced centers it is an accurate means of assessment, with sensitivity as high as 94.4%.²⁶⁷ Subsequent analysis of sentinel nodes by multiple sectioning and immunohistochemical staining for cytokeratins is detailed in Chapter 11.

Certainly, sentinel lymphadenectomy has resulted in increasing sensitivity in detecting nodal metastases. Frozen section detects about 70% of positive nodes that are eventually judged positive with H&E.⁸⁹ Immunohistochemical staining has detected an additional 10% to 20% of nodes that were thought to be negative by H&E.^{270–273} Multiple sectioning with immunohistochemical analysis of the sentinel node is clearly a powerful means of detecting metastases but would be logistically formidable for the much larger axillary lymph node dissection specimen. In the study of Giuliano and associates, among patients with positive sentinel nodes, 32% were positive on routine histology, whereas immunohistochemical staining increased the yield of positivity to 42%.²²⁸ The true significance of micrometastases detected by immunohistochemical staining alone or more recently by reverse transcription polymerase chain reaction (RT-PCR) remains to be determined.

To determine how sentinel lymphadenectomy compares with axillary lymphadenectomy as a staging technique, Giuliano and associates also examined the axillary nodes excised from 162 patients undergoing sentinel lymphadenectomy followed by complete axillary lymphadenectomy and 134 patients undergoing axillary lymphadenectomy alone.²⁷⁴ Axillary lymph node dissection specimens were examined by H&E alone, and sentinel nodes by H&E and immunohistochemical staining. The rate of detection of axillary metastases was higher in the sentinel node dissection and axillary dissection group than in the group undergoing axillary dissection alone (42% vs. 28%, respectively; $P = .05$) This difference reflected the larger number of micrometastases (<2 mm) detected in the sentinel node group (16%) than in the exclusive axillary dissection group (3%). Using H&E only, micrometastases were found in 9% of the sentinel node group and in 3% of the axillary dissection group. When the sentinel nodes were examined with immunohistochemical staining, the incidence of micrometastases increased by 7%. This study highlighted the greater sensitivity of sentinel lymphadenectomy compared with axillary dissection in detecting nodal metastases. Veronesi and associates compared 516 patients with primary breast cancer in whom the tumor was equal to or less than 2 cm to sentinel node biopsy and axillary dissection or sentinel node biopsy alone followed by axillary dissection only if the sentinel node contained metastases.²⁷⁵ The sentinel node was positive in 32.3% of the sentinel node and axillary dissection group and in 33.5% of the group having only sentinel node biopsy. There were no cases of overt

axillary metastases in the sentinel node group evaluated as negative for metastasis and not having axillary dissection.

Should axillary dissection follow the detection of a sentinel node metastasis?

While the standard of care has been to perform an axillary dissection (the techniques of which will be detailed later in this chapter) for a confirmed axillary nodal metastasis, the sentinel node technique has focused attention on certain assumptions about the value of axillary dissection. Specifically, what is the significance of a micrometastasis (≤ 2 cm) or a “submicrometastasis” (≤ 0.2 cm) as a cluster or, even more problematically, as individual cells, often detected by immunohistochemical staining, not only for prognosis but surgically as an indication for completion axillary dissection? Prognostically, the issue has significant implications for adjuvant systemic therapy as well. Complicating the study of these questions are the limitations of pathologic assessment of completion axillary dissection specimens, which are rarely evaluated with the same exhaustive techniques as are sentinel nodes, making data on the likelihood of additional nodal disease imperfect. These issues were addressed in a consensus conference on sentinel lymph node biopsy.²⁴¹ At the present time, the issue of whether completion axillary dissection confers any advantage following the detection of a sentinel node metastasis is unresolved. In the previously cited study by Veronesi and associates, in 60 of 175 patients in whom only a micrometastasis (foci <2 mm diameter) was found in the sentinel nodes, 10 (17%) had another node involved.²⁷⁵

The use of immunohistochemical staining and the detection of submillimeter metastases present a dilemma for the surgeon outside of the clinical trial setting. Controversy persists, with some questioning the value of additional dissection in view of the low probability of additional nodal disease.^{276–280} Jakub and associates²⁸¹ found that 14.5% of patients with metastases detected by positive immunohistochemical staining for cytokeratin in the sentinel node had additional nodal metastases in completion axillary dissection specimens, leading them to recommend consideration of the procedure. Studies that have considered variables that might affect the possible involvement of nonsentinel lymph nodes have demonstrated a greater likelihood with increasing tumor size²⁸² and the size of the metastasis (>2 mm).²⁸³ Clearly, such decisions must weigh the impact that a completion axillary dissection would have on adjuvant therapeutic decisions and outcome as well as morbidity. A group of 46 women with sentinel node metastases who refused or were recommended to omit axillary dissection for comorbid conditions was studied by Guenther and associates.²⁸⁴ After a mean follow-up of 32 months, none had developed an axillary recurrence, and one developed distant metastases.

An ongoing clinical trial by the American College of Surgeons Oncology Group (ACOSOG Z0011) randomizes patients with T1 or T2 tumors with clinically negative axillae and treated by breast conservation and who have a single sentinel lymph node metastasis on H&E to either have or not have a completion axillary dissection. Use of adjuvant breast radiotherapy and systemic therapy is the same for both

groups.²⁸⁵ This study should provide important data to help resolve the issue.

Are there any adverse reactions to lymphatic mapping?

The potential for allergic and anaphylactic reaction to isosulfan blue dye has now been documented. Montgomery and associates reviewed a series of 2392 patients having sentinel lymphadenectomy using isosulfan blue dye and reported allergic reactions in 1.6%, 69% of which were grade 1 (urticaria, blue hives, rash, or pruritus), 8% grade 2 (hypotension not requiring pressor support), and 23% grade 3 (hypotension requiring pressor support).²⁸⁶ No cross-reactivity was found among patients having a sulfa drug allergy. Awareness of this potential for allergic reactions allows appropriate diagnosis and treatment with diphenhydramine as well as hydrocortisone for more severe reactions.

The patient's urine is frequently blue in the hours following the procedure, and the stool, through excretion of dye in the bile, may also be blue. During surgery, falsely decreased pulse oximeter readings may result from the circulating dye. Blue dye may suffuse into the surrounding breast not encompassed by the surgery. The resulting blue hue invariably dissipates with time, and the patient should be reassured in this regard.

Radioactive colloid use for sentinel lymphadenectomy is considered safe, with radiation exposure to the patient, surgeon, and staff a small fraction of the maximum allowable yearly dose.^{241,287,288} The Consensus Conference on Sentinel Node Biopsy for Breast Cancer noted reassuringly that women who are potentially or actually pregnant are not exposed to any significant risk. Although local radiation safety precautions may differ, special precautions were not deemed necessary beyond the appropriate sealing and identification of waste materials according to institutional practice.²⁴¹

The potential complications of axillary dissection will be discussed later in this chapter. Sentinel lymphadenectomy now has a documented and predictably lower incidence of pain, paresthesias, range-of-motion limitations, seroma formation, axillary web syndrome (a cordlike extension from the axilla down the arm), and arm edema.^{289,290} A drain is not required, and arm mobility may resume immediately after surgery. Paresthesias and pain should be avoidable with careful dissection near the intercostobrachial nerve, although transient symptoms may be experienced.

Is lymphoscintigraphy required for sentinel lymphadenectomy?

Lymphoscintigraphy images lymphatic channels and lymph nodes using radioactive isotopes in the nuclear medicine department, after injection of the isotope around the tumor or biopsy cavity. The patient then lies on a scintiscanner, which tracks the radioactive isotope as it travels from the tumor site through the lymphatic channels to the sentinel node. A hard copy is made of this drainage pattern, and the sentinel node site may then be marked on the skin with ink.

The issue is whether this preoperative imaging is required in managing the breast cancer patient for whom the injection

of isotope and sentinel lymphadenectomy with a gamma probe and blue dye is to be performed. When used for malignant melanoma, lymphoscintigraphy has been of particular value in delineating patterns of lymphatic drainage from ambiguous areas such as the trunk and the head and neck, where the direction of lymphatic flow may be variable, multiple, and even unpredictable. This is useful in planning intraoperative sentinel lymphadenectomy strategies for the melanoma patient. For breast cancer, the needs are less compelling. Many lesions arise in the upper outer quadrant, where the radioactive scatter may obscure the lymphatic channels and sentinel nodes, while the drainage pattern from all other sites is overwhelmingly to the axilla. Hence, the procedure has not been considered a requirement.^{291,292} McMasters and associates found no advantage to the sentinel node identification rate, false-negative rate, or number of sentinel nodes removed if preoperative lymphoscintigraphy was performed.²⁹² Furthermore, the value of detecting occasional internal mammary node or supraclavicular node drainage patterns in altering management remains unclear at this time. Certainly, the sensitivity of intraoperative gamma probes largely obviates the information obtained by preoperative lymphoscintigraphy.

Is there an appropriate learning mechanism for sentinel lymphadenectomy?

Any institution considering the adoption of sentinel lymphadenectomy in the treatment of breast cancer patients must recognize the role not only of the surgical team but also of the pathology and nuclear medicine departments. For the procedure to have a meaningful impact on patient care, multidisciplinary cooperation and continued review and critical analysis of all components of lymphatic mapping, surgical technique, and histopathology should be in place. Traditional training in a surgical procedure relies on the expertise and experience of those transmitting the information to those being trained. The technique of sentinel lymphadenectomy, like laparoscopic surgery before, has been rapidly embraced, with few experienced surgeons to provide direct supervision. To adopt the technique appropriately and develop their competence, surgeons have been encouraged to perform the procedure and follow with an axillary dissection to protect against false-negative sentinel node biopsies by validating that nodes containing metastatic disease were indeed the sentinel nodes. Only in this way would the sentinel node reflect the status of the axilla. An area of discussion therefore became what number of such validating sentinel lymphadenectomies followed by axillary dissections should be required to ensure surgeon proficiency with the procedure.^{234,293,294} Recommendations in general were that a volume in excess of 20 procedures and a rate of failure for identifying the sentinel nodes of less than 5% appeared appropriate.²⁹⁵ Institutional experience and volume, and the level of expertise of those instructing others, would affect the appropriate number for a surgeon in a specific center. As the procedure continues to be adopted and taught in residency training and fellowship programs and as experience builds, specific issues in credentialing will be addressed.^{296,297} As experience broadens, however, it may be inappropriate to ask patients to have completion axillary

dissections for the purpose of developing surgeon proficiency with a technique that is being done largely to avoid axillary dissections.

Is internal mammary sentinel lymphadenectomy indicated?

Sentinel node identification has led to a reconsideration of the role of internal mammary node excision in the treatment of breast cancer. Isolated internal mammary nodal metastases in the absence of axillary nodal involvement have been seen in 5% to 10% of patients for whom both axillary dissection and internal mammary node dissection have been performed.^{298–300} Isolated internal mammary nodal metastases carry the same prognostic implications as isolated axillary nodal metastases.^{301,302} If the identification of such metastases would alter therapeutic management, then the determination by lymphoscintigraphy of those few patients with internal mammary drainage patterns, and sentinel lymphadenectomy of those nodes, would be justified. The presence of both internal mammary and axillary drainage has significant adverse prognostic significance, but because most patients with internal mammary drainage also have axillary drainage, an effort to map internal mammary sentinel nodes has the potential to benefit only a small number of patients.³⁰³ An added concern is the technical limitation of mapping the nodes from medial lesions; this limitation is created by the proximity of radioisotope as well as blue dye at the primary site, both techniques obscuring the potential for isolating the site of sentinel node drainage. Incisions overlying the medial upper intercostal spaces may lead to visible scars, which may become hyperplastic near a midline location, a further consideration when weighing the possible benefits and risks of internal mammary sentinel lymphadenectomy.

Two recent studies on nonaxillary sentinel lymph node biopsy, including internal mammary sentinel nodes, indicated success rates for identifying internal mammary sentinel nodes of 63%³⁰⁴ and 80%.³⁰⁵ Isolated internal mammary metastases were detected in 7.3% and 3.1%³⁰⁵ of patients. A study from Milan of sentinel lymphadenectomy for inner quadrant lesions with lymphoscintigraphic evidence of drainage to the internal mammary nodes found 12 (10%) with metastases in the internal mammary sentinel nodes. All patients had axillary dissections as well, of whom 18% (8 of 45) had axillary metastases and 5% (4 of 77) did not, the internal mammary sentinel node being the only nodal metastasis.³⁰⁶ Ongoing studies may provide reproducible guidelines, but the issue of internal mammary sentinel lymphadenectomy remains unresolved until its therapeutic impact can be more clearly determined. Certainly, the capability of assessing internal mammary nodes, with far less morbidity than was previously the case in the era of extended radical mastectomy, despite the reservations noted, invites a reconsideration of potential benefits.

Is sentinel lymphadenectomy ever indicated for ductal carcinoma in situ?

Theoretically, DCIS does not metastasize, and therefore there is no rationale for any axillary surgery, regardless of how limited. However, sentinel lymph node biopsy for DCIS in four

studies had a reported incidence of metastases of 3% to 13%.^{307–310} These unexpected incidences highlight the paradoxical limitations of histologically designating all DCIS as categorically noninvasive, particularly when such designation is based on core biopsy or incisional surgical biopsy specimens. In view of the biologic heterogeneity of DCIS, it would appear reasonable to consider sentinel node biopsy in those patients with extensive high-grade DCIS, particularly when there is associated radiographic or clinical suggestion of a mass lesion in association with the DCIS, as well as in patients with extensive disease often necessitating mastectomy. In other instances, breast conservation does not preclude performing sentinel lymphadenectomy as a staged procedure if histologic assessment demonstrates unexpected invasion. Most sentinel nodal metastases in patients with DCIS have been detected by immunohistochemical staining alone.^{309,310} With the increasing use of immunohistochemical staining of sentinel lymph nodes has come uncertainty about the biologic and prognostic significance of micrometastases detected by this technique, a group that may be expanded by routine sentinel lymphadenectomy for all DCIS.

What are the contraindications to sentinel lymphadenectomy?

Any attempt to establish restraints on the performance of sentinel lymphadenectomy runs the risk of being quickly refuted by newer data in this rapidly evolving area of investigation. Certainly, patients with palpable axillary disease or patients discovered at the time of surgery to have a palpable nonsentinel node are not candidates for initiating or continuing the procedure, respectively. Patients with T3 lesions (>5 cm) are not appropriate candidates, although it has been suggested that those whose cancers have been downstaged by neoadjuvant systemic therapy may be candidates.³¹¹ Patients with multifocal and multicentric disease, previously considered not to be candidates for sentinel lymphadenectomy, are being re-evaluated in this regard. Tousimis and associates reported no difference in the accuracy, sensitivity, or false-negative rate in sentinel lymph node biopsy for 70 patients having multifocal or multicentric breast cancer compared with literature validation studies of sentinel lymphadenectomy, most patients in those studies having single-site invasive breast cancer.^{312,313} This experience supported previous observations that regardless of location, tumors drain through afferent lymphatic channels to a common axillary sentinel lymph node.^{314,315} Whether the presently held belief that radiation to the breast or prior breast or axillary surgery is a contraindication to sentinel lymphadenectomy will be altered based on evolving experience remains to be seen.

When is axillary lymph node dissection appropriate?

Clearly, the introduction of sentinel lymphadenectomy has challenged the popular adherence to performing an axillary dissection as an essential component of the surgical treatment for most invasive carcinomas of the breast. Despite the caution that has been expressed against adopting sentinel lymphadenectomy as a standard of care until the technique and its

impact on patient outcome have been validated in prospective trials as well as by individual surgeons and institutions critically assessing both their surgical and histopathological techniques, the trend is unquestionably toward abandoning elective axillary dissection in favor of sentinel lymph node biopsy.³¹⁶ In this regard, an ongoing randomized phase III clinical trial by the NSABP (Protocol B-32) assigns patients to sentinel lymphadenectomy with axillary dissection, or to sentinel lymphadenectomy alone if there is no evidence of metastases by intraoperative imprint cytology or permanent H&E-stained sections. If metastases are found in the sentinel nodes in the latter group, an axillary dissection is performed.³¹⁷ At the present time, for patients with metastases in the sentinel nodes, patients with clinically evident axillary metastases, patients with grossly apparent axillary metastases intraoperatively that may fail to absorb dye or radioisotope, selected patients with a very high risk for harboring axillary micrometastases, and those for whom sentinel lymphadenectomy would not be appropriate, axillary dissection remains a relevant component of primary surgery.

How is axillary dissection defined?

Axillary dissection for breast cancer was originally described as an integral part of radical mastectomy and remained an essential component of the various subsequent modifications of the radical mastectomy that preserved the pectoralis major muscle.^{318,319} In that context, axillary dissection connoted a complete resection of the lymph nodes in the axilla at all three levels. Efforts were made as well to include all external mammary lymph nodes extending from the medial border of the axilla along the chest wall from the second to sixth ribs. When the pectoralis major was preserved, dissection of the level III apical nodes could be facilitated by transecting the attachment of the pectoralis minor muscle to the coracoid process. As described by one of the authors, dividing the sternal portion of the pectoralis major could further facilitate axillary exposure and dissection, following which the muscle would be reconstructed.³²⁰

When an axillary dissection is performed in conjunction with a breast-conserving procedure, the extent of dissection has often been modified. Data on elective axillary dissection for breast cancer suggest that in the absence of palpable or suspicious adenopathy encountered intraoperatively, axillary dissection most appropriately incorporates level I and II nodes because the incidence of micrometastases in level III in the absence of micrometastases in level I or II is less than 1%.^{321,322} Metastasis to level II nodes is more frequent. Although the incidence of isolated metastasis to level II was still less than 2% in the series of Veronesi and associates^{321,322} and Rosen and associates,³²³ the incidence of “skip” metastases did exceed 20% in the reports of Pigott and associates³²⁴ and of Danforth and colleagues.³²⁵ Level I and II dissection now represents the anatomic extent of axillary dissection in most reports. Certainly, the inclusion of the lymph nodes beneath the pectoralis minor muscle is easily accomplished and would appear advisable based on these studies. In Giuliano’s original sentinel lymph node description, 27% of sentinel nodes were in level II with or without a sentinel node in level I.²²

The introduction of adjuvant systemic therapy heightened the importance of axillary nodes as a predictor of recurrence,

even while the therapeutic role of axillary dissection was being questioned. Proposals that axillary “sampling” might provide the same prognostic information as a more complete axillary dissection, with less morbidity, failed to gain acceptance and were completely retired with the accurate identification and excision of intraoperatively mapped and dyed or radioisotopically labeled sentinel lymph nodes. The random sampling of lateral nodes without such efforts at precise delineation of the draining nodes from the specific site of the primary cancer has been associated with significant rates of axillary recurrence exceeding 10%, the recurrence rate being inversely related to the number of nodes sampled.¹³⁶ When axillary dissection is performed, it should be performed as a formal anatomic procedure to include nodes within defined boundaries. This further enables the accurate identification and preservation of related neurologic structures, injury to which could be a source of morbidity.

Despite refinements in indications for axillary dissection, the major issue of controversy remains the uncertainty of its therapeutic impact on survival. Recent attempts to refine the indications for axillary dissection have focused on whether the procedure is indicated (1) when the risk for additional micrometastases is low following a sentinel node biopsy and (2) when the results of axillary dissection are not likely to alter subsequent adjuvant therapy, particularly in postmenopausal patients.^{326–328} Refinement of indications has been particularly important with more widespread adoption of breast-conserving procedures, whereby an axillary dissection for a sentinel micrometastasis is most often an additional surgical procedure, in contradistinction to when it is performed en bloc with a mastectomy, or when an axillary dissection following mastectomy, sentinel lymphadenectomy, and reconstruction can pose additional technical challenges. The adoption of induction systemic therapy for more locally advanced breast cancers and its application to trials of stage II and even stage I disease may significantly alter even the prognostic value of axillary staging.

Should an axillary dissection be performed at the same time as a segmental excision?

When a patient has a clearly defined lesion diagnosed as invasive cancer by needle biopsy and a demonstrable metastasis in the sentinel node or nodes at surgery, it is appropriate to perform an axillary dissection at the same time as segmental excision. When a metastasis is not demonstrable, and when a more diffuse malignant pattern not appreciated clinically or mammographically is demonstrated histologically in the segmental excision specimen, necessitating either re-excision or, in some cases, a recommendation for mastectomy, axillary dissection is obviously dependent on final sentinel node histopathology. An advantage of sentinel lymphadenectomy is that it allows better technical planning of mastectomy and axillary dissection if they are required. Furthermore, the issue of immediate reconstruction can also be more optimally approached with the knowledge that an axillary dissection will or will not be performed.

A common problematic patient in this regard is the woman with a palpable mass but ill-defined carcinoma in a fibro-nodular breast in which clear mammographic, sonographic, or even MRI assessment of the extent of the cancer may be

compromised by the density and nodularity of surrounding breast parenchyma. Such ill-defined lesions in the patient desirous of breast conservation are best assessed by a staged procedure—performing the segmental excision and sentinel lymphadenectomy and then awaiting full histopathologic evaluation. If a more extensive infiltrative or intraductal component is found that could not be appreciated by palpation or radiographic evaluation, and the axilla is accurately staged by histologic study of the sentinel node, the issue of mastectomy can be more objectively discussed with the patient, as can immediate reconstruction. If the lesion has been histologically confirmed to be encompassed by appropriate tumor-free margins, breast conservation can be accepted with greater confidence. Sentinel lymphadenectomy provides accurate information on the appropriateness of a subsequent axillary dissection.

What is the appropriate incision for an axillary dissection?

An axillary dissection is best performed through a curvilinear incision that follows a natural skin crease placed below the hair-bearing area of the axilla. When it follows sentinel lymphadenectomy, it can encompass that incision with a skin ellipse. The medial extent of the incision is kept below the edge of the pectoralis major. Posteriorly, the incision extends to the posterior axillary line, although it can be extended more posteriorly to allow additional traction on the skin for better exposure of the axilla. Extending the incision posteriorly is preferable to extending the incision medially over the edge of the pectoralis major. The sentinel lymphadenectomy incision is best planned with a view to the possibility of extending it into a full axillary dissection incision.

For most lesions in the upper outer quadrant, it is aesthetically preferable to use a separate axillary dissection incision (Fig. 24–20). A second incision in the axilla is less likely to create a visible scar and defect than when an attempt is made to perform the segmental excision and sentinel lymphadenectomy and possible axillary dissection en bloc through a single

incision. An exception is a lesion high in the tail of the breast, where the incision used to perform the segmental excision through a natural skin crease below the hair-bearing area of the axilla would be directly contiguous with a sentinel lymphadenectomy and possible subsequent axillary dissection incision.

How is the patient positioned?

The patient is positioned with the posterior axillary line at the edge of the table. The breast and axilla are prepared and draped with the arm free and out on an armboard at a right angle to the patient. It is not necessary to place a pad beneath the shoulder to assist in exposure of the axilla. With slight rotation of the table toward the contralateral side and with the patient in the reverse Trendelenburg position, the axilla can be well positioned for dissection, with less posterior stretch on the shoulder girdle than if a pad were used to project the axilla anteriorly. Similarly, one should not position the arm superiorly at an oblique angle because unnecessary traction in that direction, particularly if done rapidly or for an extended period of time, may stretch the brachial plexus. As already discussed, undue traction on the arm, which may stretch the brachial plexus, may create a brachial plexitis with its attendant neurologic symptoms and even paralysis.³²⁹ Prepared and draped, the arm free it can be gently positioned in a medially abducted direction, thereby facilitating retraction on the pectoralis major and minor muscles to enhance exposure of the medial axillary contents (Fig. 24–21).

What is the technique of axillary lymph node dissection?

The incision is outlined, and skin and subcutaneous tissue are transected with a thin ellipse encompassing the sentinel lymphadenectomy incision if this has been performed. Flaps are raised beneath the subcutaneous layer medially to the edge of

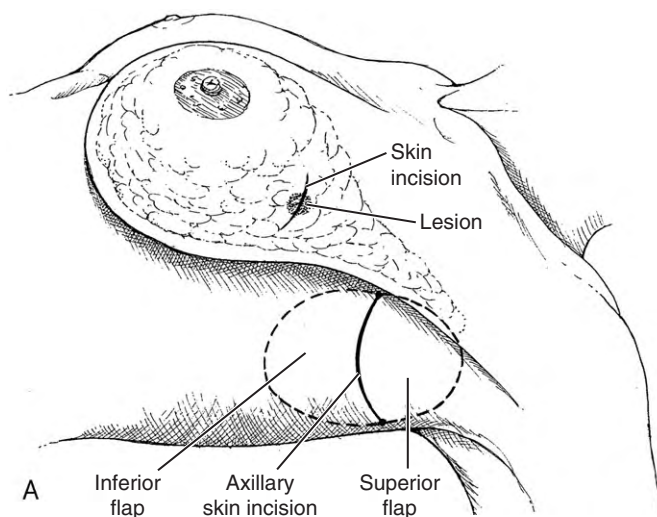

Figure 24–20 A and B, Separate incisions for segmental excision and axillary dissection for a lesion in the upper outer quadrant of the breast. In most instances, it is an extension of the sentinel lymphadenectomy incision following detection of sentinel node metastases.

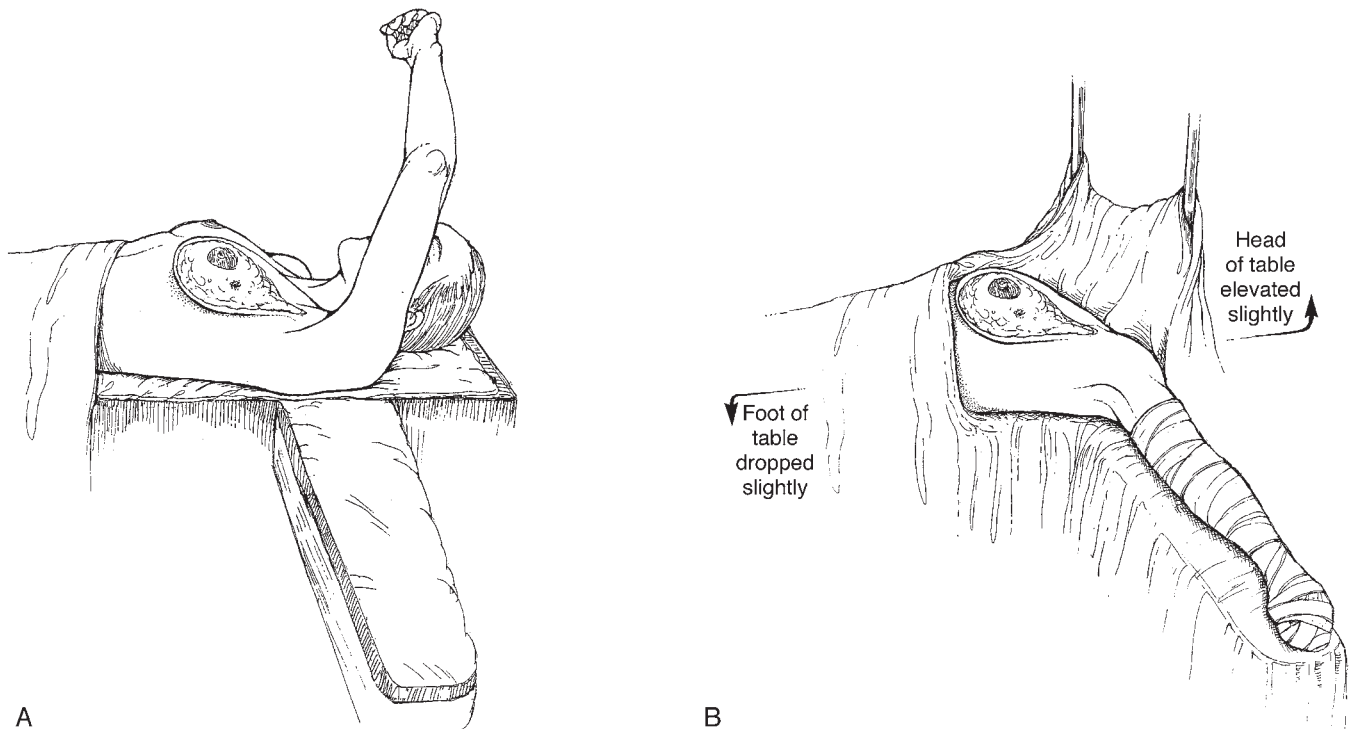

Figure 24-21 A and B, The breast and axilla are prepared and draped with the arm free and at a right angle to the patient. This allows arm mobility during the procedure, which facilitates exposure of the axillary contents.

the pectoralis major, superiorly to its tendinous insertion, inferiorly to the level of the sixth rib (to incorporate the external mammary nodes), and posteriorly to the edge of the latissimus dorsi, which is directly at the posterior limit of the skin incision. In an obese patient, the edge of the latissimus dorsi may be elusive at first, but unnecessary posterior dissection through the fat in an attempt at its identification should be avoided because this may be an additional source of seroma formation postoperatively. Clear definition of the edge of the latissimus dorsi, particularly at its tendinous insertion superiorly, ensures inclusion of the most lateral nodes in the lateral axillary group in the dissection specimen. Occasionally, a muscular band is encountered traversing the axillary vein, arching from the latissimus dorsi to the insertion of the pectoralis major. Dividing this muscular arch enables identification of the edge of the latissimus dorsi superiorly. In elevating the flaps, traction is placed superiorly and inferiorly with the use of sharp rake retractors. When the flaps are elevated, a self-retaining retractor may then be used to maintain exposure along this axis (Fig. 24-22).

After skin flaps have been elevated and the margins of the dissection have been defined, the thin fascial layer overlying the lateral pectoralis major muscle fibers is dissected laterally while the pectoralis major is easily retracted medially. With medial traction on the pectoralis major, the lateral edge of the pectoralis minor is defined. The medial pectoral nerve branches and vessels are preserved while the clavipectoral fascia contiguous with the pectoralis minor fascia is opened parallel to the lateral edge of the muscle. The clavipectoral fascia is further incised from the upper edge of the pectoralis minor proceeding laterally, thereby exposing the lymphoadipose

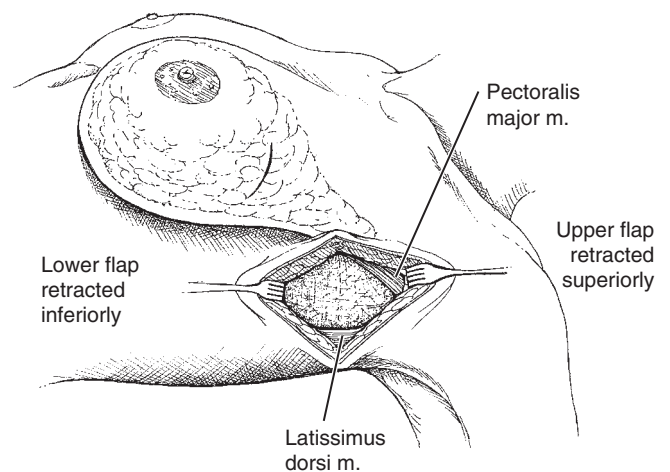

Figure 24-22 Flaps are elevated to expose the lateral axilla.

contents of the axilla (Fig. 24-23). With a right-angle retractor providing traction superiorly and medially on the upper portion of the pectoral muscles, and with gentle traction inferiorly on the lymphoadipose tissue, the axillary vein is identified. A plane of dissection is frequently easy to identify just above the axillary fat as it wraps itself just superior to the axillary vein, and this is divided. An exerted effort to dissect all of the soft tissue off the brachial plexus and the adventitia of the axillary vein is inappropriate. Although Rotter's nodes may be dissected free, care should be taken to protect the medial pectoral nerve and vascular bundle, which may be seen lateral to

Figure 24-23 Retraction is placed on the pectoral muscles, and the clavicular fascia is divided to expose the surgical anatomy of the axilla.

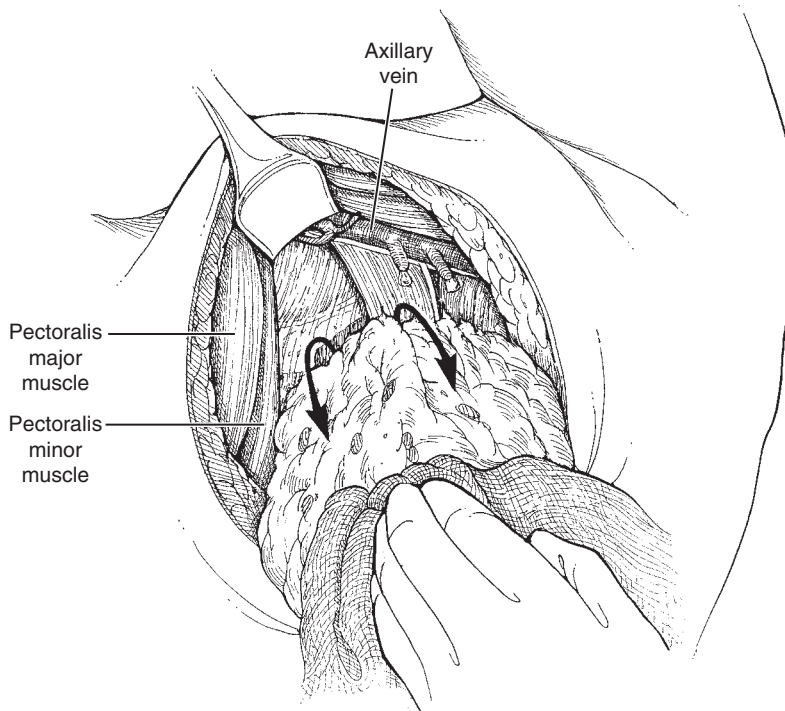

Figure 24-24 Axillary dissection proceeds from level II laterally.

the pectoralis minor muscle but in some instances may enter the pectoralis minor before some of its fibers emerge to innervate the lateral pectoralis major muscle. Dividing the fascia lateral to the border of the pectoralis minor enables retraction medially and facilitates the dissection of level II nodes subjacent to the superior extension of the muscle (Fig. 24-24).

When nodes are palpable on preoperative evaluation and confirmed or noted to be enlarged at surgery, particularly if apparent enlargement extends just lateral to or beneath the pectoralis minor, it is appropriate to extend the axillary

dissection to include the nodes at the apex (level III). For this purpose, it may be helpful (although not always necessary) to divide the insertion of the pectoralis minor from the coracoid process after incising the fascia over the coracobrachial muscle. Division of the pectoralis minor will require division of branches of the medial pectoral nerve, but care should be taken to preserve the lateral pectoral nerve and thoracoacromial vessels, which emerge medial to the pectoralis minor (Fig. 24-25). Nevertheless, division or injury of branches of the medial and lateral pectoral nerves is likely when the

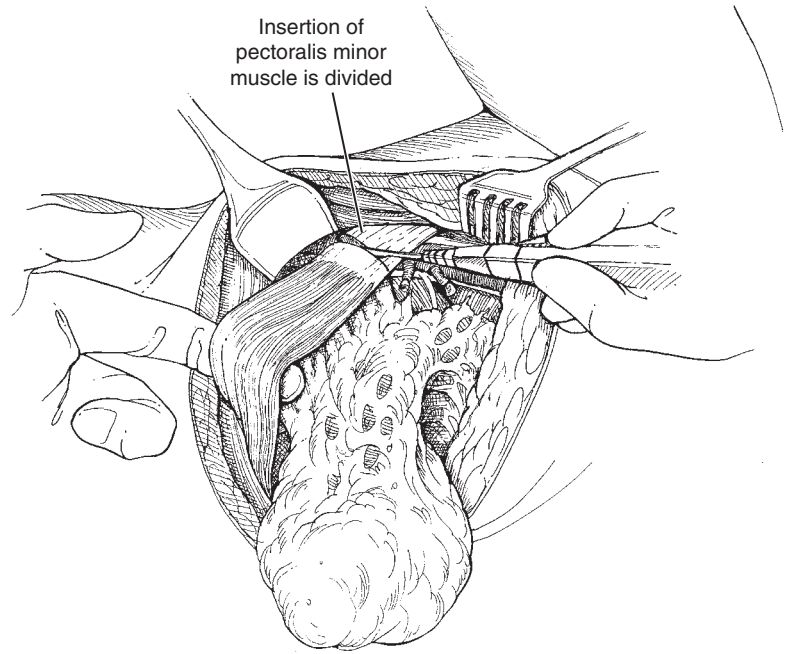

Figure 24–25 When complete axillary dissection is performed, division of the insertion of the pectoralis minor from the coracoid process may facilitate the apical dissection.

interpectoral space is entered by division of the insertion of the pectoralis minor muscle, which in turn may lead to varying degrees of atrophy of the pectoralis major, particularly of its lateral border.³³⁰ Division of the pectoralis minor to achieve a complete axillary dissection should therefore be applied selectively.

To allow clear access to the apex of the axilla, the pectoral branches of the thoracoacromial vessels are sacrificed. In dissecting free the level II or, when indicated, level III nodes, it is appropriate to have an assistant support the forearm in a position directed toward the contralateral side and parallel to the patient. This facilitates retraction of the pectoralis major and exposure of the nodes at this higher level. Although the use of an illuminated right-angle retractor may be of some value, with appropriate proper positioning of the arm, gentle lateral traction on the axillary contents, and medial retraction on the pectoral muscles, this has not been necessary in our experience. Lymphatic dissection then proceeds off the inferior axillary vein, dividing and ligating vascular tributaries as the procedure progresses laterally. All branches of the axillary vein and artery are divided and ligated from the level of the thoracoacromial vessels. Posteriorly directed subscapular vessels are not ligated.

In most instances in which the pectoralis minor is divided from the coracoid process to facilitate exposure of the apical lymph nodes, the thoracoacromial vessels and lateral pectoral nerves are preserved. The highest points in the dissection, either the apical nodes or the level II nodes, are tagged to facilitate orientation and identification by the pathologist. As the dissection proceeds laterally, the inferior axillary contents are dissected off the serratus anterior fascia. The intercostobrachial nerve is identified as it exits the second intercostal space and is preserved whenever possible. Preservation of this nerve is achieved by dissecting it from the surrounding axillary fat as it courses upward and lateral to innervate the axillary skin and medial upper arm. If the intercostobrachial

nerve is transected, paresthesias of the skin of the axillary and medial arm will result, although this may abate with time because of the richness of sensory innervation of the axilla and upper arm, as previously described.³³¹ Preservation of the intercostobrachial nerve or its superior fibers when it is arborized is clearly desirable, as has been well recognized,³³² but when it is sacrificed, sensation may be expected to return or improve in most patients. Clearly, temporary paresthesias in the early postoperative period may occur even with preservation, but sensation in such instances will more predictably return.³³³ Certainly, the thoroughness of the lateral axillary dissection when grossly involved nodes are encountered should not be compromised by a compulsive effort to preserve anatomically the intercostobrachial nerve despite the desirability of keeping sensory innervation intact.

As the dissection moves to the junction of the serratus anterior and subscapularis muscles, the lateral intercostal perforating vessels and nerves are divided and ligated. The lymphoadipose tissue is continually retracted and swept laterally off the serratus anterior fascia. The fascia of the serratus anterior may coalesce in a line that may be mistaken for the long thoracic nerve. A gentle incision in the filmy adventitia about 1 to 2 cm lateral and parallel to the chest wall will facilitate clear visualization of the nerve throughout its course over the lateral chest to the fourth or fifth intercostal space. With lateral traction applied to the axillary contents that have already been freed, and after a sharp incision lateral to the long thoracic nerve throughout its visible length, the nerve is gently reflected and returned medially to its position along the chest wall, further securing its safe preservation (Fig. 24–26).

After the incision in the filmy adventitia overlying the axillary contents and the identification, gentle medial retraction, and preservation of the long thoracic nerve, another incision is made paralleling the chest wall into the thin subscapularis fascia. With the arm elevated slightly and with gentle traction exerted medially on the dissected axillary contents, the

Figure 24-26 Dissection proceeds laterally to preserve the long thoracic nerve, while the intercostobrachial nerve is preserved whenever possible throughout its length.

thoracodorsal nerve and vessels are easily identified. The arm is then again placed downward at a right angle to the patient, and by following the plane established by incision into the filmy subscapularis fascia and gentle traction laterally, the thoracodorsal nerve and vessels can be easily preserved and the axillary contents further dissected lateral to these structures. Adherence of grossly involved lateral axillary nodes to the thoracodorsal bundle may, in rare instances, necessitate its sacrifice with minimal discernible consequence.

Dissection is then completed to the edge of the latissimus dorsi and the lateral extent of the axillary vein where the specimen is transected (Fig. 24-27). Tagging the lateral margin of the axillary dissection further orients the specimen for the pathologist. The wound is irrigated with saline solution, and meticulous hemostasis is ensured.

Should the axilla be drained?

Controversy exists over the advisability of drainage following an axillary dissection. The hollow that exists after removal of the lymphoadipose contents, as well as the movements of the chest wall during respiration and of the arm, make the accumulation of serum, lymph, and inflammatory exudate inevitable. Although such fluid accumulation requiring aspiration is basically a source of annoyance without lasting sequelae, it may lead to secondary infection and a delay in initiating adjuvant therapy. Arm immobilization, flap-tacking sutures, and even bovine spray thrombin have been proposed

to minimize this complication.³³⁴ Closed-suction drainage, however, has been the mainstay of efforts to minimize this problem. Drainage is advisable not only to lessen fluid accumulation but also to provide appropriate negative pressure that allows the overlying skin to adhere to the newly formed hollow of the axilla. It has been noted that seromas requiring at least a single aspiration occur in about 30% of patients with drains left in place until the drainage has decreased to minimal levels (20 mL/day).³³⁵ However, drainage exceeding 100 mL/day is common in the first 2 to 3 days after axillary dissection. Continued drainage of the axilla until the volume decreases to less than 20 mL/day, common by postoperative day 5, would seem judicious and certainly is easily managed on an ambulatory basis. A closed-suction or drainage system using a single-limb Jackson-Pratt drain or a double-limb Hemovac system brought out through separate stab wounds beneath the lower flap and secured to the skin is advisable, the drains being very gently held away from the neurovascular structures with loosely tied absorbable sutures placed in a site in the serratus anterior muscle. A subcutaneous closure of 2-0 or 3-0 absorbable sutures, followed by a subcuticular closure and the application of Steri-Strips to the skin, is then completed (Fig. 24-28). Efforts to minimize drainage and decrease the length of time closed-suction drainage is required have focused on the use of fibrin sealants, but concerns regarding cost, viral safety, and the need for closed-suction drainage despite their use have limited their widespread adoption despite favorable reductions in days to drain removal and fluid drainage in a prospective randomized trial.³³⁶

Figure 24-27 Completion of the axillary dissection.

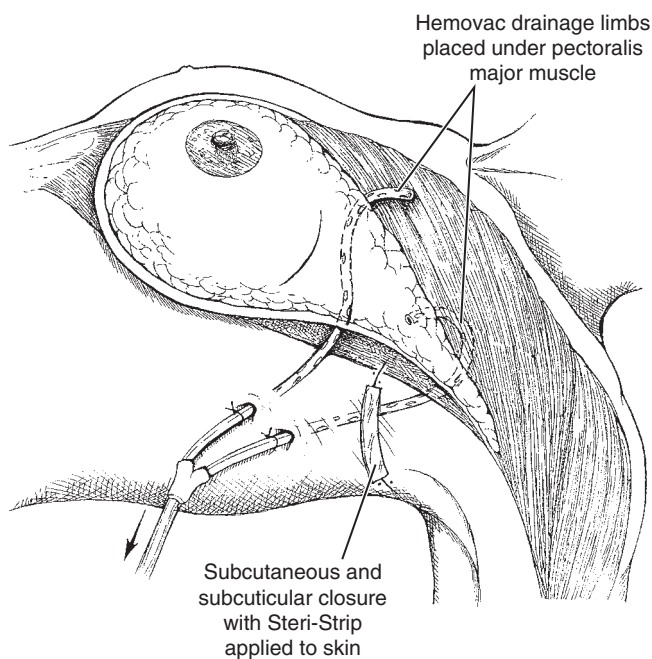

Figure 24-28 The incision is closed over closed-suction drainage.

Is physical therapy required after axillary dissection?

Normal shoulder mobility is preserved when an axillary dissection is performed with the appropriate care to protect the neuromuscular structures as previously outlined. Shoulder immobilization has been advised to decrease postoperative seroma formation after axillary dissection, although the duration of such limitation of movement has not been defined.³³⁷

Certainly, vigorous physical therapy would seem inappropriate following an axillary dissection that anatomically preserves neuromuscular function. If closed-suction drainage is employed, modest mobility of the arm is advisable to minimize stiffness and the risk for a frozen shoulder if immobility is prolonged. On the first postoperative day, the patient is encouraged to elevate the arm so that the head can be touched. This allows any inhibition in mobilizing the arm to be overcome and reassures the patient that normal range of motion is intact. Vigorous arm motion is discouraged while closed-suction drainage is in place. When it is clear that adherence of the skin to the base of the underlying axillary hollow is ensured and that seroma formation is not occurring, the patient is encouraged to increase the use of the arm with full range-of-motion activity. Some serous accumulation may result, which is easily managed by simple aspirations until the space seals and fluid no longer collects. Particularly with older patients, prolonged arm immobilization, which may lead to a frozen shoulder that in turn requires physical therapy, should be discouraged. These guidelines are also appropriate after mastectomy, as will be discussed.

MANAGEMENT OF LOCAL AND REGIONAL RECURRENCE AFTER BREAST-CONSERVING SURGERY

Cancer recurrence after excision and radiation therapy is dependent on many variables, which include most significantly the extent of the initial surgery and margin status but also the adequacy of radiation dosage and the technique and timing of radiation; histopathologic characteristics and architectural pattern, including the extent of intraductal disease when an invasive cancer is being treated or the grade of histopathology when an exclusively intraductal cancer is being

treated; lymphatic vessel invasion; and clinical factors such as age and even family history and *BRCA1* or *BRCA2* mutations. The potential role of molecular biologic markers as a predictor of risk for local recurrence remains to be defined. A recurrence near the original excision site, a brief time to recurrence, and an identical histologic pattern would suggest that it evolved from residual disease. As discussed in Chapter 26, 70% to 80% of the recurrences seen within 10 years of treatment are adjacent to or in the same quadrant as the original excision, which has prompted the application of boost doses of radiation to the site of tumor excision in selected instances.^{338,339} The longer the time to recurrence, the greater the chance that the recurrence will be noted in another quadrant, although even with more prolonged disease-free intervals, most recurrences are in the vicinity of the initial excision. Whether the recurrence is viewed as the progression of residual disease or as a new primary lesion, reported incidences at 5 years double by 10 years.^{340,341} In a review from the National Cancer Institute in Milan of 2233 women treated by breast-conserving therapy (quadrantectomy, axillary dissection, and radiotherapy), local failures occurred at a rate of about 1% per year for the first decade after treatment,³⁴² an incidence not dissimilar to the risk for contralateral breast cancer.³⁴³ It might be expected that with the appropriate selection of patients for breast conservation based on reported experiences to date, as well as the application of surgery that optimizes tumor-free margins and improvements in radiation technique, the incidence of recurrence in the breast would decrease in future series. Whether breast cancer recurrence leads to decreased survival remains unanswered. Meric and colleagues, in a retrospective review of more than 1000 patients, identified positive surgical margins and breast cancer recurrence as independent variables of poor disease-specific survival.⁹⁵ Such an analysis, however, does not necessarily implicate breast cancer recurrence as the initiator of distant relapse.

Until the biologic significance of breast cancer recurrence is elucidated, efforts at optimal local treatment remain essential. It must be appreciated as well that effective surgery and radiotherapy do not eliminate the risk for a new cancer developing in the treated breast, and therefore continued surveillance of both the treated and the untreated opposite breast remains essential.

What is the treatment of recurrence after breast-conservation therapy?

Patients with a recurrence after breast-conservation therapy should be evaluated for concurrent distant metastases, which will be detected in about 10% of patients.^{330,344,345} For the remaining 90% of patients, the issue will be whether breast conservation is still possible or whether mastectomy is mandatory. Clearly, evidence of inadequate initial surgery or radiotherapy in a patient who develops mammographically detected intraductal carcinoma adjacent to the site of initial surgery suggests that an additional attempt at breast conservation may be warranted. Kurtz and associates³⁴⁶ reported on a selected group of patients treated by wide excision following ipsilateral breast recurrence. Patients were divided into those treated for recurrence before or after the first 5 years of initial treatment; the authors noted subsequent ipsilateral failure rates of 36% and 22%, respectively. Further, a breast failure

rate of 50% occurred in 14 patients reported by Dalberg and associates following wide excision for breast recurrences.³⁴⁷ Until specific criteria are developed for selecting patients for whom continued breast conservation might be appropriate, these experiences warrant the continued recommendation of mastectomy as the procedure of choice for ipsilateral recurrence following breast-conserving surgery and radiation. Locoregional control rates of 85% at 5 years and disease-free survival rates exceeding 40% at 5 years have been reported.^{348,349} Certainly, the recommendation for mastectomy is particularly compelling for patients whose initial surgery and radiation therapy were performed with techniques and precautions directed toward achieving maximal local disease control, for those whose recurrence is at a site in the breast clearly separate from the initial excision, for those whose initial treatment surgically encompassed a significant segment of breast, and for those whose recurrence demonstrates lymphatic permeation or a prominent intraductal component.

The local and regional recurrence rates reported after mastectomy following recurrence in the irradiated breast are, in most series, less than 10%.^{330,335,337,339,350} Reconstruction in this setting should not be discouraged in most instances. Because irradiated tissue is less malleable and less likely to withstand the potential ischemia of tissue expansion and implant placement, autologous tissue transfer techniques are more appropriate, as discussed in Chapter 25.³⁵¹ The surgical management of the axilla is obviously dependent on whether a sentinel lymphadenectomy or axillary dissection was performed initially and also on the pathologic findings of the recurrent cancer. If the recurrence is an invasive lesion and the axilla was not previously dissected, a level I and II dissection is performed with the mastectomy, reserving a complete dissection to level III for patients with palpable or intraoperatively detected axillary metastases. Sentinel lymphadenectomy may be appropriate in the absence of clinical axillary metastases, but the impact of prior surgery and radiotherapy may preclude this technique. Certainly, the appropriateness of sentinel lymphadenectomy in this setting remains to be determined.

Survival rates following mastectomy for recurrence have been reported to be comparable to those following mastectomy for primary lesions. In the largest reported series of Kurtz and associates,³⁴⁰ the 5-year survival rate was 69%, with a survival rate of 84% if the recurrence was more than 5 years after initial treatment, decreasing to 48% if the recurrence was within the first 2 years of initial treatment. Prognostic and adjuvant therapeutic considerations are being evaluated but are likely the same as with mastectomy for a primary carcinoma. The phrase "salvage mastectomy" in this setting may therefore inappropriately connote a situation of desperation that may not be justified.

What other malignant lesions can occur after breast-conservation and radiation therapy?

Angiosarcoma of the breast has been reported following breast-conserving surgery and radiation therapy. Lymphedema of the conserved breast has been implicated as a contributing cause.³⁵²⁻³⁵⁴ A latency period of 4 to 7 years from primary therapy to presentation has been reported.³⁵⁵⁻³⁶¹ The patient may be noted to have a bluish or purple plaquelike eruption or nodules with surrounding erythema (Fig. 24-29),

Figure 24-29 Angiosarcoma of the breast presenting 72 months after breast-conserving surgery and radiation therapy.

which may be incorrectly attributed to trauma or an unrelated cutaneous eruption. A high index of suspicion is essential to enable a diagnostic biopsy to be performed expeditiously. Treatment has generally been mastectomy, but long-term survival data are not available. In a review of all reported cases in the English literature with at least 1-year follow-up by Monroe and associates,³⁵⁶ 55 of 75 patients (73%) developed tumor recurrences after surgery, most (84%) within 1 year. The most common site of “distant” failure has been the contralateral breast. Preliminary encouraging results with adjuvant hyperfractionated postoperative radiotherapy have been reported.³⁵⁷

How is recurrence in the axilla managed?

Axillary recurrence following axillary dissection, as previously discussed, should be rare. Repeat axillary dissection rather than axillary radiation is indicated, if feasible, because surgery is associated with high rates of local control. In a study from the University of Texas M. D. Anderson Cancer Center on 44 patients with axillary recurrence as the initial treatment failure, 40 (91%) had had an axillary node dissection as part of their initial treatment; axillary control of disease was achieved in 31 patients (71%) at a median follow-up of 70.8 months. Control was most successful in those patients treated with surgery as well as radiotherapy and systemic therapy. Distant metastases occurred in 50% of patients.³⁶² Adjuvant radiotherapy and systemic therapy would appear appropriate despite limited reported experience. If there is a synchronous breast recurrence, mastectomy is appropriate, but in the absence of any mammographic or palpable breast recurrence, mastectomy is not indicated. Certainly with a diagnosed breast cancer recurrence, efforts should be made to ascertain whether there is an axillary recurrence, because the association with a breast recurrence either simultaneously or at a later time may be as high as 71%, as reported in a study from the University of Pennsylvania.³⁶³ In a study from the Netherlands, axillary recurrence occurred in 59 of 4669 patients, 208 of whom had bilateral axillary dissections, for a total of 4877 axillary dissections (1%).³⁶⁴ Axillary recurrence

following breast conservation with axillary dissection and radiotherapy has been associated with survival rates of 25% to 70% in reported experiences.^{362,363,365}

TOTAL MASTECTOMY

How is total mastectomy defined?

Total mastectomy refers to removal of the breast, including the tail of Spence, which extends into the axillary space. Implicit in the designation of the procedure as a total mastectomy is the attempt to remove all breast tissue, and it should not be referred to as a simple mastectomy. Also implicit in the designation of this procedure as a total mastectomy is the absence of a formal axillary lymph node dissection. Not uncommonly, however, those lateral lymph nodes in direct juxtaposition with the tail of the breast are incorporated in the specimen when the breast is totally excised. The appearance of such nodes in the specimen does not justify the description of the procedure as a modified radical mastectomy or as a mastectomy with lateral axillary dissection, both terms connoting a formal dissection of at least the level I lymph nodes.

What are the indications for total mastectomy?

Total mastectomy is reserved for instances in which the anatomic distribution of cancer does not allow breast conservation, or the patient selects mastectomy as her preferred form of treatment, but formal axillary dissection is not indicated because the definable cancer is exclusively noninvasive. As previously discussed, there may be a small subgroup of patients with invasive carcinomas who are unlikely to benefit from axillary staging. At the present time, these are well-differentiated lesions smaller than 1 cm (T1a and T1b), such as pure tubular or colloid carcinoma, in which the risk for axillary metastases is very much less than 5%. In the absence of other findings in the breast, most of these patients are treated with breast conservation. The issue of sentinel lymphadenectomy in such situations is not resolved, and certainly axillary dissection with mastectomy is therefore rarely an issue. Sentinel lymphadenectomy in such instances may be a reasonable adjunct to total mastectomy. Because total mastectomy is frequently performed for noninvasive but architecturally diffuse lesions associated with a significant risk for microinvasion, a level I axillary dissection in such instances has been considered appropriate,³⁶⁶ although sentinel lymphadenectomy in such instances as well may largely supplant any such formal procedure. Likewise, concomitant immediate reconstruction is particularly appropriate, as discussed in Chapter 25.

What incisions should be used for total mastectomy?

Histologically favorable lesions treated by total mastectomy are those that particularly enable the maximal preservation of skin and that may further optimize the aesthetic results when

immediate reconstruction is also performed. Traditional mastectomy incisions were developed for procedures often designed for large, palpable lesions with secondary skin changes. Even with modifications and the placement of incisions in a transverse direction, incisions often extended from the mid-sternum to the posterior axillary line. There is no support for the large extent of these incisions when the risk for skin involvement is not at issue, and this is particularly so for noninvasive cancers. Although the site of pathologic changes and the placement of prior incision scars, when present, largely determine the direction and extent of skin incisions, for the most part incisions that adhere to the central areolar circumference and extend medially for a short distance in the area between the edge of the areola and sternum and laterally between the areola and posterior axillary line are appropriate and preferable when immediate reconstruction is planned (Fig. 24–30A–D). A variety of skin-sparing mastectomy incisions (a term first used by Toth and Lappert³⁶⁷) have been used to further optimize the aesthetic benefits of immediate reconstruction by preserving the patient's own breast envelope, creating less conspicuous incisions, and reducing the volume of tissue transferred when autologous flap techniques are employed (Fig. 24–30E). Not only incisions that adhere closely to the areolar edge but also double incisions that closely encompass the nipple–areolar complex and elliptically excise a tumor, biopsy, or excision site at some distance from the central breast, preserving the skin between these two sites, may be used as well in skin-sparing mastectomies (Fig. 24–30F). Incisions that adhere closely to the edge of the areola may be used, particularly when the areolar distance is generous and in women whose breasts are small.³⁶⁸ Conversely, the desire to spare skin must be balanced by a recognition that excessive flap length may risk skin necrosis for variable distances along the edge of the closure. In planning incisions for a normal or large breast, an ellipse that encompasses the areola may be preferable to incisions that attempt to preserve all of the skin except for the central nipple–areolar complex. “Tennis-racquet” extension or separate axillary incisions may be used to allow sentinel lymphadenectomy or even lateral axillary dissections to be performed, delivering the tail of the breast and dissected axillary contents with the specimen through the mastectomy incision. Caution must also be taken for patients with a smoking history whose skin microcirculation may be particularly compromised by generous flap length. Furthermore, flaps of excessive length run the risk for variable degrees of marginal necrosis in all patients and may also limit access and exposure to the desired anatomic landmarks. Flap necrosis may be increased in skin-sparing mastectomy with reconstruction, as compared with traditional mastectomy incisions,³⁶⁹ but the variability in selection criteria, flap length, and patient characteristics makes comparisons difficult. Careful attention to detail and to flap viability intraoperatively is essential, as discussed in Chapter 25.

How thin should flaps be?

The superficial fascial encasement of the breast is the appropriate landmark for developing flaps. In obese patients, the flaps would inevitably be thicker, in view of the more significant subcutaneous fat layer, whereas they would be thinner in

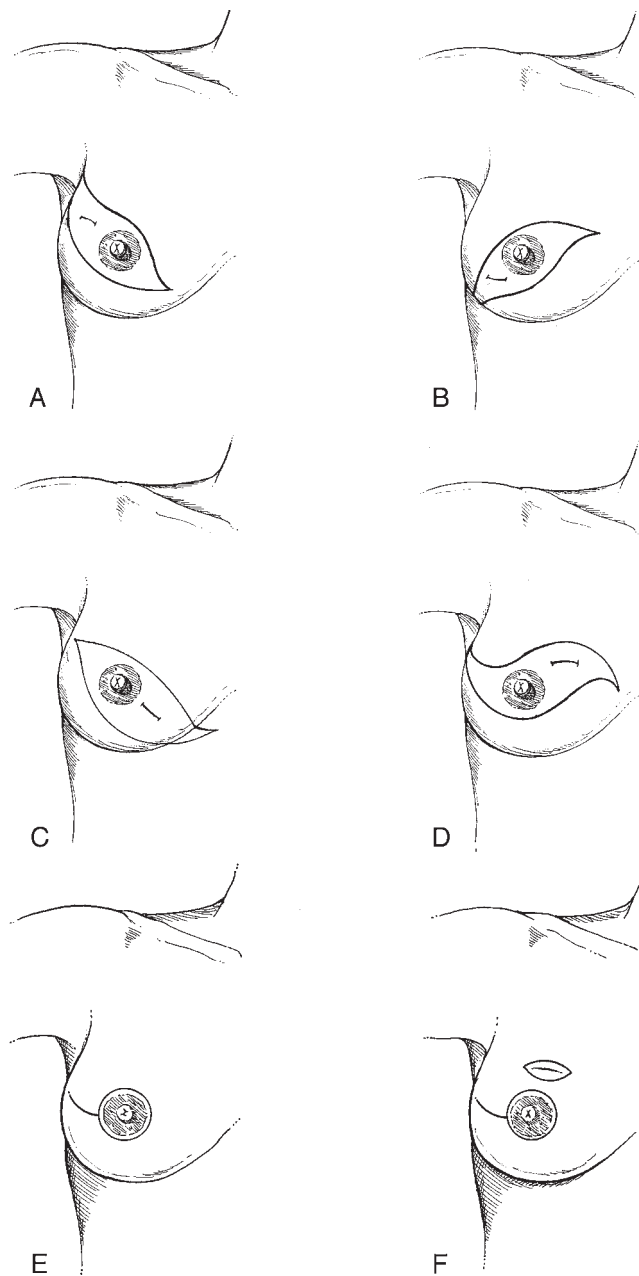

Figure 24–30 A to D, Appropriate incisions for a total mastectomy incorporate the central nipple–areolar complex and biopsy site when present. E and F, Efforts to preserve the skin envelope are particularly appropriate when concomitant reconstruction is planned.

lean patients. There have been no data to support efforts to create excessively thin flaps, and, particularly with skin-sparing incisions, such attempts may result in venous congestion, ischemia, and subsequent zones of flap necrosis.³⁷⁰ Flaps at the level of the superficial fascia are raised to the clavicle superiorly, to the sternum medially, to the rectus sheath inferiorly, and to the latissimus dorsi laterally. Excessive or uneven areas of subcutaneous fat, or the overvigorous use of electrocautery for hemostasis, can create fat necrosis that increases the risk for edema, infection, and areas of marginal flap loss.

What is the extent of the breast excision?

The breast and axilla are prepared and draped in the usual fashion with the arm free to allow positioning that facilitates exposure of the lateral axilla and inclusion of the tail of the breast. After the incision is outlined and incised and the flaps are raised, the breast and pectoralis major fascia are dissected off the muscle to its lateral border (Fig. 24–31). The pectoralis major is reflected medially, and the pectoralis minor is

identified. Superiorly, the clavipectoral fascia is incised, and with traction inferiorly and laterally, the tail of the breast is delivered from the foramen of Langer and dissected free from the axilla. The specimen is then dissected laterally, staying superficial to the fascia of the serratus anterior and subscapularis muscles, because no effort is made to perform a formal dissection of the axillary contents. However, for patients with extensive DCIS that is high grade, a sentinel lymphadenectomy may be performed at the inception of the procedure as previously discussed, or a level I axillary dissection is

Figure 24–31 A to D, Total mastectomy. The breast and pectoralis major fascia are dissected off the muscle to its lateral border.

performed if the distribution of radiographic or even palpable findings makes the reliability of lymphatic mapping less certain, as discussed in the subsequent description of total mastectomy and axillary dissection.

After completion of the mastectomy, the wound is irrigated with saline solution, and meticulous hemostasis is ensured. The flaps are inspected to ensure their viability. If there is obvious ischemia at any skin edge, it is preferable to excise this margin, particularly if a concomitant reconstruction is planned. Flap necrosis with an underlying tissue expander or with any form of reconstruction can prolong the postoperative healing phase. It is far preferable to delineate intraoperatively any skin edges that are likely to become necrotic than to have to débride such tissue postoperatively, particularly in the setting of a breast reconstruction.

If a concomitant reconstruction is not performed, the wound is closed after Hemovac catheters or another closed-suction system has been placed through separate stab wounds. To minimize fluid accumulation beneath the flaps, interrupted absorbable sutures that incorporate underlying muscle to “tack” the flaps and potentiate adherence of skin to the chest wall are helpful.³⁷¹ As previously noted, fibrin sealants remain under continued investigation and have not gained wide acceptance as promoters of flap adherence; these are certainly less needed in procedures that do not include axillary dissections. A subcuticular skin closure is completed, although approximating interrupted dermal sutures or even skin sutures or skin staples may be appropriate when there is tension on the closure. In obese patients and in patients with large pendulous breasts, it is not uncommon to have a “dog ear” at the lateral pole of the incision. A vertically placed excision may minimize this redundant skin, which often becomes a source of concern and annoyance to the patient, particularly when it protrudes over the patient’s brassiere or is visible in sleeveless clothing.

TOTAL MASTECTOMY AND AXILLARY LYMPH NODE DISSECTION

How is total mastectomy and axillary lymph node dissection defined?

Procedures that combine en bloc mastectomy and axillary lymph node dissection are often referred to as *modified radical mastectomies*. There may be significant variability in the extent of such operations, however. For example, Patey’s operation divided the pectoralis minor to ensure complete axillary lymph node dissection.³⁷² Roses and associates described a procedure that divided the sternal portion of the pectoralis major at its tendinous insertion as well as the pectoralis minor to further facilitate the completeness of axillary dissection, reconstructing the pectoralis major at the end of the procedure.³⁷³ As discussed, isolated metastases to the apical level III lymph nodes are uncommon in the absence of level I or II nodal involvement, and a dissection to ensure complete removal of the apical nodes has been largely abandoned for clinical stage I patients.

Given the potential variability of modifications of the radical mastectomy, it is therefore appropriate when performing a total mastectomy and axillary lymph node dissection to

designate the extent of the dissection. Most patients today who have a modified radical mastectomy are more appropriately referred to as having a total mastectomy and axillary lymph node dissection (levels I and II), rather than the generic designation of “modified radical mastectomy.” The latter has varied in different contexts from a total mastectomy with a limited lateral axillary dissection, to a total mastectomy with level I axillary dissection, to a total mastectomy with levels I and II axillary dissection, to a total mastectomy with axillary dissection of all three levels. If a complete axillary lymph node dissection of levels I, II, and III is performed, then the procedure is best designated a total mastectomy with complete axillary lymph node dissection.

What are the surgical considerations in performing a total mastectomy and axillary dissection?

The procedure combines en bloc total mastectomy, as already described, with the axillary dissection, as also described. For most patients without palpable axillary lymphadenopathy and no discernible involved nodes at surgery, a level I and II dissection is appropriate. For patients with significant palpable axillary nodes or grossly apparent lymph node involvement near the edge of the pectoralis minor muscle at surgery, a complete axillary dissection is appropriate. A complete axillary dissection may be facilitated, if necessary, by division of the attachment of the pectoralis minor muscle to the coracoid process.

The methods of incision and development of the skin flaps are dependent on location, breast size, lesion size, and secondary clinical characteristics. Skin-sparing incisions may be aesthetically advantageous when concomitant reconstruction is planned. Incisions that adhere to the periareolar circumference with a linear extension toward the axilla have been used for total mastectomy and axillary dissection in appropriate selected patients with T1 and T2 lesions. Reported experience suggests that this does not increase the risk for local recurrence.³⁷⁴ As in the previous discussion, however, such incisions should not compromise the extent of surgery or the required exposure and should balance the aesthetic goals with the risk for flap necrosis.

The preparing and draping are performed with the arm free, as previously discussed for axillary dissection, the abdomen being included if a transverse rectus abdominis flap reconstruction is planned. A transverse or oblique incision with the most lateral extension below the hair-bearing area of the axilla is preferred, with adjustments dependent on the size and location of the lesion. The flaps are raised above the level of the superficial fascia, and the breast and fascia of the pectoralis major muscle are dissected as described for a total mastectomy. The pectoralis major is then retracted medially to expose the lateral axillary contents, with traction on the breast to facilitate this exposure. The dissection is extended to the lateral border of the pectoralis minor muscle. The lateral border of the pectoralis minor is identified, and as described previously, the clavipectoral fascia is opened and the axillary dissection performed (Fig. 24–32). If a formal dissection to most definitively encompass the apical (level III) nodes is desired, as previously discussed, the pectoralis minor may be detached from the coracoid process. The extent of dissection

Figure 24-32 Total mastectomy and axillary dissection. The pectoral muscles are reflected medially, the clavipectoral fascia is incised, and the axillary contents are exposed.

is as described for axillary dissection, and the highest level, be it level II or level III, is tagged to orient the specimen for the pathologist. The axillary contents are then dissected free from the chest wall, proceeding laterally. The intercostobrachial nerve is preserved whenever possible, and the long thoracic nerve as well as the thoracodorsal nerves and vessels are identified and preserved (Fig. 24-33). The thoracodorsal bundle is essential if a latissimus dorsi flap reconstruction is planned; thus, its preservation is particularly important if this option is selected or if it might be used in the future. The lateral margin of the axillary dissection is also tagged for orientation of the specimen by the pathologist.

After removal of the specimen and thorough irrigation of the wound, reconstruction is commenced, as discussed in Chapter 25. If immediate reconstruction is not planned, Hemovac catheters are placed through separate stab wounds at the lower margin of the inferior flap, and the lateral limb is guided to the axilla and carefully secured beneath the pectoralis major muscle and away from neurovascular structures with a carefully placed and loosely tied absorbable suture. The medial limb is similarly guided and secured over the pectoralis major. Tacking sutures may be placed, as discussed for total mastectomy, to minimize seroma formation, and the skin is closed, as also described for a total mastectomy.

The management of drains and the advisability of arm mobility are the same as discussed for axillary dissection. Concomitant reconstruction may alter the recommendations, as also discussed in Chapter 25.

RADICAL MASTECTOMY

Is a radical mastectomy ever indicated for operable breast cancer?

The performance of a radical mastectomy for operable cancer of the breast is rarely indicated. The 25-year follow-up of the NSABP (Protocol B-04) comparing radical mastectomy, total

Figure 24-33 The total mastectomy and axillary dissection are completed.

mastectomy without axillary dissection but with postoperative radiation, and total mastectomy with axillary dissection only if nodes became positive demonstrated no advantage over radical mastectomy.⁷⁴ Likewise, the 20-year follow-up of the World Health Organization study comparing radical mastectomy with breast-conserving therapy for patients with tumors 2 cm or smaller showed no advantage to radical mastectomy.³⁷⁵ These reports have sealed the fate of radical mastectomy, a procedure that faded following the initial reports of these studies more than 2 decades earlier. In instances in which there is unexpected adherence or infiltration of the pectoralis major muscle by an overlying lesion, resection of this region of the muscle, followed by radiation therapy or resection of the entire sternal portion, if involved, may be performed. Inclusion of both pectoral muscles is reserved for

more locally advanced disease refractory to neoadjuvant, systemic, and radiation therapy, but certainly not for earlier-stage breast cancer.

COMPLICATIONS OF MASTECTOMY AND AXILLARY DISSECTION

What are the complications of segmental or total mastectomy?

Complications of segmental or total mastectomy are infection and hemorrhage. Both are rarely encountered, although overly vigorous use of electrocautery to prevent hemorrhage may produce significant fat necrosis that may contribute to infection. Use of antibiotics prophylactically and while drains are in place is appropriate. Attention to flap viability further minimizes the risk for infection. Even with mastectomy, blood loss requiring transfusion should be very rarely required. Attention to drain function following mastectomy promotes flap adherence and prevents the accumulation of blood that may elevate the flap and potentiate further hematoma formation. Bleeding should be rapidly attended not only for hemodynamic reasons but also to prevent the wound complications from nonadherence of flaps, disruption of reconstruction when autologous tissue is used, or fluid accumulation and potential infections when prosthetic reconstructions are performed. Careful attention to a history of coagulopathies, anticoagulation, and the use of aspirin, vitamin E, anti-inflammatory medications, or any herbal use is essential in planning any surgical management.

How common is seroma formation?

Some serous collection is to be expected after mastectomy and axillary dissection. As previously discussed as it relates to axillary dissection, closed-suction drainage is advisable in the first postoperative week to minimize prolonged seroma formation, which, if undrained, would require repeated aspirations and could become secondarily infected. As noted, intraoperative antibiotic coverage, as well as the continued use of antibiotics when drains remain in place, is advisable. Prolonged seroma formation after drain removal is managed by aspiration but may rarely require reinsertion of a closed-suction drain if prolonged or excessive.

The influence of shoulder exercises on seroma formation has been assessed for axillary dissection performed with breast conservation or with total mastectomy. As also discussed, vigorous arm mobilization is not appropriate in the early postoperative period when drains are in place. Delaying shoulder exercises for a week postoperatively has not been associated with arm dysfunction in several studies and may diminish seroma formation.^{376–378}

How common is lymphedema?

Lymphedema of the arm of any degree is often a cause of great concern and potential disability to the patient following breast

cancer treatment. Despite its nonmalignant cause, even a minimal degree of swelling or a sense of arm heaviness may become a constant physical reminder of the original cancer. Although the initial presentation of lymphedema is often insidious and subtle, it can expand into more obvious and disabling enlargement because increased lymphatic pressure prevents diffusion of lipids and protein while promoting fibrosis and susceptibility to infection in a continued vicious circle of progressive stagnation and swelling. Although certain factors that contribute to lymphedema, including obesity and variations in lymphatic anatomy, are not readily controllable, some aspects of therapy and subsequent management should be appreciated as they relate to this problem.

The retreat from radical mastectomy, as well as the retreat from postoperative radiation therapy following mastectomy, significantly reduced the incidence of the severe lymphedema that was a feared long-term sequela of radical surgery in an earlier era. The risk for lymphedema is attributable to the extent of axillary dissection and the use of postoperative radiotherapy.³⁷⁹ Although the degree of lymphedema varies in reported series and depends on the specific criteria used, as well as the time from surgery at which patients are assessed for this problem and the extent of the axillary dissection performed, the long-term risk following breast-conserving surgery with complete axillary dissection without axillary radiation was reported by Veronesi and associates³⁸⁰ to be less than 5%.

Using objective criteria, Lin and associates³⁸¹ noted an increase in arm circumference on the operated side compared with the unoperated side in 16% of patients. In a study of 200 patients having a level I and II axillary dissection, 112 of whom had breast conservation and 88 of whom had total mastectomy, Roses and associates evaluated arm swelling 1 year or more after surgery.³³³ All patients had arm circumference measurements at the same four sites on both the operated and nonoperated sides. No patient had an axillary recurrence. A difference in arm circumference of more than 2 cm in any of the four sites of the operated compared with the nonoperated side was 13%. Seven patients (3.5%) had mild swelling of the hand. Heavy and obese body habitus were the only significant predictors of edema on multivariate analysis. Other recently reported incidences of lymphedema after axillary dissection demonstrate a wide range, from 5% to 25.5%.^{382–388} Meric and associates found an incidence of edema less than 3 cm below the elbow in 13 of 294 (4.5%) patients treated with breast conservation, 260 of whom had axillary dissection.³⁸⁹ One hundred patients had nodal irradiation, including 10 of the 13 with significant edema. Limiting radiation to the axilla in only selected instances, as discussed in Chapter 26, has contributed to a decreased incidence of this complication.

The extent of axillary dissection with both mastectomy and breast-conserving surgery, not always precisely defined, no doubt influences the frequency of the complication, but the significant and debilitating lymphedema seen in previous eras, when radical mastectomy followed by chest wall irradiation was standard, has diminished. It will certainly diminish markedly as sentinel lymphadenectomy increases.³⁹⁰ When axillary dissection is performed, long-term attention to minimizing the risk for cellulitis in the arm, which can lead to further inflammation and fibrosis of primary and collateral lymphatic channels, is also important in minimizing the risk

for lymphedema. Patient education in this regard is essential, with particular attention to infection prevention, as discussed in more detail in Chapter 39. Physician measurement of arm circumference may also allow prompt identification of patients in whom changes identify the risk for progressive edema and therefore make them worthy of particular attention to minimize further change.³⁹¹ Older women may have a particular susceptibility to arm problems following axillary dissection, including swelling, with all of these changes amplified significantly by preexisting arthritis.³⁹²

How is lymphedema of the arm treated?

Lymphedema is best managed by arm elevation when the patient is in a recumbent position, elastic pressure-graded sleeves for daytime use when the arm is in a dependent position, and weight reduction and control whenever appropriate. Manual massaging to promote dilation of nonobstructed collateral lymphatics may further assist in reducing chronic lymphedema. Compression from the wrist to the upper arm is desirable, with the addition of a gauntlet extension for patients with hand swelling. Proper fitting of a sleeve with appropriate compression is necessary. Compression devices in the evening may be of some value for cases refractory to these initial measures. The use of such sequential-gradient compression devices in chronic situations should be extremely judicious because significant pressures applied for prolonged periods of time may be injurious, further traumatizing lymphatics and promoting the progression of lymphedema. The use of intermittent pneumatic compression has been recommended as an effective means of enhancing decompressive therapy.³⁹³ All compression devices should be used with caution in patients with cardiovascular disease, active infection, or neurologic symptoms in the affected extremity.

Drug therapy, most commonly with diuretics, is of unproven efficacy. Diuretics do not affect the underlying osmotic pressure caused by the protein-rich lymphedema fluid. Casley-Smith and associates³⁹⁴ have reported on the use of 5,6-benzo- α -pyrone to stimulate macrophage activity to eliminate stagnant proteinaceous material in lymphedema fluid, with mild improvement in a controlled trial. A variety of surgical approaches to managing severe chronic lymphedema, from excising deep fascia to improve lymphatic drainage, to omental transfer to create additional lymphatic drainage channels, to microsurgical lymphovenous anastomoses, to myocutaneous flaps, to liposuction, have failed to achieve reproducible satisfactory outcomes. Clearly, infections of the arm should be treated aggressively with antibiotics and elevation, and continuous, assiduous skin care for the affected arm should be encouraged. Early diagnosis and further efforts to minimize its progression are a major component of treatment of an often refractory and progressive problem.

How common is lymphangiosarcoma with chronic lymphedema?

A rare complication of chronic lymphedema is lymphangiosarcoma, first described in the postmastectomy patient by Stewart and Treves in 1948.³⁹⁵ Vascular-appearing nodules in the edematous extremity are the hallmark. There is usually a

prolonged interval between mastectomy and the development of lymphangiosarcoma, with mean intervals in the 10-year range. Despite vigorous efforts at local therapy, including amputation, reported survivors are rare, with a median survival of less than 2 years.³⁹⁶

What is the significance of edema of the breast?

Edema may be noted in the breast of the patient after treatment by breast conservation in conjunction with axillary dissection and radiation. This may be seen in the early post-treatment phase, with erythema of the skin often accompanying the edema. It may be particularly noted in a large pendulous breast with an added component of dependent edema. It may be confused with early recurrence or infection or with inflammatory breast cancer. Resolution is common, but it may take a prolonged period until collateral lymphatic drainage develops.

What are the complications resulting from nerve injury?

The nerves at risk in an axillary dissection, as discussed, are the intercostobrachial nerve, the long thoracic nerve, the thoracodorsal nerve, and the medial and lateral pectoral nerves. Division of the intercostobrachial nerve may create numbness or paresthesias of variable distribution in the upper medial arm and axilla, many of which resolve in the months after surgery on account of the richness of sensory innervation, as detailed earlier. A common complaint is a sense of swelling of the upper medial arm not dissimilar to the sense of swelling noted around the lips or cheek following the local anesthesia of dental procedures. Some element of numbness may persist. In a series of 200 patients previously cited,³³³ numbness or paresthesias to the skin of the upper medial arm or axilla from intercostobrachial nerve sacrifice or injury occurred in 76.5% of patients in the initial postoperative period, but with prolonged follow-up, complete resolution was achieved in 22%, and the problems were improved in an additional 59%. This experience is similar to that reported by Salmon and associates.³³¹ In the study of Paredes and associates,³⁹⁷ truncal section of the intercostobrachial nerve affected axillary and arm sensitivity in almost all patients when assessed after surgery; axillary anesthesia or analgesia persisted in more than 50% of patients. Most patients had a return of arm sensation after 12 months, 30% having complete return of sensation to both the axilla and arm. With nerve preservation, more than 50% of patients had early anesthesia or analgesia to the axilla and arm, almost all resolving after 12 months. Preservation of the intercostobrachial nerve fibers is therefore to be encouraged, but division of these fibers is not uniformly associated with long-term denervation.

Division of the thoracodorsal nerve is rarely associated with any deficiency noted by the patient, with the exception of a limitation of backward motion of the extended arm. The denervation of the latissimus dorsi, however, eliminates that structure from consideration as a method of reconstruction. As previously discussed, division of the long thoracic nerve creates a winged scapula resulting from denervation of the

serratus anterior muscle. Division of branches of the medial pectoral nerve may result in atrophy of the lateral portion of the pectoralis major, whereas division of the lateral pectoral nerve, rarely encountered except if injured in detaching the insertion of the pectoralis minor, will create more significant atrophy of the sternal portion of the pectoralis major muscle.

Patients may experience a phantom breast phenomenon ranging from the perception of the presence of the breast to painful sensations that are not associated with the chest wall. Likewise, chest wall discomfort or itching or pain, often referred to as a tightening or spasmodic episodes of burning, may occasionally be experienced, particularly in the first year after surgery. Although pain after axillary dissection may be difficult to assess in the immediate postoperative period, of 2.5% of patients reporting pain requiring analgesia beyond the immediate postoperative period, none seen in long-term follow-up noted pain requiring analgesia attributable to the axillary dissection.³³³ Nevertheless, the impact of axillary dissection may be additive to preexisting arthritis and can adversely affect quality of life.³⁹²

Are there any postoperative complications specific to mastectomy?

Although significant hemorrhage should be rare after mastectomy, failure to secure appropriate hemostasis of the medially located perforating branches that originate from the internal mammary artery, or the laterally located branches off the thoracodorsal vessels, may be a specific source of postoperative hemorrhage. A rare complication, even more uncommon now that radical mastectomy is rarely performed, is a pneumothorax from puncture of the pleura. This could result from a hemostat's being applied too vigorously when attempting to secure hemostasis on the chest wall, particularly hemostasis of medial perforating vessels from the internal mammary artery, which may retract out of direct vision. Recognition of the possibility of this occurrence in the postoperative patient who develops respiratory distress is obviously essential to a rapid diagnosis and expeditious management with closed-suction pleural drainage. Similarly, attributing sudden significant chest pain to the surgical incision is inappropriate because the discomfort of uneventful surgical procedures on the breast and axilla is usually minimal and clearly different from the pleural pain that may result from a pulmonary embolus.

What is the appropriate length of hospitalization following procedures that include mastectomy or axillary lymph node dissection?

The emphasis on the containment of escalating medical costs has focused attention on the length of hospitalization following surgical procedures for breast cancer, particularly mastectomy or lymph node dissection, with or without breast reconstruction. The medical issue is not whether a short length of hospitalization, often only 1 day or less, can be achieved, but whether this adversely affects patient care. Indeed, it has even been suggested that shortened hospitalization after breast surgery can improve patient care.³⁹⁸

The major indication cited for hospitalization in such patients is the management of drainage and pain. Less definable is the issue of emotional security and balancing the psychosocial support that may be facilitated by the hospital setting with the potential enhancement of confidence and sense of self-control that earlier discharge may give the patient. In a study of 208 patients discharged after a median length of stay of 1 day following axillary dissection, 0.6 day following segmental excision and axillary dissection, and 1 day following total mastectomy and axillary dissection, there was no apparent adverse effect resulting from early discharge. A readmission rate of 1.5% and infection rate of 1.5% were reported, but no dissatisfaction was noted from patients, and the authors reported a subjective sense of improved psychological and physical recovery.³⁷⁶ Clearly, more data are required that address the emotional and physical issues.

Despite efforts to implement shortened length of hospital stay, dissatisfaction with a mandatory policy of early discharge following breast cancer surgery has prompted the passage of legislation by the New York State Assembly and Senate to lengthen the potential length of stay. The 1997 New York State Women's Health and Cancer Rights Act guarantees coverage of inpatient hospital care following mastectomy or segmental excision and axillary dissection for a period of time to be determined medically appropriate by the attending physician in consultation with the patient. The Act also covers reconstructive surgery for all stages of reconstruction.³⁹⁹ The issue of length of stay is patient dependent and not rigid. Clearly, segmental excision and sentinel lymphadenectomy may be appropriately managed on an outpatient basis, but even in such instances, completion of an axillary dissection for operatively detected sentinel nodal metastases requires flexibility as to the need for limited hospitalization. The issue requires consideration of the age and the medical and psychological condition of the patient, which are further affected by the available family and social support, and the patient's geographic access to medical care. More data that address these questions are required before physicians and patients are coerced into a uniform policy of rapid discharge applied to all patients. At the present time, physician advocacy for the patient's physical and emotional needs is the highest priority. Nursing and psychosocial support and education should be instituted preoperatively and in the early postoperative period. This will facilitate the most appropriate and efficient use of the inpatient setting and lead to effective continuity of care as an outpatient. It will ensure that discharge from the hospital is accomplished safely and in the best interests of the patient with full patient and family confidence, rather than being perceived by them as based exclusively on reimbursement considerations.

LOCAL RECURRENCE FOLLOWING MASTECTOMY

How common is local recurrence following mastectomy?

Chest wall recurrences in the skin, subcutaneous fat, or muscles, as well as recurrences in the axilla if an axillary dissection

was a component of the original mastectomy, are most appropriately referred to as *local* recurrences. Chest wall recurrences have a reported incidence of 6% following mastectomy.⁴⁰⁰ In a recent series of 565 cases of skin-sparing mastectomy and immediate breast reconstruction, a local recurrence rate of 5.5% was reported, with a mean disease-free interval for those patients who experienced recurrence of 19.8 months (range, 2.9 to 61.6 months). In multivariate analysis, tumor grade and the presence of lymphovascular invasion were independent variables predictive of local recurrence.⁴⁰¹

Recurrences in the supraclavicular or parasternal regions, emanating from nodal metastases beyond the field of initial surgical treatment, are best referred to as *regional*. The American Joint Committee on Cancer has reclassified proven metastases in supraclavicular nodes from distant metastatic disease (stage IV) to locally advanced breast cancer (stage IIIC) to reflect improved survival rates compared with patients with metastatic disease at distant sites.⁴⁰²

The frequency of local and regional recurrence for stages I and II breast cancer is clearly related to the stage of the original cancer.⁴⁰³ The extent of axillary nodal involvement, specifically four or more positive nodes and extranodal extension of tumor, is a significant risk factor for locoregional recurrence.⁴⁰⁴ Other biologic characteristics, such as hormone receptor status,⁴⁰⁵ high-grade histologic characteristics,⁴⁰⁶ and younger age of the patient,⁴⁰⁷ as well as the use of adjuvant systemic therapy, are less well defined but may affect the incidence of local recurrence. The type of mastectomy (radical, total mastectomy with axillary dissection) has not been demonstrated to affect local recurrence.⁴⁰⁸ Most local and regional recurrences present within the first 5 years after initial treatment, but 10% to 20% appear later.^{409,410} The median time to recurrence in a series of 130 patients with chest wall recurrence after mastectomy at the University of Texas M. D. Anderson Cancer Center was 25.5 months.⁴¹¹ Although recurrences after 10 years from initial treatment are uncommon, there are reports of local recurrences as late as 40 years after initial treatment.⁴¹²

How is local recurrence diagnosed?

Any nodule or nodules presenting in the scar or in the skin, subcutaneous fat, or muscle should be suspected of being a local recurrence. Erythema presenting either focally or as a broad rash, sometimes with induration, should be suspected of representing a local recurrence as well. Supraclavicular or parasternal nodules should likewise be suspected of representing regional recurrences (Fig. 24–34). Although local recurrences are most common in the region of the scar or in the skin flaps, chest wall recurrences in skin or subcutaneous tissues beyond the periphery of initial surgery may occur. The possibility that these represent local recurrences must be appreciated. Not uncommonly, multiple nodules, as well as the synchronous presentation of both local and regional metastases, may be noted.⁴¹³

Skin and subcutaneous nodules, as well as bulkier, deeper, or regional recurrences, can be expeditiously diagnosed by fine-needle aspiration biopsy. Because local and regional recurrences may be associated with synchronous distant metastases or the development of distant metastases at a later date, the assessment of distant metastases is mandatory before

Figure 24-34 Parasternal recurrence in the second intercostal space from internal mammary nodal metastases following mastectomy.

embarking on therapy.⁴¹⁴ A bone scan and computed tomography (CT) scans of the head, chest, abdomen, and pelvis or PET scans are appropriate to establish the diagnosis of any distant disease as well as to provide a baseline for these patients who are at a particularly high risk for future systemic relapse. However, in the previously cited M. D. Anderson Cancer Center experience, of 130 patients with chest wall recurrence following mastectomy, with a median follow-up of 68.5 months after diagnosis of breast cancer and 37.4 months after diagnosis of chest wall recurrence, 51.5% had not developed distant metastases.⁴¹¹

How is local recurrence treated?

Local recurrence is best excised whenever possible. This is certainly true for small isolated lesions in the skin flaps, which may be excised with margins of at least 1 cm to achieve tumor-free margins and closed primarily. Prolonged local control may result from local surgery alone.⁴¹⁵ Except for these specific instances of solitary, easily resectable recurrences, particularly when they present after prolonged disease-free intervals from initial mastectomy, most patients will develop further local recurrence. Persistent, progressive local recurrence can be a source of significant morbidity, with ulceration, bleeding, pain, and extension around the chest wall through the soft tissues (carcinoma en cuirasse) that may restrict normal chest wall expansion. Extensive progression of local recurrence may be resistant to treatment. Therefore, additional local radiotherapy at the time of initial presentation and treatment should be considered. The use of radiotherapy has been associated with significantly improved prolonged survival.⁴¹¹ Available data suggest that the entire anterior ipsilateral chest wall should be treated because more limited fields are associated with a high rate of progressive local recurrences.⁴¹⁶ The same principles should apply for recurrences in tissues surrounding an autologous breast reconstruction. Radiation following resection can be used, although fibrosis of the soft tissues in the reconstruction can alter the appearance of the reconstructed breast.^{417,418}

The supraclavicular region is associated with about a 20% rate of regional recurrence that may progress to infiltrate the brachial plexus with significant motor function sequelae and pain, so that supraclavicular irradiation would seem appropriate. Internal mammary recurrence, however, is uncommon. If an axillary dissection was part of the initial treatment, axillary recurrence should also be uncommon. Furthermore, axillary radiation results in increasing rates of arm lymphedema. Irradiation of the internal mammary nodes and axilla, therefore, is best not included in treatment fields unless there is specific clinical or radiographic suspicion of recurrence at these sites. For bulky fixed disease, efforts at chemotherapy and radiotherapy may be successful, but failure to achieve a complete response may require chest wall resections, which are best closed by autologous myocutaneous flaps⁴¹⁹⁻⁴²⁴ (Fig. 24-35). Toi and associates⁴²⁵ reported on 15 patients with full chest wall resections supported by perioperative and postoperative systemic treatment. Thirteen patients underwent combined resection of the sternum with defects ranging in size from 30 to 200 cm². Reconstruction was by transverse rectus abdominis myocutaneous flaps in 14 cases and by a latissimus dorsi myocutaneous flap in 1 case. In 4 cases, the chest wall was reinforced by Marlex mesh. The reported 5-year survival rate was 47.1%, with two patients surviving longer than 5 years without distant metastases. Three patients developed local recurrence, all having had

microscopically positive margins, one responding to radiation therapy and surviving more than 5 years.

Is there a role for systemic therapy in the treatment of local or regional recurrence?

Available data demonstrate that systemic therapy improves 5-year survival for patients whose disease-free interval from mastectomy to recurrence exceeds 2 years; for those who had stage I disease compared with stage II at initial treatment; and for those with a single resectable site of recurrence compared with multiple sites or bulky or unresectable recurrent disease.⁴²⁶ Nevertheless, most patients die from metastatic disease by 10 years. In a series from the Joint Center for Radiation Therapy, the 10-year survival rate for patients treated with radiation for locoregional recurrence after mastectomy was 36% if the recurrence had developed more than 2 years after mastectomy, and 7% if recurrence happened less than 2 years after mastectomy.⁴²⁷ In a review of 69 patients from the M. D. Anderson Cancer Center having a locoregional relapse as their first evidence of recurrence following mastectomy and adjuvant chemotherapy, 19 (27.5%) were alive and free of disease at a median follow-up of 6.6 years. The two factors that significantly affected survival were whether recurrence was during or after adjuvant therapy, and whether the patient was

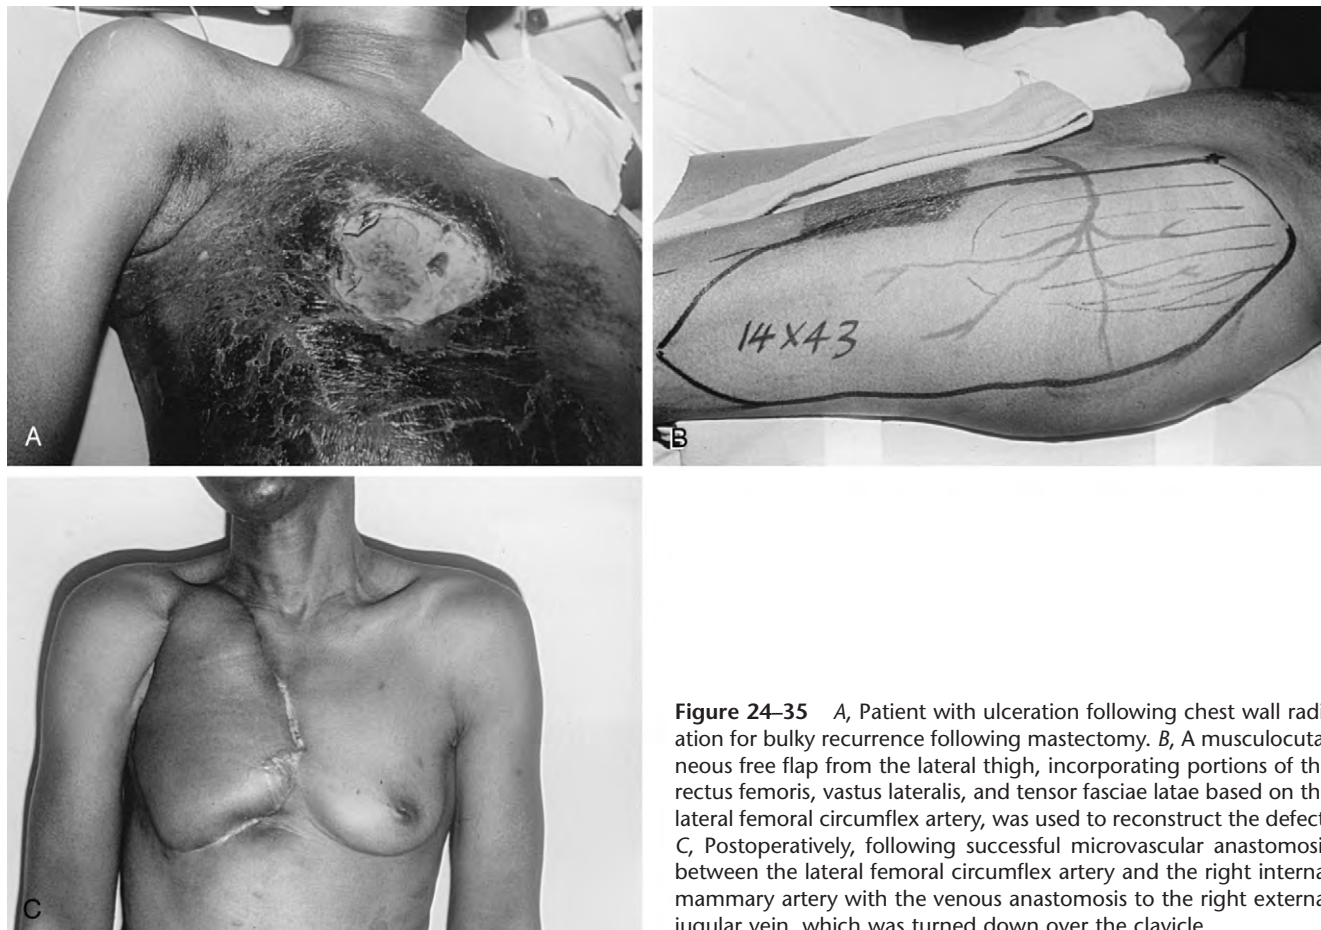

Figure 24-35 A, Patient with ulceration following chest wall radiation for bulky recurrence following mastectomy. B, A musclocutaneous free flap from the lateral thigh, incorporating portions of the rectus femoris, vastus lateralis, and tensor fasciae latae based on the lateral femoral circumflex artery, was used to reconstruct the defect. C, Postoperatively, following successful microvascular anastomosis between the lateral femoral circumflex artery and the right internal mammary artery with the venous anastomosis to the right external jugular vein, which was turned down over the clavicle.

rendered disease free after recurrence.⁴²⁸ Factors that have also been implicated for improving survival after chest wall recurrence include a prolonged time to recurrence,^{429–432} negative nodal status of the original cancer,^{411,433,434} and a limited extent of recurrence by size and number of nodules.^{435,436}

Although it would seem appropriate to treat patients with systemic therapy following local therapy for locoregional recurrence, there are no prospective controlled data to support this approach.^{437,438} Given the dire prognostic implications of locoregional recurrence in patients with short disease-free intervals, particularly while receiving adjuvant systemic therapy, dose-intensive chemotherapy is a consideration for future investigation in such subsets of patients. The impact of antihormonal therapy is likewise unknown, although in the treatment of recurrences that are hormone receptor positive, systemic treatment plans that incorporate antihormonal strategies would seem appropriate. Appropriate molecular assays should obviously be obtained on all excised and resected recurrences. Certainly, prolonged survival for subgroups of patients with chest wall recurrence after mastectomy is achievable and fully justifies aggressive treatment, the foundation of which is complete surgical resection.^{411,428–434}

Reconstruction Following Surgery for Breast Cancer

Nolan S. Karp and Stephen R. Colen

HISTORY

Since the introduction of the radical mastectomy by William Halsted more than 100 years ago, women have desired breast reconstruction. These procedures were discouraged at first because surgeons thought that the reconstructed tissue would obscure local recurrence.

The first attempts at breast reconstruction were in the 19th century and used fat grafts. This technique failed owing to the lack of blood supply. The next attempt to reconstruct a breast following a radical mastectomy was performed by Tanzini in 1906.¹ He was the first surgeon to perform a musculocutaneous flap using the latissimus dorsi for breast reconstruction. This technique failed to gain favor, and subsequent attempts over the first 60 years of the 20th century involved tubed pedicled flaps from the other breast or from distant sites.²⁻⁶ These techniques were often complicated by tissue loss, multiple procedures, scars, and inadequate results.

In 1963, Cronin and Gerow⁷ introduced the silicone gel breast prosthesis. This device was not without significant problems because most surgeons at that time were using it after performing radical mastectomies.⁸⁻¹⁰ The implants were difficult to cover and did not correct the total soft tissue defect. During that era, the goal of reconstruction was simply to improve the patient's appearance in clothing. Any better cosmetic result was not possible.

The advent of the modified radical mastectomy operation greatly improved the results that could be achieved with implant reconstruction. The skin flaps were thicker, and the pectoralis major muscle remained intact. The heartier skin flaps allowed gradual expansion of the skin flaps by the implant. Submuscular placement of the implant also became possible. These techniques, combined with procedures to modify the contralateral breast, resulted in more acceptable reconstructions. This trend toward more optimal cosmetic results has continued as incisions have decreased in length and breast-conserving surgery has become more commonplace.

The development of the musculocutaneous flap was a major step in improving the quality of breast reconstruction. The latissimus dorsi myocutaneous flap allowed replacement of the missing skin, reconstruction of the anterior axillary fold, and coverage of an implant. The latissimus dorsi, however, did not provide sufficient soft tissue for total autologous reconstruction.

The introduction of the transverse rectus abdominis myocutaneous (TRAM) flap in the early 1980s allowed single-stage total autologous breast mound reconstruction. This flap took advantage of the abundant tissue usually present in the lower abdomen. The development of microvascular techniques, at about the same time, allowed for better-vascularized reconstructions and more options for autologous reconstruction.

TIMING OF BREAST RECONSTRUCTION

Is immediate reconstruction appropriate?

Current trends toward less radical surgery for breast cancer, preserving the pectoralis major muscle and overlying skin, along with better reconstructive techniques, have made breast reconstruction at the time of mastectomy a standard procedure. All of the reconstructive techniques traditionally available can be safely performed in the immediate setting. Several studies have shown that the addition of reconstruction does not delay adjuvant systemic therapy or interfere with the monitoring of the mastectomy site for possible local recurrence.¹¹⁻¹⁸

What are the advantages of immediate reconstruction?

Frequently, the results of immediate reconstruction are cosmetically superior to delayed reconstruction owing to careful planning of incisions and skin preservation by the collaborating oncologic and plastic surgeons.¹⁹ The economic advantage of immediate reconstruction is obvious because the cost of a second hospitalization is eliminated.²⁰

The psychological benefits of immediate reconstruction are significant. Patients undergoing immediate reconstruction often relate no feelings of physical loss. Frequently, mastectomy is recommended for early-stage cancers with diffuse intraductal involvement. Reconstruction at the time of mastectomy allows these patients to resume a normal lifestyle as quickly as possible with fewer daily reminders of their disease. When mastectomy is performed for advanced or recurrent

disease, the immediate reconstruction gives the patient added confidence that the cancer may be cured.

When is delayed reconstruction appropriate?

Despite the many positive aspects of immediate breast reconstruction, certain clinical situations are best treated with delayed reconstruction. When it is uncertain whether radiation therapy will be required, the reconstructive procedure may be delayed until the surgical pathology is reviewed and the radiation decision made. When radiation to the chest wall is required, the chance of achieving a cosmetically successful implant reconstruction is decreased, and these patients are often treated with flap reconstructions after radiation is completed.²¹ Cordeiro and colleagues have shown that acceptable results can be achieved with tissue expander–implant reconstruction followed by postoperative radiation therapy when a specific protocol is followed.²² Flap reconstructions that are subjected to radiation therapy often become suboptimal, with a loss of flap volume and an increased incidence of fat necrosis.

If the viability of the mastectomy skin flaps is questionable at the completion of the mastectomy, it is advisable to delay the reconstruction until healing is complete. This is especially important in patients undergoing tissue expander placement, because skin necrosis and expander exposure can result when necrosis of skin flaps occurs. In patients who smoke, are diabetic, or have collagen-vascular disease, assessment of skin flap viability at the time of mastectomy may be difficult, and great care and selection must be exercised before immediate tissue expander placement.

When there is questionable pathology in the contralateral breast or the patient is considering contralateral mastectomy, it is best to delay the reconstruction because bilateral reconstruction is most successful when both sides are reconstructed in the same operation.

Some patients simply cannot decide whether to undergo reconstruction or what type of reconstruction to have. These patients should be advised to defer reconstruction and be reassured that a successful reconstructive outcome is likely in the future.

What information should be reviewed with the patient before a decision regarding immediate reconstruction?

Often, the patient is referred to the plastic surgeon immediately after the diagnosis of breast cancer and recommendation for a mastectomy. This initial consultation, at which the patient is provided with information that will help her make an educated, informed decision, is very important. The patient is often under great psychological stress and must absorb a tremendous amount of information in a very short period of time. The plastic surgeon must make the breast reconstruction information concise and complete so that the patient can make an informed decision.

If the best choice for reconstruction is to be made, several key questions must be answered before the mastectomy.

1. *What is the risk for cancer's developing in the contralateral breast? Does the contralateral breast require biopsy to*

resolve the pathologic issues, which would determine the need for contralateral mastectomy? These issues are important because the approach to bilateral reconstruction might be quite different from the approach to unilateral reconstruction.

2. *Is it feasible to alter the contralateral breast to obtain symmetry, or will the oncologic surgeon or mammographer object, feeling it will interfere with future monitoring?* This decision may alter the technique of breast reconstruction.
3. *Will postoperative chest wall radiation be required?* Radiation can significantly compromise the likelihood of success with reconstruction.
4. *Has the patient definitely decided on mastectomy, or is breast conservation an alternative?* When the reconstructive process is perceived as very complicated, the patient may choose breast conservation.

At the initial consultation, the patient must be given all information about alternatives and expected outcome. Patients undergoing immediate breast reconstruction usually follow the referral guidance of their oncologic surgeon and rarely seek second opinions. Showing the patient photographs of average as well as excellent reconstructions helps the patient understand the spectrum of surgical outcomes. It is also helpful to review diagrams of the surgical procedures with the patient so that she can better comprehend the scope of the surgery.

Facilitating discussion with other patients who have gone through the reconstruction process and the associated decision making is often the most helpful service one can provide. Only when all issues are addressed will the correct reconstructive decision be made. When there is significant uncertainty by either the reconstructive surgeon or the patient, reconstruction should be deferred.

What issues should be discussed with the oncologic surgeon before mastectomy?

During the past 10 years, techniques for breast reconstruction have been refined so that results are better and more reliable. By far, the biggest step toward achieving superior results in breast reconstruction has resulted from the more common use of the skin-sparing mastectomy. Maintaining the intrinsic shape of the breast at the time of mastectomy by sacrificing minimal skin and maintaining the envelope of the breast has allowed the reconstructive surgeon to achieve superior results by all techniques.

Skin-sparing mastectomy has made immediate breast reconstruction a more viable choice for the patient considering mastectomy as the method of treatment for breast cancer. Toth and Lappert in 1991 were the first to report the use of skin-sparing mastectomy with superior aesthetic results.²³

The goal of a skin-sparing mastectomy is to remove the entire breast parenchyma as well as the nipple–areolar complex while preserving as much breast skin as possible. Because existing biopsy scars must also be removed, it is advisable for the oncologic surgeon to keep these biopsy incisions as close to the areola as possible so as not to require additional skin excision at the time of the mastectomy. Appropriate sentinel lymph node biopsy or axillary lymph node dissection can be

performed through either the skin-sparing mastectomy incision or a separate axillary incision.

When the existing skin envelope shape is preserved during the skin-sparing mastectomy, symmetry with the contralateral breast is facilitated. When bilateral mastectomy is performed, removing equal and minimal amounts of skin facilitates symmetry. Carlson and associates in 1998 showed that skin-sparing mastectomy significantly reduced the need for contralateral symmetry procedures in the other breast.²⁴

Various types of skin incisions are used to perform a skin-sparing mastectomy. Considerations in choosing the type of incisions include the size of the areola, the size of the breast, the presence of previous biopsy scars, the need to modify the other breast, the type of reconstruction chosen, and the presence of diabetes or a history of cigarette smoking.

The periareolar incision removes the entire nipple–areolar complex as well as a few millimeters of surrounding skin because ductal tissue can extend into the surrounding skin. This incision is ideal when an autologous reconstruction has been chosen and the areola is of adequate size. Care should be taken when using this incision in diabetics or smokers because the viability of the long skin flaps can be compromised. Periareolar incisions with lateral extension can facilitate axillary dissection when additional exposure is required. The modified ellipse incision converts the periareolar incision into an ellipse and is useful when the areola is relatively small, a tissue expander reconstruction has been chosen, or the contralateral breast will be reduced (Fig. 25–1). It is our opinion that the reduction mammoplasty or anchor incisions should be avoided because of the increased incidence of skin flap necrosis. Slavin and coworkers reported using periareolar incisions in 55% of their patients, the periareolar with lateral extension in 27%, the periareolar with medial and lateral extensions in 10%, and the ellipse in 8%.²⁵ Many of the series reporting on incision selection show a tendency to use the

Figure 25–1 Three types of skin-sparing mastectomy incisions. A, Periareolar. B, Periareolar with lateral extension. C, Elliptic.

periareolar incision later in their series, as surgeons become more skilled in this technique.²⁶

All techniques of breast reconstruction can be used after skin-sparing mastectomy. When tissue expander or implant reconstruction is chosen, the mastectomy incision must be closed primarily, making the modified ellipse the incision of choice. Both TRAM flap and latissimus dorsi flap reconstructions allow closure of the incision using the skin paddle of the flap. Mastectomy skin flap problems are easier to manage with autologous reconstruction than with implant reconstruction.

Studies in the literature show no difference in local recurrence in patients undergoing skin-sparing mastectomy when compared with patients who have undergone non-skin-sparing mastectomy.²⁷

The coordinated effort of the oncologic and reconstructive surgeon to preserve native breast skin by performing skin-sparing mastectomy produces superior cosmetic reconstructions without increased oncologic risk or morbidity.

What issues should be considered in determining the type of reconstruction?

Several factors must be considered when selecting the type of breast reconstruction to be performed. When recommending a specific reconstructive technique to the patient, the basic body anatomy, general medical condition, age, risks for contralateral disease, and patient preference as well as expectations all must be evaluated.

Anatomic considerations must include the necessity of altering the contralateral breast with reduction, mastopexy, or augmentation as well as the availability of tissues at the various donor sites. Patients undergoing a long surgical procedure and recovery must be in good general health to minimize operative and postoperative morbidity. Smoking limits the success rates of certain flap techniques for breast reconstruction. A history of diseases, such as diabetes and collagen-vascular disease, that result in microcirculatory impairments may also compromise the success rates of certain flap techniques.

Previous radiation to the chest wall is another important variable because any technique that involves implants has a high failure rate in irradiated tissues.²⁸ Flap reconstruction is more prone to complications in irradiated tissues, but a satisfactory result is usually possible.²⁹ Any patient with significant back problems should not undergo a TRAM flap because weakening of the abdominal wall musculature may exacerbate existing dormant back problems. In young patients, an increased risk for contralateral breast cancer over the life span influences the choice of procedure because bilateral reconstructions are best when the same technique has been used on both sides. Certain flap techniques (including TRAM flap) cannot be done a second time if contralateral reconstruction becomes necessary. Older patients do not tolerate complex flap reconstructions as well as younger patients. The patient's expectations for achieving symmetry with a contralateral breast often make certain techniques preferable in specific situations. Ultimately, if the patient is given enough information by the reconstructive surgeon, her preference will be a large factor in technique selection.

Recovery time and her feelings about the use of implants may be significant issues.

What are the two basic forms of breast reconstruction?

Techniques for breast reconstruction can loosely be divided into two basic categories: autologous techniques and implant techniques. Autologous, or flap, procedures include TRAM flaps, latissimus dorsi flaps, gluteus maximus flaps, or lateral thigh flaps. All have specific advantages and disadvantages. Implant procedures may be simple implant, tissue expander techniques, or latissimus dorsi flap with implant or tissue expander placement. In general, flap techniques have longer operative times, greater perioperative morbidity, longer recovery time, and more postoperative pain. Flap techniques are basically one-stage procedures, whereas tissue expander procedures involve two stages. Flap techniques are true immediate reconstructions. The patient undergoing simultaneous mastectomy and reconstruction with a flap never experiences the anatomic defect resulting from mastectomy, whereas the patient receiving a tissue expander after a mastectomy is just starting the reconstructive process. The final result of an implant reconstruction is never as soft and pliable as an autologous tissue reconstruction.

Ultimately, all reconstructions are judged on the degree of symmetry with the contralateral breast. A patient with large, ptotic breasts almost always requires reduction or mastopexy of the contralateral breast because the available donor site tissue or the ability to expand the mastectomy site is limited when size and ptosis are the predominant goals. Autologous tissue reconstructions more readily allow for precise symmetry at the expense of additional scars and donor site morbidity. Despite initial concerns, patients reconstructed with flap tissue do not appear to have delayed diagnosis of local or regional recurrence of their breast cancer.³⁰

Implant reconstructions tend to have minimal ptosis and often produce a reconstruction that assumes the shape of the implant. These limitations of implant reconstructions may require augmentation of the contralateral breast. Implants may result in interference with future mammograms, a long-term risk in the contralateral breast. In addition, the implants may develop capsular contractures, deflate, or rupture. When mastectomy flaps are thin, the implant may be palpable, or rippling may be visible. The use of the latissimus dorsi myocutaneous flap may add additional camouflage to the implant as well as increased ptosis and shaping not possible with implant reconstructions alone.

The immediate latissimus dorsi flap and implant reconstruction essentially skips the expansion phase with its inherent delay and morbidity. The latissimus dorsi is often an excellent choice when previous radiation has been administered or the patient has underlying microcirculatory problems.

Understanding the patient's goals and priorities is essential. Often, patients will compromise their expectations in favor of a simple, less complicated technique. Defining the patient's needs is an important part of the reconstructive surgeon's evaluation. Understanding the limitations and expected results of the techniques available is important so that the patient can make an informed decision.

IMPLANT BREAST RECONSTRUCTION

What are the limitations of one-stage implant reconstruction?

The simple placement of an implant for breast reconstruction, either as an immediate procedure or as a delayed procedure, is a one-stage technique with minimal morbidity. The indications for this procedure were reduced significantly with the development of textured, anatomically shaped tissue expanders. Freeman in 1962 and 1969^{31,32} and Snyderman and Guthrie in 1971³³ described the subcutaneous placement of an implant after mastectomy. In 1981, Gruber³⁴ reported that submuscular breast reconstruction significantly lowered the risk for capsular contracture. The development of the Becker expander-implant facilitated a one-stage implant reconstruction technique.³⁵ The Becker device can serve as both an expander and a final implant, making it possible to offer a one-stage procedure to a larger percentage of patients.

In the immediate breast reconstruction setting, several factors may make simple implant placement difficult. The immediate placement of an implant of adequate size to achieve symmetry with the contralateral breast may be impossible because of soft tissue deficiency or questionably viable skin flaps. It may be necessary to place a smaller implant initially and later exchange it for a larger one. This approach offers minimal, if any, benefit over two-stage tissue expander techniques.

In the delayed reconstruction setting, it may be easier to place an implant of adequate size. The ultimate result, however, is often inferior to a two-stage expander-implant reconstruction. Creation of a well-demarcated inframammary fold and maintaining adequate breast projection at the correct level may be difficult. When any degree of ptosis is present, the ability to simulate this ptosis is enhanced by placing a tissue expander low and then, at the second stage, creating a properly positioned inframammary fold while maintaining adequate breast projection. In selected cases in which the contralateral breast is small, there is no ptosis, and the inframammary fold is indistinct, simple implant placement may be adequate. Often, even in these cases, too much upper-pole breast fullness is created on the reconstructed side after the implant is placed.

Most one-stage implant breast reconstructions, whether done using the Becker implant-expander or simple implant, would benefit from a second procedure to reposition the implant and create a more distinct inframammary fold.

When previous chest wall radiation has been given or is planned postoperatively, achieving a long-term successful reconstruction by implant placement techniques is less likely.²¹

Early experience in breast reconstruction with smooth-surfaced tissue expanders demonstrated a high incidence of capsular contracture during the expansion phase that ultimately limited full expansion. During the period of time that these devices were used, simple implant reconstruction offered several theoretical advantages because capsular contracture rates were initially much lower when simple implants were placed submuscularly. The development of textured, anatomically shaped tissue expanders and implants

decreased the risk for capsular contracture.³⁶ The improved contour has made simple implant reconstruction an infrequent procedure.

TISSUE EXPANDER-IMPLANT TECHNIQUE

What are the advantages of tissue expander-implant reconstruction?

In 1957, Charles G. Neumann, while working in the Department of Surgery at New York University, fashioned a balloon to a polyethylene tube and expanded the scalp to reconstruct the upper two thirds of a traumatically avulsed ear.³⁷ This single case report documents the first clinical use of tissue expansion, but the era of tissue expansion in breast reconstruction did not begin until more than 20 years later, when Chadomer Radovan presented his experience with this technique.³⁸ At about the same time, William Grabb³⁹ performed clinical studies using the breast tissue expander device. Since that time, numerous laboratory and clinical studies have helped to define the role of tissue expansion in both general reconstructive surgery and breast reconstruction.^{37,40-42}

Trends toward more conservative mastectomies create new challenges for the reconstructive surgeon. Basic principles of reconstruction always favor the use of autologous tissues with similar color, texture, and subcutaneous fat. The postmastectomy defect lacks both skin and underlying breast mound. The skin envelope must have adequate laxity to allow the breast mound to project sufficiently and remain soft in consistency. When possible, careful planning with the oncologic surgeon, at the time of the mastectomy, makes the achievement of these goals easier. The smaller mastectomy defect and the ability to begin reconstruction at the time of mastectomy make tissue expansion a prime method to reconstruct the absent breast. The tissue expander is an ideal tool to prepare the remaining mastectomy skin to receive a permanent prosthesis.

Advances in tissue expander design have simplified the expansion procedure and made it more predictable and successful. Complete expansion has become easier; with the development of textured surfaces on the expander, the capsular response has been decreased during the expansion phase.³⁶ The texture also helps to prevent expander movement or migration during expansion. This allows for maximum expansion in precise areas. The introduction of an anatomic shape to the expander allows preferential expansion of the lower pole of the breast skin.

Who are appropriate candidates for tissue expansion reconstruction?

In general, patients with small, minimally ptotic breasts who have undergone a total mastectomy are good candidates for tissue expander reconstruction. Patients with large, ptotic breasts will require significant modification of the contralateral breast to achieve symmetry. Furthermore, recurrence of ptosis in the larger breast may make an initial good result deteriorate over time.

Which patients are not candidates for tissue expansion reconstruction?

Patients who have inadequate soft tissue after mastectomy to cover the tissue expander are not candidates for tissue expander-implant reconstructions. The radical mastectomy patient, with thin flaps and absent pectoralis major muscle, requires the addition of soft tissue and is not a candidate for tissue expander-implant reconstruction. Other patients who have undergone extensive skin excisions with tight closure and thin flaps are also better treated with flap reconstructions. Patients who have undergone previous breast-conserving surgery with radiation therapy as part of their treatment and patients who require postoperative chest wall radiation following a mastectomy also are less ideal candidates for tissue expander-implant reconstructions. Radiation injury to the chest wall tissues makes adequate expansion difficult and increases the risks for expander or implant complications, such as infection, implant exposure, rib fracture, and capsular contracture.^{21,28} Alternative, usually autologous, reconstructive techniques are chosen for these patients. If one chooses to use tissue expansion in irradiated patients, both patient and surgeon must be prepared to abandon the technique if complications occur. A secondary plan should be available for completion of the reconstruction. Many of these cases can be successfully salvaged with a latissimus dorsi flap or other autologous reconstruction.

To achieve maximum symmetry with an implant reconstruction may require significant alteration of the contralateral breast by mastopexy, augmentation, or reduction. These issues must be considered and discussed with the patient, oncologic surgeon, and mammographer before reconstruction.

What issues in operative planning for immediate implant reconstruction should be considered by the oncologic surgeon?

Every effort should be made to develop healthy skin flaps, of uniform thickness, during the mastectomy. Ischemic flaps will delay healing of the incision and limit the uniform skin expansion required to achieve a good result. As discussed in Chapter 24, very long flaps, created to preserve large amounts of native breast skin, should be avoided. Rather, the goal should be to provide enough skin to comfortably close the incision without redundancy. Traditional guidelines for skin excision should be followed, adhering to standard oncologic principles. When bilateral mastectomy is being performed, every effort should be made to perform symmetrical skin excisions. Careful preoperative discussion with the oncologic surgeon is essential to achieve good results using this technique of reconstruction (Fig. 25-2).

What are the considerations in choosing the type of expander?

An anatomically shaped tissue expander with a textured surface and integrated port is desirable. Previous experience with smooth-surface expanders resulted in capsular contracture in

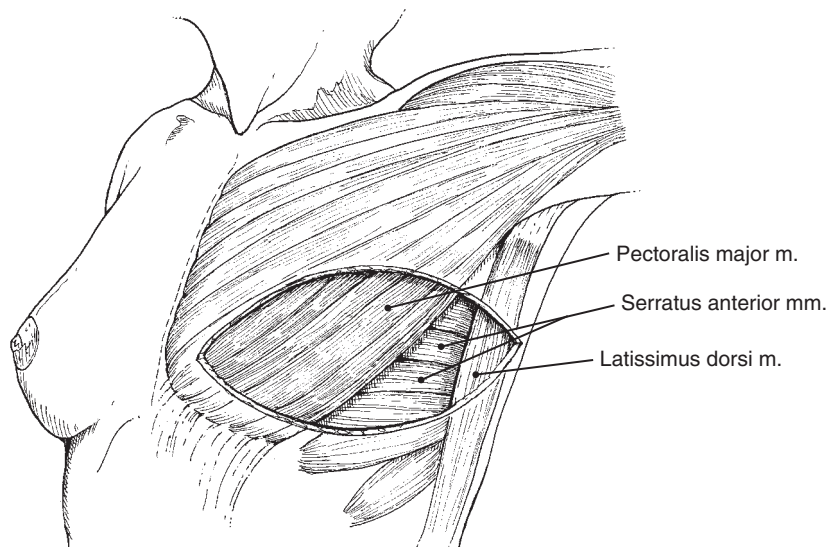

Figure 25-2 Chest wound after mastectomy.

a significant number of patients,⁴⁰⁻⁴³ which limited full expansion and the creation of a soft, pliable skin envelope of adequate size to accept the final implant. The anatomic shape allows for preferential expansion of the lower pole skin, thus achieving adequate anterior projection in the reconstructed breast. The use of an expander with an integrated port, rather than a remote port, makes the expansion process less painful because the skin over the integrated port is usually anesthetic, whereas the skin over a remote port has sensibility. Complications of port malfunction are also less likely with the integrated port.

The primary consideration when choosing the size of the tissue expander to be used is the width of the contralateral breast. One should always choose a tissue expander at least as wide as the contralateral breast. Smaller expanders are used in patients with narrow breasts, and larger sizes are used in patients with wider breasts. When bilateral mastectomy has been or is being performed, the size of the tissue expander is based on the preexisting base width, unless the patient prefers to have smaller or larger breasts. This discussion is part of the preoperative consultation with the patient.

What preoperative measures are taken with tissue expansion reconstruction?

With the patient standing, the inframammary fold position of the contralateral breast is marked, and a line is drawn to the middle of the chest. With the patient standing and examined from the side, the point of maximum breast projection is noted, as well as the breast's position relative to the inframammary fold. In the immediate reconstruction patient, alteration of the contralateral breast by mastopexy, reduction, or augmentation is performed during the implant exchange procedure. When a delayed reconstruction is being performed, the symmetry procedure may be performed at the time of the initial tissue expander placement. The future expected position of maximum breast projection is planned at the time of the expander placement. The location of the point of maximum breast projection is important because the tissue expander will be positioned so that the maximum anteroposterior expansion will be achieved to correspond to the point of

maximum breast projection on the unoperated breast. This may require positioning the expander several centimeters below the inframammary fold during the initial procedure. The single most important determinant for ultimate success of breast reconstruction using these techniques is achieving maximum anteroposterior expansion at the point of maximum breast projection. The end point of the expansion process is when adequate projection, rather than a specific volume, is achieved.

What intraoperative measures are taken with tissue expansion reconstruction?

Positioning of the expander must allow for maximum expansion at the desired level as well as the ultimate achievement of a normal inframammary fold. To achieve these two goals, the lower flap must frequently be undermined in the subcutaneous plane to a level inferior to the inframammary fold of the contralateral breast. This position is determined as discussed previously. To achieve a normal inframammary fold, the lower one third of the tissue expander is usually not covered with muscle. Close approximation of the dermis of the lower flap to the chest wall may be required at the second-stage operation to achieve a normal inframammary fold; therefore, any extra thickness of tissue in the inframammary fold should be avoided. The upper two thirds of the tissue expander are placed subpectorally. Other authors prefer total muscle coverage of the expander.⁴⁴ We have found that total muscle coverage is unnecessary and often does not allow complete expansion, resulting in a poor aesthetic result.

In the immediate-reconstruction setting, if the skin flaps are questionably viable, the placement of the expander is aborted and performed as a delayed procedure. This avoids the postoperative complication of tissue expander exposure and infection.

When an immediate reconstruction is being performed, the pectoralis major muscle is divided transversely where it joins the anterior rectus sheath. This division is continued medially and superiorly along the origin of the pectoralis major muscle to allow for adequate medial expansion (Fig. 25-3A and B). Most often, the tissue expander is filled with

Figure 25-3 A and B, Transection of the medial pectoralis major muscle to place the tissue expander. C, Pectoralis major muscle sutured to the serratus anterior muscle over the tissue expander.

about 100 mL of saline, and the pectoralis major muscle is redraped and sutured lateral to the serratus anterior muscle using absorbable sutures (Fig. 25–3C). These sutures stabilize the expander in its position, prevent lateral migration of the expander, and reestablish the anterior axillary fold. If an axillary dissection has been performed, two closed-suction drains are used. Otherwise, only one drain is used. Skin closure is performed in two layers using interrupted buried dermal sutures and interrupted or intracuticular skin sutures. Aggressive postoperative trimming of questionable skin edges will minimize the risk for expander exposure as well as allow for expansion to begin as early as possible.

When a tissue expander is being placed as a delayed procedure, the same technique of muscle covering the upper two thirds of the expander is employed. The lower flap, in the region of the inframammary crease, is frequently thinned by either direct vision or liposuction. More fluid is placed into the tissue expander than in the immediate-reconstruction setting, and expansion is begun earlier. Wound closure is more often done with a subcuticular suture after reapproximation of the deeper tissues. A drain is usually placed for 24 to 48 hours to minimize fluid collection and maximize the chances for tissue adherence to the tissue expander.

What postoperative measures are taken with tissue expansion reconstruction?

When a tissue expander is placed immediately, the patient is usually sent home with the drains in place, and the drains are removed in the office in 5 to 7 days. Repeated aspiration of postoperative seromas is to be avoided whenever possible because this will increase the risk for infection and possible expander perforation. The only seromas aspirated are axillary seromas, and this is done following immediate reconstruction. All patients receive 1 week of antibiotics. Limited use of the ipsilateral arm is allowed during the first 2 weeks, and all range-of-motion exercises are delayed for this period of time. Skin sutures are removed in 2 weeks, and expansion is usually begun at that time.

When a tissue expander is being placed as a delayed procedure, a drain is usually placed for 24 to 48 hours to minimize

fluid collection and maximize the chances for tissue adherence to the tissue expander. Range-of-motion exercises are begun 5 to 7 days after surgery.

What guidelines are followed for the expansion phase?

The goals of expansion are to achieve an adequate skin envelope for the permanent implant. This will result in a soft, pliable, natural-appearing breast. The amount of overexpansion must be adjusted based on the thickness of the skin flaps and the type of implant that will ultimately be used. All implants may ripple, and this may be visible through the skin. The tendency for rippling is greater with saline implants, especially when placed under thin flaps. When saline implants are used and the flaps are thick, overexpansion by 25% to 30% is recommended. This allows for trimming of excess skin at the exchange procedure, potentially creating a better-shaped breast in the final reconstruction. When the flaps are thin, overexpansion is kept to a minimum. Expansion will tend to thin the flaps further and accentuate visible rippling. In general, silicone implants have less rippling than saline implants, but the same general principles for overexpansion apply to patients receiving silicone implants.

In the immediate setting, when chemotherapy is being given, the exchange procedure is not done until the chemotherapy has been completed and the patient's laboratory values have returned to normal. In these cases, the final stages of expansion are delayed until chemotherapy is nearly completed. If an expander has been placed and the patient must receive chest wall radiation, the expander is usually fully expanded before radiation treatments begin. The patient's local response to radiation is followed closely. Removal of saline should be considered if the local reaction is severe and the health of the expanded skin is jeopardized.

In most circumstances, expansion is done weekly in the office using sterile technique and a 23-gauge butterfly needle. The end point for expansion is achievement of adequate anteroposterior projection (or slight overprojection) (Fig. 25–4). The patient's breast is allowed to remain fully expanded for 1 month before the exchange procedure.

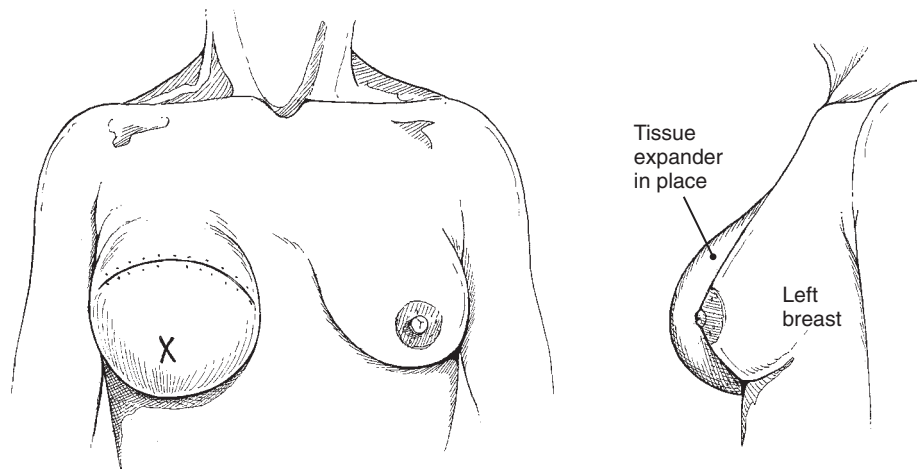

Figure 25–4 Appearance of the chest after completion of the tissue expansion process.

Figure 25-5 Measurement of the contralateral breast before selection of the permanent breast implant.

How is the appropriate implant selected for the exchange procedure?

The first consideration in planning the exchange procedure is choosing the appropriate implant. Available implants are either round or anatomically shaped. Anatomic implants are available in numerous shapes that vary in width, height, and projection. Evaluation of the contralateral breast is key to choosing an implant for exchange. When previous modification of the contralateral breast has been performed by reduction or mastopexy, the exchange procedure should be done only after enough time has elapsed to allow the modified breast to settle into a stable position. If modification of the normal breast is planned at the time of implant placement, its final shape and volume must be predicted at this stage to facilitate implant selection. The goals at placement of the permanent implant are to match the width, height, projection, and volume of the contralateral breast (Fig. 25-5). A general idea of the volume can be estimated by knowing the volume in the expander that matched the volume of the existing breast. Width, height, and projection are measured and the appropriate implant selected from available charts. One should always have many different-sized implants available at the exchange procedure. Saline implants look best when they are slightly

overfilled, thus minimizing rippling. Often, the asymmetrical orientation of an anatomic implant will help match the contralateral breast shape.

What are the guidelines for inserting the implant?

Creation of an appropriately positioned and contoured inframammary fold is important. Preoperatively, the inframammary fold position of the contralateral side is marked with the patient standing. These marks are transferred to the expanded side. The expander is removed through the mastectomy incision, and the new inframammary fold position is liposuctioned through two or three small access incisions in the future inframammary crease. This removes any excess subcutaneous tissue, facilitating close approximation of dermis to chest wall. Several 1½-inch, 25-gauge needles are passed through the skin into the expanded pocket at the inframammary fold position (Fig. 25-6A). Using the needles as a guide, the operator sutures the capsule on the anterior surface of the pocket to the capsule on the chest wall with monofilament sutures. An effort is made to attach the dermis of the anterior flap to the chest wall. Although this maneuver often produces

Figure 25-6 A, Marking the inframammary fold with needles as a guide to suturing the anterior and posterior capsules together. B, Appearance of the chest after placement of the permanent breast prosthesis.

dimpling of the skin, this dimpling ultimately resolves in 3 to 6 months. Multiple sutures are placed internally, and often external bolsters are added to reinforce the attachment of the anterior capsule to the chest wall (Fig. 25-6B). Capsulotomy and capsulectomy are performed whenever and wherever necessary, and the implant is filled to the appropriate volume with the patient in the sitting position on the operating table. Excess skin is then trimmed along the mastectomy incision to enhance shape and maximize projection. Final shape is more a function of the shape of the implant than the shape of the skin envelope. Overexpansion facilitates the ability to trim skin at the second procedure. When extensive capsulotomy or capsulectomy has been necessary, a closed-suction drain is placed.

Postoperatively, activity is restricted for 2 weeks, and the patient receives prophylactic antibiotics for 7 days. External bolsters are removed after about 5 to 7 days. The skin under the external bolsters must be monitored frequently to avoid pressure necrosis during the immediate postoperative period.

When extensive contralateral breast reduction surgery is performed, an adjustable implant should be considered on the reconstructed side to facilitate future size changes postoperatively. The ports on these adjustable implants are easily removed in the office (Fig. 25-7).

What are the potential complications of tissue expansion reconstructions?

In the immediate breast reconstruction setting, assessment of skin flap viability at the completion of the mastectomy is very important, especially in smokers, in whom microcirculatory compromise is likely. Any marginally perfused tissues should be trimmed to healthy tissue. In rare situations, fluorescein can be helpful to assess questionable areas of viability. If the plastic surgeon is still unsure about the viability of the skin flaps, immediate placement of a tissue expander should be abandoned and delayed reconstruction planned after primary

Figure 25-7 A patient after reconstruction with a tissue expander and breast prosthesis.

healing has occurred. Aggressive skin edge trimming, early in the postoperative period, will prevent expander exposure as well as minimize the time for wound healing. This allows inflation of the expander to begin as early as possible. If the expander is exposed in the early postoperative period, removal is recommended to avoid infection and potential systemic complications.

The early diagnosis and treatment of a hematoma is essential. If left untreated, a hematoma will increase the risk for capsular contracture and infection and make adequate expansion difficult.

When infection becomes apparent, antibiotic therapy should be instituted as soon as possible. Initial infection most often presents as cellulitis of the breast skin and only secondarily involves the expander pocket. Once the expander pocket is involved, the infection behaves like an abscess and requires removal of the expander, drainage of the space, and antibiotics. Replacement of the expander is delayed for 3 to 6 months until the tissues are soft and freely moveable over the chest wall. When the expander is replaced, organism-specific antibiotics are used. The risk for infection is increased in patients who have had prior radiation therapy or lymph node dissection.⁴⁵

Capsular contracture during the expander phase can prevent full expansion. In the past, expansion with smooth expanders often resulted in significant capsular response. Expansion often needed to be abandoned because of discomfort and the inability to create a soft skin envelope of adequate size and projection to receive the final implant. At the time of implant placement, near-total capsulectomy was required to obtain a good result. The development of textured expanders has significantly decreased the incidence of capsular contracture during expansion. The tissue adherence between the expander surface and the envelope results in a thin, pliable capsule, making capsulectomy unnecessary at the time of implant placement. Infection, hematoma, and seroma are still significant causes of increased capsular response and contracture, despite the textured surface on the expanders.

Seroma formation may occur after mastectomy with or without axillary dissection. Proper drain placement at mastectomy and proper management of these drains can minimize seroma formation. Drains should remain in place long enough to minimize seroma formation. Nevertheless, seroma formation will occur in a significant number of cases following immediate placement of tissue expanders. Careful aspiration of the seroma by the plastic surgeon will be required. When a tissue expander is present, the risk for perforation with aspiration requires careful technique away from the expander surface. Repeated aspirations also increase the risk for infection within the expander envelope, which can result in an increased capsular response or even abscess formation.

Using small-gauge needles during inflation and carefully aspirating any seroma can minimize loss of volume in the expander during the expansion phase. Significant deflations require replacement of the tissue expander. Permanent saline implants may deflate at any time after their placement. These deflations are most often due to valve malfunction. Tissue ingrowth into the implant valve can make the implant valve incompetent, allowing for slow loss of saline from the implant. Newer valves are being developed to make deflations less likely. Care must be taken to ensure that the valve is sealed after the implant is filled.

Rib fracture is a rare complication of tissue expansion and most often occurs if the chest wall has been irradiated. Avoidance of tissue expanders in irradiated patients, as well as slow expansion and careful monitoring in nonirradiated patients, should eliminate this complication. If significant localized pain develops during expansion, the status of the underlying rib should be evaluated by radiographs. If a rib fracture is present, the tissue expander should be removed and other reconstructive techniques offered to the patient.

LATISSIMUS DORSI MYOCUTANEOUS FLAP RECONSTRUCTION

Initial attempts to reconstruct the radical mastectomy defect using silicone implants were often unsuccessful because of the absent pectoralis major muscle and thin skin. In 1976, the pedicled latissimus dorsi musculocutaneous flap was used for the treatment of radiation necrosis of the chest wall.⁴⁶ In 1977, the latissimus dorsi was used as an island pedicle flap for breast reconstruction.^{47,48} The large, fan-shaped muscle could be completely transposed anteriorly to replace the absent pectoralis major muscle and re-create the anterior axillary fold, as well as provide a well-vascularized muscle and skin envelope to receive an implant. The skin island, when properly designed, could replace the skin removed at mastectomy. Initially, a smooth silicone implant was placed under the latissimus dorsi muscle, and significant incidence of capsular contracture resulted.^{36,49,50} With the development of the TRAM flap, which did not require an implant, the latissimus dorsi flap became a secondary reconstructive choice. The development of textured implants, as well as expanders, has decreased the incidence of capsular contracture significantly.^{36,50} In selected cases, when adequate subcutaneous fat is available over the latissimus dorsi muscle, no implant is required, and a total autologous breast reconstruction is possible.⁵¹⁻⁵⁴ Despite the trend toward less radical cancer surgery, the latissimus

dorsi myocutaneous flap still plays a significant role in breast reconstruction.

Who is a candidate for latissimus dorsi flap reconstruction?

Patients who require the addition of autologous tissue to achieve breast symmetry with implants or who are not good candidates for TRAM flap reconstruction may benefit from the latissimus dorsi flap. The patient who has a large skin requirement at the mastectomy site and ptosis in the contralateral breast is usually best treated by autologous tissue techniques rather than by tissue expander and implant techniques. When the TRAM flap or another autologous tissue donor site is not an option because of lack of tissue, previous surgery, smoking, obesity, diabetes mellitus, or collagen-vascular disease, then the latissimus dorsi flap can be reliably used. The blood supply to the latissimus dorsi flap is excellent, even in patients with a compromised microcirculation. It is rare to have total or partial loss of a latissimus dorsi flap.

What are the advantages of latissimus dorsi flap reconstruction?

The latissimus dorsi flap and implant offers several advantages over tissue expander–implant techniques. The latissimus dorsi skin component replaces the skin removed at mastectomy and avoids the morbidity of tissue expansion. The latissimus dorsi flap provides a true, immediate breast reconstruction completed in one stage at the time of mastectomy. The latissimus dorsi muscle provides an envelope of tissue under the mastectomy skin. Ripples are less visible when a latissimus dorsi flap is used. This technique can often salvage a cosmetically poor tissue expander–implant reconstruction. When a tissue expander has been placed and chest wall radiation is required postoperatively, adequate expansion is often difficult to achieve.^{21,28} In these cases, the addition of a latissimus dorsi flap can salvage a reasonable cosmetic result. Patients who have undergone breast conservation and develop tumor recurrence require total mastectomy. If the TRAM flap donor site is not available, the latissimus dorsi flap with an implant is a good second choice.

What are the anatomic considerations in latissimus dorsi flap reconstruction?

The latissimus dorsi muscle receives its primary blood supply from the thoracodorsal artery, a branch of the subscapular artery (Fig. 25–8). This single vessel runs deep to the insertion of the muscle, freely separated from the muscle at this level. The artery enters the muscle at the mid-scapular level and quickly branches within the muscle.⁵⁵ Musculocutaneous perforators provide blood supply to the skin over the muscle. A branch from the proximal thoracodorsal artery supplies the serratus muscle. When the proximal thoracodorsal vessel has been divided, the serratus branch will usually provide adequate blood supply to the latissimus dorsi muscle through retrograde flow from the intercostal vessels.^{56,57} The abundant blood supply to both the muscle and the overlying skin allows

for numerous flap design options to solve many clinical problems in breast reconstruction.

What are the preoperative considerations in planning a latissimus dorsi flap reconstruction?

A complete evaluation of the reconstructive requirements of the chest wall is an essential part of the planning of all types of breast reconstruction. It is especially important when a latissimus dorsi myocutaneous flap is being used. The volume of autologous tissue available with this flap is limited, and its positioning on the chest wall is critical to achieve a good cosmetic result.

The upper chest wall contour depends primarily on the adequacy of the pectoralis major muscle. The pectoralis major muscle is absent in the radical mastectomy patient, and even in the modified radical mastectomy patient, pectoralis major atrophy can occur secondary to denervation during axillary dissection. Reestablishment of a symmetrical upper chest wall contour takes high priority and may require de-epithelialization and subcutaneous placement of the skin flap paddle. Anterior axillary fold contour may need reconstruction. Transposition of the entire latissimus dorsi muscle with anterior positioning of its insertion enables reconstruction of the anterior axillary fold. The location and orientation of the mastectomy scar should be noted. The preferred final position of the skin island is in the lower lateral aspect of the reconstructed breast. High incisions and vertical incisions are best left alone when planning the flap inset. In these cases, a new incision should be planned so that an inferolateral inset is possible. When the chest wall has been irradiated, the skin requirements may be significantly greater than expected preoperatively. In situations in which the skin requirements are greater than can be provided by the latissimus dorsi skin island, a tissue expander, rather than an implant, should be placed at the time of flap transfer.

Evaluation of the latissimus dorsi muscle, subcutaneous tissue, and skin laxity is important. When the examination reveals that the latissimus dorsi muscle has been denervated at the time of axillary dissection, the thoracodorsal vessels have most likely been divided. Transfer of the musculocutaneous unit must then be based on the serratus branch of the thoracodorsal vessels, which will perfuse the flap through the intercostal vessels.⁵⁷ The need to base the flap on serratus vessels may limit the arc of rotation of the muscle and the ability to transfer the entire muscle anteriorly. This will limit the amount of tissue available for reconstruction, and an alternative reconstruction might be considered. The vascularity of the flap may also be significantly less when the flap is transferred on these secondary vessels. If a patient is a smoker, is diabetic, or has any other systemic microcirculatory disorders, partial or complete flap loss is more likely.

The laxity of the skin on the back is quite variable, as is the orientation of the greatest skin-laxity axis. When designing the skin island, these factors must be considered. Some patients have large amounts of subcutaneous fat, either just below the posterior axillary fold or lower on the back. Incorporating the subcutaneous fat excess under the skin island can add a large amount of autologous tissue to the flap and simplify the reconstruction.

Figure 25-8 Anatomy of the lateral chest muscles.

What guidelines are followed when designing the skin island?

Various skin island designs are possible (Fig. 25-9). The orientation of the skin island is based on several variables. The best cosmetic scar is obtained when the long axis of the flap follows the natural lines of the skin of the back (see Fig. 25-9A). Frequently, a wide skin paddle with generous subcutaneous tissue can be obtained by this design. When there is excess skin and subcutaneous tissue at the posterior axillary fold, a fleur-de-lis pattern over this site will maximize the transfer of autologous tissue⁵⁸ (see Fig. 25-9B). Another useful skin island position is a vertically oriented skin paddle placed laterally on the back. This design allows for easy inset of the skin island lateral to and low on the anterior chest wall (see Fig. 25-9C). Complete muscle coverage both above and below the implant is possible, and a visible scar directly on the back is avoided. One must be prepared to modify any of these designs based on the reconstructive objectives. When elevating the latissimus dorsi myocutaneous flap, additional subcutaneous tissue can be harvested by beveling the incision through the subcutaneous tissue to incorporate large amounts of fat over the entire muscle surface. When this is performed over extensive areas of the back, consideration must be given to the effect on the subcutaneous tissue blood supply and ultimate healing of the donor site scar. With extensive harvest of tissue, donor site healing may be compromised.⁵⁴ A true

autologous breast reconstruction, not requiring an implant, can sometimes be achieved by including extensive subcutaneous fat with the muscle flap.⁵¹⁻⁵⁴ Usually, a small implant is still required to assist with breast projection.

In general, the donor site from a latissimus dorsi skin island 10 cm in width or less can easily be closed primarily without undue skin tension. If a larger skin island is required, a tissue expander may be required under the latissimus dorsi muscle before flap elevation to facilitate primary closure of the donor site. When a tissue expander is placed under the transposed musculocutaneous flap, a textured expander is preferable because it will allow for less capsular response and ultimately a softer, more pliable skin envelope. When a permanent prosthesis is placed, an adjustable implant is sometimes preferable to allow for small postoperative adjustments of implant volume and to maximize symmetry. This is especially important if a symmetry procedure is done on the contralateral breast at the same time as flap placement.

What are the intraoperative considerations before commencing the latissimus dorsi flap reconstruction?

When a latissimus dorsi myocutaneous flap is being used for immediate reconstruction, the width of the skin removed at mastectomy is noted, and an attempt to replace this exact

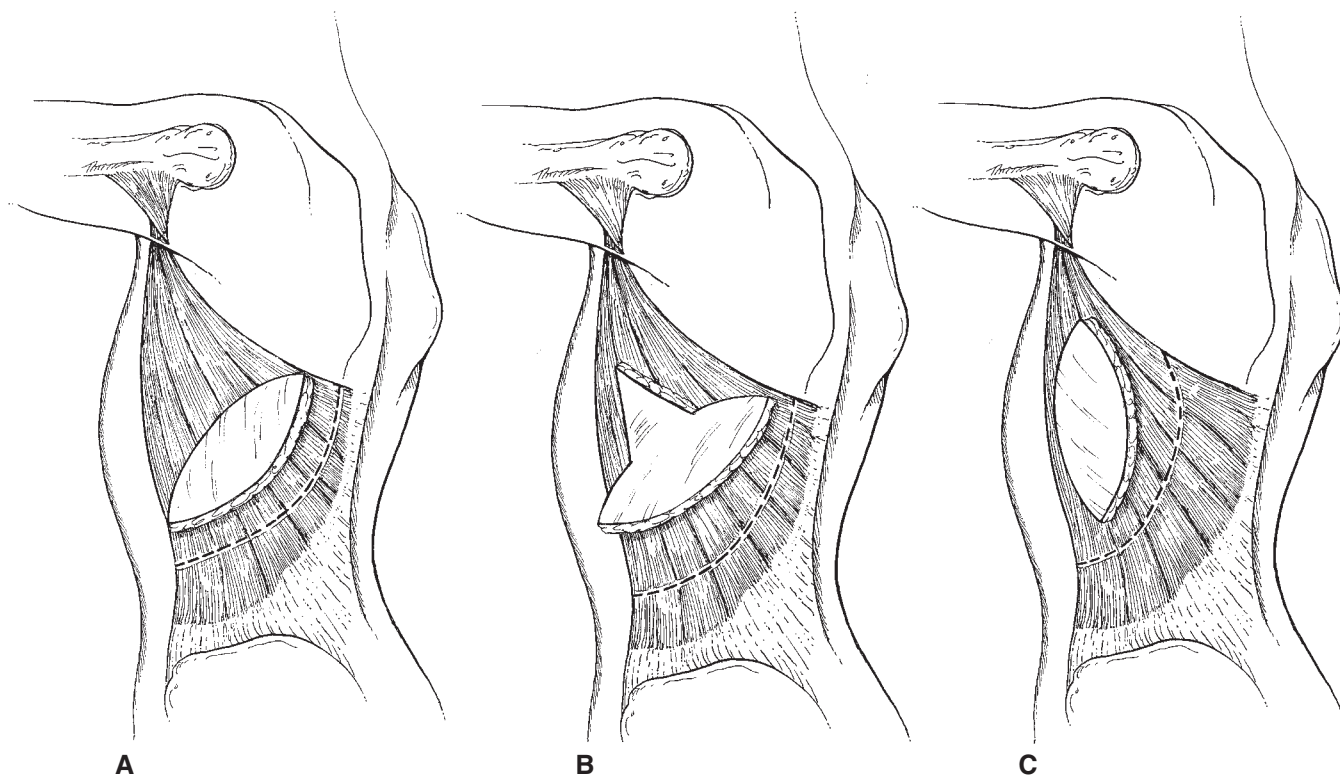

Figure 25-9 Skin islands for latissimus dorsi myocutaneous flaps. *A*, Oblique skin island. *B*, Fleur-de-lis skin island. *C*, Vertical skin island.

dimension is made when designing the skin paddle on the back (see Fig. 25-9). Coordinated preoperative planning with the oncologic surgeon will greatly facilitate this. At the completion of the mastectomy, the plastic surgeon should examine the adequacy and patency of the thoracodorsal vessels. Following this, the anterior chest wound is closed temporarily with staples, and the patient is repositioned in the lateral position. Prior placement of a beanbag will facilitate the repositioning. When the general surgeon is comfortable performing a mastectomy with the patient in a three-fourths lateral position, repositioning the patient may be unnecessary. As discussed in Chapter 24, particular care must be exerted to avoid prolonged posterior extension of the arm and stretching of the brachial plexus.

When the latissimus dorsi flap is being used for delayed breast reconstruction, the procedure is begun with the patient supine on the beanbag. The site for the flap on the anterior chest is opened, and the mastectomy defect is re-created. For patients who have had a previous radical mastectomy, wide subcutaneous undermining is required so that the upper chest wall deformity and anterior axillary fold can be reconstructed with the flap. When the defect on the chest wall is more limited, as is often the case following a simple mastectomy, the dissection is best done subpectorally in the upper chest so that the implant will be placed under the muscle. While the patient is in the supine position, the anterior border of the latissimus dorsi muscle is identified; this will facilitate the flap transfer. Once the anterior dissection has been completed, an assessment of the skin requirement should be made so that proper flap design on the back can be planned. The patient is then placed in the lateral position after the anterior incision is temporarily closed with staples.

How is the flap harvested?

The skin incisions are made for flap harvest, and a subcutaneous bevel is created to include as much subcutaneous tissue as possible with the flap. Variable degrees of beveling are possible, depending on the requirements for autologous tissue. When extensive fat is included with the flap, care must be taken to preserve the subdermal vessels to the skin of the back, to minimize wound healing problems following flap closure. The extent of inferior flap dissection will depend on how much muscle is needed to cover the implant. When the flap is transferred anteriorly, the lower portion of the latissimus dorsi muscle frequently ends up superior. The amount of inferior latissimus dorsi muscle required varies depending on the orientation and placement of the skin paddle and the amount of upper chest wall deformity. With the traditional oblique transverse skin paddle orientation, several centimeters of the inferior portion of the muscle are usually needed.

The flap dissection is performed medially to the midline. Superiorly, the dissection is continued to the upper border of the latissimus muscle and along the junction of the teres major and latissimus muscles to the insertion of the latissimus muscle. The lateral border of latissimus muscle is identified from the planned inferior muscle division to the axilla. The muscle is then divided inferiorly with cautery, taking care to remain above the serratus muscle along the lateral border. The latissimus muscle is raised from inferior to superior, while the serratus muscle is maintained against the chest wall. The upper border of the latissimus dorsi is dissected free and continued superiorly between the teres major and latissimus

dorsi to its insertion onto the humerus. Before this mobilization is completed, the serratus branch of the thoracodorsal vessels is identified on the anterior surface of the serratus muscle. Identifying this vessel will allow definitive identification of the thoracodorsal vessels.

When the anterior axillary fold requires reconstruction, the insertion of the latissimus dorsi muscle onto the humerus is divided while the vascular pedicle is protected. This maneuver allows anterior transposition of the entire muscle, including its tendinous insertion. Depending on the extent of transposition required, the serratus branch is either preserved or divided. If the thoracodorsal vessels have been ligated proximally, then the serratus branch, filled retrograde through the intercostal vessels, can be used to provide adequate blood supply to the entire latissimus dorsi myocutaneous unit. After the thoracodorsal pedicle is identified, the separation of the teres major from the latissimus is continued superiorly. Division of this attachment must be complete because the anterior rotation will be limited by the teres major attachment. The thoracodorsal nerve is usually transected at this time to prevent unnatural-appearing contractions postoperatively. When the entire muscle is transposed and an anterior axillary fold reconstruction has been performed, the nerve is left intact because its contractions are in the normal orientation. Leaving the nerve intact does not appear to increase muscle bulk. The muscle bulk is affected in a much more significant way when the resting length of a muscle is significantly altered than when the motor branch is divided. The musculocutaneous unit is then transferred anteriorly through a wide tunnel into the anterior mastectomy defect. Keeping the tunnel high in the axilla will minimize the fullness that is seen more inferiorly when the tunnel is lower down. Two closed-suction drains are placed, and the back is closed in layers. The patient is repositioned in the supine position. The arms are placed on arm boards so that the patient may be placed in a sitting position on the operating table during final closure of the breast incision to best assess symmetry and breast shape.

How is the flap positioned?

With the patient in the sitting position, the flap is oriented in the planned position, and the adequacy of skin provided by the latissimus dorsi muscle unit on the back is assessed. When there is concern about skin adequacy, a textured tissue expander rather than a final implant is chosen. This allows for postoperative expansion of the chest wall skin and flap skin so that better symmetry can be obtained. When adequate skin is available but the size of implant is uncertain, an adjustable implant should be selected to allow for small adjustments postoperatively. Most often, a textured implant, either round or anatomically shaped, is selected. When the anterior axillary fold requires reconstruction, the tendinous insertion of the latissimus dorsi muscle is attached between the deltoid muscle and the coracobrachialis muscle to simulate the contralateral pectoralis major muscle. When reconstructing a radical mastectomy defect or when there is a significant soft tissue requirement superiorly extending up to the clavicle, de-epithelialization of the skin paddle may be required to provide upper chest wall contour. When a tissue expander or implant is used, every attempt should be made to achieve total muscle coverage over the implant, using the transferred latissimus muscle and the existing pectoralis major muscle (Fig. 25–10). One closed-suction drain is placed anteriorly, and a tension-free skin closure is performed in a layered fashion.

Symmetry procedures can be done either at the time of the latissimus dorsi flap or at a later date. Delaying contralateral breast surgery improves the chance of obtaining optimal symmetry. This is especially true if a tissue expander has been placed under the latissimus dorsi flap.

What are the guidelines for postoperative management?

A broad-spectrum antibiotic is begun in the operating room and continued for 1 week postoperatively. Suction drains are

Figure 25–10 Latissimus dorsi myocutaneous flap inset on the chest.

Figure 25-11 Latissimus dorsi myocutaneous flap breast reconstruction.

removed when 24-hour drainage is less than 50 mL. Despite this regimen, about 20% to 50% of patients will develop a seroma at the flap donor site.^{54,59} If the seroma is small, it will usually be self-limited and resolve over several weeks. When it is larger, aspiration may be required. When the muscle insertion has not been transferred anteriorly, range-of-motion exercises are begun 2 weeks after surgery, and full activity is allowed after 6 weeks. When a seroma occurs, range of motion should be limited until resolution of the seroma. When the insertion of the latissimus dorsi has been reattached anteriorly, abduction of the arm is limited for 6 weeks, allowing the suture line to heal. When a tissue expander has been placed under the latissimus dorsi muscle, expansion is usually begun 1 week postoperatively, and full expansion is achieved as rapidly as possible. Following 1 month of full expansion, an exchange of the tissue expander for a permanent or adjustable textured implant and any symmetry procedure on the contralateral breast is performed. Nipple reconstruction is deferred for 6 weeks to 3 months to allow the final contour of both the reconstruction and the contralateral breast to stabilize (Fig. 25-11).

What are the potential complications of latissimus dorsi flap reconstruction?

Hematoma may occur at the donor site or anterior chest and can be avoided by meticulous hemostasis during the procedure. The patients are instructed to avoid aspirin and non-steroidal anti-inflammatory drugs for 2 weeks preoperatively. If there is a history of previous hematoma or easy bruising, a complete coagulation evaluation should be done preoperatively. Untreated hematomas around the implant or expander will result in an increased incidence of capsular contracture.

Infection is rare following latissimus dorsi flap breast reconstruction. When an implant has been used and an infection occurs, aggressive treatment with intravenous antibiotics is necessary. Despite this treatment, removal of the implant or tissue expander may be required to cure the infection. Repeated aspirations of a chronic seroma may increase the

incidence of infection. These aspirations must be done under sterile conditions. The aspirate should always be cultured, and if there is growth, appropriate treatment should be instituted.

Seroma occurs in 20% to 50% of patients, despite adequate closed-suction drainage.^{54,59} Biweekly aspirations may be required to resolve the seroma.

Vascular inflow complications resulting in either partial or complete flap necrosis are rare. Preoperative evaluation of thoracodorsal nerve function as a guide to thoracodorsal vessel patency is a reliable tool. When the thoracodorsal pedicle is intact, postoperative flap ischemia is most often due to pedicle injury during flap elevation or pedicle kinking on transfer of the flap. When the thoracodorsal vessels have been divided, the patent serratus branch is capable of sustaining the entire flap territory in most cases. Knowledge of this situation preoperatively will allow for proper flap design and elevation to minimize the risk for flap ischemia.

Capsular contracture around an implant with the resulting breast deformity and pain was a common complication when smooth implants were used.⁴⁹ With the development of textured tissue expanders, as well as textured implants, the incidence of capsular contracture is lower, but still significant.³⁶ Treatment of established capsular contracture may require capsulectomy and implant replacement or autologous tissue reconstruction.

The reported incidence of saline implant deflation is less than 2% during the first 2 years after placement; when it occurs, however, replacement with a new implant is necessary.⁶⁰

Brachial plexus stretch injury following latissimus dorsi flap reconstruction can occur.⁵⁹ This stretch injury occurs either from hyperabduction of the shoulder during flap dissection or from positioning problems in patients with long-standing shoulder immobility. It is important to assess shoulder mobility preoperatively. When limitations exist, care must be taken during the surgical procedure.

Donor site scar hypertrophy and donor site deformity are most often related to the orientation of the flap design and the volume of subcutaneous tissue included in the harvest. Vertical orientation along the anterior latissimus dorsi border or oblique transverse orientation of skin excision along lines of skin tension usually results in satisfactory scars.

In conclusion, the latissimus dorsi flap is a very useful reconstructive technique for breast reconstruction. Its abundant vascular supply and well-perfused overlying skin and subcutaneous tissue make this flap both reliable and versatile.

UNILATERAL BREAST RECONSTRUCTION WITH THE PEDICLED TRAM FLAP

The TRAM flap allows reconstruction of the breast without prosthetic implants. Use of this flap requires a longer, more complex surgical procedure, with the occasional need for blood transfusions. This flap can provide the natural ptosis that cannot often be duplicated with a breast implant. Autologous tissue has tactile sensation more like breast tissue. The flap develops sensory return through nerve ingrowth into the flap from the mastectomy bed.⁶¹ Excellent symmetry can more typically be achieved with TRAM flap reconstruction.

The TRAM operation can be performed as a microvascular free flap, a single-pedicled flap using one rectus muscle, or a double-pedicled flap using both rectus muscles. The choice of flap is based on the preference of the individual surgeon as well as on the specific patient's situation. Patients who are smokers and patients who require a large volume of tissue may benefit from a microvascular free flap. A double-pedicled TRAM flap may also be used in these patients. Unfortunately, double-pedicled flaps require sacrifice of all or part of both rectus abdominis muscles. This may result in significant abdominal wall weakness, which may be unacceptable to some patients.⁶² Prior right upper quadrant subcostal-type incisions prevent use of a right rectus abdominis pedicled TRAM flap. This would be an indication for use of either a left rectus muscle pedicled TRAM flap or a microvascular free flap.

What are the anatomic considerations in TRAM flap reconstruction?

The female anatomy is notable for a prominent infraumbilical fat pad. This fat may be carried as a pedicled flap by the deep superior epigastric artery or as a free flap using the deep inferior epigastric artery as the primary blood supply. The skin and fat in a TRAM flap closely approximate the texture and size of normal breast. The rectus abdominis muscle is bilateral and originates from the fifth, sixth, and seventh ribs as well as from the xiphoid process.⁶³ The muscle is wider proximally and narrows as it approaches the pubis. Typically, there are three tendinous inscriptions. The most inferior is in the area of the umbilicus. The middle inscription is halfway between the umbilicus and the costal margin. The superior inscription is close to the costal margin. The shape, density, and location of the inscriptions are variable (Fig. 25–12).

The support system of the abdominal wall consists of five bilateral muscles: the transversalis, internal oblique, external oblique, rectus abdominis, and pyramidalis muscles. The vertical support of the abdominal wall is formed by the linea alba and the two linea semilunaris ligaments. The anterior rectus sheath and the tendinous inscriptions form the transverse support of the abdomen.⁶⁴ The posterior rectus sheath is absent below the semilunar line, about halfway from the umbilicus to the pubis, but does provide some support above the arcuate line (see Fig. 25–12). The posterior sheath should not be relied on to provide lasting abdominal wall strength. The anterior rectus sheath should always be repaired after harvest of the rectus muscle.

The anterior abdominal wall blood supply is from the deep superior epigastric artery, the deep inferior epigastric artery, the superficial inferior epigastric artery, and the 8th through 12th intercostal arteries. The superficial external pudendal vessels and the superficial and deep circumflex iliac vessels also contribute blood supply to the abdominal wall (Fig. 25–13).

The deep superior epigastric artery descends from the internal mammary artery, leaves the mediastinum between the costal and sternal attachments of the diaphragm, and enters the rectus sheath about 1.5 cm from the midline. The deep superior epigastric artery runs underneath the rectus abdominis muscle and eventually enters the muscle proximal to the first tendinous inscription. Below the second tendinous inscription, the branches of the deep superior epigastric artery are reduced in caliber and communicate with similar vessels from the deep inferior epigastric artery. The deep superior epigastric artery is located in the middle third of the rectus abdominis muscle. The deep inferior epigastric vessel arises from the external iliac artery just superior to the inguinal ligament. The deep inferior epigastric artery is larger in diameter

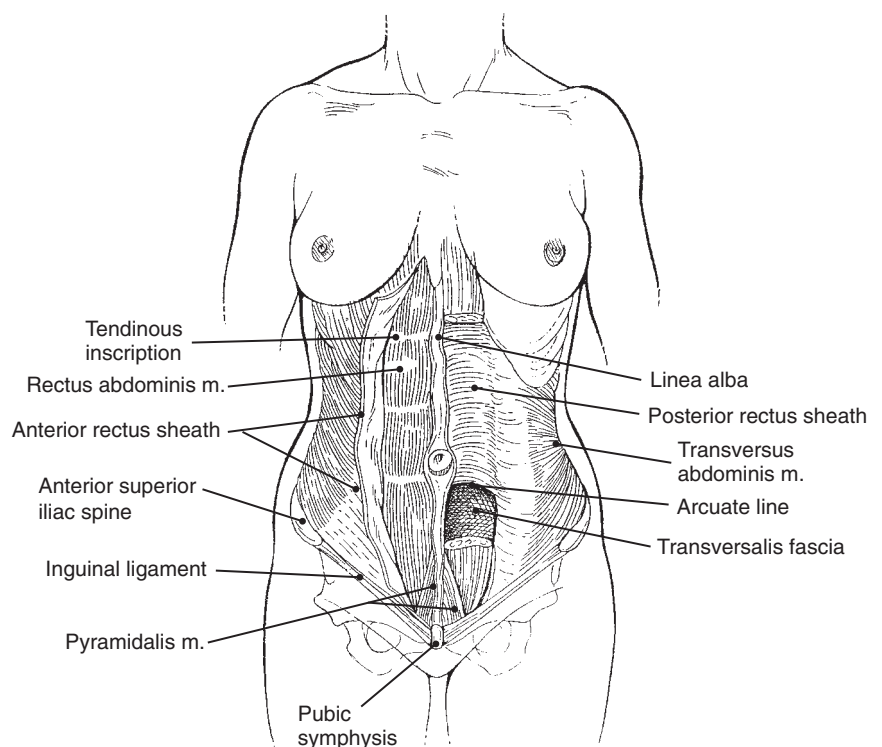

Figure 25–12 Anatomy of abdominal wall musculature.

Figure 25-13 Vascular anatomy of the abdominal wall.

than the deep superior epigastric artery. Typically, the deep inferior epigastric artery enters the rectus sheath in the area of the linea semilunaris about 3 to 4 cm below the umbilicus.

Most cutaneous and subcutaneous perforating vessels from the deep inferior epigastric artery are in the area of the umbilicus. For the pedicled TRAM flap to survive, the deep superior epigastric artery flap depends on the deep inferior epigastric artery perforators flowing in a retrograde fashion through choke vessels. Blood then courses into the subcutaneous tissue through the perforators. There is a network from two major sources of arterial blood to the skin: direct cutaneous perforators and indirect perforators. The direct cutaneous perforators parallel the connective tissue framework and then reach the subdermal region, whereas the indirect perforators supply blood mainly to the fat and other deep structures and then onto the skin, therefore, indirectly.⁶⁵

The major blood supply to the anterior abdominal wall skin is through the vascular perforators in the periumbilical region. The blood is transported by the subdermal plexus or the prefascial plexus of the abdominal wall.

What are the determinants of arterial blood supply to the TRAM flap?

The angiosomes of the body, a network of vascular territories, have been described by Taylor and Palmer.⁶⁶ The cutaneous blood supply to each of these vascular territories is through a single source vessel. The TRAM flap may be placed in several different positions on the abdominal wall. Each type of position is supplied by a primary angiosome. The upper

abdominal pedicled TRAM flap lies over the angiosome of the deep superior epigastric artery (Fig. 25-14A). The lateral portion of the flap is a secondary angiosome supplied by the lateral intercostal arteries. The contralateral side of the flap is supplied by second and third angiosomes: the contralateral deep superior epigastric artery and the contralateral intercostal arteries.⁶⁶

The mid-abdominal pedicled TRAM flap (Fig. 25-14B) has a skin paddle that overlies the vascular pedicle of the deep inferior epigastric artery. For the deep superior epigastric artery to supply this flap, blood must flow through the intramuscular choke vessels into the deep inferior epigastric artery and then through the periumbilical perforators into the skin. The skin paddle is therefore in the second angiosome of the flap. The tip of the ipsilateral side of the flap is in the third angiosome supplied by the lateral cutaneous intercostal arteries. The contralateral side contains the third and fourth angiosomes.

The lower abdominal pedicled TRAM flap (Fig. 25-14C) depends on the deep superior epigastric artery filling from the deep inferior epigastric artery and then through the perforators to the overlying paraumbilical skin. A single vascular pedicle can perfuse an adjacent vascular territory, but attempts to perfuse a third or higher vascular territory put the flap at risk for significant necrosis.⁶⁴ The pedicled TRAM flap procedure is a series of tradeoffs. The higher the flap is placed on the abdominal wall, the more reliable the flap is when based on the deep superior epigastric artery perforators, but the more visible is the abdominal scar. The lower the flap is placed on the abdominal wall, the better the aesthetic appearance of the abdominal scar, but the less reliable the blood supply to the flap.

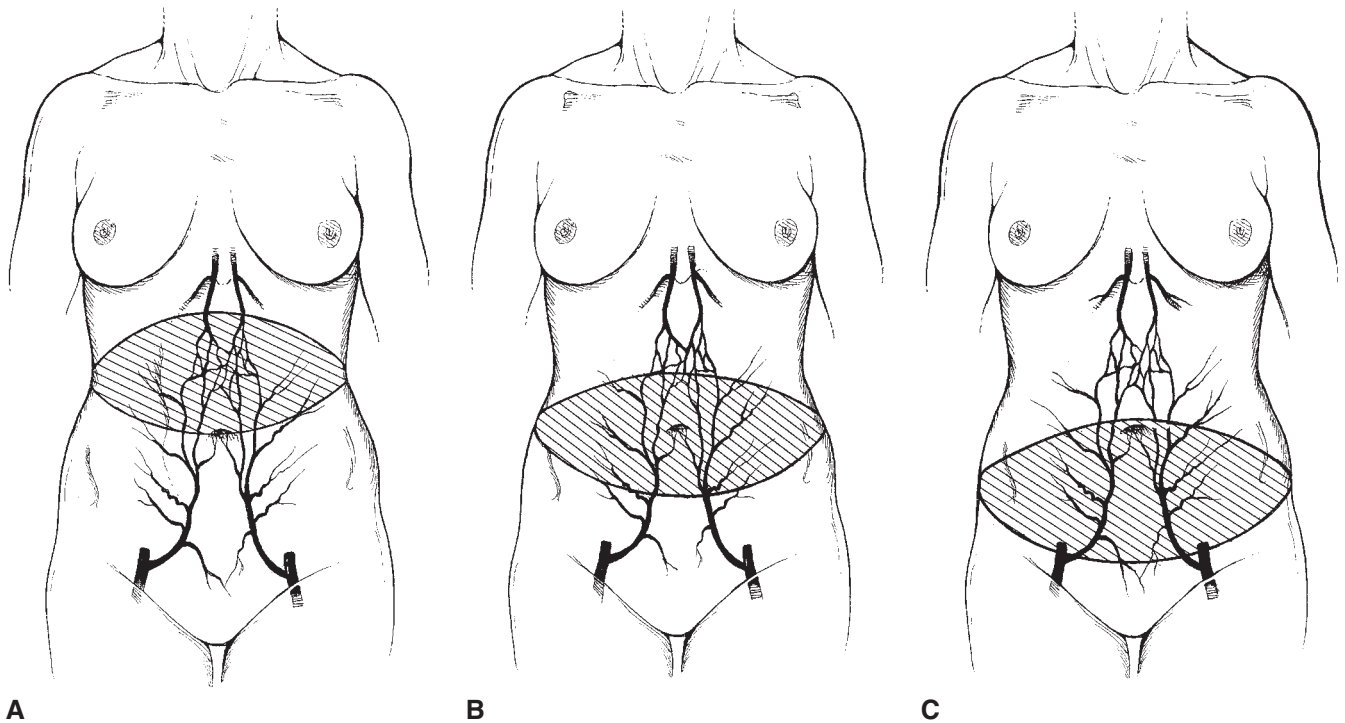

Figure 25-14 A, Position of the upper abdominal TRAM flap. B, Position of the mid-abdominal TRAM flap. C, Position of the lower abdominal TRAM flap.

Microvascular deep inferior epigastric TRAM flaps sacrifice minimal muscle, and deep inferior epigastric artery perforator flaps sacrifice no muscle and have lower abdominal scars, but the surgeon must have the technical ability to perform microsurgery. In addition, the surgeon must be willing to withstand the intermittent, although infrequent, total loss of a flap.

What are the risk factors for successful TRAM flap reconstruction?

Several risk factors increase the failure rate of the pedicled TRAM flap. Obesity, particularly when the patient is greater than 25% over the ideal body weight, is associated with increased TRAM flap complications.⁶⁷ Patients who smoke are at increased risk for small vessel disease and, therefore, increased risk for tissue necrosis.⁶⁷ The risk increases with the amount and length of smoking. Diabetes mellitus may also be associated with an increased risk for flap necrosis.

Abdominal scars that disrupt the periumbilical perforators are an absolute contraindication to any TRAM flap⁶⁷ because there is no way that the flap can survive without perforators.

Liposuction is the most common cosmetic surgical procedure performed for women. The number of women who have had liposuction and will have breast cancer is increasing. Shaw and colleagues have shown that the microvascular free TRAM flap can be performed safely in women who have had abdominal liposuction.⁶⁸

Obviously, major systemic illnesses, such as severe cardiac disease, chronic pulmonary disease, and hypertension, are relative contraindications to TRAM flap reconstruction based on the severity of these processes. All patients must be assessed and carefully evaluated before consideration for surgery.

Although blood transfusion with the pedicled TRAM flap is usually not necessary, patients should be cross-matched and prepared for transfusion. Whenever possible, autologous blood should be available. This may not be possible in immediate reconstructions because the patient frequently desires to have surgery very quickly. Donor-related blood should be considered in situations in which autologous blood is not available.

The TRAM flap is an operation that can be performed only once. Therefore, patients who are at high risk for bilateral breast cancer should be advised that unilateral reconstruction with a TRAM flap will preclude performance of the operation on the other side, at a later date, if needed.

What are the preoperative considerations in planning a TRAM flap reconstruction?

The extent of the mastectomy wound varies from patient to patient depending on the extent of soft tissue resection that is performed by the oncologic surgeon. To achieve a symmetrical soft tissue volume, the skin that is missing must be replaced in its entirety along with the missing soft tissue volume. When possible, skin-sparing mastectomy improves the aesthetic result of the reconstruction. Singletary⁶⁹ has shown that the regional recurrence after skin-sparing mastectomy is a function of the biology of the tumor and the stage of the disease and is not affected by the use of immediate reconstruction or skin-sparing mastectomy.

In cases of immediate reconstruction, the skin that is being excised from the breast can be measured, and the skin paddle can be copied exactly on the TRAM flap. The weight of the soft tissue that is required for reconstruction can be estimated by weighing the mastectomy specimen. The dimensions of the

mastectomy specimen can also be measured. All data that are available should be used to try to match the defect that is created. The skin replacement must be as close to exact as possible. If an inappropriate amount of skin is present in the mediolateral dimension, the breast will appear too wide or too narrow. If the amount of skin in the superoinferior dimension is wrong, the breast will have either too much or too little ptosis. It is always helpful if the oncologic surgeon saves as much skin as possible in the medial portion of the breast. This will allow preservation of the cleavage fold.

After the defect and the chest wall are assessed, the abdomen must be evaluated. The location of scars, the amount of fat, and the abdominal wall strength need to be noted. Pedicled TRAM flap is not possible if the patient has had bilateral subcostal incisions. A unilateral subcostal scar will prevent the use of a pedicle from that side. The presence of a unilateral subcostal scar does not preclude the use of the muscle on the other side. Patients who have undergone abdominoplasty surgery are not candidates for TRAM flaps.

The amount of fat available in the abdomen must be evaluated. The patient should be asked to tighten the abdominal wall to assess how much of the abdominal fat is extrafascial. The amount of fat present on one side of the abdomen must be estimated. Is this fat enough to reconstruct the breast with a single pedicle? If there is not enough fat available on one side of the abdomen, consideration must be made for a double-bipedicled TRAM flap reconstruction or a microvascular free flap. The strength of the abdominal wall must be assessed. If the abdominal wall is weak and lax, particularly below the arcuate line, then the TRAM flap should be placed higher on the abdomen. In addition, the weaker the abdomen, the more likely that the patient will require closure of the wound with prosthetic material. All patients should be told about the possibility that prosthetic material may be used for abdominal wall closure. Many patients who are undergoing TRAM flap reconstruction expect a totally autologous reconstruction. These patients should be aware that prosthetic material is frequently used to close the abdomen.

Are all abdominal scars a contraindication to TRAM flap reconstruction?

If bilateral subcostal scars are present, a microvascular free TRAM flap should be considered. Midline scars are not a contraindication to the TRAM flap. The presence of a midline scar will make the tissue contralateral to the pedicle unusable for the reconstruction. If more tissue than is available on one side of the abdomen is needed for breast reconstruction, then either a double-pedicled or free TRAM flap should be considered.

Appendectomy scars are usually not a contraindication to TRAM flap breast reconstruction. The position and length of appendectomy scars vary among patients. For right breast reconstruction, using a TRAM flap with a left rectus abdominis pedicle, there is usually sufficient tissue for the reconstruction, with all tissue lateral to the appendectomy scar discarded. For left breast reconstruction, there occasionally are problems with the right rectus abdominis pedicle after appendectomy. One might consider using a left rectus abdominis pedicle. If a right rectus abdominis pedicle is used, the appendectomy scar must be very lateral. All tissue lateral to

the appendectomy scar must be considered to be unreliable. A double-bipedicled or microvascular TRAM flap may be indicated in this situation.

What are the considerations in selecting the location of the TRAM flap on the abdomen?

The lower abdominal fat is the ideal tissue to be used in TRAM flap reconstruction. This is the area where most women have a fatty deposit. Also, the lower TRAM flap provides the ideal scar and the ideal abdominal aesthetic result. In cases in which unilateral tissue is adequate to reconstruct the breast, the lower abdominal TRAM flap is usually satisfactory.

Unfortunately, the lower abdominal TRAM flap is the most poorly vascularized in a single superior pedicled TRAM formation. When the patient is obese, smokes, or has complicated medical problems, one should consider placing the pedicled TRAM flap in either the mid-abdominal position or the upper abdominal position. Raising the TRAM flap on the abdomen increases the vascularity of the pedicled flap. However, as one raises the TRAM flap on the abdomen, the most useful infraumbilical fat is more likely to be excluded from the flap.

Another consideration is that as the TRAM flap is raised on the abdomen, the rotation of the pedicle and therefore the flap onto the chest becomes more difficult. In the mid-abdominal or upper abdominal position, ipsilateral flaps rotate onto the chest more easily than contralateral flaps because there is a shorter distance to travel. Therefore, when the TRAM flap is placed higher on the abdomen, an ipsilateral pedicle should be considered.

What determines the number and choice of TRAM flap pedicles?

The single-pedicled TRAM flap offers less destruction and subsequent weakness to the abdominal wall than the double-pedicled TRAM flap.⁶² The single-pedicled TRAM flap is limited by the amount of tissue that can be carried for breast reconstruction. This tissue becomes more limited when the patient has additional risk factors, such as smoking, obesity, or other medical problems, that may decrease the vascularity of the flap, resulting in partial flap loss.⁶⁷ In these patients, or when the volume of tissue required to fill the mastectomy defect is greater than can be carried with a single-pedicled TRAM flap, a double-pedicled or microvascular free TRAM flap is indicated. Patients who have had chest wall radiation should have the best-vascularized tissue used for breast reconstruction: double-pedicled TRAM flap or microvascular free flap. The double-pedicled TRAM flap causes much more weakness to the abdominal wall,^{62,70} and prosthetic closure is needed in most cases.

What determines the choice of an ipsilateral versus contralateral pedicle for TRAM flap reconstruction?

The contralateral TRAM flap pedicle offers the advantage of an easier flap rotation than the ipsilateral pedicle. In the

ipsilateral TRAM, the pedicle tends to sit on top of itself and rotate on itself. The muscle will often defold under the flap, which can cause kinking and decreased blood supply. The contralateral single-pediced TRAM flap is rotated 90 degrees (Fig. 25–15A). This is clockwise for right breast reconstruction and counterclockwise for left breast reconstruction. In most cases, this is the superior method for reconstructing the breast. Rotating the contralateral pedicle 180 degrees (Fig.

25–15B) is safe and should be considered when the defect is wide and extends onto the chest or axilla. The ipsilateral pedicle (Fig. 25–15C) is indicated when the pediced TRAM flap is carried high on the abdomen and the contralateral pedicle may not reach the mastectomy wound. The most favorable rotation for a double-pediced TRAM flap is 90 degrees (Fig. 25–15D). This is counterclockwise for a left defect and clockwise for a right defect.

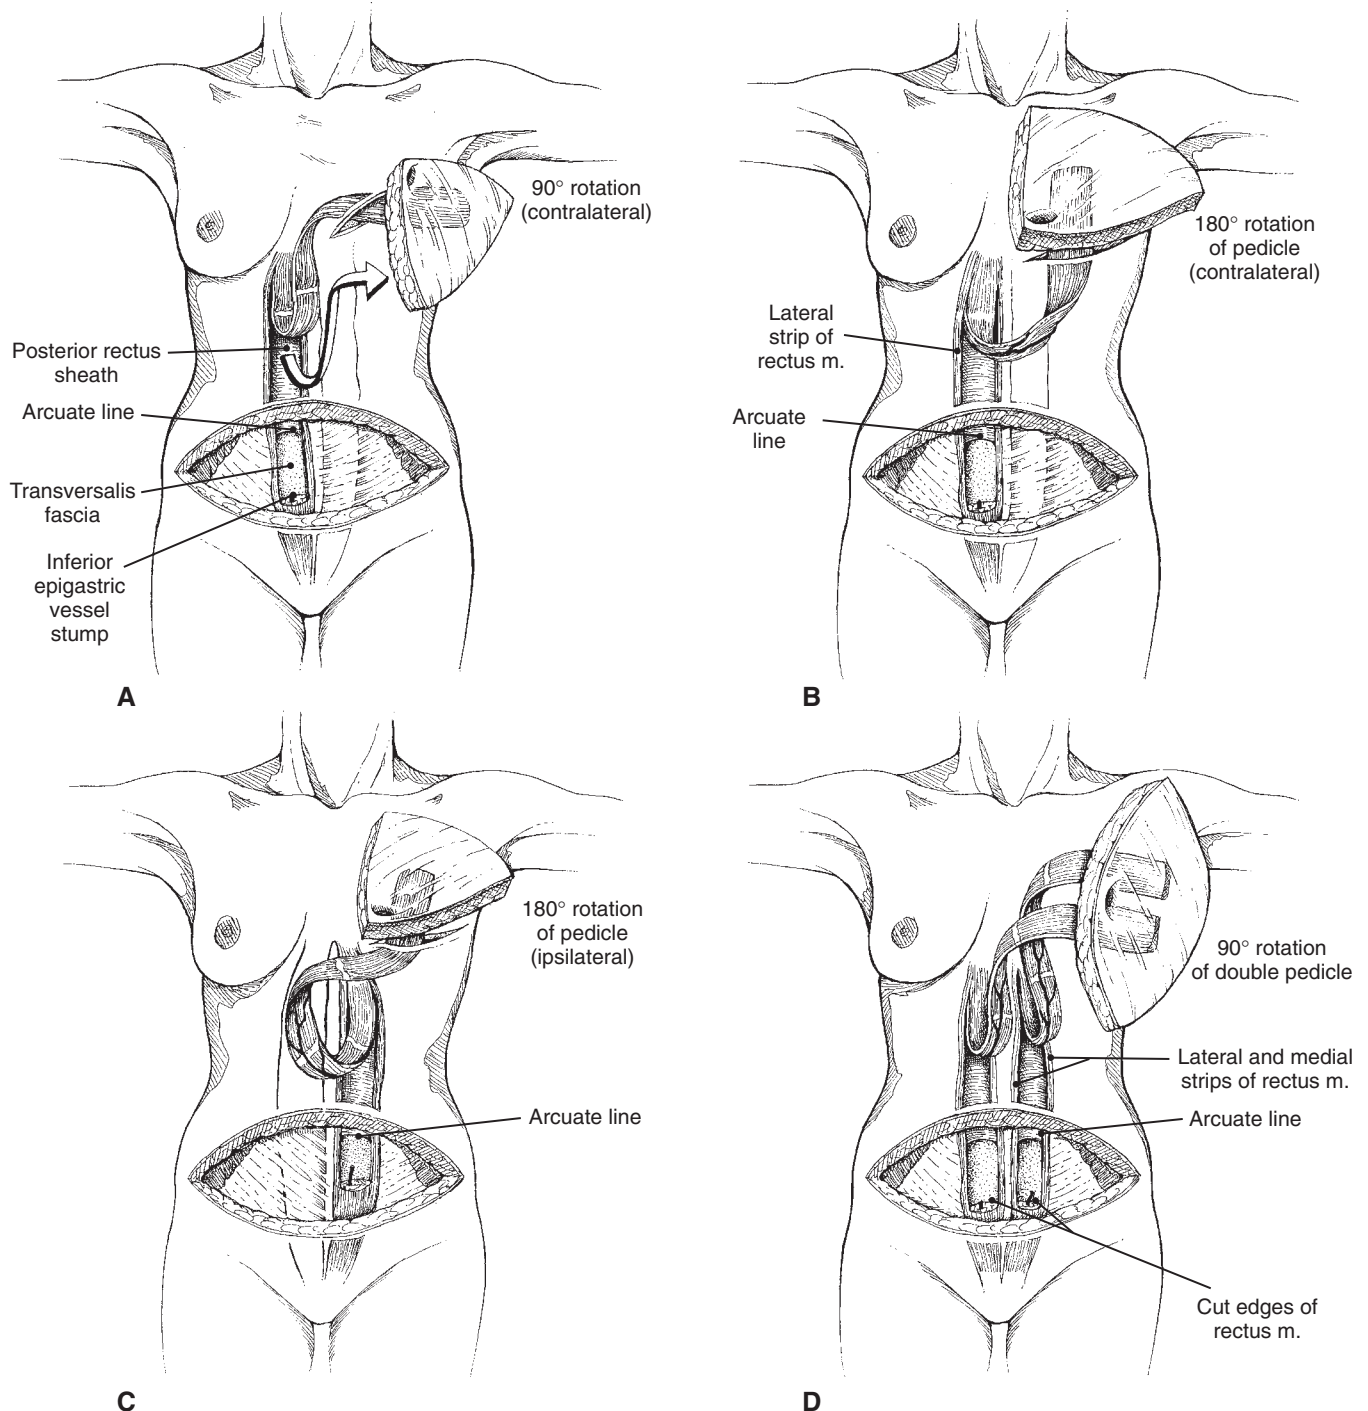

Figure 25–15 A, Contralateral single-pediced TRAM flap with 90-degree rotation. B, Contralateral single-pediced TRAM flap with 180-degree rotation. C, Ipsilateral single-pediced TRAM flap with 180-degree rotation. D, Double-pediced TRAM flap with 90-degree rotation.

What are the preoperative considerations in planning a TRAM flap reconstruction?

The patient should be marked in a standing position. The markings are carried out in a manner that has been developed by Hartrampf⁶⁴ (Fig. 25–16A and B). The highest point of the mastectomy defect is located and marked. The parasternal point is marked, and the highest point in the anterior axillary fold is marked. The inframammary fold is marked. The medial and lateral extents of the reconstruction are marked by comparing with the unaffected side. In the cases of immediate reconstruction, the mastectomy skin ellipse that is taken should be measured and essentially copied on the abdominal TRAM flap site. In a delayed reconstruction, where the skin dimensions are not available, the amount of skin needed in the flap is estimated. This can be done with a soft ruler, as demonstrated in Figure 25–16. The measurements over the normal breast are compared with the mastectomy defect, and the difference is the width of the skin paddle that is going to be required on the chest. The abdomen is marked using the superior portion of the umbilicus as the superior mark. The inferior margin is drawn from the suprapubic crease laterally along a natural fold. The superior and inferior marks converge in the area of the anterior superior iliac spine. The junction of the two incisions can be raised or lowered based on the patient's preference and desire to keep the scar as high as possible so that it is not visible in high-riding beach or exercise clothes. Additional fat is marked above the upper skin incision to be incorporated into the flap. The more skin that is required for reconstruction, the more likely that the flap will extend onto the side of the abdomen contralateral to the pedicle. If more skin ptosis is desired, the flap is extended laterally

to provide additional skin. In an immediate reconstruction, the flap dimensions can be marked quite accurately. In a delayed reconstruction, a certain amount of estimation is necessary.

How is the patient positioned?

The patient is placed on the operating table in the supine position. The operating table is checked to be sure that the patient can be moved into a sitting position. This is essential during the operation. The same positioning technique is used for an immediate or delayed reconstruction. Both arms are placed on arm boards. It is critical that all bony prominences be carefully padded. The entire chest and abdomen from clavicles to pubis are prepared and draped.

What are the intraoperative considerations?

In an immediate reconstruction, the mastectomy is performed first. In certain situations, it is possible to perform the mastectomy and the TRAM flap harvest at the same time. The TRAM flap harvest is begun by first making the superior incision through the skin and dermis. The incision is beveled upward to include as much fat and perforators as possible. The fascia is located, and the upper abdominal flap is developed to above the costal margin. A tunnel is made between the abdomen and the chest wounds. The tunnel, in the case of a contralateral pedicle, should go over the contralateral costal margin, across the sternum, and into the chest wound. Little, if any, of the inframammary fold should be interrupted. A

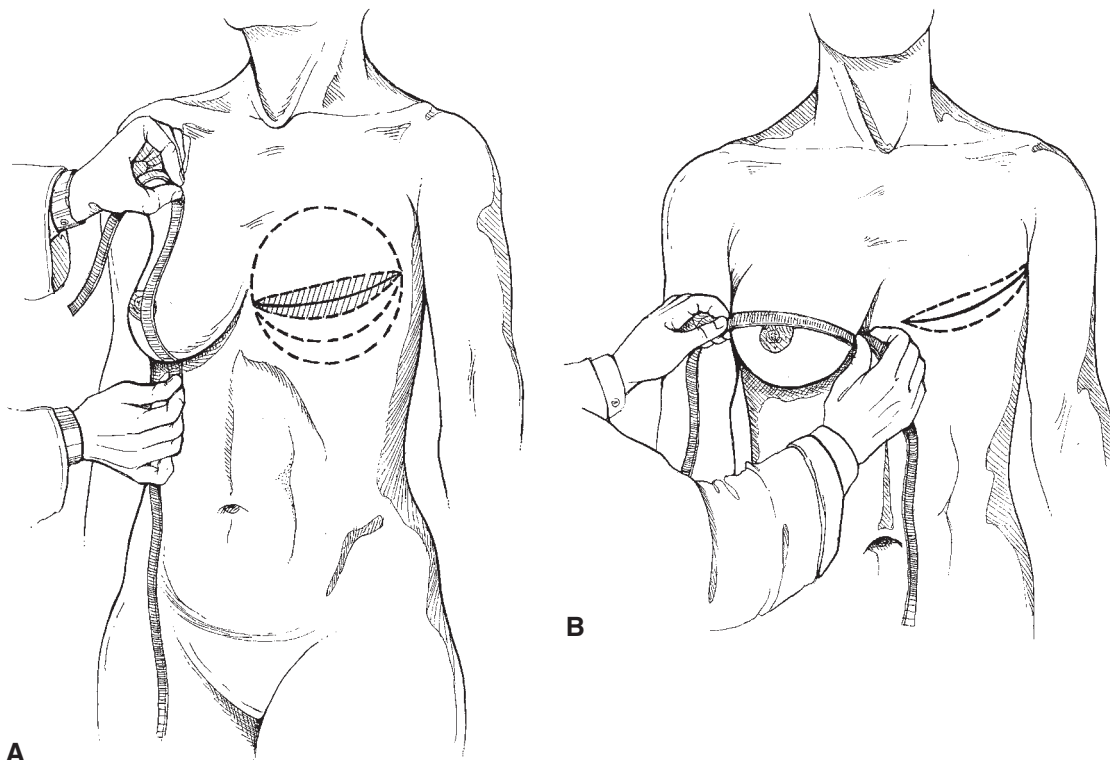

Figure 25–16 A and B, Measuring the dimensions of the normal breast to determine the amount of tissue needed in the TRAM flap.

natural inframammary fold is always superior to one that must be created using sutures. The tunnel must be wide enough to admit a normal-sized hand. The tunnel dissection and hemostasis should be completed (Fig. 25–17A). The inferior flap incision is then made. The umbilical incision is made and kept small, with a diameter that rarely exceeds 1.5 cm. The umbilical incision is deepened down to the fascia. The flap contralateral to the pedicle is elevated across the midline to the medial row of perforators. Notation should be made of the number and location of perforators. On the pedicle side, the pedicle dissection begins by incision of the fascia superior to the flap on the rectus abdominis muscle. Usually, a small strip of fascia is left on the muscle, and the remaining fascia is carefully stripped from the muscle superior to the skin paddle. The entire muscle is encircled above the skin paddle. The lateral portion of the skin paddle on the side of the pedicle is dissected to the lateral line of perforators.

Lateral or medial portions of muscle may be left in place in the abdominal wall or may be taken with the flap. The amount of muscle that is spared depends on the location of the perforators. If there is significant muscle present lateral or medial to the respective rows of perforators, the muscle may be separated from the flap pedicle and preserved. Ideally, the location of the superior pedicle should be identified and followed within the muscle with Doppler before muscle splitting. The muscle is split with scissors. This is done laterally in most cases and is done medially only when there is significant muscle medial to the medial row of perforators. The medial muscle often is not preserved because it is thought to be denervated and poorly vascularized after TRAM flap harvest. The lateral muscle, however, probably retains some intercostal innervation and vascularity⁷¹ (Fig. 25–17B and C).

If there is a question of poor flap vascularity or if additional blood supply through “supercharging” the flap is planned, the inferior epigastric pedicle is dissected down to the iliac vessels (Fig. 25–18). The rectus muscle flap is transected distally, and the flap is connected only by the superior pedicle and muscle. Hemostasis is carefully obtained. Any clearly nonviable areas of the skin paddle are removed from the flap before transfer to the chest. The flap is then transferred to the chest (see Fig. 25–17C).

How is the abdominal defect closed?

The abdominal closure in a single-pedicle TRAM flap usually does not require prosthetic material. The abdomen is closed with either interrupted or running nonabsorbable sutures. If the closure is tight, an external oblique myofascial release can be performed laterally, on the side of the pedicle, to decrease the tension. The closure can be reinforced with a second layer of running sutures. In cases of abdominal laxity, the side of the abdomen opposite the pedicle should be pliated to move the position of the umbilicus toward the midline. This plication is also performed with nonabsorbable monofilament-type sutures. The abdominal closure is completed, and the umbilical position is set.

How is the TRAM flap inset performed?

The TRAM flap inset is usually fairly easy if the preoperative planning was done properly. If there is any question about the

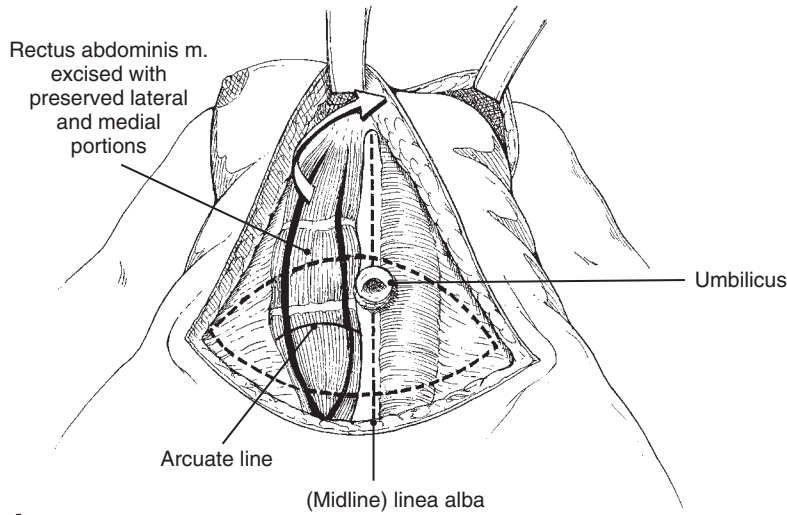

adequacy or location of tissue, the flap may be temporarily inset and the skin paddle re-marked with the patient in a sitting position. The inset is usually done with the patient in a sitting or semisitting position. Usually, the superior edge of the skin paddle is incised in the marked areas. Superior sutures are placed between the flap and chest wall after tapering the superior portion of the TRAM flap. The tapering extends to the subdermal level along the superior portion of the flap. The tapering is essential so that the breast does not appear bulky in the upper area. The patient is evaluated for symmetry. If further ptosis is needed, more of the skin paddle is exposed from the inferior portion of the flap. Only one incision on the breast flap skin ellipse is made at a time. The flap is re-inset and again checked for symmetry. After the upper portion of the breast flap has been sutured into position, the skin of the upper portion is closed. The lower portion of the breast is again temporarily stapled into place and checked for symmetry. This is the final time to decide how much skin is going to be used in the skin paddle and therefore how much ptosis is to be created. The final line of the incision is marked, and the inferior skin flap is de-epithelialized. The inferior portion of the flap does not need to be sutured to the chest. The flap essentially hangs from the superior sutures. The inferior portion of the flap sometimes is rolled onto itself to give added breast projection. If there is too much tissue, the flap is thinned. The thinning is usually performed on the undersurface of the flap. After the best shape has been produced, the skin incisions are closed. A Hemovac drain is placed in the axilla and under the flap (Fig. 25–19).

BILATERAL BREAST RECONSTRUCTION WITH THE PEDICLED TRAM FLAP

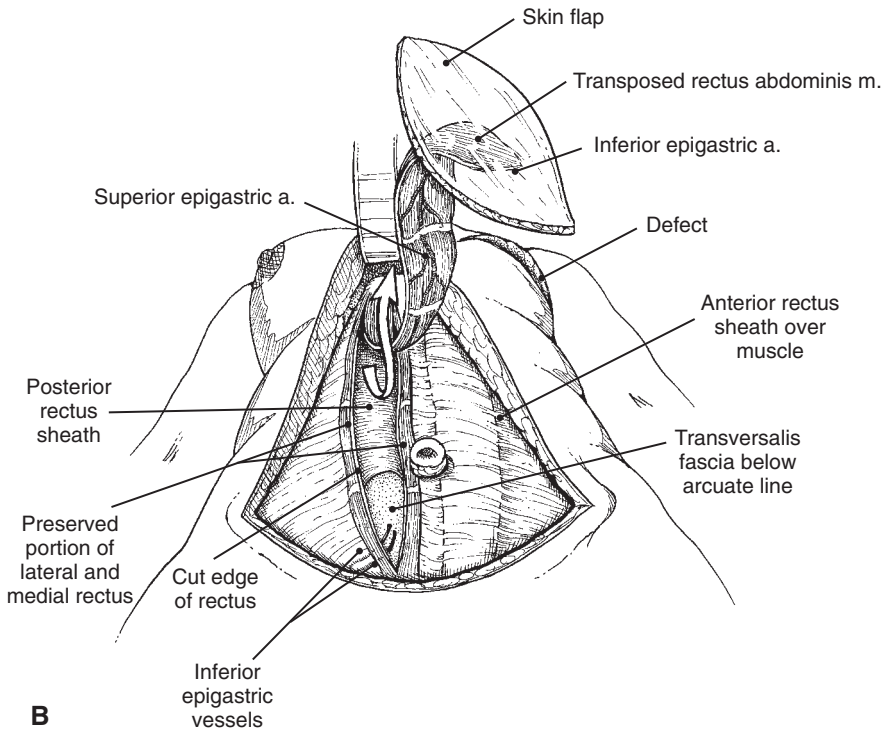

The TRAM flap is an excellent choice for bilateral breast reconstruction. Frequently, in unilateral reconstruction, a significant amount of flap tissue is discarded because it is either not well vascularized or not needed in the reconstruction. The bilateral TRAM flap reconstruction offers tissue that is often sufficient in size to make two breasts. If the patient lacks a large abdominal panniculus, the breast size may be smaller than before mastectomy. The bilateral TRAM flap uses both rectus abdominis muscles and produces significantly more abdominal weakness than a unilateral TRAM flap.⁶²

What are the preoperative considerations in immediate bilateral TRAM reconstruction?

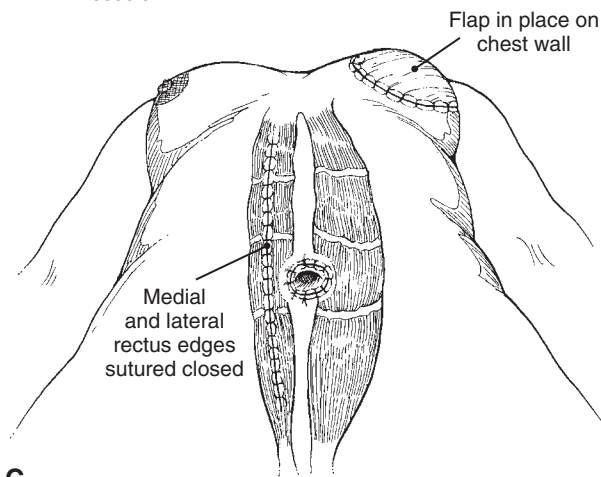

As in unilateral breast reconstruction, the reconstructive surgeon must plan the surgical incisions with the oncologic surgeon at the beginning of the case. Symmetry of the incisions, when possible, will result in a better reconstruction. This is not always possible based on the locations of the primary lesions. It is better to include more skin in the mastectomy specimens and have symmetrical defects than to minimize the extent of the skin incisions and have asymmetrical defects. If possible, symmetrical skin-sparing incisions are desirable.

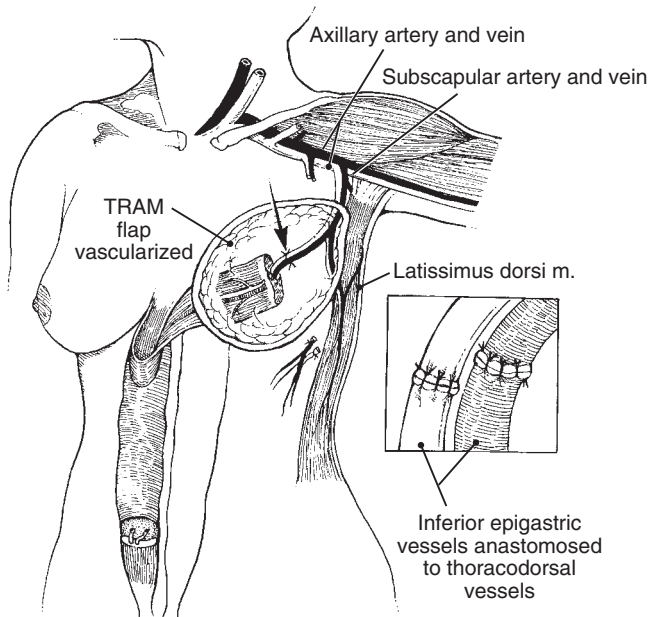

Figure 25–18 “Supercharging” the pedicled TRAM flap by microvascular anastomosis to the thoracodorsal vessels.

Figure 25–19 Unilateral TRAM flap breast reconstruction.

What are the preoperative considerations in delayed bilateral TRAM reconstruction?

When evaluating a patient for bilateral reconstruction after mastectomies, one must take note of the locations of the incisions. In addition, some patients have had a modified radical mastectomy on one side and a radical mastectomy on the other side. Even if the same mastectomy operation was performed on both sides, the volume requirements are sometimes different. All factors must be noted in the initial consultation before the onset of reconstruction. It is the goal of the reconstructive surgeon to make the breasts as symmetrical as possible. If more tissue is needed on one side for reconstruction, the TRAM flap can be asymmetrically split in such a way that this is accomplished.

What determines the choice of ipsilateral versus contralateral pedicled TRAM flaps for bilateral reconstruction?

When performing bilateral pedicled TRAM flaps, the flaps can be rotated either ipsilaterally or contralaterally. As in unilateral breast reconstruction, the contralateral pedicle technique (Fig. 25–20A) is the safest way to position the breast flaps because it results in a very direct route for vascular inflow and outflow to the flap. With 90-degree flap rotation and a contralateral pedicle, the thickest portion of the breast flap tends to be in the superior pole of the pocket. This may be a difficult problem to deal with at the time of inset. Using a contralateral pedicle with a 180-degree rotation can solve this problem (Fig. 25–20B). In addition, the use of contralateral pedicles results in minimal disruption of the inframammary folds. Ipsilateral pedicles at 90-degree rotation are possible in bilateral breast reconstruction. The same problems that exist with unilateral reconstruction are present with bilateral reconstruction, that is, the pedicle tends to fold under the flap.

How is the abdominal defect closed after bilateral TRAM elevation?

The abdominal wall closure is much more difficult in bilateral breast reconstruction than in unilateral single-pedicled reconstruction.⁷² The closure of both sides of the abdomen should be performed simultaneously. If one side is closed before the other side, it may be difficult to close the second side. Either running or interrupted sutures may be used. In almost all cases, mesh will be needed either to reinforce the closure or to complete it. Lateral external oblique myofascial release may be performed to decrease the tension on the fascial closure.

How is the breast shaped after bilateral TRAM reconstruction?

The breast is shaped similarly to unilateral reconstruction. The superior portion of the flap is inset first. The tissue is again sutured superiorly and allowed essentially to hang. If contralateral pedicles are used, there is usually minimal disruption in the inframammary fold. If the inframammary fold needs to be created, this can be done using monofilament sutures. Obviously, symmetry should be as close as possible (Fig. 25–21).

MICROVASCULAR FREE FLAP BREAST RECONSTRUCTION

Microvascular Free TRAM Flap

The microvascular free TRAM flap offers improved flap blood supply and less abdominal wall trauma than the single-pedicled TRAM flap.^{62,73,74} Abdominal wall function improves faster after a free TRAM flap than after a single-pedicled TRAM flap, but 6 months after surgery, the difference becomes insignificant.⁷⁵ The free TRAM flap is ideally suited for immediate breast reconstruction when the subscapular

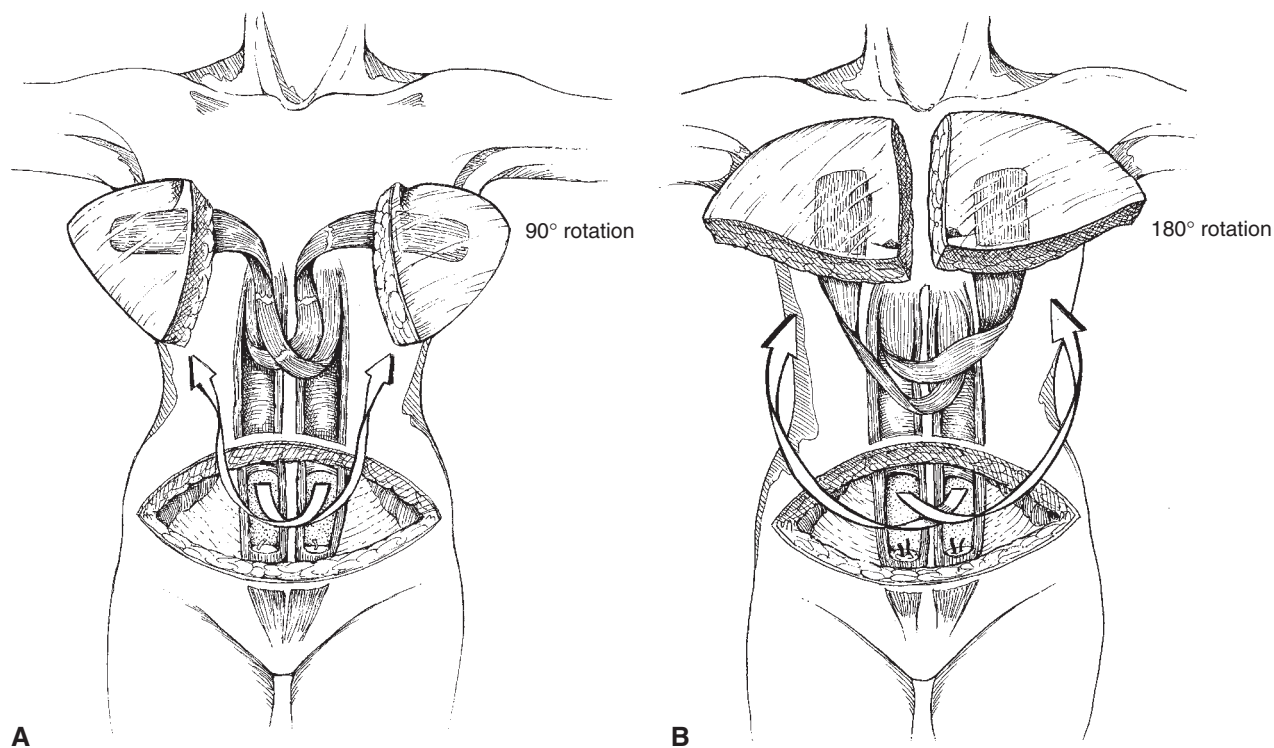

Figure 25-20 A, Bilateral TRAM flap reconstruction with contralateral flaps and 90-degree rotation. B, Bilateral TRAM flap reconstruction with contralateral flaps and 180-degree rotation.

Figure 25-21 Bilateral TRAM flap breast reconstruction.

trunk is exposed during the mastectomy and is easily available for microvascular anastomosis.

The disadvantages of the free TRAM flap are the requirement that the surgeon be proficient in microsurgery and the rare risk for total flap loss.⁷⁶⁻⁷⁸ Pedicled TRAM is almost never

complicated by total flap loss but is more frequently complicated by fat necrosis and partial flap loss.^{67,78} The cost of performing free TRAM flaps is not significantly higher than that of pedicled flaps in experienced hands.⁷⁹

What are the contraindications to free TRAM flap reconstruction?

Although any kind of TRAM flap is relatively contraindicated in patients who smoke, are obese, or have severe medical problems, the relative contraindication is less for the free TRAM flap, which is better vascularized and less prone to tissue loss. Smokers are asked to stop smoking for at least 2 weeks before surgery and for 4 to 6 weeks afterward. In patients who require a large amount of tissue for breast reconstruction or who have had chest wall irradiation, the free TRAM flap and the bipedicled TRAM flap are the best options for reconstruction.

What are the preoperative considerations with free TRAM flap reconstruction?

Most free TRAM flaps are performed for immediate reconstruction. The incisions for the mastectomy are planned with the oncologic surgeon. Although oncologic considerations always take precedence over aesthetic ideals, an effort should be made to spare as much skin as possible. The flap can be elevated either simultaneously with the mastectomy or afterward, depending on the level of comfort the oncologic surgeon and the reconstructive surgeon have with simultaneous

operating room logistics. The operating room logistics and patient positioning are similar to that for a pedicled TRAM flap.

What are the considerations when sentinel lymph node evaluation is performed at the same time as the mastectomy and reconstruction?

As more breast oncologic surgeons become comfortable with sentinel lymph node biopsy, the use of this technique will increase. If the sentinel lymph node evaluation is positive for metastatic disease, the recommendation is to perform a completion axillary lymph node dissection. If the diagnosis is established intraoperatively by frozen section or touch prep, and then the axillary dissection is completed, reconstruction may proceed using the thoracodorsal vessels as possible microvascular recipient vessels. If the diagnosis of axillary metastatic disease is established postoperatively, the subsequent axillary lymph node dissection could endanger the blood supply to the free flap if the thoracodorsal vessels were used as recipient vessels.

Kronowitz and coworkers⁸⁰ showed that 35% of patients with clinically negative axillae at initial presentation have axillary lymph node involvement at the time of mastectomy and free flap breast reconstruction. In their study, patient age younger than 50 years, tumor size greater than 2 cm, and lymphovascular invasion on the initial biopsy were independent predictors of axillary metastasis in the clinically node-negative patients.⁷⁴

If sentinel lymph node evaluation is to be performed, particularly in higher risk patients, a nonaxillary site should be considered for recipient vessels for microvascular breast reconstruction. If a sentinel lymph node is found to have metastatic disease and a free flap reconstruction was performed using axillary based vessels, a reoperation will have to be performed with both the oncologic and reconstructive surgeon present. The risks and timing of this operation have to be discussed carefully with the patient.

What is the initial assessment intraoperatively?

In the case of delayed breast reconstruction, the chest incision should initially be reentered and the recipient vessels assessed for the possibility of microvascular anastomosis. Either the internal mammary or thoracodorsal vessels are usually used. If the thoracodorsal vessels are very scarred or were previously injured, then either the internal mammary vessels should be evaluated as recipient vessels or a pedicled TRAM flap should be performed.⁸¹ At the level of the third interspace, the internal mammary vessels have been shown to be reliable.^{82,83}

In immediate reconstruction, the thoracodorsal vessels are used more commonly. The more proximal vessels are larger and offer easier microvascular anastomosis. Usually, an area proximal to the serratus branch is comparable in size to the deep inferior epigastric vessels. The communication between the serratus branch and the thoracodorsal vessels should be left intact to allow potential latissimus dorsi elevation, based on retrograde blood flow, if such a need should arise.

How is the free TRAM flap prepared?

The upper incision of the free TRAM flap is usually at or just above the umbilicus, and the inferior incision is about 2 cm above the pubis. The upper incision is made first, and the abdominal flap is elevated proximally as far as is necessary to allow abdominal wall closure. The incision is beveled to include as much fat and periumbilical perforators as possible. The skin flap is redraped and the site of the inferior incision confirmed. The inferior incision is then opened and beveled inferiorly to include as much fat as possible. The contralateral deep inferior epigastric pedicle is usually used because this appears to provide the best flap lie. Others⁸⁴ use the ipsilateral pedicle. The skin flap on the side opposite the inferior epigastric flap pedicle is elevated past the midline to the medial row of perforators on the pedicled side. The pedicled side flap is elevated to the lateral row of perforators. Inferiorly, the flap is elevated to the most inferior perforator. The anterior rectus sheath is incised lateral to the lateral row of perforators. The inferior epigastric pedicle is identified and dissected proximally and distally. The pedicle is dissected to near its origin. The intercostal neurovascular bundles are left intact to preserve innervation to the portion of rectus abdominis muscle that is not taken with the flap. The point of entry of the inferior epigastric pedicle into the rectus abdominis muscle is identified, and the muscle lateral to this point is separated longitudinally using scissors. A similar procedure is performed medially to preserve a medial strip of muscle. The amount of medial muscle left intact is less important because the muscle is not innervated.⁷¹ The inferior and superior portions of the muscle are then transected, and the flap is connected only by the pedicle (Fig. 25–22). The deep inferior epigastric pedicle is transected, and the flap is brought to the chest wall. Although minimal rectus abdominis muscle is taken with the flap, the function of the entire rectus muscle is affected by the surgery.⁸⁵

How are the microvascular anastomoses performed?

The rectus abdominis muscle is sutured to the chest wall, and the vessels are aligned. The patient is tilted away from the side of the breast reconstruction. Self-retaining retractors are placed in the wound, and the operating microscope is brought into the field. The vein or veins are usually anastomosed with a microvascular coupler, and the artery is sutured with 9-0 microvascular sutures. The TRAM flap is reperfused, and attention is placed to the abdominal wall closure (Fig. 25–23).

How is the abdominal defect closed?

The anterior rectus sheath is closed with running or interrupted permanent sutures, and the opposite rectus fascia is plicated to centralize the umbilicus. Any supraumbilical laxity may be plicated at this time if indicated. The superior abdominal flap is closed over suction drains, and the patient is flexed as needed. Prosthetic material is almost never used.

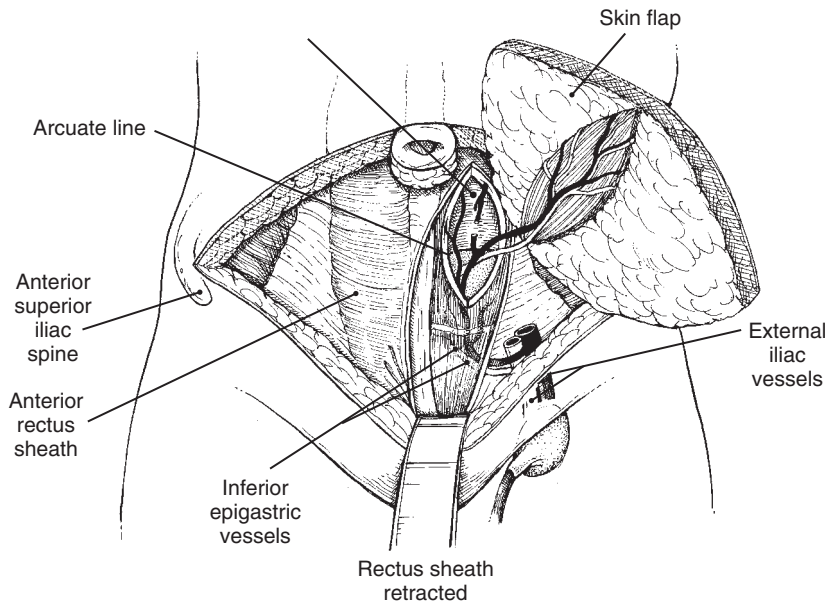

Figure 25–22 Mobilization of the free TRAM flap.

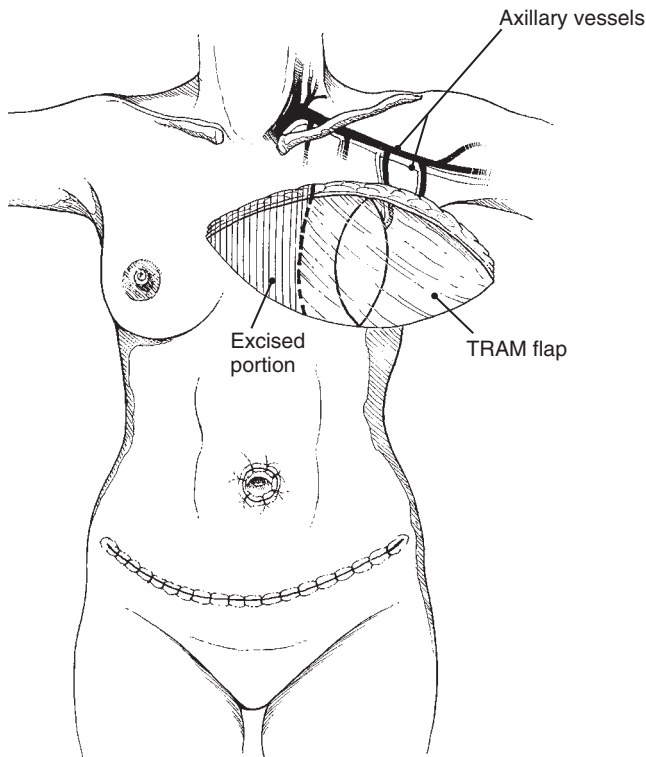

Figure 25–23 Inset of the free TRAM flap.

How is the TRAM flap inset performed?

The flap is inset with the patient in the sitting position. The rectus muscle is sutured to the chest wall in the appropriate position. The pedicle is evaluated for kinking, and the muscle position is adjusted as needed. The rectus muscle should be stable on the chest to minimize motion in the pedicle and lateral migration of the flap. A suction drain is placed in the axilla and under the flap. The flap is temporarily sutured or stapled in place and inset in a manner similar to a pedicled TRAM flap (see Fig. 25–23).

Figure 25–24 Muscle-sparing free TRAM reconstruction.

How is the patient managed postoperatively?

Postoperatively, the flap is minimally dressed and is monitored with visual inspection, temperature monitoring, or Doppler evaluation. The patient is allowed out of bed on the first postoperative day. Arm motion is limited, and abduction is discouraged. One aspirin is given daily for 30 days. No other anticoagulation is used. The patient is allowed to begin arm exercises 2 to 3 weeks postoperatively. Abdominal exercise is limited for 2 months (Fig. 25–24).

What are the complications of microvascular versus pedicled TRAM flaps?

The most devastating complication of microvascular free TRAM flap surgery is total flap loss from microvascular thrombosis in the early postoperative period. The incidence

varies from about 1% to 4% in experienced hands, whereas total flap loss occurs in less than 1% of pedicled TRAM cases. However, the incidence of fat necrosis and partial flap loss is substantially less in microvascular free TRAM cases than in pedicled TRAM cases. The incidence of abdominal wall complications (hernia and bulging) also is less in microvascular free TRAM cases than in pedicled TRAM cases. The cost of surgery and the length of hospitalization are not substantially different for microvascular free TRAM and pedicled TRAM cases.

Deep Inferior Epigastric Artery Perforator Flap

What are advantages of the deep inferior epigastric artery flap compared with a microvascular TRAM flap?

The deep inferior epigastric perforator (DIEP) flap is similar to a TRAM flap, but no muscle is harvested with the flap.^{86–88} The flap is based on the perforating vessels originating from the deep inferior epigastric vessels and traversing through the rectus abdominis muscle to supply the skin and fat of the abdomen. Because no muscle is taken with the flap, there is a decreased incidence of abdominal weakness, bulging, and hernias.^{80,82}

What are the anatomic considerations in perforator flap reconstruction?

The microvascular free TRAM generally incorporates three to six perforators in the flap design. The DIEP flap usually incorporates one to three perforators. The anatomy of the perforators has been extensively studied in humans with Doppler ultrasound, and all patients have been found to have at least two perforators.⁸⁹ The perforator course through the rectus abdominis muscle varies. In 65% of cases, the perforator has a short intramuscular course. In other cases, the perforator may go through a tendinous intersection, have a long intramuscular course, or have a subfascial course.⁹⁰

How is the flap harvest different in DIEP flaps compared with muscle-sparing free TRAM flaps?

The harvest of the DIEP flap is similar to that of the muscle-sparing free TRAM flap until the point that the medial and lateral rows of perforators are exposed. At that point, the largest perforator is chosen, and the anterior rectus sheet is opened around this neurovascular bundle. The muscle is split in the direction of the fibers to expose the DIEP. A second or third perforator is kept with the flap if it is aligned with the first perforator. Branches from the pedicle are divided, and the flap is now a skin and fat flap based on the deep inferior epigastric vessels. The microsurgery and flap inset are performed in a manner similar to a microvascular free TRAM flap (Fig. 25–25).

Figure 25–25 Mobilization of the deep inferior epigastric perforator (DIEP) flap.

What are the results of the DIEP flap?

The DIEP flap has a lower incidence of abdominal complications, such as hernia and bulging. Patients are able to achieve abdominal function near or at preoperative levels within 6 months.^{91,92} The incidence of total flap loss and technical problems with the microsurgical anastomosis is similar to that of free TRAM flap cases.

There is a greater incidence of fat necrosis in DIEP flaps than in microvascular TRAM flaps. This is thought to be due to the less robust blood supply of the DIEP flap when compared with the microvascular TRAM flap.⁹³

As with pedicled and microvascular free TRAM flaps, DIEP flaps have an increased incidence of fat necrosis, fibrosis, and flap contracture with postoperative radiation therapy.⁹⁴

Gluteal Free Flaps

The superior gluteal flap was first reported by Fujino⁹⁵ and then popularized by Shaw.^{96,97} This flap is typically considered a secondary or tertiary choice for free tissue reconstruction of the breast because of the increased operative time, complexity, and morbidity associated with the procedure. The patient considered for free gluteus microvascular transfer is usually not a candidate for TRAM flap (insufficient tissue or abdominal scars) but desires an autologous breast reconstruction.

What are the advantages and disadvantages of a superior gluteal flap?

The advantages of the superior gluteal free flap include abundant tissue for reconstruction, inconspicuous donor site, and minimal functional loss. Shaw and colleagues have

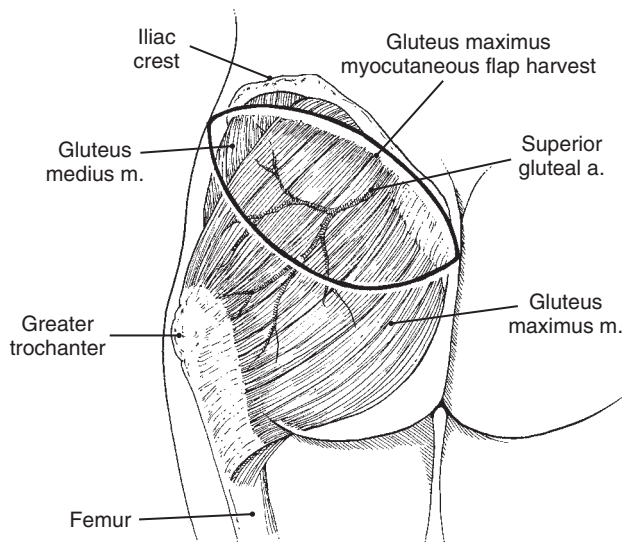

Figure 25-26 Anatomy of the superior gluteal flap.

demonstrated the spontaneous restoration of sensation in the flap without nerve reconstruction.⁹⁸

The disadvantages of the superior gluteal free flap include the risk for total flap loss and greater operative time common to all free flap procedures. In addition, the superior gluteal flap is technically much more difficult to harvest than the TRAM flap, and the recipient vessel dissection (usually internal mammary) is more difficult than dissection of the thoracodorsal vessels.

What are the anatomic considerations in a free superior gluteal flap reconstruction?

The gluteus maximus muscle originates from the posterior third of the iliac crest, sacrum, sacrotuberous ligament, and coccyx. The muscle inserts on the gluteal tuberosity of the femur. The superior gluteal artery, vein, and nerve course between the gluteus medius and piriformis muscles. The origin of these vessels is 5 cm inferior to the posterior superior iliac spine and 2 to 3 cm lateral to the sacrum. The vessel supplies a cutaneous territory that exceeds the size of the gluteus maximus muscle. The skin island (Fig. 25-26) can be made anywhere over the gluteal area as long as it includes a cuff of muscle that includes the pedicle. The upper half of the muscle is vascularized by the superior gluteal vessels. The lower half of the muscle is vascularized by the inferior gluteal vessels. These vessels pass through the space between the piriformis and superior gemellus muscles along with the internal pudendal vessels and the sciatic nerve, inferior gluteal nerve, and posterior femoral cutaneous nerve. The dual vascularity of the gluteus muscle allows splitting of the muscle and preservation of blood supply.

Typically, a flap with a skin width of 8 to 10 cm can be harvested from the buttocks with primary closure of the donor site wound. This is usually sufficient to provide the necessary volume and ptosis to an average-sized breast. The length of the flap is usually 20 to 30 cm. The flap is much thicker in depth than the TRAM flap, usually 10 to 15 cm.

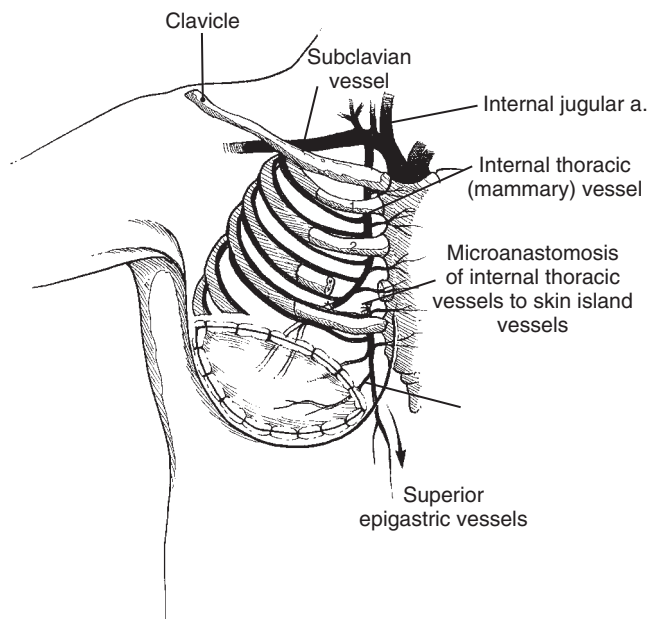

Figure 25-27 Inset and microvascular anastomosis of the superior gluteal flap.

The pedicle of the myocutaneous gluteus flap is usually very short, and the internal mammary vessels are chosen as recipient vessels in most cases (Fig. 25-27). Usually, the third costal cartilage is removed to provide access to the vessels. Harvest of the flap using the superior gluteal artery perforators, not taking any muscle with the flap, provides a longer flap pedicle and easier microsurgical anastomosis.⁹⁹

In these cases, the thoracodorsal vessels may be used for microanastomosis. The thickness of the flap and the central pedicle position may make vascular anastomosis difficult. The internal mammary artery is more reliable than the vein. In cases in which the vein is too small for microanastomosis, the cephalic vein or external jugular vein may be rotated down to become the recipient vein.¹⁰⁰ Vein grafts may also be used. The internal mammary vein becomes more reliable proximally.⁸¹⁻⁸³

What are the advantages of an inferior gluteal free flap?

The inferior gluteal free flap offers the following advantages over the superior gluteal free flap: a longer pedicle, greater volume of tissue, and a lower incision that may be less conspicuous. The main disadvantages of the inferior gluteal flap are exposure of the inferior gluteal nerve, of the motor nerve to the gluteus maximus muscle, and of the sciatic nerve in the dissection.^{101,102} Postoperatively, there is some discomfort with sitting related to the scar in the inferior gluteal fold. The longer pedicle allows the use of the thoracodorsal vessels for microvascular anastomosis. In addition, the pedicle in the inferior gluteal flap is located more toward the edge of the flap when compared with the superior gluteal flap. This allows more straightforward microvascular anastomosis. With either gluteal flap, positioning of the patient on the operating table is difficult. A corkscrew-type position usually makes simultaneous dissections possible.

After the microsurgery is completed, the flap is inset and the muscle used to fill out the infraclavicular hollow, and the lateral portion of the flap is used to re-create the anterior axillary fold or is folded on itself to enhance projection.

How is the patient managed postoperatively?

The postoperative care of the patient with a gluteal free flap involves maintaining the hip in extension over the first few postoperative days. The patient is gradually allowed to sit in a chair and then to ambulate. The patient is usually discharged 5 to 7 days after surgery. There is minimal functional deficit because only a small portion of the muscle is sacrificed. Seromas are the most common donor site complication and either resolve spontaneously or require aspiration.

Transverse Lateral Thigh Flaps

The lateral thigh flap was developed as an alternative site for harvest of autogenous tissue for breast reconstruction. The same patient who is a candidate for the gluteal flap is often a candidate for the lateral thigh flap. There often is significant redundant tissue in the thigh area compared with the abdomen or buttock. Like the gluteal area, the fat in the lateral thigh tends to be more rigid than the fat in the abdomen. This tends to result in a more projecting, youthful breast.

What are the anatomic considerations in a lateral thigh flap?

The vascular pedicle of the lateral thigh flap is the lateral femoral circumflex vessels that perfuse the skin through the

musculocutaneous perforators of the tensor fascia lata. The axis of the flap (Fig. 25–28) is a line that goes from a point 10 cm inferior to the anterior superior iliac spine to the gluteal fold. This is the location of the pedicle. The axis of the flap may not coincide with the location of the greatest amount of fat in the thigh. The decision on the exact site of the skin island should be made with the patient. As long as a portion of the flap is over the pedicle axis, the tissue will be vascularized. The width of the skin island is about 7 to 8 cm. The size depends on the ability to close the wound. The length is usually 20 to 25 cm. The skin incisions are made, and the subcutaneous tissues are beveled for 4 to 5 cm. This creates extra fat for upper and lower pole fullness. Simultaneous chest vessel dissection and flap harvest is usually possible. The thoracodorsal vessels are usually used as recipient vessels for microsurgical anastomosis.

What are the intraoperative and postoperative considerations for a lateral thigh flap?

The flap is positioned in the chest pocket to attain the appropriate shape. The lateral position of the pedicle makes flap inset easier than in the gluteal flaps. The pedicle length is always longer than the superior gluteal pedicle and usually at least as long if not longer than the inferior gluteal pedicle. There usually is good vessel size match, although occasionally the flap vein is 6 to 7 mm in size. The risk for donor site hematoma may be reduced by prolonged closed-suction drainage and suture closure of the defect to obliterate as much of the dead space as possible. The main drawback to this flap is the visible location of the scar and the contour deformity that usually results. The contour deformity may be improved with liposuction of the contralateral unoperated side.⁶⁴

Figure 25–28 A and B, Anatomy of the lateral thigh flap.

NIPPLE-AREOLA RECONSTRUCTION

Breast mound reconstruction improves the patient's body image after mastectomy. Nipple-areola reconstruction allows closer symmetry and increases patient acceptance of the reconstructed breast. The nipple-areola is the initial focus of attention when visualizing the breast. In cases in which the mound reconstruction is slightly less than optimal, an excellent nipple-areola reconstruction may make the reconstructed breast look much more like the normal breast. Wellisch and colleagues¹⁰³ found that patients who had nipple-areola reconstruction had greater satisfaction than those who did not. The nipple-areola reconstruction should be considered a normal step in the process of total breast reconstruction. The patient should be aware of all stages in the reconstructive process before the initial procedure. If this is done, nipple-areola reconstruction will be accepted as a logical step in the reconstructive process.

What are the anatomic considerations in nipple-areola reconstruction?

The nipple-areola should be located on the most prominent portion of the breast. This will be the first area seen when the reconstructed breast is visualized. The nipple should point slightly upward and outward. There is significant variation in the shape and size of the nipple-areolar complex. The average nipple projects 3 to 7 mm. The average areola diameter is 35 to 45 mm.⁶⁴ The surface of the areola varies from smooth to rough. The number and prominence of the Montgomery glands is variable. The goal in nipple-areola reconstruction is to match the unoperated, normal breast. The nipple position should be marked with the patient in the upright position. Ideally, the patient should be sitting or standing in front of a mirror and participate actively in the planning process.

What are the choices for nipple reconstruction?

The most realistic nipple reconstruction is from the contralateral nipple. This is the only site that can perfectly match the color of the normal nipple.¹⁰⁴ The areola may be tattooed at a later date. The shape of the contralateral nipple is very important in the decision-making process. There must be enough nipple available to remove about 50% of the donor nipple and result in normal-appearing donor and recipient nipples. Unfortunately, the nipple is a sensitive donor site. This is particularly true in the mastectomy patient for whom nipple sensibility is of sexual importance. Aside from oncologic concerns, most patients reject the normal nipple as a donor site for nipple reconstruction.

Local flaps are reliable donor tissues that are accepted by most patients. These flaps can be created with or without skin graft reconstruction of the areola.¹⁰⁵⁻¹⁰⁸ Skin graft reconstruction of the areola may be performed using axillary or abdominal "dog ears" if available. Labia donor sites are avoided because of increased patient morbidity. In general, skin grafts are avoided if a new scar would be created to harvest the graft. If a skin graft is to be used for areola reconstruction, and no

previous incision site is available for graft harvest, the groin is used.

Tattooing may be used to match the color of the contralateral areola.¹⁰⁹⁻¹¹¹ This is a particularly good method in patients who have smooth areolas. Patients with coarse areolas will do better with grafts. Tattooing may still be required to match the color. Prominent Montgomery glands may be matched with cartilage grafts.

What is the nipple-sharing technique?

The nipple-sharing technique is essentially a composite graft. The success of such a graft depends on meticulous preparation of the recipient site with absolute hemostasis. The larger the area of contact with the graft, the greater the chance of graft take. If the patient has a long nipple, the tip of the nipple can be amputated as a cap and placed as a graft on the recipient site. The donor site will close primarily. The nipple may also be harvested as a wedge or as a transverse slice⁶⁴ (Fig. 25-29). Postoperative care is the same for all three procedures. A protective dressing is left in place for 7 to 10 days before its removal and the assessment of graft take.

What is the Skate-type flap?

The Skate-type flap raises a local flap from the breast mound that is wrapped upon itself to produce a nipple. The donor site will require skin graft reconstruction. The procedure is demonstrated in Figure 25-30. The nipple position is marked as previously described. The size of the areola is determined by comparing with the normal breast. A transverse line is marked across the areola at the superior base of the flap. The section above this line is de-epithelialized. A circle is drawn in the center of the areola to represent the proposed nipple diameter. Lines are drawn from the medial and lateral edges of this nipple site to the most inferior point of the areola (the 6-o'clock position). The medial and lateral wings of the flap are dissected in a deep dermal plane. The dissection

Figure 25-29 Nipple reconstruction by the nipple-sharing technique.

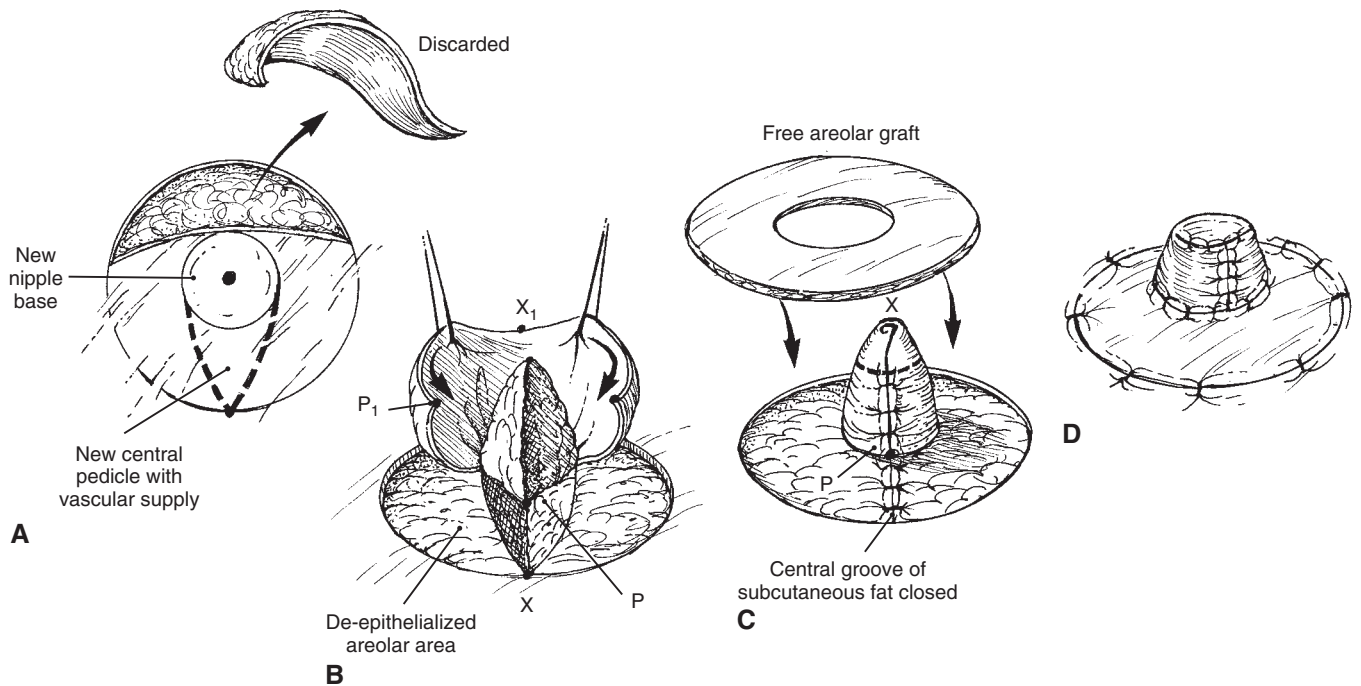

Figure 25-30 Skate-type nipple-areola reconstruction. A, Markings. B, Flap elevation. C, Flap rotation and graft preparation. D, Final appearance.

Figure 25-31 Local flap nipple reconstruction. A, Markings. B, Flap elevation. C, Flap rotation. D, Final appearance.

goes into the subcutaneous plane in the area directly inferior to the nipple. The flap is mobilized and elevated, and the skin flaps are wrapped around the central subcutaneous pedicle. The flaps are sutured together with absorbable sutures, and the tip of the flap is shortened to the appropriate length. The inferior-central exposed subcutaneous fat is closed with absorbable sutures, and a full-thickness skin graft is harvested from a previously determined area. The dressing consists of Telfa and a plastic syringe hub fashioned into a nipple splint that is held in place with Steri-Strips. The dressing is left in place for 7 to 10 days. If the graft is too pale after complete healing, it may be tattooed at a later date.

When is a local flap without areola skin graft indicated?

In patients who either are not good candidates for skin graft areola reconstruction or do not want additional scars associated with skin graft harvest, a local flap and areola tattooing is

a good option for nipple-areola reconstruction.^{110,112} The local flap is raised for nipple reconstruction, and the donor sites are closed primarily without the need for skin grafts. The procedure is demonstrated in Figure 25-31. The nipple position is carefully marked as previously discussed. The diameter and height of the normal nipple are carefully measured. The nipple reconstruction should be made larger than the other side to allow for some contraction of the flap. Two triangular flaps are marked medially and laterally from the nipple base. The width of the triangles should be equal to the proposed height of the nipple. The flaps are raised initially in the deep dermal plane going into the subcutaneous tissue as the nipple area is approached. A semicircular flap is raised at the inferior edge of the flaps to make a nipple cap. The entire flap is elevated to an erect position, and the triangular flaps are wrapped around the base and sutured in place with absorbable sutures. The semicircular flap is sutured to the top of the nipple. The donor sites are closed directly. The areola is usually tattooed postoperatively after the wounds are completely healed.

What is the advantage of nipple-areola tattooing?

Areola tattooing offers several advantages over skin grafts. There is no donor site. The color can be controlled and modified with time. The nipple can be made darker than the areola. The procedure can be performed in the office with minimal anesthesia and no sedation. When a skin graft is present, tattooing can improve the nipple color even if the graft is the appropriate color. Tattooing may also camouflage poor take of a graft or a shape of a graft that is not optimal. The tattoo color should probably be made slightly darker than the normal nipple-areola to allow for normal fading. Nipple-areola tattooing is usually performed after healing is complete.

SYMMETRY PROCEDURES

When symmetry procedures are necessary, all issues must be discussed with the patient and other treating physicians. The need for contralateral breast surgery may alter the choice of technique chosen for breast reconstruction.

When choosing a method of breast reconstruction, it is often possible to select a technique that will closely match the contralateral breast in size and shape. Other times, the method chosen will require alteration of the contralateral breast to achieve symmetry. Some patients may even request surgery on the normal breast for either cosmetic or functional reasons. In patients with very large breasts, mammograms following breast reduction surgery will be easier to interpret. The timing of the symmetry procedure and the technique chosen should not interfere with either the patient's cancer treatment or future monitoring of the contralateral breast.

Available techniques include augmentation, reduction, mastopexy, or a combination of these techniques. Not only is the selection of technique important, but its timing is also critical to achieving the best cosmetic results.

What are the potential problems of augmentation?

Usually, augmentation is useful in small-breasted women who have undergone implant reconstruction and need additional upper breast fullness in the normal breast to achieve symmetry.

Studies have documented the interference an implant can cause to proper mammographic interpretation.¹¹³⁻¹¹⁷ When the implant is small, placed subpectorally, and remains soft, the degree of mammographic distortion is minimal. The use of saline implants placed underneath the pectoralis muscle has significantly reduced the incidence of capsular contracture and subsequent firmness of the breast. Most often, the implants have been large silicone implants placed in a subglandular position with the expected 30% to 40% incidence of capsular contracture and subsequent hardening of the breast. This makes mammography both difficult and painful to perform. Often, several additional views are required to maximize parenchymal visualization. Long-standing implants can

develop calcifications in the surrounding capsule that can also interfere with mammographic interpretation.

When augmentation is being considered, carefully documented consultations with the oncologic surgeon and mammographer are important. Augmentation is best performed at the time of final implant placement to achieve best symmetry.

When is contralateral breast reduction indicated?

Contralateral breast reduction is most often required when patients have breasts larger than a C cup. It is extremely difficult to achieve symmetry in these large, usually ptotic breasts by any reconstructive technique. If tissue expansion were chosen, the degree of expansion required would often result in extreme thinning of the overlying skin, and sufficient ptosis is usually impossible to attain. In the ptotic patient, autologous tissue reconstructive techniques are preferable, assuming there is adequate donor site tissue available.

Breast reduction is best performed at the time of flap reconstruction or tissue expander placement, especially in the delayed setting. Over several months, the reduced breast will develop ptosis, allowing for an accurate implant placement when a tissue expander has been placed in the contralateral breast. Breast reduction techniques all result in some internal breast scarring postoperatively. These mammographic changes are well understood and do not interfere with interpretation.¹¹⁸ When breast reduction is performed, it is important to choose a technique that has a low risk for fat necrosis. When fat necrosis occurs within the breast, it can pose diagnostic problems, usually requiring biopsy. In selected cases, free nipple graft techniques are preferable to pedicle techniques. This technique results in the lowest risk for fat necrosis postoperatively. The long-term stable contour achieved with free nipple graft techniques is also preferable in very large-breasted older women. Free nipple graft techniques also allow for removal of all subareolar ductal tissue, theoretically reducing the possible development of breast cancer. Liposuction is avoided in breast reduction owing to potential distortion of the internal architecture of the breast, which may make future mammographic interpretation more difficult.

When is mastopexy indicated?

Mastopexy is often required when significant ptosis exists in the contralateral breast and symmetry is the goal of reconstruction. Mastopexy, similar to breast reduction, is best performed at the time of the initial reconstructive procedure because some recurrence of ptosis is common over 6 months to 1 year postoperatively. Available mastopexy procedures either reshape the skin or internally reshape the breast mound. Internal architectural distortion should be minimized in these patients. It is best to avoid mastopexy techniques that extensively reshape the breast gland. In general, long-term results have been very similar for both internal reshaping procedures and dermal procedures.

BREAST RECONSTRUCTION AFTER BREAST-CONSERVING SURGERY AND RADIATION THERAPY

Increasingly, segmental excision and radiation therapy have become the established treatment for many patients with breast cancer. The aesthetic result after breast-conserving surgery is affected by the extent of surgical resection of the tumor, the location of the tumor, and the orientation of the skin incisions.^{119,120} An unsatisfactory aesthetic result is related most commonly to poorly designed skin and parenchymal resections and the failure to reapproximate breast tissue when closing. Significant resection (quadrantectomy) is more likely to result in aesthetic problems than are more limited segmental excisions.¹²⁰ The size of the breast compared with the size of the excision is critical in determining the likelihood of distortion. The larger the excision relative to the breast size, the more likely that there will be cosmetic problems.

Radiation therapy often results in tissue erythema and edema that is followed with time by fibrosis, contracture, and telangiectasia formation. The decreased vascularity of the irradiated tissue may result in fat necrosis and diffuse calcification. The breast may develop retraction and contracture that superiorly dislocates the breast relative to the chest wall.

Berrino and associates¹²⁰ noted an incidence of unsatisfactory outcomes after lumpectomy and radiation therapy of 16% to 22%. They developed a classification system to describe the various types of deformity that occur after breast conservation and radiotherapy, among which the most difficult to correct was cutaneous parenchymal deficiency with or without subcutaneous tissue loss.

How can deformities in the conserved breast be treated?

Minimal deformities may be treated with local flaps, scar release, or tissue rearrangement. More extensive defects require release of all scar contracture and replacement with new tissue.

The risk for locally recurrent cancer in patients treated with breast-conserving surgery and radiation therapy has been reported as high as 10% to 20% in 10 years.¹²¹⁻¹²³ Any reconstructive technique that might interfere with surveillance of the breast is unacceptable. The use of breast prostheses could potentially obscure the visualization of small lesions mammographically. Even with specialized mammographic techniques, portions of the breast are likely to be missed.

Myocutaneous flaps will provide sufficient tissue to correct almost any tissue defect. Slavin and coworkers¹²⁴ reported that these tissues do not compromise mammographic interpretation. The muscle flap tissue becomes fibrofatty as soon as about 6 months after surgery and eventually becomes radiolucent.¹²⁴ Adjacent breast tissues are not concealed or obscured mammographically. In addition, the myocutaneous flap tissues are well vascularized and improve blood supply to the surrounding tissues. This produces a less dense breast than in irradiated breast tissue without muscle flap augmentation. The flap reconstruction of the breast should be delayed for 2

to 3 years after the surgical procedure until the erythema, edema, fibrosis, and contracture have stabilized.

Most defects after lumpectomy or quadrantectomy and radiation therapy are easily treated with latissimus dorsi myocutaneous flaps. This flap is well tolerated and has minimal donor site morbidity. The rectus abdominis myocutaneous flap is reserved for larger defects. The rectus abdominis flap donor site is associated with more donor site morbidity than the latissimus dorsi. In addition, if there is a breast cancer recurrence, the rectus abdominis will not be available for salvage reconstruction.

At the time of the reconstruction, the breast tissue must be assessed. This consists of evaluating the missing cutaneous component, the parenchymal volume loss, and the nipple malposition. The skin loss usually is greater than expected as a result of shrinkage from the radiation therapy. The flap skin island should be made slightly larger than the anticipated defect. In addition, there is likely to be some muscle atrophy, and the overall flap volume should be slightly larger than appears to be needed.

PSYCHOLOGICAL IMPACT OF BREAST RECONSTRUCTION

Today, almost all women with breast cancer are likely to be offered either breast-conserving surgery or mastectomy and reconstruction. The options for reconstruction have increased as the surgery for breast cancer has decreased. Most patients have multiple options available to reconstruct the breast. The gross distortion associated with the radical mastectomy is very rare. Most patients who choose breast reconstruction are satisfied with the surgery.¹²⁵

Various studies¹²⁶⁻¹²⁸ have shown that up to one third of patients who undergo mastectomy have significant emotional distress and sexual dysfunction. Clifford and colleagues,¹²⁹ in a study of women undergoing delayed breast reconstruction, showed that women who sought reconstruction were exhibiting positive coping and assertive, effective problem-solving behavior. Teimourian and Adham¹³⁰ showed that reconstruction was like a “reverse mastectomy” and neutralized the destructive effect of the loss of the breast.

What is the psychological benefit of breast reconstruction?

There is no dispute that breast reconstruction is beneficial to the patient. In the early days of breast reconstruction, the timing of the reconstruction (immediate vs. delayed) was of some dispute. The earlier advocates of breast reconstruction^{131,132} felt that the patient should cope with the defect created by the mastectomy and the use of a prosthesis before reconstruction, assuming that the patient would value the reconstruction more after having to deal with the ablation. In addition, there was a fear that the reconstruction would delay detection of recurrence of the breast cancer. Dowden and associates¹³³ helped allay fears that the reconstruction adversely affected the outcome after recurrence. Johnson and coworkers¹³⁴ showed that the outcome in breast cancer

patients depended on the biology of the tumor and not on the presence of a breast prosthesis. The satisfaction rates with the reconstructions were similar in delayed-reconstruction patients and in immediate-reconstruction patients. Schain and colleagues¹³⁵ noted that women who had immediate reconstruction were less anxious, less depressed, and less hostile than those who had delayed reconstruction.

Breast reconstruction after mastectomy has been shown to increase sexual responsiveness.^{130,135} Gerard¹³⁶ showed that women who have breast reconstruction are more easily sexually aroused than women who have had mastectomy alone.

Wellisch and colleagues¹⁰³ studied the psychosexual impact of nipple-areola reconstruction after breast reconstruction. They found that the group that had nipple-areola reconstruction had increased satisfaction with the overall reconstruction, nude appearance, size, softness, and sexual sensitivity compared with patients who had reconstruction without creation of the nipple-areola.

Women who feel that they will be psychologically, socially, or sexually improved with breast reconstruction should be offered the procedure at the earliest possible time after mastectomy.

Radiotherapy for In Situ, Stage I, and Stage II Breast Cancer

Randy E. Stevens

Radiation therapy has an integral role in the curative treatment of breast cancer. After conservative surgery for ductal carcinoma in situ (DCIS) or invasive carcinoma, radiation therapy of the breast improves the likelihood of locoregional freedom from disease and thereby enhances the long-term possibility of breast preservation. After mastectomy, in carefully selected patients, locoregional radiation therapy reduces the risk for recurrence and possibly prolongs survival. Therefore, clinicians caring for patients who have breast cancer require a clear understanding of the pertinent principles of radiation therapy: selection criteria, techniques of treatment, beneficial results, and side effects.

BASICS OF RADIATION BIOLOGY

How does radiation cause changes in the patient's tissues?

X-rays, gamma rays, electrons, and heavy particles (neutrons, protons) are believed to produce cell damage by indirectly or directly forming irreparable double-stranded DNA breaks.¹ When the cell next enters mitosis, it cannot divide, and cell death occurs (reproductive death).^{1,2} One exception to this process is the interphase death of lymphocytes.

The precise mechanism of DNA damage is different for x-rays, gamma rays, and electrons (low linear energy transfer [LET] radiation) than for heavy particles (high LET radiation).¹ Low LET radiation results in sparse electron-tissue interaction. It is unlikely to deposit two electrons in the same DNA molecule. Rather, a single-stranded DNA break may occur. A second "hit" is required to yield a double-stranded DNA break. Both hits are likely to occur by an indirect mechanism: the result of an electron ionizing a water molecule and yielding a hydroxyl radical. Hydroxyl radicals can migrate a short distance (100 Å, or 10 nm) and, if near a DNA molecule, result in an interaction that produces a single-stranded break. The hydroxyl radical has a half-life, in microseconds, that can be prolonged by oxygen or electron-affinic compounds and shortened by free radical scavengers.³ In contrast, high LET radiation deposits energy densely over a short distance. If it

happens to pass through a DNA molecule, two hits that produce double-stranded damage may occur.¹ Consequently, high LET radiation produces DNA damage independent of oxygen concentration.¹

Regardless of the mechanism of DNA damage, the end result, reproductive cell death, explains the variation in rapidity of cell death (whether normal or malignant tissue). More rapidly dividing tissues display the effects of radiation, including cell death, faster than slowly dividing tissues.⁴ The mucosa of the oral cavity, for example, shows damage sooner than does neural tissue.

Radiation sensitivity (see later) also varies with cell cycle.⁵ Cells in the G₂ and M phases are more sensitive to ionizing radiation than cells in the G₀, G₁, or S phases.⁵ Rapidly dividing neoplastic or normal tissues (e.g., skin, gastrointestinal mucosa, bone marrow) pass through mitosis more often, and radiation effects are seen sooner, than in more slowly dividing systems (e.g., subcutaneous tissues, kidney, brain). For the most part, neoplastic tissue behaves more like rapidly dividing (acute-responding) tissue than more slowly dividing (late-responding) tissue.^{6,7}

What factors alter normal or tumor tissue response to radiation?

Time-Dose-Volume Relationships

Long-term or late effects are those detected more than 6 months after completion of radiation therapy. As the volume of normal tissue irradiated to a given dose increases, the risk for long-term damage increases.⁸ A small volume can be treated to a higher total dose (compared with a larger volume and lower total dose) while maintaining the same risk for long-term effects. With the availability of modern computer-generated dose-volume histograms (percentage of organ treated vs. dose), the wealth of human data being collected is yielding an improved understanding of dose-volume relationships. This improved understanding should translate into reduced normal tissue toxicity in the future.

Dose fractionation (dose per time) is intimately related to radiation effects on normal and neoplastic tissue.⁹ For example, 7000 cGy given continually over 7 weeks in 200-cGy fractions often cures squamous cell carcinoma of the

supraglottic larynx. The same 7000 cGy in 200-cGy fractions but delivered with a 2-week interruption will yield a lower local control rate.¹⁰ Total dose, dose per fraction, and overall time are interrelated and critical to the likelihood of tumor control and normal tissue effects.

Radiation sensitivity refers to the fraction of cells surviving after exposure to a given dose of ionizing radiation. Dose (energy per unit mass) is reported in gray (1 Gy = 1 J·kg⁻¹) or centigray (100 cGy = 1 Gy). Before use of standard international units, dose was recorded in rad (radiation absorbed dose; 1 rad = 1 cGy). In addition to cell cycle, variables affecting radiation sensitivity include the type of stem cell,¹ oxygen,¹¹ heat,¹² and certain chemotherapeutic agents.¹³⁻¹⁵

Oxygen is important to permit low LET radiation to produce double-stranded DNA breaks.¹¹ However, it remains controversial as to whether supplemental oxygen, hyperbaric oxygen, electron-affinic agents, or transfusions to increase oxygen-carrying capacity can improve cell kill. In hypoxic tumors, reoxygenation is postulated to occur spontaneously. After the oxygenated periphery of the tumor has been irradiated and cell death occurs, the previously hypoxic segments have less competition from other tumor cells for available oxygen. The newly reoxygenated tumor can effectively be damaged by subsequent ionizing radiation.

Chemotherapeutic agents may be used before, during, or after radiation therapy. They may be used to decrease the number of clonogens that the ionizing radiation must eliminate (e.g., doxorubicin or cyclophosphamide, methotrexate, 5-fluorouracil [CMF]) or synchronize cells in more sensitive phases of the cell cycle (e.g., paclitaxel [Taxol], which arrests cells in mitosis), yielding improved cell kill for a given dose of ionizing radiation.

Radioresponsiveness is the observable response of the malignancy to ionizing radiation, a combination of radiation sensitivity and cell loss due to the kinetics of the cell system. The overall likelihood of death is also dependent on fractionation, the percentage of organ irradiated or the size of the tumor (for tumor response), total dose prescribed, radiation sensitizers, ability to repair sublethal DNA damage, role of potentially lethal damage, and, in tumors, ability to repopulate during radiation.

Normal rates of cellular proliferation of non-neoplastic and neoplastic tissues may continue during irradiation. However, irradiation of tissues may induce some cells to accelerate their growth rate to replace cells destroyed by radiation. In normal tissue, this recruitment repopulates early-responding tissues to a greater extent than late-responding tissues. Therefore, long-term damage in skin and bone marrow, which are early-responding tissues, is minimized. In neoplastic tissue, accelerated repopulation may begin while the tumor appears grossly to be shrinking.⁷⁻⁹ The surviving neoplastic clonogens proliferate faster than at the beginning of radiation. This accelerated regeneration may be important in inflammatory carcinoma of the breast, as well as other malignancies, and appears to act as an impediment to cure of disease.

How do a patient's normal tissues heal after radiation therapy?

Nonlethal cellular damage (DNA breaks) after radiation therapy may be repaired. Further ionizations may result in cell

death. Two types of cell injury, called *potentially lethal* and *sublethal*, do not immediately lead to cell death. Potentially lethal damage requires the cellular environment to be modified for repair. If the required condition (e.g., a change in temperature, oxygen) can be met, the cell can survive. Repair of sublethal damage occurs, and is clearly demonstrated, when radiation is fractionated (divided into many small doses) and several hours intervene between doses (fractions). For many stem cells, sublethal damage repair has occurred after 6 to 8 hours. Fractionated radiation therapy exploits the difference in the ability of normal and malignant tissues to repair damage caused by ionizing radiation. After a multiweek course of radiation therapy, the damage is greater in the neoplastic tissue (optimally resulting in neoplastic cell kill) than in the normal tissue, or the damage is in the process of being repaired, thus allowing ionizing radiation to be an effective and well-tolerated therapeutic modality in the eradication of neoplasms.

BASICS OF THE PHYSICAL CONSIDERATIONS OF RADIATION THERAPY

What is ionizing radiation?

Ionizing radiation may be either electromagnetic or particulate packages of energy. The electromagnetic spectrum ranges from low-frequency (long-wavelength) radio waves, to intermediate-frequency visible and ultraviolet light, to high-frequency (short-wavelength) x-rays and gamma rays. X-rays and gamma rays, by virtue of their greater frequency, have relatively higher energy and are more penetrating in tissue, a property that is useful therapeutically. X-rays and gamma rays differ in the way they are formed. Gamma rays are emitted from the nucleus during decay of a radioactive isotope. X-rays are produced extranuclearly, usually by a machine that accelerates electrons, which bombard a heavy-metal target, releasing energy as heat and x-rays.

Particulate radiation includes electrons, protons, neutrons, negative pi mesons, alpha particles, and atomic nuclei. All of these examples of particulate radiation have been used in radiation therapy. Electrons are the most frequently employed, especially in the treatment of malignancies of the breast. Because these types of radiation have physical mass and charge, they do not penetrate tissues as easily as x-rays or gamma rays, a property that can be exploited clinically. Whether electromagnetic or particulate, ionizing radiation travels as a packet of energy (photon), which, when absorbed in tissue, results in ionization and, ultimately, in biologic damage.

Three mechanisms of ionization are possible, depending on the energy involved: (1) the photoelectric process, (2) the Compton effect, and (3) pair production.¹⁶ The photoelectric process is the most common mechanism of x-ray interaction in diagnostic radiology because the equipment generally operates in the kilovoltage energy range. The likelihood of absorption of the ray is proportional to the cube of the atomic number (Z^3) of the tissue it encounters. This explains the whiter appearance of bone and the gray or blackish appearance of air on a diagnostic radiograph (Fig. 26-1). By contrast

Figure 26-1 Radiograph of the breast and chest wall. The x-ray beam is tangential to the chest wall. This film was taken using a simulator that generates x-rays in the kilovoltage range, similar to diagnostic x-ray units. The bones (ribs) appear white; the lung appears black.

Figure 26-2 Port film of a breast treatment portal. Because this film was taken using a linear accelerator (megavoltage-range x-rays), the contrast between the bone and lung is muted, demonstrating the relative independence of the Compton effect on atomic number.

with the photoelectric process, modern radiation therapy employs beams in the megavoltage range (at least 1 million volts). The Compton effect, the prevailing mechanism of x-ray interaction with tissue at megavoltage energies, is not dependent on atomic number but on the density of the absorbing medium (electrons per gram). Therefore, the differential absorption of bone compared with that of soft tissue is much less. This property helps create far more homogeneous radiotherapy than could be produced by older equipment. When comparing a port film (a localizing film taken using a treatment beam) to a diagnostic energy x-ray from a treatment simulator, the relative difference in the importance of atomic number and density of the two processes is apparent (Fig. 26-2). A practiced eye and extreme care are therefore required to ensure that treatment fields are precisely aimed throughout a course of treatment.

Figure 26-3 Linear accelerator. This Varian 2300 C linear accelerator can produce 6- and 18-MV photons as well as several energies of electron beam.

What is the hallmark of modern radiation therapy? What is a linear accelerator? How does it work?

“Modern radiotherapy” refers to the era of megavoltage treatment and was not widely available in the United States until the 1960s. Radiation therapy delivered before the megavoltage era used energy in the orthovoltage (150 to 500 kV) or super-voltage (500 to 1000 kV) range. Many undesirable effects resulted from treatment with the lower-energy machinery. Because of the importance of the photoelectric effect and the increased absorption of radiation in bone compared with soft tissue, orthovoltage radiation therapy could not effectively reach tumors behind bones and inflicted unnecessary injury in the bone. In addition, orthovoltage machinery lacked skin sparing; therefore, redness and reaction of the skin frequently limited the dose that could be delivered to the underlying tumors.

Currently, the most common machines providing megavoltage radiation therapy are linear accelerators (Fig. 26-3). A linear accelerator has several advantages over orthovoltage and cobalt 60 therapy:

1. It produces a higher-energy x-ray beam that enables greater skin sparing and more effective treatment of deep-seated lesions.
2. In addition to the x-ray beam, linear accelerators can provide a therapeutically useful high-energy electron beam. Electrons have a discrete range and, relative to photons, have most of their tissue interactions within a small distance. Therefore, there is a more abrupt falloff of dose beyond the electron's range of penetration. The range is proportional to the energy of the electron, and most modern linear accelerators produce a number of selectable electron energies that can be customized to the individual patient's anatomy and needs. Electrons, in general, are less skin sparing than photons and are useful for treating

superficial lesions. In comparison to photons, less shielding is required to attenuate an electron beam (the shielding requirement increases as the energy of the electron increases). Taking these factors together, electrons are particularly well suited for therapy of a superficial lesion.

3. The sharper beam edge of linear accelerators permits increased shaping of a treatment portal to match the desired target.
4. The dose rate from a linear accelerator is greater (or varied if necessary), allowing treatment to be accomplished faster (with less patient movement) and a patient to be placed farther from the machine, which generally results in more homogeneous irradiation.
5. There is absolutely no personnel exposure (pertinent to cobalt 60 therapy) or need to change the radioactive material because of decay of the isotope.
6. Accelerators often produce more than one energy x-ray beam, several energy electron beams, customized blocking from inside the head of the machine, a quality assurance computer-controlled system ensuring precise delivery of the proposed treatment, and three-dimensional “conformal” radiation therapy, which combines advances in imaging with precision delivery using multiple beams.

PATIENT SELECTION FOR BREAST-CONSERVING THERAPY, FOLLOWED BY RADIOTHERAPY, INCLUDING DUCTAL CARCINOMA IN SITU OR EARLY-STAGE INVASIVE CARCINOMA

Are all patients candidates for breast-conserving therapy?

Most patients who have DCIS stage 0 or American Joint Committee on Cancer (AJCC) stage I or II and some with stage III invasive breast cancer are potential candidates for breast preservation; however, patient- and disease-related factors may contraindicate conservative surgery or the use of radiation therapy for a specific patient. Host-related contraindications may be either major or minor and may have a medical or cosmetic basis. Pregnancy is a nearly absolute contraindication to radiation therapy. Prior therapeutic irradiation of the breast had been an absolute contraindication, but re-irradiation may be possible in selected patients (see later). Other contraindications, such as the ratio of tumor to breast size, the presence of collagen-vascular disease, the location of the lesion within the breast, and comorbid medical conditions, are relative contraindications, as discussed below. Disease-related factors are covered later in the discussion of invasive or intraductal disease. For the reader who wants an advance look, a summary is provided in Table 26–1.

Why are pregnancy and prior breast irradiation nearly absolute contraindications to curative irradiation of the breast?

In the first two trimesters of pregnancy, when the developing fetus is most sensitive, radiation therapy is contraindicated

Table 26–1 Contraindications to Breast Radiotherapy

Major Pregnancy Prior therapeutic breast irradiation Gross or mammographically evident multicentric carcinoma (involving more than one quadrant of the breast) Diffuse (malignant-appearing) microcalcifications Systemic lupus erythematosus, scleroderma
Minor Large tumor-to-breast size ratio Comorbid medical or psychiatric conditions (see text)

because of internal scatter of ionizing radiation from the region of the breast to the fetus.¹⁷ Radiation therapy has been delivered in the third trimester when medically essential without evident damage to the fetus (e.g., in Hodgkin’s disease, before the development of curative regimens of chemotherapy). However, because there is a medically equivalent treatment for early-stage breast cancer (i.e., mastectomy), radiation therapy should not routinely be used during pregnancy.

Previous radiation therapy in substantial doses is the other nearly absolute contraindication to irradiation of the breast if the treatment fields overlap.^{17,18} Patients who received mantle-field radiation therapy and subsequently developed breast cancer are not offered conservative surgery and standard radiation therapy to the breast as a first choice. Normal tissues “remember” prior radiation-induced changes and cannot withstand substantial additional treatment. Re-irradiation may result in soft tissue necrosis, rib fractures, pneumonitis, and cardiotoxicity (for left breast lesions).^{19,20} With time, however, there is at least partial repair of previous radiation-induced damage to the normal tissue. If many years have elapsed, some patients are now being offered re-irradiation to the breast or partial breast.^{21,22} Re-irradiation may be most useful if the second cancer is not in the original or index quadrant of the first cancer and appears to be a new cancer, not a recurrence. Again, however, given the equally curative medical option of mastectomy, re-irradiation should not be the first recommendation, and time since the original radiation therapy, as well as total dose prescribed and the technique used, should be meticulously considered.

Is multicentric disease an absolute contraindication to breast-conserving therapy?

Multicentric disease (carcinoma in more than one quadrant of the breast) is generally managed by mastectomy. Definitive breast surgery requires removal of all gross and radiographically evident disease with final free surgical margins. When the carcinoma is in more than one quadrant, definitive surgery results in removal of breast tissue from two quadrants and, after the whole-breast portion of the radiation therapy, additional treatment to the tumor beds (boost portal). In many patients, cosmesis may not be acceptable with two lumpectomies in two different quadrants, and mastectomy is recommended. Multicentricity may also portend a higher burden of microscopic disease in the remaining breast tissue and an increase in the local recurrence rate despite free surgical mar-

gins, lack of residual disease on postoperative breast imaging (i.e., dedicated breast magnetic resonance imaging [MRI]), and meticulous radiotherapeutic technique. Small series suggest that breast conservation surgery followed by radiation therapy may yield acceptable local control and survival in selected patients with multiple ipsilateral synchronous cancers.²³

What are the relative contraindications to conservative surgery and radiation therapy?

There are three common relative contraindications to conservative surgery and radiation therapy: (1) a disparate tumor-to-breast size ratio, (2) collagen-vascular disease, and (3) comorbid medical conditions.

Ratio of Tumor to Breast Size

The goal of breast preservation is a cosmetically appealing outcome. Therefore, the amount of breast tissue requiring resection, the initial size of the breast, and anticipated symmetry of the breasts after surgery need to be considered. For example, wide resection of a 3-cm tumor in a patient with an A-cup breast size and resection of the same lesion in a patient with a D-cup breast size may both be technically feasible. However, the amount of remaining breast tissue and its appearance will likely be vastly different. There is no universally agreed-upon tumor-to-breast size ratio beyond which conservative surgery is contraindicated, but the likely appearance following treatment must meet the patient's expectations.

The pendulous or large breast has been the subject of much discussion and has been reported to be a relative contraindication to conservative surgery and radiation therapy.^{24–28} With poor technique (lack of a high-energy linear accelerator, inhomogeneity of dose across the breast, and omission of tissue compensation techniques), marked skin reaction and poor long-term cosmesis have been reported.^{24,29} Certainly, fibrosis, skin retraction, persistent edema, or all three are possible, but with the use of special treatment devices, high-energy linear accelerators, and appropriate treatment planning, the acute and long-term reactions often can be kept to an acceptable level.^{24,29} After treatment, about 85% to 90% of appropriately treated patients rate their cosmesis as good to excellent.^{24,27}

There is also debate about the influence of a subareolar tumor. Those subareolar tumors that require resection of the nipple–areolar complex result in cosmetic alterations that are acceptable to many patients, but others, despite symmetry when clothed, will find the absence of a nipple unacceptable and opt for mastectomy and reconstruction. Radiation therapy for this site is otherwise equally efficacious.

Patients who have synchronous or metachronous bilateral breast cancers are usually candidates for conservative surgery and radiation therapy. Technically, it is more difficult to treat both breasts, and therapy must be carefully planned to avoid overlap of the right and left breast treatment portals. The planning session and time required for daily therapy are longer than those of patients having one breast treated because of the increased number of treatment fields. Otherwise, treatment is essentially identical to that required when only one breast is involved.

Collagen-Vascular Disease

Although the absolute number of patients affected by collagen-vascular disease who have undergone breast radiotherapy is small, reports indicate a higher-than-average rate of severe soft tissue reactions, including necrosis and nonhealing ulceration requiring surgery.^{30–36} Because the *raison d'être* of breast preservation is excellent cosmesis and this goal is less likely to be reached, mastectomy with or without reconstruction is generally recommended to patients who have early-stage breast cancer and scleroderma or systemic lupus erythematosus.

Comorbid Medical Conditions

Occasionally, comorbid medical conditions preclude a patient's ability to tolerate treatment. Examples of such situations include congestive heart failure and inability to breathe comfortably in a supine position, inability to abduct the ipsilateral arm (e.g., stroke, severe arthritis, bursitis, rotator cuff injury), inability to comprehend or follow instructions, and inability to maintain the treatment position for the required time or manage the radiation-induced changes. Medical conditions preventing delivery of radiotherapy are uncommon, but consultation with a radiation oncologist before definitive surgery is particularly important to avoid an unnecessary additional surgical procedure if the patient is not a candidate for radiation therapy.

Patients who have pacemakers require special consideration.^{37,38} In situations in which a pacemaker was within the radiation field (direct beam), isolated instances of transient or permanent pacemaker malfunction have been reported.^{39–44} Guidelines developed by the American Association of Physicists in Medicine suggest that the patient's cardiac status and pacemaker should be evaluated by a cardiologist before beginning radiation therapy.⁴⁵ The pacemaker should be at least 2 cm from the path of the direct radiation beam. The total dose to the pacemaker (from scattered radiation) should be calculated and kept to a maximum of 500 cGy. The pacemaker and the patient's cardiac status should be actively monitored during the first treatment session.

TECHNICAL ASPECTS OF BREAST RADIATION THERAPY

When can radiation therapy generally begin?

Wound healing is usually adequate by 2 weeks after surgery, and treatment planning can be done any time thereafter, as appropriate. Occasionally, accumulation of a seroma and required repeated drainage (causing fluctuations in the breast contour and skin marks) may delay simulation. Usually, the timing of simulation is determined by the ability of the patient to abduct and maintain the arm (after axillary dissection) in the treatment position. On average, treatment commences between 4 and 6 weeks after surgery.

Patients who receive chemotherapy after breast-conserving surgery receive the chemotherapy before radiation therapy. Radiation therapy begins about 3 to 4 weeks after chemotherapy is completed and blood counts are adequate.

What steps are required to plan treatment?

Radiation therapy must be delivered precisely to the entire tumor bed and to as little normal tissue as possible. To do this, a planning simulator, a machine with diagnostic x-ray and fluoroscopy capabilities that reproduces the exact geometry of the treatment machine, is used to project simulated treatment beams onto the patient. State-of-the-art simulators have computed tomography (CT) scan capability as well and demonstrate the path of the simulated beam in the patient (Fig. 26-4). The radiographic capabilities allow localization of the treatment volumes and critical normal structures and generate a verification radiograph. Shielding is customized to block areas of normal tissue that do not require treatment and yet allow irradiation of the entire tumor. The projected light field, mimicking the actual treatment, outlines the field on the patient's skin, and reference points are marked to facilitate reproducible daily positioning.

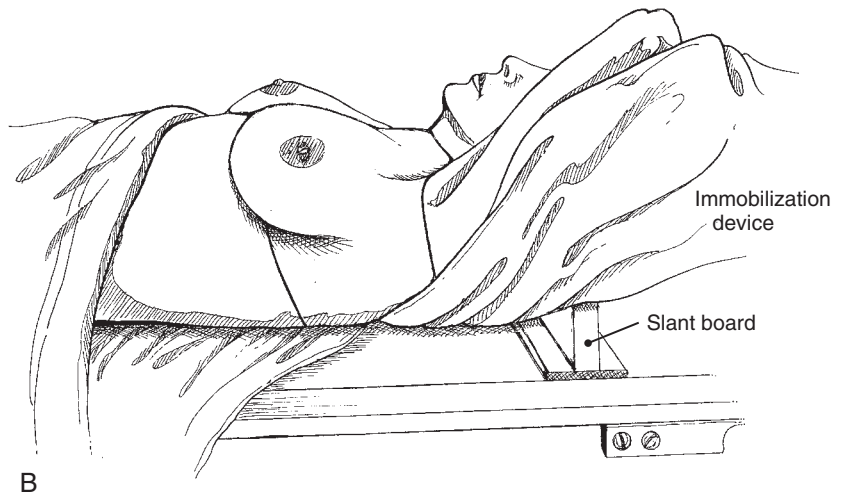

Because of the time required for treatment, the ideal treatment position is both reproducible and comfortable. The generally preferred position has the patient lying supine, immobilized in a breast board, cradle, or mold individually constructed for patient comfort and reproducibility (Figs. 26-5 and 26-6). A slant board often is placed under the mold to reduce the curvature of the chest wall and allow the breast to be effectively treated while including a smaller volume of

Figure 26-4 Patient on a slanted breast board in treatment position undergoing computed tomography scan simulation.

Figure 26-6 The Vac-Loc immobilization device. The Vac-Loc is inflated to the desired amount and molded to immobilize the ipsilateral arm, the head, and the chest wall. It provides support for the arm as well as reproducibility of treatment position.

Figure 26-7 Slant board. Many types of slant boards are available. As pictured here, the board is placed under an immobilization device. Plexiglass or Lucite inserts of several sizes are available, so that the elevation of the slant boards can be customized to straighten the curvature of each patient's chest wall.

lung (Fig. 26-7). The ipsilateral arm is abducted above the head to keep it out of the path of the treatment beams.

Precisely how are the beams aimed?

Radiation therapy of the breast is usually delivered using two beams that are tangential to the chest wall: right anterior oblique and left posterior oblique for the left breast, and left anterior oblique and right posterior oblique for the right

breast (Fig. 26-8). With the patient in the treatment position, skin marks are placed just beyond the lateral, superior, and inferior borders of the breast tissue. Medially, the border of the field is the patient's midline. Using a CT scan or fluoroscopy in the treatment position, the angles for the antero-medial and posterolateral oblique fields are chosen such that the entire breast is included and the volume of lung and possibly heart (in some left breast treatment fields) is minimized. The amount of lung that must be included in the tangential fields varies from patient to patient but generally is less than 3 cm from field edge to the chest wall at the midplane between the portals (the site of maximum exposure of lung) (Fig. 26-9). In fact, in more than 80% of patients, inclusion of the entire breast (even with a margin for respiratory motion) can be accomplished with 2 cm or less lung.

What refinements optimize treatment planning?

Occasionally, a special treatment device may be required to minimize dose to normal tissue or ensure reproducibility of daily positioning. A very pendulous breast may fall over the lateral aspect of the chest wall, and encompassing the entire breast would result in an increased amount of lung tissue in the treatment portal if nothing else were done. A treatment device, such as an Aquaplast mold, a bra, or Spandage, may be used to place the breast in a position that reduces the amount of lung in the treatment portal. If the tumor was not deep (i.e., near the chest wall), the patient may also be treated in the prone position, allowing the pendulous breast to hang forward away from the chest wall and reduce the volume of lung irradiated.

When the desired target volume encompasses only the breast, care should be taken to minimize irradiation of the dissected axilla. This will keep the risk for lymphedema as low as possible. A slant board helps to lower the superior border of the breast tissue; abducting the arm raises most of the axilla up and away from the treatment field. Occasionally, a lesion high in the tail of the breast tissue may necessitate treatment of a larger portion of the axilla. The surgeon's use of separate breast and axillary incisions can help the radiation oncologist minimize unnecessary treatment of the axilla.

As fields are designed at simulation, permanent small India ink tattoo dots or temporary purple carbolfuchsin skin marks are placed. These marks are used each day to position both the patient and the radiotherapy fields. Digitally reconstructed radiographs of the treatment fields are created from the CT scan plan, or diagnostic-quality films are taken by the simulator (see Fig. 26-9). The films subsequently are compared to port (beam) films or digital images taken on the treatment unit before the first treatment and weekly for quality assurance (Fig. 26-10).

At simulation, a CT scan is taken of the breast and underlying structures (e.g., ribs, lung, heart, contralateral breast, and lymph nodes). The physician delineates the precise area to be treated. Using a computerized treatment planning system, the physicist and physician design treatment fields to provide a homogeneous dose to the breast while minimizing the volume of and dose to adjacent normal tissues such as lung and heart (Fig. 26-11). If a CT simulator is not available, a contour of the breast is taken manually using solder wire, plaster of Paris,

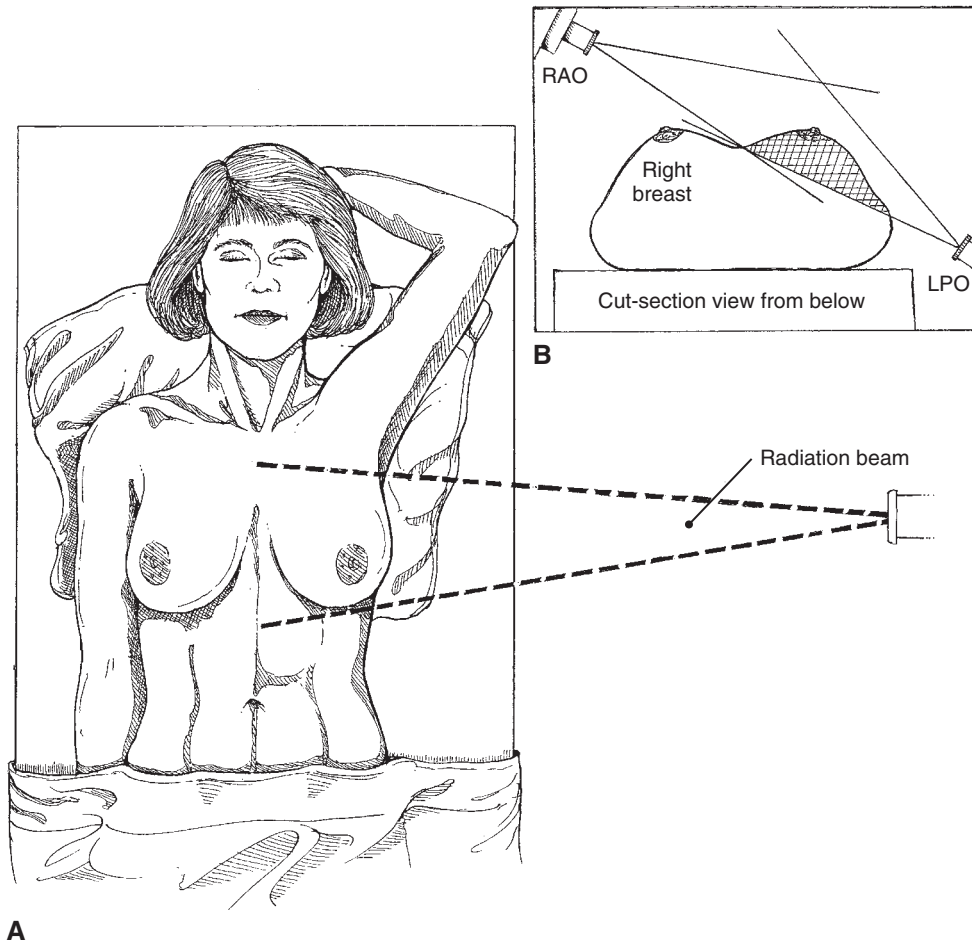

Figure 26-8 Schematic diagram of the fields used in the treatment of a patient's left breast: left posterior oblique (LPO) and right anterior oblique (RAO) fields. *A*, Patient in LPO position. *B*, Cut-section view from below.

or Aquaplast (a plastic that is malleable when warm and hardens as it cools). The CT simulator and sophisticated treatment planning software facilitate a three-dimensional plan to deliver a homogeneous dose to the breast (frequently less than 10% maximum variation in dose) by imposing various materials in the treatment beams to compensate for differences in tissue thickness or by adding additional fields (above the

Figure 26-10 Portal film of the same treatment field as shown in the simulator localization film in Figure 26-9. The portal film demonstrates the reproducibility of field in the treatment room compared with that taken at simulation.

Figure 26-11 Computed tomography scan of the breast with superimposed isodoses using wedges and shielding to minimize the range of doses across the breast tissue (inhomogeneity).

standard two tangential portals) and changing the angles of the fields. In most cases, wedge-shaped tissue compensators are placed in the lateral or medial fields, or in both, to compensate for the smaller volume of breast tissue near the nipple. (If wedges are not used, the thinner aspect of the breast will receive a higher dose of radiation compared with the wider posterior portion of the breast; Fig. 26-12.) The wedge may be a physical device placed on a tray near the patient or an intrinsic device in the head of the linear accelerator. A physical wedge placed near the patient is the less preferable solution because x-rays that interact with the wedge produce scatter electrons, some of which reach the patient. Reports document an increased dose to the contralateral breast with placement of a physical wedge in the medial (anterior oblique) portal.^{46,47} Because of concern about development of a subsequent contralateral breast carcinoma with increasing dose to the contralateral breast (see the discussion of long-term effects), some authors have recommended placement of a physical wedge in the lateral tangent only. The preferred solution uses an intrinsic wedge contained in the head of some linear accelerators, far away from the patient. In this situation, wedges can be placed in the medial and lateral tangents, optimizing the dose distribution in the ipsilateral breast and yet minimizing scatter to the contralateral breast.

More recently, advances in computerized software have facilitated optimization of the homogeneity of dose across the volume to be treated by using intensity-modulated radiation therapy (IMRT).⁴⁸ IMRT uses inverse treatment planning to shape the radiation field to each patient's tumor or treatment area and away from or around the patient's normal tissues. A sophisticated multileaf collimator provides 120 0.5- to 1.0-cm lead-lined leaves to customize the shape of each radiation beam (Fig. 26-13). The position of the leaves can be set for the entire treatment of the field or can vary during the treatment of an individual field. This "dynamic multileaf collimation" provides the variation in intensity across each radiation beam or field. For treatment of breast cancer using IMRT or an IMRT-like technique, patients who previously would have had more marked acute and late toxicity because of difficult anatomy, such as a large breast or marked change in slope of the breast tissue across the treatment volume, modulating the intensity of the treatment beam and minimizing the

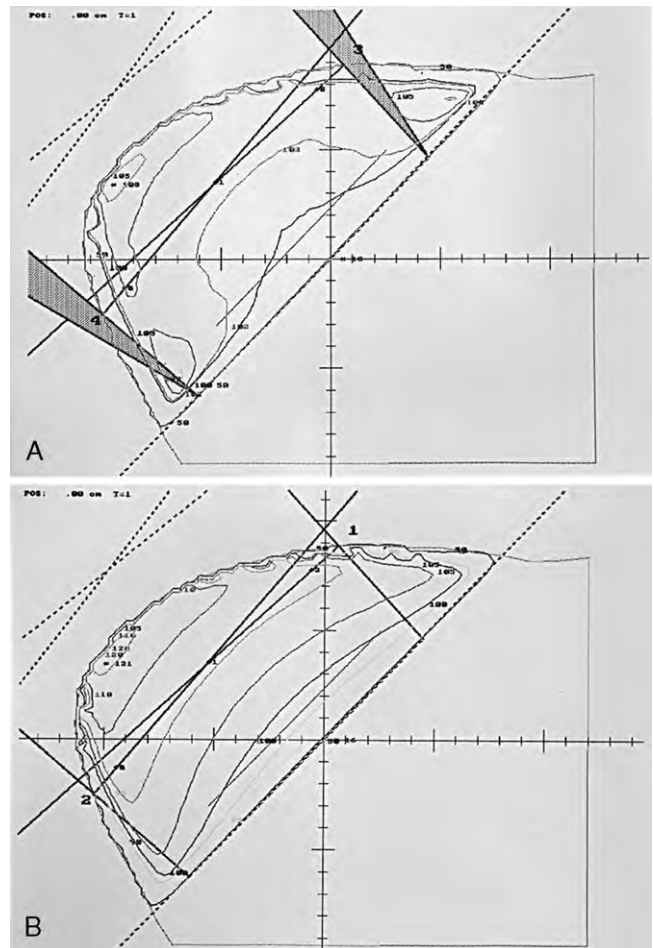

Figure 26-12 A, Computer-generated treatment plan of a breast using 6-MV photon therapy with the beams arranged tangential to the chest wall. A wedge (triangular beam-shaping device) is used in each field to compensate for the smaller separation of the anterior aspect of the breast. B, The same patient's treatment plan without wedges. The lines (and superimposed numbers), isodose lines, connect points of equal dose. If, for example, 100% of the dose is planned to encompass the whole breast, A (with wedges) shows that small areas of the breast anteriorly and laterally will receive 105% of the prescribed dose. B shows that, anteriorly, the same breast would receive 121% of the prescribed dose without the use of wedges. Therefore, wedges allow a more uniform dose distribution.

inhomogeneity across the patient's breast translates into decreased skin reaction and, potentially, decreased late effects (discussed later).

Why should a linear accelerator be used?

For the initial, whole-breast portion of treatment, 6-MV photon therapy generated by a linear accelerator generally is employed. The 6-MV photons provide an optimal balance between skin sparing and nearly full-dose deposition to 1.0 to 1.5 cm below the skin surface. (Higher energies underdose the superficial breast tissue; cobalt 60 therapy gives a higher skin dose and may compromise cosmesis.) The 6-MV photons have a slight advantage over 4-MV photons in that the

homogeneity of dose distribution usually is improved for the patient of average or larger breast size.

Should the entire breast be treated uniformly, or is a boost dose important?

After completion of whole-breast radiotherapy to a dose of 4500 to 5000 cGy, a boost to the area of the original tumor generally is employed (Figs. 26–14 and 26–15). The boost is used for two reasons. First, the area of the original lesion has been shown to have the highest bulk of microscopic residual disease.⁴⁹ Clinically, this correlates with the observed patterns of recurrence—mostly at or near the index lesion.^{50–56} Second, hypoxia from surgically disturbed vasculature in the tumor bed may also require an increased dose to eradicate microscopic residual disease¹¹ (see prior discussion regarding oxygen effect). Therefore, a higher total dose to the initial tumor bed decreases recurrence rates.⁵⁷ The higher dose is limited to a small volume (the volume at highest risk for recurrence)

Figure 26–13 Intensity-modulated breast field showing the multileaf collimation (*jagged lines*) to modulate areas of the breast (decrease the dose) in the thinner areas that would otherwise receive a higher dose.

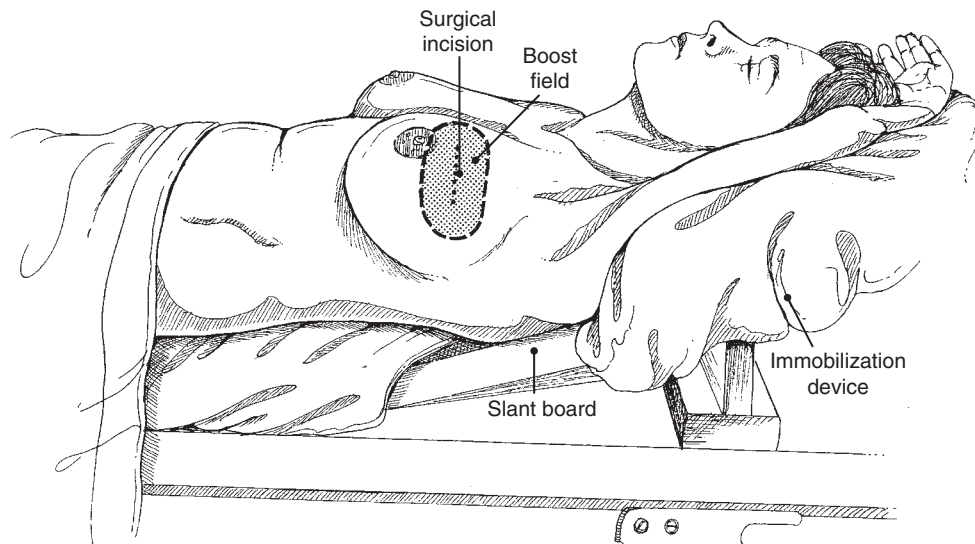

Figure 26–15 Diagram of an electron boost portal as viewed on the skin. If clips have not been placed in the tumor bed, a 3-cm margin is placed around the incision, as shown here. If CT scan planning is used; the tumor bed (boost portal) is localized from the postoperative changes in the tumor bed on CT scan.

because doses above 5000 to 6000 cGy to the whole breast result in an increased incidence of breast edema and poor cosmesis.^{58–60} The boost may be delivered using external-beam techniques (most commonly electron-beam therapy from a linear accelerator, as shown in Fig. 26–14), three-dimensional conformal therapy using photons or IMRT, or brachytherapy or intraoperative radiotherapy.^{55,56,61–64} Electrons, as opposed to photons, have a discrete range that is dependent on their energy. Beyond their useful range, the dose falls off abruptly. Thus, they can be selected to treat the desired tumor volume homogeneously yet spare underlying normal tissues.

Brachytherapy is the placement of radioactive material into or next to the tumor or tumor bed. In breast radiotherapy,

Figure 26–14 Simulation film of a boost portal for use in radiation therapy of the breast. Radiopaque clips were placed in the tumor bed at the time of surgery. A 1-cm margin is usually placed around the clips. The incision is also included in the field. Only the area within the circle will be treated. The hatched area outside the circle is not treated.

temporary single- or double-plane implants of iridium 192 can be placed into the tumor bed to deliver the intended dose, 1500 to 2000 cGy over 1½ to 2 days (low-dose-rate brachytherapy) or about 680 cGy divided between two brief treatments 6 hours apart using a high-dose-rate remote afterloader. Low-dose-rate brachytherapy requires local anesthesia, patient hospitalization, limited visitors, and precise identification of the tumor bed (because the dose falls off very rapidly in proportion to the inverse square of distance). The high-dose-rate brachytherapy avoids hospitalization and personnel exposure and provides similar control rates. When performed by an experienced radiation oncologist, interstitial brachytherapy and electron-beam therapy boost result in similar local control.^{64–68} The electron-beam technique is more commonly used for the boost portion of the treatment because the patient remains an outpatient, the procedure is not invasive, and cosmesis is as good or superior.^{26, 64–68}

Treatment planning for the electron-beam boost can be accomplished clinically with ultrasound guidance or CT scan planning.^{69–71} First, the surgical tumor bed must be localized. This is most accurately accomplished if clips have been placed in the biopsy cavity at the time of surgery⁷² (see Fig. 26–14). If surgical clips, ultrasound guidance, or CT scanning is not available, the clinician must use the incision in combination with the preoperative mammogram or ultrasound (see Fig. 26–15). Therefore, the radiation oncologist must know the position of the surgical incision relative to the location of the preoperative tumor. The treatment angle is then chosen (clinically or with ultrasound or CT) to provide the shortest path to the tumor bed and the incision. For electron-beam therapy, the depth from the skin surface to the base of the tumor bed is measured to determine the appropriate electron energy because the range of penetration varies with the energy of the electrons. (See prior discussion of electrons.) Although theoretically the most accurate,⁷³ CT scan–based planning has not been shown to reduce the local recurrence rates compared with the other planning methods.

Cerrobend blocking can be used to individualize the shape of the treatment portal and prevent treatment of more breast tissue than is medically necessary (Fig. 26–16). Cerrobend, a combination of cadmium, bismuth, and tin, has the ability to attenuate a treatment beam almost as effectively as lead and melts when heated to moderate temperatures. It can be poured into molds (and hardened) into any shape desired, further customizing treatment.

Figure 26–16 Left, Headrest used for patient positioning, reproducibility, and comfort. Right, Cerrobend has been poured and cut to the customized shape for the patient's boost portal. Only the oval area inside (not covered by) the Cerrobend will receive the prescribed dose.

Is the volume to be treated always the same?

For patients who have DCIS or stage I invasive carcinoma, the risk for a regional nodal recurrence is 0% to 5%,^{51,63,74–76} and only the breast is treated (most commonly, two portals whose central axes are aimed tangential to the chest wall). For stage II invasive carcinoma, whether after conservative surgery or mastectomy, each patient's risk for regional nodal recurrence is evaluated individually. If the risk for nodal recurrence is greater than 10% to 15% or regional nodal irradiation may result in clinical benefit, simulation of the breast or chest wall and relevant nodal region is advised. The specific indications for regional nodal irradiation are considered in the discussions of invasive carcinoma and the postmastectomy patient.

If regional nodal irradiation is to be delivered in addition to whole-breast radiotherapy, treatment planning becomes a more complex process. Lack of attention to precise matching of the nodal and breast portals can result in underdosing or overdosing of a region. Overlap at the skin surface has resulted in classic “matchline fibrosis,” a ridge of fibrosis that may be associated with telangiectases and impaired cosmesis.^{58–60,77}

If the supraclavicular region is to be treated, usually the superior border of the breast tangents is lowered to the angle of Louis. The medial, inferior, and lateral tangent borders generally are unchanged. The inferior border of the supraclavicular field is the superior border of the breast portal. The medial border usually is placed at the ipsilateral pedicles. The lateral border is generally at the medial edge of the humeral head. Superiorly, the field is usually placed at the inferior aspect of the cricoid cartilage (Fig. 26–17).

If the axillary apex is to be treated, the lateral border of the supraclavicular field is generally extended to cover the posterior axillary skin fold. The lateral and inferior borders of the axillary field are those of the supraclavicular field. The medial border includes the chest wall and 1 cm of lung (to allow for respiratory movement), and the superior border is placed along the clavicle.

The internal mammary field is usually 6 cm in width. The medial border extends 1 cm past midline (toward the contralateral breast). Laterally, it abuts the medial edge of the tangential breast field. Usually, it extends superiorly and inferiorly to cover the first through third intercostal spaces. The medial border of the breast tangents and inferior border of the supraclavicular fields are determined by the borders of the internal mammary field.

Several technical discussions of the simulation for regional nodal irradiation have been published.^{78–80} Inclusion of the nodal region at simulation and treatment increases the length of time required for simulation, daily setup, and treatment. (See the discussion of the indications for regional nodal irradiation in the invasive carcinoma and postmastectomy portions of this chapter.)

Does the entire breast require treatment?

Whole-breast radiation therapy is the standard of care for treatment of DCIS and early invasive carcinoma after lumpectomy or wide excision. For selected patients with early invasive ductal carcinoma, partial-breast irradiation may yield similar

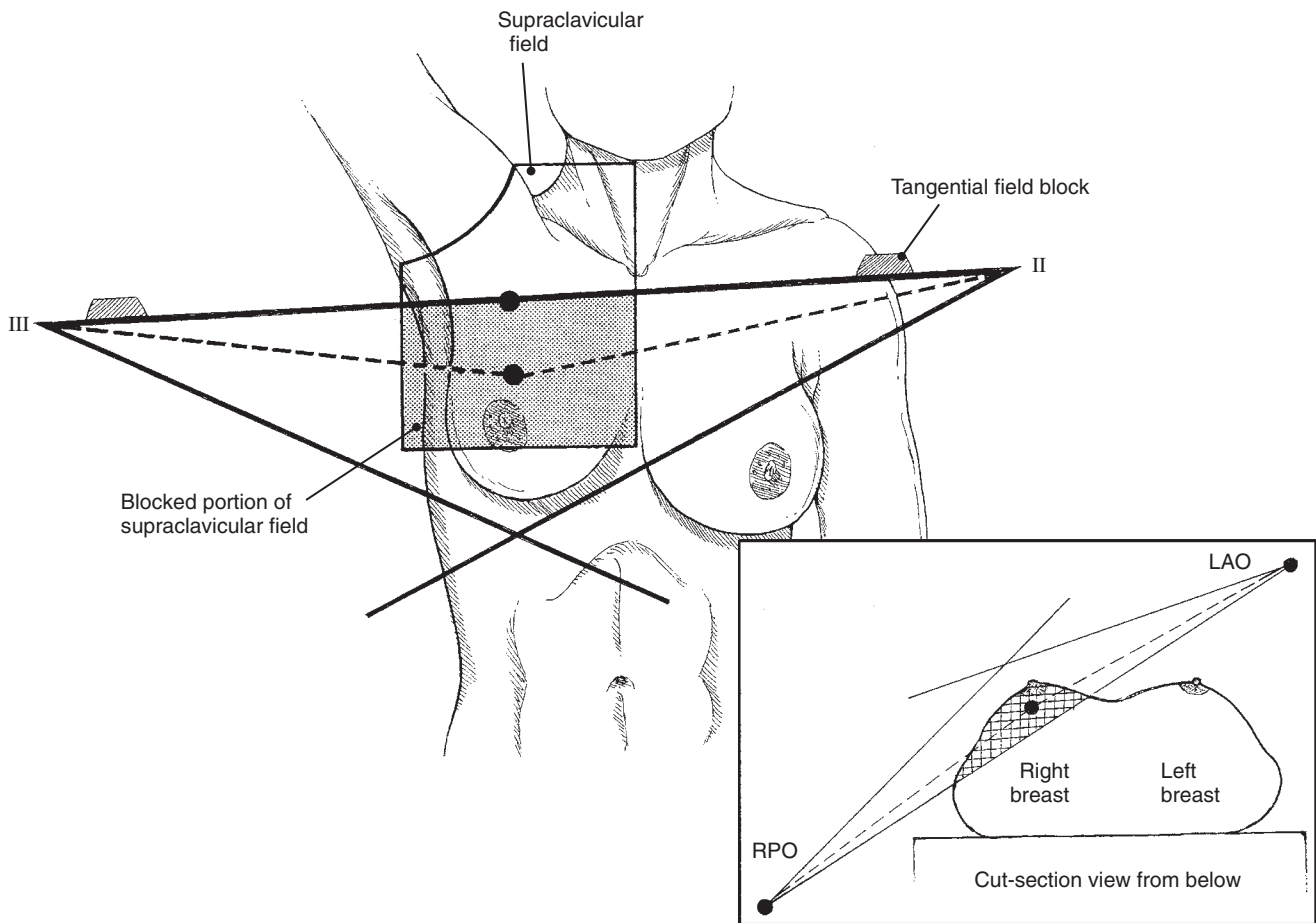

Figure 26-17 Schematic diagram of radiotherapy portals when irradiation of the supraclavicular lymph nodes is planned. The supraclavicular portal (*shaded region*) is treated from an anterior or anterior oblique approach. Note that the superior edge of the breast tangent portals is straight (horizontal) so that there is no overlap between the supraclavicular and breast portals. LAO, left anterior oblique; RPO, right posterior oblique.

local control and survival with greater convenience, similar or improved cosmetic result, and similar or reduced side effects. Partial-breast irradiation can be delivered with three-dimensional conformal radiation therapy,⁸¹ IMRT, or low-dose-rate or high-dose-rate interstitial brachytherapy using multiple catheters or using a newer single catheter with a balloon placed into the tumor bed. Partial-breast irradiation can also be delivered by intraoperative radiation therapy (IORT) using electron-beam therapy or x-rays. Each technique has its own advantages and disadvantages.

IMRT is the most recent and most sophisticated version of three-dimensional conformal radiation therapy.⁴⁸ Using advanced computerized treatment planning software, a target or treatment volume is delineated, and dose limitations are prescribed to the adjacent normal tissues. A treatment plan is constructed to deliver the prescribed dose to the tumor or tumor bed precisely while meeting the usual tissue constraints. To accomplish true IMRT to a breast tumor bed, additional fields and longer treatment times are used than with the standard two tangential fields. The potential advantages include more even dose distribution across the intended target, lower dose to the presumed normal surrounding breast tissue, and therefore, possibly better cosmesis and decreased acute toxicity (i.e., erythema and edema). The potential

disadvantages include a larger volume of adjacent normal tissue exposed to a lower dose of radiation and more leakage radiation, which could yield a higher risk for later nonbreast cancer malignancies.

Interstitial breast brachytherapy can be performed at the completion of the lumpectomy or up to several weeks later. A series of catheters are implanted into the breast tumor bed, and radioactive material is subsequently placed into the catheters based on the treatment plan so that the tumor bed with a 1- to 2-cm margin is irradiated.⁸² Low-dose-rate brachytherapy delivers a slow continuous dose of radiation, usually with iridium 192 implanted in the catheters over about 96 hours.⁸³ The patient is in the hospital in an “isolation room” during this time. The entire course of treatment is delivered in 4 days and, including surgery and planning, can be completed within 10 days to 2 weeks of surgery. Because of the isolation during treatment, the cost of hospitalization, and the development of high-dose-rate brachytherapy, low-dose-rate therapy is less frequently performed.

High-dose-rate brachytherapy uses a radioactive source (most often iridium 192) with a higher activity and delivers therapy in multiple short treatments on an outpatient basis. The source remains in a lead-lined container, usually in the radiation therapy department. The breast catheters are

connected to the high-dose-rate machine, and treatment is delivered in about 10 minutes. For partial-breast therapy, an average of 10 treatments are prescribed and delivered as 2 treatments per day, separated by 6 hours. The total treatment course is completed in 5 days.^{83,84} Advantages of high-dose-rate brachytherapy include the shorter course of therapy compared with conventional external-beam radiation therapy, the lack of hospitalization required, and lack of personnel exposure.

Balloon catheter–based brachytherapy using the MammoSite device (Proxima Therapeutics, Marietta, GA) is a subset of high-dose-rate brachytherapy.⁸⁵ The dose and treatments are similar to those described earlier.⁸⁶ The applicator is a single catheter with an expandable balloon at one end. The applicator may be placed into the tumor bed at lumpectomy or about 2 weeks later once the final margins and pathology are available (Fig. 26–18). The balloon is inflated to fill the cavity and create a uniform spherical dose distribution providing a full dose at 1 cm beyond the edge of the balloon.

IORT uses a mobile linear accelerator to deliver electron-beam therapy^{87,88} or uses a mobile x-ray device. The applicator can be placed directly into the tumor bed after lumpectomy, and the surrounding normal tissue (i.e., skin and chest wall) can be displaced or shielded to improve the therapeutic ratio. A single relatively high-dose treatment is performed. The advantages include accurate localization of the tumor bed, the ability to shield adjacent tissue, and the short treatment course. The disadvantages include the lack of final pathology and margin status, the possible fibrosis after a single high dose, and the potential impact on wound healing. In one series, the entire quadrant was treated after quadrantectomy, which was shown to reduce optimal cosmetic result in a

randomized trial; hence, the primary end point in this series is not cosmesis.

The limiting step for partial-breast treatment is appropriate patient selection. A discussion of the selection criteria and available results is provided in the section on invasive breast cancer.⁸⁹

What does the patient experience during each fraction of radiation?

Patients typically spend about 15 to 20 minutes in the treatment room. Most of that time is spent in placing the patient in the identical position she was in at simulation. Each treatment room should have overhead, left, and right lateral lasers. With the patient in the supine treatment position (on a slant board or resting in a polystyrene or other mold, if used at simulation) and with the ipsilateral arm abducted, the lasers (calibrated each morning) are aligned with the tattoos placed on the patient's skin at simulation. The linear accelerator is then rotated to the treatment angles determined at simulation. The light field is aligned with the field borders placed on the patient's skin at the conclusion of simulation (tattoos or carbolfuchsin). Before the first treatment, and then weekly, a verification film or digital image is taken on the treatment unit to confirm that the treated field internally matches (and continues to match) the simulated field. The treating radiation oncologist verifies, in the treatment room, the field set by the technologist and subsequently views and approves the verification films. Before treatment is delivered, the parameters set by the technologists operating the treatment unit (e.g., angles of the fields, appropriate field dimensions, and treatment time) are verified by a computer-based quality assurance

system. For breast therapy, treatment takes about 1 minute per field. With IMRT or more than two fields, the treatment and setup time increase. After the first field is treated, the technologists reenter the treatment room and set the angles for the second field. The quality assurance steps in the treatment room and at the computer console are repeated.

While treatment is in progress, the technologists are outside of the treatment room at the computer console. Audio and video monitors allow constant observation of and communication with the patient. During treatment, the patient will not experience any treatment-specific sensations. She will hear mechanical noises from the machine. When she leaves the treatment room, she will feel no different than when she entered.

How precise is radiation therapy and how is its quality ensured?

Radiation therapy is extremely precise, generally to within 2 mm in both length and width. To ensure this precision, in addition to physicians and technologists, a complement of physics staff should always be on site: medical physicists, dosimetrists, and block cutters. All equipment, including the linear accelerators, simulators, and lasers, should undergo rigorous daily calibration and quality assurance testing before treatment of the first patient.

Weekly verification films confirm the precision of the machine and the proper positioning of the patient. Facilities that adhere to meticulous technique review their quality assurance processes in regularly held meetings attended by clinicians, physicists, dosimetrists, technologists, and nurses.

DUCTAL CARCINOMA IN SITU

What treatment options are available for ductal carcinoma in situ?

Until relatively recently, the recommended treatment option for DCIS—mastectomy—created a paradox of logic. Certainly, mastectomy yielded local control rates of 96% to 100%.^{90–94} The cosmetic and psychological cost of the procedure, however, seemed unnecessarily high, especially when more aggressive invasive carcinomas were being cured by conservative surgery and radiation therapy. Yet, progress was stymied by two misperceptions: (1) DCIS was thought to be inherently radioresistant, and (2) the occasional pathologically observed microscopic multicentricity of DCIS was thought to preclude local control using radiation therapy.^{92,93,95–98} However, as the routine use of mastectomy was re-evaluated, the presentation of DCIS also was changing. Carcinoma in situ is now the most frequently detected breast cancer presenting as a nonpalpable radiographic abnormality. The smaller volume of disease at diagnosis and increasing demand for breast preservation has allowed the option of breast-conserving surgery with or without radiation therapy to expand to DCIS.

The intent of radiation therapy in addition to excision is to improve local control by eradicating any occult residual microscopic in situ or invasive carcinoma left behind after

cosmetically optimal local excisions. The wide range in recurrence rates^{93,96,99–111} after conservative surgery or radiation therapy, or both, shows that the term *ductal carcinoma in situ* encompasses a spectrum of diseases. As discussed in Chapters 8 and 23, several investigators have worked to re-stratify and classify in situ lesions into prognostically useful groups intended to help guide therapy. Currently, three treatment options may be offered, depending on the perceived biologic aggressiveness of the lesion: (1) wide excision alone, (2) wide excision followed by breast radiotherapy, or (3) mastectomy with or without reconstruction.

Which patients benefit from radiation after breast-conserving surgery?

Although there probably is a subgroup of small, biologically less aggressive, well-defined, unifocal lesions of DCIS that can be adequately treated with wide excision alone (without radiotherapy), the specific criteria to define them have yet to be unambiguously established.^{95,99,112–116} In the literature, depending on the patient population studied, recurrence rates may approach 16% to 59% at 3 to 7 years after excision alone.^{95,99,111,117–120} Lagios and colleagues,^{107,121} based on a nonrandomized prospective series, and Silverstein and coworkers,^{122,123} based originally on a retrospective series, have proposed prognostic criteria for treatment recommendations.

In 1989, Lagios and colleagues¹⁰⁷ described the care of 79 selected women who underwent wide excision alone for treatment of nonpalpable mammographically detected microcalcifications no larger than 25 mm that proved histologically to be DCIS. The margins of resection had to be free of disease. A postexcision mammogram documenting complete excision of microcalcifications was mandatory. The patient had to be compliant with follow-up evaluation and the breasts considered “favorable for clinical and mammographic evaluation.” Meticulous step-section processing, not sampling, of the resected breast tissue was performed. The average lesion measured only 6.8 mm. At 4 years, 10% of patients had developed a local (in the same quadrant as the index lesion) recurrence; in half of this 10% the recurrence was invasive, and in the other half it was noninvasive. The authors retrospectively stratified the lesions based on grade and presence or absence of comedonecrosis. At 2 years, high-grade lesions with comedonecrosis had a 19% risk for recurrence. None of 33 low-grade lesions of the non-necrotic cribriform or micropapillary types had recurred.

Silverstein and coworkers used size, grade, and presence or absence of necrosis and retrospectively developed the Van Nuys Prognostic Index (VNPI) to guide treatment decisions for DCIS.^{122,123} One to three points each for size, grade, and necrosis and width of the surgical margin are combined to achieve a score ranging from 3 to 9. The higher score portends a higher risk for recurrence, and the score is used to assess risk and propose therapy. In 2001, the VNPI was expanded to include age. The University of Southern California (USC) VNPI score now ranges from 4 to 12 points (Table 26–2). The risk for recurrence increases with the number of points. Based on this retrospectively devised scoring system, Silverstein and coworkers recommend radiation therapy after wide local resection, or the preferred oncoplastic resection, for patients with USC VNPI scores of 7, 8, or 9.¹²³ Excision alone is

Table 26–2 University of Southern California Van Nuys Prognostic Index Scoring System

Score	Pathology	Margin Width (mm)	Tumor Size (mm)	Age (yr)
1	Not high grade No necrosis	≥10	≤15	>60
2	Not high grade Necrosis	1–9	16–40	40–60
3	High grade	<1	>40	<40

Data from Silverstein MJ. An argument against routine use of radiotherapy for ductal carcinoma in situ. *Oncology* 2003;17:1511–1533.

recommended for scores of 4, 5, or 6. Mastectomy is recommended for scores of 10, 11, or 12.

The prospective randomized clinical trials described below do not agree with the Van Nuys recommendations. A benefit in risk for recurrence is demonstrated in all of the groups with DCIS compared with excision alone. There are several valid criticisms of the USC VNPI recommendations. First, the study began as a retrospective analysis and spans 30 years, 1972 to 2003, a time when many changes in the details of breast surgery, mammography, and radiation therapy occurred. The treatment options (i.e., wide excision or wide excision and radiation therapy) were not used equally throughout the study. Radiation therapy was delivered more often earlier in the study years when diagnostic (including mammography) and therapeutic technologies were less advanced.¹¹³ Post-biopsy mammography or specimen radiography, routine margin assessment, and re-excision when necessary have lessened the burden of carcinoma remaining after excision.^{97,124,125} With these technologic and clinical advancements, current VNPI 8 and 9 lesions, for example, might have the volume of microscopic residual disease following surgery lowered to a level that can be controlled with wide excision and radiotherapy.

Second, the meticulously detailed sectioning method used by Silverstein and Lagios and their coworkers yields a more highly selected group of specimens compared with the more common standard sampling methods. Applying the VNPI criteria to lesions processed by standard methods could understage a lesion and lead to undertreatment, a higher recurrence rate, and an increased risk for invasive carcinoma at recurrence.

Third, size, grade, and margin width are difficult to reproducibly assess.^{111,113,115,116} At present, interobserver variability may result in disparate treatment recommendations for a given specimen. Only one study has applied the Van Nuys criteria prospectively.¹²⁶ Thus, although it is possible that the factors delineated by Silverstein and colleagues are predictive, a prospective randomized trial is needed to validate the ability of the VNPI to guide treatment recommendations. Compiling the data from all patients with DCIS treated with breast-conserving surgery, those with the least risk for recurrence after excision alone have the following:

- Nonpalpable DCIS
- Low-grade DCIS
- Free margins, generally at least 1 cm
- Small lesions, less than 1.5 to 2.5 cm, depending on the study and the pathologic technique

Additional selection criteria for wide excision alone include the following:

- A lesion detected radiographically, usually as microcalcifications that, if recurrent, would theoretically be detected more easily and earlier
- A compliant patient who will undergo serial screening and clinical follow-up evaluations as prescribed

However, even in this best prognostic group, the studies described subsequently continue to show a statistically significant improvement in local recurrence with postoperative radiation therapy.

What evidence is there that breast-conserving surgery and radiation therapy are effective treatment for DCIS?

Four published prospective randomized trials and numerous retrospective studies support the use of limited surgery and radiation therapy for DCIS.^{98,99,117–120,127–133}

The National Surgical Adjuvant Breast Project (NSABP) Protocol B-17 randomized the care of 818 women who had DCIS to wide excision alone or wide excision and radiation therapy. Patients were accrued from 1985 to 1990.⁹⁹ Stratification variables included age, axillary dissection, histology (DCIS or DCIS with lobular carcinoma in situ [LCIS]), and method of detection (palpation, mammography, or both). All patients had free surgical margins. With a median follow-up of 57 months, the results indicate a statistically significant decrease in any type of breast cancer recurrence in the treated breast at 5 years for women receiving radiation therapy: 7% versus 16% ($P < .001$). Noninvasive recurrences were reduced from 10.4% to 7.5% ($P = .055$), and invasive recurrences were reduced from 10.5% to 2.9% ($P < .001$) with radiation therapy. Updated results, now with 12 years of follow-up, confirm the reduction in recurrence when radiation therapy follows wide excision. Patients who received wide excision followed by radiation therapy had an overall recurrence rate of 16% at 12 years, compared with 32% at 12 years for patients who did not receive radiation therapy.¹³¹ A retrospective subset analysis of pathologic features including grade, size, and margin status documented the benefit of radiation therapy for *all* groups in the NSABP study.¹¹² However, this study has been criticized for its lack of prospective pathologic stratification, mammographic-pathologic correlation, and serial subgross sectioning.¹¹⁶

The European Organisation for Research and Treatment of Cancer (EORTC) 10853 trial randomized 1010 women with DCIS to wide excision alone or wide excision followed by radiation therapy. The design was similar to that of the

NSABP B-17 trial.¹³² At a median follow-up of 4 years, as published, and at 7-year follow-up in a subsequent presentation, there is a statistically significant reduction in overall, noninvasive, and invasive recurrence in the group of women receiving radiation therapy after wide excision. At 7 years, the crude local recurrence rates were mastectomy, 2%; conservative surgery alone, 31%; and conservative surgery with radiotherapy, 13%. Young age and involved margins increased the risk of recurrence. Radiation therapy after conservative surgery statistically reduced local recurrence rates in all histologic subgroups; the largest risk reduction was noted for DCIS with comedocarcinoma.^{132a}

The United Kingdom Coordinating Committee on Cancer Research (UKCCCR) prospectively randomized 1700 patients with DCIS, in a 2 × 2 factorial design, to breast-conserving surgery followed by close surveillance and tamoxifen, radiation therapy, or both tamoxifen and radiation therapy.¹³³ Again, postoperative radiation therapy decreased the risk for ipsilateral recurrence of DCIS and invasive carcinoma compared with no additional therapy. Tamoxifen alone affected only recurrence of DCIS. At a median 52 months, radiation therapy statistically significantly reduced the risk for an invasive and noninvasive ipsilateral recurrence. The magnitude of reduction in risk parallels that seen in the NSABP B-17 and the EORTC trials. Six percent of patients who received radiation therapy, as compared with 14% of women who did not receive breast radiotherapy, experienced a recurrence.

NSABP B-24 followed B-17 and, accepting the proven benefit of radiation therapy after breast-conserving surgery, randomized 1800 women to radiation therapy alone or radiation therapy with tamoxifen.^{129,131} There was not a wide excision-alone arm. In contrast to all of the other prospective randomized trials discussed, free margins were not required. Published data at 5 years and 7 years continue to document 85% to 90% local control rates with the addition of radiation therapy. The benefit of tamoxifen remains controversial. In this study, in a subset analysis, the benefit was seen only for DCIS expressing estrogen receptor (ER).

NSABP B-06,⁹⁸ a three-arm trial comparing lumpectomy with or without radiation therapy with mastectomy, was designed for early-stage invasive carcinoma of the breast. However, on central review of the pathology specimen (after enrollment), it was noted that 76 cases of DCIS had been entered in error and randomized to lumpectomy with or without radiation therapy. Although the cases were not stratified by size or grade (free margins were required), the series forms an unintentional prospective randomized database. After 7 years of follow-up, the patients with DCIS randomized to receive radiation therapy enjoyed a statistically significant reduction in local recurrence rate (7% vs. 43%; $P = .01$).

One retrospective multicenter series¹³⁴ simulated a contemporary patient population by selecting the 110 patients who presented with nonpalpable, mammographically detected DCIS, who were treated with gross total excision and radiation therapy. At 5 and 10 years, the local recurrence rates were 7% and 14%, respectively, with a 10-year cause-specific survival rate of 96%. Recurrences were noninvasive in 60% of patients and invasive in 40%. The median time to local recurrence was 5 years, although the range was wide (2 to 15 years). At 4.5 years after salvage therapy, 14 of 15 patients had no evidence of disease. No difference in local recurrence after

radiation therapy was found when results were stratified by presence or absence of necrosis or nuclear grade. Recurrence rates were increased with positive or close (<2-mm) margins (29%) compared with uninvolved margins (7%). Women younger than 50 years of age had a higher recurrence rate (25%) compared with older women (2%). The rates did not reflect a difference in margin status, grade, or necrosis.

Compiling the available prospective and retrospective series employing wide excision and radiation therapy for treatment of DCIS, the following conclusions can be drawn:

1. At 10 years, about 85% of patients undergoing conservative surgery followed by radiation therapy have preserved their breasts.^{95,99-101,103-105,118,119,134-138}
2. At 10 years, overall survival is 92% to 100% for patients treated by conservative surgery and radiation therapy.^{95,99,101,115,134,135,137,138}
3. Sixty to 100% of recurrences are in the vicinity of the original lesion (true or in-field recurrence).⁹⁹
4. About 50% of all recurrences are invasive carcinoma and 50% noninvasive carcinoma.^{97,99-101,132-135}
5. Residual suspicious microcalcifications on a postexcision mammogram should be resected and not treated solely by radiation therapy.^{102,103}
6. The presence of comedonecrosis may increase the recurrence rate.^{112,118,134,136}
7. Involved or close margins increase the risk for recurrence after radiation therapy in most studies.^{112,117,118,120,127,134,138,139} In the NSABP B-24 study, involved margins did not increase the likelihood of recurrence.^{129,136}
8. High grade and larger size have not consistently correlated with an increased risk for recurrence.^{112,134,135} However, Vicini and Neuschatz have found size to be prognostic.^{120,139}
9. Young age may be an independent prognostic factor for local recurrence after radiation therapy for DCIS.^{102,134} Vicini and Recht propose that younger patients may have more adverse prognostic pathologic factors, such as larger size of the DCIS and smaller resections for the amount of DCIS in an attempt to optimize the cosmetic outcome.¹⁴⁰
10. The long-term outcome of local excision for DCIS that recurred after radiation therapy and wide excision is unknown. Thus, at present, recurrences following limited surgery and radiation therapy either should be treated by mastectomy (because long-term local control and survival approach 100% after salvage mastectomy) or should be part of a carefully controlled clinical trial.
11. Radiation therapy should be delivered to the entire breast. Partial-breast irradiation is under investigation and should be offered, at the present time, only as part of a clinical trial.

Are there additional selection criteria for treatment of ductal carcinoma in situ followed by radiation therapy?

In addition to disease-related factors, as just discussed, the host-related criteria described previously need to be considered.

What volume should be treated?

Only the breast requires radiation therapy after conservative surgery for DCIS. Because axillary lymph node metastases are reported in less than 1% of patients (when axillary dissection is performed) and nodal recurrence is equally rare, there is no need for regional nodal irradiation.

Because of the possibility of microscopic foci of residual carcinoma (separate from the index lesion), as learned from patients with DCIS who have undergone mastectomy, and because of the risk for recurrence in quadrants distant from the original lesion after conservative surgery (with or without radiation therapy), the entire breast requires treatment. However, because two thirds of the recurrences are seen at the site of the index lesion (see discussion of boost), the tumor bed, with its highest concentration of potential microscopic residual disease and, possibly, hypoxia after surgery, should receive a greater total dose than is delivered to the adjacent breast tissue. In select cases in which the DCIS is small, the margins are well-free (that is, 1 cm), or no residual carcinoma is found on re-excision, the boost *may* be omitted.

Summary

Wide excision with radiotherapy is an effective treatment for DCIS. Overall, the 10-year survival rate, including salvage therapy, is 92% to 100%, compared with 96% to 100% for immediate mastectomy. Because 80% to 90% of women preserve their sensate breast and have satisfactory cosmesis, most patients and physicians have accepted radiation therapy as a reasonable option for the treatment of DCIS. Mastectomy, however, remains an appropriate alternative for patients who want the lowest possible risk for recurrence and are willing to sacrifice their breast. Improved selection will likely yield even lower rates of recurrence and higher efficacy of salvage therapy in the future. Each patient's care must be approached in a multidisciplinary fashion and the potential risks and benefits of all potential treatment options discussed.

Additional patient factors such as life expectancy, comorbid medical problems, and family history should be used in the decision process. If excision or radiation therapy is chosen, meticulous mammographic-pathologic correlation is required. Re-excision of involved or close margins is strongly recommended whenever possible. Attention to the myriad details of radiation therapy technique must be routine.

INVASIVE CARCINOMA

Breast preservation for patients with invasive carcinoma (which historically anteceded breast-conserving surgery for in situ disease) became an achievable goal with the advent of megavoltage-quality radiation. Treatment of the breast parenchyma with a relatively lower dose to the skin (and therefore better long-term cosmesis) enabled the role of surgery for breast cancer to evolve from the classic Halsted mastectomy to tumor-directed breast-conserving surgery with adjuvant radiation therapy. In addition to anecdotal reports and retrospective analyses, randomized trials that began in the 1970s established the option of conservative surgery and radiation therapy as an effective treatment for stages I and II invasive carcinoma of the breast.^{51–56,141–143}

What evidence is there that breast-conserving therapy is as effective as mastectomy?

Six prospective randomized trials have compared conservative breast surgery and radiation therapy with mastectomy.^{51–56,143,144} The studies differ in terms of patient selection, surgical and radiation therapy techniques, and the use and types of chemotherapy, but they clearly demonstrate that breast preservation is possible without compromising survival (Table 26–3). However, it is important to review the details of the studies to understand the manner in which patients were selected and treated as they relate to outcome.

Table 26–3 Results of Prospective Randomized Trials Comparing Conservative Surgery and Radiation Therapy with Mastectomy

IGR, Institut Gustave Roussy; NCI, National Cancer Institute; NSABP, National Adjuvant Breast and Bowel Project; US, United States; EORTC, European Organisation for Research and Treatment of Cancer; DBCG, Danish Breast Cancer Group; M, mastectomy; CS-RT, conservative surgery and radiotherapy; N0, no involvement of lymph nodes; N1, moveable involved axillary lymph nodes.

Probably the most influential trial, the NSABP B-06 trial,^{51,144-146} conducted from 1983 to 1987, accrued 2105 women and randomized one third to treatment by lumpectomy alone, one third to lumpectomy and breast radiotherapy, and one third to mastectomy. After 15 years of follow-up, and after a National Cancer Institute audit, 1039 patients remained eligible and analyzable.^{144,146} Requirements of the trial included an invasive carcinoma of up to 4 cm in diameter. Axillary lymph nodes may have been involved or uninvolved. Levels I and II of the axilla had to be dissected. Importantly, the margins of resection were required to be free of carcinoma (in the lumpectomy groups) on microscopic examination. If the margins were involved, the protocol recommended that the patient undergo mastectomy. In the radiation therapy arm, 5000 cGy was delivered to the whole breast, without wedges (generally considered essential today to produce homogeneity of dose) or a boost. Regional lymph nodes were not irradiated. 5-Fluorouracil and melphalan were prescribed for all patients who had pathologically involved axillary lymph nodes. No significant difference was observed in either overall survival or disease-free survival between the lumpectomy plus radiation therapy group and the mastectomy group.^{144,146}

The five other prospective randomized series⁵²⁻⁵⁶ confirmed the NSABP conclusions and provided additional information regarding breast preservation therapy and survival:

1. The type of conservative surgical procedure, whether segmental excision,⁵¹ tumorectomy,^{53,55,56} or quadrantectomy,⁵² when followed by breast irradiation, does not affect survival.
2. Delivery of inadequate radiotherapy doses may compromise survival. In two trials from Guy's Hospital in London, wide excision (without axillary dissection) and radiation therapy were compared with mastectomy.¹⁴⁷⁻¹⁴⁹ Following wide excision, patients received 3800 cGy to the breast and 2700 cGy to the axilla. The breast-preservation group experienced a higher rate of ipsilateral breast and axillary recurrence, systemic failure, and death. In contrast, prospective randomized trials (see Table 26-3) that prescribed 4500 to 5040 cGy to the whole breast⁵¹⁻⁵⁶ (and, in most trials,⁵²⁻⁵⁶ a 1500- to 2500-cGy boost to the tumor bed) demonstrated no difference in survival between the mastectomy and breast-preservation groups.
3. Routine indiscriminate administration of regional nodal irradiation does not improve survival. Early on in the Milan trial (a study in which women with invasive carcinomas 2 cm or smaller were randomized to quadrantectomy, axillary dissection, and breast radiotherapy or radical mastectomy), patients with involved axillary lymph nodes received regional nodal irradiation.⁵² In the EORTC trial, patients with tumors up to 5 cm were randomized to mastectomy or tumorectomy with a 1- to 2-cm margin of normal-appearing breast tissue.⁵³ One half of the patients with involved axillary lymph nodes were randomized to receive regional nodal irradiation. In both the Milan and the EORTC trials, regional nodal irradiation did not improve survival. Better selection of the patient population for regional nodal irradiation (see later) *may* affect survival, but regional nodal irradiation for all patients who have involved axillary lymph nodes does not.

What factors affect the risk for local recurrence after conservative breast surgery and radiation therapy?

Variables that appear to affect local control include the residual tumor burden (as represented by the volume of tissue resected),¹⁵⁰ the presence of multifocal or multicentric disease,¹⁵¹⁻¹⁵⁴ the margin status,^{151,155-165} the use of radiation therapy,^{144,146,166-168} the presence of an extensive intraductal component,^{159,163,169-171} the dose of radiation therapy,^{57,147-149,158,169,172-174} the timing of radiation therapy,^{164,165,172,175-178} the use of chemotherapy,^{51,179-181} and patient age.^{57,144,151,155,163,166,182-186} Factors that are more debatable but that may affect local control include the presence of lymphovascular or perineural invasion,^{184,187-189} the presence of necrosis,^{183,189,190} the presence of an inflammatory infiltrate,^{144,188,191} and the ER and progesterone receptor (PR) status.^{161,192,193} Factors that do not appear to affect the rate of ipsilateral breast recurrence include tumor size (T1 vs. T2),^{51,177,193,194} the location of the carcinoma within the breast,^{195,196} the histology,¹⁹⁷⁻²⁰⁰ and the presence or absence of microscopic involvement of the axillary lymph nodes.^{51,56,177,194,201}

What data suggest that radiation therapy lowers local recurrence rates?

In the NSABP B-06 trial, after 15 years of follow-up, patients randomized to lumpectomy plus radiation therapy had a statistically significant reduction in ipsilateral breast recurrence compared with patients treated by lumpectomy alone (12% vs. 36%; $P < .001$).^{51,144} This reduction in risk for local recurrence with use of radiation therapy after breast-conserving surgery has been confirmed in all six prospective randomized studies.^{52-56,144} This statistically improved benefit in ipsilateral breast tumor recurrence persists in studies selecting the patients with the most favorable breast tumors in whom it was thought radiation therapy might have no benefit.

Is radiation therapy always necessary?

Some investigators have attempted to define a "good" subset of patients who have a very small risk for experiencing a local recurrence, even without radiation therapy.^{166,172,202} The most likely population should theoretically be those patients who have small, low-grade, well-differentiated (including pure tubular and medullary) invasive ductal carcinomas resected with wide margins, and, possibly, older patients who have ER-positive lesions who have undergone quadrantectomy.¹⁶⁶ However, four prospective randomized series of selected women who had invasive breast carcinomas smaller than 2.5 cm treated with or without radiation therapy demonstrate a statistically significant improvement in ipsilateral breast recurrence rates with the use of radiation therapy, regardless of the surgical procedure used (lumpectomy, sector resection, or quadrantectomy).^{166-168,203-207} A retrospective subset analysis of one series revealed that women older than 65 years who had quadrantectomy (with removal of skin and pectoralis fascia) and axillary dissection did not have a further reduction

in risk for local recurrence with the addition of radiation therapy.^{166,203} A survival benefit was seen for women with involved lymph nodes who received postoperative radiation therapy compared with those women with involved lymph nodes who did not receive postoperative radiation therapy and for those women with an extensive intraductal component on pathology who received radiation therapy.²⁰³ (See later discussion of the impact of age on recurrence rates.)

The NSABP completed a prospective randomized trial of 1009 women with invasive carcinoma 1 cm or smaller after lumpectomy, randomized to radiation therapy and placebo (RT), tamoxifen (tam), or both (RT/tam).¹⁶⁸ At 8 years, the risk for ipsilateral breast tumor recurrence was statistically significantly reduced in patients who received postoperative radiation therapy (2.8% RT/tam; 9.3% RT; 16.5% tam).

In a similarly designed prospective randomized trial conducted in Germany, 361 patients with pT1pN0, receptor-positive, grades I and II tumors were randomized to no further therapy, tamoxifen, radiotherapy, or both tamoxifen and radiotherapy. At 6-year follow-up evaluation, patients receiving breast-conserving surgery alone had a threefold greater incidence of local recurrence than patients who received radiation therapy. The authors concluded that even these heavily selected patients benefit from tamoxifen and breast radiotherapy.

Several single-arm prospective and heavily selected retrospective series document statistically increased or unacceptably high rates of local recurrence^{202,208–212} after breast conservation surgery alone (with or without hormonal therapy), whereas a few investigators recommend accepting the higher recurrence risk and withholding radiotherapy, most frequently in “elderly” patients.

At present, after segmental excision or lumpectomy for invasive carcinoma, radiation therapy is generally recommended. Given that postoperative radiation therapy affects local recurrence more than survival, the impact of local recurrence, both medically and emotionally, needs to be considered. Withholding radiation therapy is most appropriate for the physiologically elderly (as opposed to the chronologically elderly) patient. Data are maturing for two prospective randomized series and will help to better define those patients whose risk of recurrence may be only minimally acceptably increased with conservative surgery without radiation therapy.

What is the effect of multicentricity and multifocality?

Gross *multifocal* disease is defined as areas of macroscopic carcinoma separated by small amounts of normal breast tissue. Depending on the investigator’s definition, the lesions must be either in the same quadrant or within 5 cm of each other. Gross *multicentric* disease, in contrast, reflects gross lesions in two distinct quadrants or separated by more than 5 cm. Despite wide excision of all macroscopic disease and radiation therapy, multifocality or multicentricity may impose a higher local recurrence rate.^{151–154,213,214}

The increased recurrence rate most likely reflects the greater burden of microscopic disease remaining after resection of multicentric or multifocal carcinoma, as compared

with the burden of microscopic residual disease after resection of a macroscopically unifocal carcinoma. Even if the residual microscopic carcinoma could be controlled, the larger (or multiple physically distinct) segmental excisions required to obtain tumor-free margins will likely compromise cosmesis. One small series reports adequate control and acceptable cosmesis for multiple ipsilateral synchronous carcinomas.²³ Therefore, for cosmesis as well as control, mastectomy with or without reconstructive surgery generally is the preferred surgical option for multicentric disease. Similarly, diffuse malignant-appearing microcalcifications seen on mammography are often associated with diffuse carcinoma^{213–215} and should be treated as gross multicentric disease.

What is the effect of margin status?

The status of the margin of resection has been correlated with the risk for recurrence and should be assessed on all specimens. A margin may be classified as free (uninvolved or clear), close (within 1 or 2 mm), or focally or diffusely involved.^{157,158} Gross involvement is that which is apparent before microscopic examination. Both the EORTC¹⁵⁹ and Milan¹⁶⁰ breast conservation trials, as well as single-institution data,^{57,151,155,157,161–163} demonstrate a twofold to fivefold increase in local recurrence rates if microscopically involved margins exist. For example, in the data of Veronesi and colleagues,¹⁶⁰ involved margins, after tumorectomy, correlated with a 17% 5-year recurrence rate, compared with an 8.6% rate with free margins.

In some cases, greater doses of radiation therapy may compensate for involved margins of resection.^{158,169,174} Solin and associates¹⁵⁸ used a sliding-scale radiotherapy dose based on margin status and found no increase in recurrence rates with involved margins. Patients who had microscopically involved margins received a total dose of 6500 to 6600 cGy to the tumor bed, whereas patients who had free margins of resection received a total tumor bed dose of 6000 to 6400 cGy. The EORTC randomized women with a microscopically involved margin to a 10- or 26-Gy boost dose.⁵⁷ Because the tolerance of normal breast tissue sets the upper limit of the dose that can be delivered and still produce acceptable long-term effects and cosmesis, and because involved margins require a higher dose for optimal local control, free margins of excision should be obtained whenever possible. An increased boost dose appears capable of controlling a slightly higher volume of microscopic residual disease, such as a focally or microscopically involved margin of resection.

What is the effect of an extensive intraductal component?

The original definition of an *extensive intraductal component* (EIC), by Schnitt and coworkers in 1984,¹⁷⁰ required an invasive ductal carcinoma with (1) at least 25% of the primary tumor consisting of intraductal carcinoma and (2) intraductal carcinoma beyond the primary invasive carcinoma. The 5-year rate of ipsilateral breast cancer recurrence after radiation therapy in lesions with EIC was 23%, compared with 6% without EIC.¹⁷⁰ However, on subsequent reanalysis of the specimens with EIC, margin status was shown to be the

overriding prognostic factor.^{158,216} (Many of the patients were treated before our current appreciation of the importance of margin status.) Patients whose tumors had EIC but uninvolved final margins of resection had recurrence rates similar to patients without EIC. In contrast, patients who had intraductal carcinoma at the resection margin *and* EIC experienced up to a 50% recurrence rate. Thus, EIC in association with involved margins appears to be a marker for extensive microscopic residual intraductal carcinoma. Holland and associates²¹⁷ have provided detailed clinicopathologic data that explain the implications of EIC. The authors reviewed mastectomy specimens and simulated a lumpectomy; in cases in which EIC would have been diagnosed by lumpectomy, the residual microscopic disease was greater in amount and extended farther from the primary tumor mass.

Although the precise definition of EIC varies among other studies, Bartelink and associates,¹⁵⁹ Kurtz and colleagues,¹⁶³ and Smitt and coworkers¹⁷¹ confirm the increased recurrence rates after conservative surgery and radiation therapy for tumors that have EIC and involved margins. In contrast, the NSABP B-06 study,⁵¹ the Joint Center for Radiation Therapy study,¹⁷⁰ the EORTC series,¹⁶¹ and others^{218,219} document the efficacy of conservative surgery and radiation therapy in EIC-containing tumors if clear margins of resection are obtained. The work of Kurtz and colleagues¹⁶³ supports an increased risk for recurrence despite final clear margins. Their study, however, did not employ inked margins for pathologic analysis. Veronesi and associates found a statistically significant impact of EIC on local recurrence even in patients undergoing quadrantectomy.²⁰³

Preoperative and postoperative mammograms, as well as specimen radiography, are particularly valuable in the management of EIC. Because patients who are found to have EIC frequently have microcalcifications extending beyond the reference lesion on mammography, the distribution of the microcalcifications can be framed preoperatively by needle localization to guide the surgical resection. Postoperatively and before radiation therapy, mammography can be repeated to confirm total clearance.^{159,214} If mammographic and pathologic analyses reveal an optimal resection (no residual suspicious microcalcifications and free margins of resection), the patient is likely to have a salutary outcome from conservative surgery and radiation therapy. Re-excision should be employed if residual disease is suspected based on margin status or mammography if breast-conserving therapy is still desirable.

How does the volume of resection affect outcome?

Resection of larger volumes of breast tissue may result in lower rates of local recurrence,^{57,220} potentially at the cost of cosmetic appearance.²²¹ Veronesi and colleagues,^{150,203} in a prospective study, randomized 148 women to treatment by (1) quadrantectomy, axillary dissection, and radiation therapy (QUART) or (2) tumorectomy with an intended 1-cm margin followed by radiation therapy (TART). At 39 months, 13% in the tumorectomy group, compared with 5% in the quadrantectomy group, had developed a local recurrence. However, an analysis by actual margin status was not described. In contrast, Vicini and associates²²² analyzed rates of recurrence by extent of resection and found that tumorectomy with a 1- to

2-cm margin yielded recurrence rates similar to those seen with larger volumes of resection if the margins of resection were uninvolved and EIC was not present.

What is the effect of radiotherapy dose and the use of a boost on local control?

The dose per fraction, dose per week, and total dose affect local control. A minimum of 800 cGy per week should be delivered. Kurtz and colleagues¹⁶³ and Osborne and coworkers²²³ each reported increased local recurrence rates with delivery of less than 800 cGy per week. Fraction sizes less than 180 cGy may also increase the risk for local recurrence. Local control (and cosmesis) are optimized with conventional fractionation of 180 to 200 cGy per fraction, 5 days per week (greater doses per fraction often lead to impaired cosmetic outcome).²²⁴ Inadequate total doses delivered to the breast or regional lymph nodes, as shown in the Guy's Hospital series, resulted in an increased incidence of recurrence.¹⁴⁷⁻¹⁴⁹ The minimum dose to the whole breast should be 4500 to 5000 cGy. The role of and appropriate dose of additional radiotherapy localized to the tumor bed only (boost) is dependent on the use of re-excision and the presence or absence of residual carcinoma, the final margin status, and possibly the radiation therapy technique used for the whole-breast portion of the treatment. The rationale for the local boost at the primary tumor site is based on histopathologic and clinical findings. Holland and colleagues⁴⁹ have shown that microscopic residual carcinoma is most likely to occur within 2 cm of the margins of resection and is progressively less likely to occur with increased distance. The clinical correlate is reproduced in many series: 60% to 95% of recurrences occur at the site of the index lesion.^{177,187,225,226}

Although the NSABP series achieved a high local control rate without using a boost, free microscopic margins of resection were required, and the lack of wedges gave parts of the breast a dose considerably higher than the 5000 cGy prescribed and thereby risked diminished cosmesis. Series using wedged compensation techniques typically prescribe 4500 to 5000 cGy to the whole breast, and most deliver a boost to the tumor bed of 1000 to 2500 cGy.⁵²⁻⁵⁶ Extrapolation from series in which final margin status determines the total dose supports the ability of a graded boost dose to control a higher bulk of residual microscopic disease.^{57,64,162,192}

The absolute necessity of a boost in patients who have free margins of resection is less than clear.²²⁷ In the EORTC "boost-no boost" trial designed to clarify the role of the boost, 5569 patients with tumors up to 3 cm and free margins after tumorectomy and lymph node dissection were randomized to receive (1) 16 Gy as either an electron or an iridium boost or (2) no boost after 50 Gy to the whole breast.^{57,228} At 5-year follow-up, use of a boost significantly improved local control.⁵⁷ The magnitude of the benefit was greatest in patients 40 years of age or younger, in whom local recurrence was halved by the addition of a boost dose.⁵⁷

Who can receive partial-breast irradiation?

Selection criteria for partial-breast irradiation are continuing to evolve. The data with longest-term follow-up use

interstitial brachytherapy. The acceptance of balloon catheter-based brachytherapy extrapolates from interstitial brachytherapy. Only time will show whether treatment using a single catheter and a radioactive source in a single position yield results equal to treatment with an interstitial planar implant with sources in multiple locations. Three-dimensional conformal treatment has short follow-up, as does intraoperative radiotherapy. In the interim, physicians should remain meticulous in their selection of patients for partial-breast brachytherapy.

Vicini and colleagues²²⁹ treated 199 patients with interstitial partial-breast brachytherapy using low- or high-dose-rate therapy. The inclusion criteria required free surgical margins (≥ 2 mm), infiltrating ductal carcinoma less than 3 cm, patient age older than 40 years, and uninvolved lymph nodes. Patients with infiltrating lobular carcinoma, an extensive intraductal component, DCIS, or “clinically significant” areas of lobular carcinoma in situ were excluded. The incidence of local recurrence at 5 years was 1%. Additional series confirm these good results.^{230,231} Series documenting either increased recurrence²³² or increased toxicity^{233,234} require careful study to better define patient selection, dose fractionation, and technique.

Early results with the MammoSite balloon catheter brachytherapy device (approved by the U.S. Food and Drug Administration in 2002) show acceptable toxicity, feasibility, and at 2 years, adequate cosmesis and control^{235,236} (see Fig. 26–18A and B). Longer follow-up is clearly necessary. A national registry, initially industry sponsored, opened in 2002 and closed in July 2004, will provide a wealth of data for MammoSite-based partial-breast brachytherapy. On protocol, eligibility included an infiltrating ductal carcinoma 2 cm or smaller, free surgical margins, negative axillary lymph nodes, and patient age at least 47 years. Patients with infiltrating lobular carcinoma or DCIS were not eligible. Additional technical factors were required, including minimum and maximum balloon size, shape and conformity of the balloon, and a minimum distance from the surface of the balloon to the skin of 7 mm (but ideally 1 cm or more)²³⁷ (Fig. 26–19). A National Cancer Institute–funded clinical trial in development will compare partial-breast and whole-breast irradiation.

IORT may be another acceptable approach to partial-breast radiotherapy. After a dose-escalation trial,²³⁸ a single relatively

Figure 26–19 Computed tomography scan slice of a breast with the MammoSite balloon inflated with diluted Hypaque. The desired spherical shape of the balloon and the acceptable distance from the surface of the balloon to the skin are shown.

large fraction of electron-beam therapy is delivered in the operating room after the breast surgery.^{239,240} Two hundred thirty-seven patients with tumors smaller than 2 cm underwent breast-conserving surgery with sentinel lymphadenectomy.²⁴¹ The median age was 59 (range, 33 to 80) years. At 19 months of median follow-up, 1.4% had an ipsilateral breast recurrence, 0.5% supraclavicular recurrence, and 0.5% distant failure. Longer follow-up is required for clinical control, recurrence rates, and longer-term cosmetic results.

External-beam–based partial-breast irradiation using three-dimensional conformal treatment planning or IMRT is also being investigated to treat the tumor bed and a margin of normal tissue. The dose and fractionation have been extrapolated from brachytherapy series. One group has performed a dose-escalation feasibility assessment.²⁴² Again, the tumor bed must be precisely delineated, and care must be taken to limit the integral dose to the surrounding normal tissues. Several techniques have been proposed.^{242–243} Acute toxicity appears acceptable.^{242,244} Follow-up, again, is short.

At present, unless the patient is participating in a clinical trial, partial-breast irradiation should be carefully used. Meticulous radiographic screening is necessary preoperatively to exclude patients who may have multifocality or multicentricity. Patients who have a stage 1 infiltrating ductal carcinoma, free margins, no extensive intraductal component, and nonlobular histology may be candidates. A discrete age criterion is not defined, but young patients may be at increased risk for recurrence based on existing breast-conserving therapy data.

The potential advantages of partial-breast irradiation may be numerous. In addition to convenience and a cosmetic improvement for the patient with a large pendulous breast (smaller-breasted patients have a high likelihood of good to excellent cosmetic outcome with standard therapy), re-irradiation and repeat breast-conserving surgery may be possible for the patient with a new primary tumor in a discrete quadrant many years after her first surgery and partial-breast irradiation. This is an active and exciting time for breast specialists and their patients as improved screening and improved technologies are leading the way toward refinements and reductions in therapy with similar control rates and similar or improved cosmetic results.

Ideally, when should radiotherapy begin?

Theoretically, the longer the delay between surgery and the institution of radiation therapy, the higher the risk for local recurrence because residual tumor cells are allowed to proliferate.²⁴⁵ However, several variables, including margin status, axillary lymph node status, and chemotherapy, may modify the risk. Nixon and associates²⁴⁶ retrospectively analyzed 591 patients who had pathologically uninvolved lymph nodes and did not receive chemotherapy. No difference in recurrence rates was found in patients starting radiation therapy 5 to 8 weeks after surgery, as compared with 0 to 4 weeks after surgery. However, other series^{157,178} found an increased recurrence rate if radiotherapy was delayed beyond 7 weeks after surgery.

In patients receiving chemotherapy, deferring radiation therapy until the completion of chemotherapy may result in a delay of up to 4 to 8 months, depending on the chemotherapy regimen. Recht and colleagues¹⁶⁴ found that local recurrence rates were higher in patients who received 4

months of CMF followed by radiotherapy, as compared with radiotherapy first. On subset analysis, the local recurrence rate was most increased in patients who had involved or unknown margins of resection. At 5 years, the local recurrence rate was 26% when radiation therapy was delivered after chemotherapy and 14% when radiation was delivered before chemotherapy. Although two series^{247,248} have found no difference, several others^{165,249,250} also have found an increase in local recurrence with delayed radiotherapy. Thus, if unknown or involved margins exist, re-excision should be considered prior to the initiation of chemotherapy. If re-excision is not or cannot be performed, radiotherapy may be interdigitated into the treatment plan before the completion of chemotherapy.

Concomitant chemoradiotherapy avoids delaying either modality and potentially minimizes systemic and local failure. However, some investigators have commented that patients treated by concurrent therapy may tolerate less dose-intensive chemotherapy because of an increase in bone marrow suppression^{251,252} and have an increase in side effects and a suboptimal cosmetic result²⁵¹⁻²⁵⁵ (see discussion of cosmesis). If radiation therapy is to be delayed until the completion of chemotherapy, clear margins of resection must be ensured.

What is the effect of chemotherapy on local control?

Chemotherapy, when added to conservative surgery and radiation therapy, further reduces the risk for local recurrence.^{51,144,179-181} This reduction, however, does not compensate for the effect of radiation therapy. Despite chemotherapy, if radiation therapy is delayed for 4 or more months (or withheld⁵¹),^{164,165} there is an increase in risk for local recurrence, especially in patients who have microscopically involved margins.^{164,181}

Tamoxifen, in patients who have ER-positive tumors, may also lower local recurrence rates after conservative surgery and radiation therapy.^{168,181} However, tamoxifen alone does not provide optimal local control even in small tumors with uninvolved lymph nodes.^{168,207} The NSABP randomized 1009 women with invasive carcinoma and uninvolved lymph nodes to receive tamoxifen, radiation therapy, both, or neither. Patients receiving radiation therapy, as compared with tamoxifen alone, had a 50% reduction in risk for ipsilateral breast tumor recurrence. The recurrence rate at 8 years was 9% with radiation therapy but 3% with radiation therapy and tamoxifen.¹⁶⁸

Results from the recently published German prospective randomized trial of 360 patients with pathologic stage I invasive cancers corroborate the NSABP results. Tamoxifen further lowers the risk for ipsilateral breast tumor recurrence provided by breast radiotherapy.²⁰⁷ Aromatase inhibitors should have a similar effect, although long-term data are not yet available.

Are any other additional histopathologic factors associated with local recurrence?

An increased risk for local recurrence has been reported after conservative surgery and radiation therapy (and

after mastectomy) for lesions that do not express ER (ER-negative tumors)^{161,183,228} and for those that have a high nuclear grade,^{168,177,182,188,190,191,256,257} lymphovascular invasion,^{144,177,184,188,189} tumor necrosis,^{185,188,191} or an inflammatory infiltrate.^{144,168,188-191} These histopathologic factors are more commonly associated with young age.^{168,185,186,258}

Is there an effect of age on local recurrence?

Young age (usually defined as younger than 40 years) is frequently associated with other factors that predict for local recurrence: EIC, ER-negative lesions, lymphovascular infiltrate, high histologic grade, inflammatory infiltrate,^{186,258} and involved margins.^{57,151,155} However, reports exist both supporting^{151, 155,182,184,203} and refuting^{259,260} the increased risk for recurrence in younger patients. Smaller volumes of resected breast tissue and involved margins may have contributed to the higher local recurrence rates seen in these series.^{57,258} Analyses of associated factors have not been performed routinely and may confound the importance of age as an independent prognostic factor for ipsilateral breast recurrence. With optimal surgery and correction for additional prognostic factors, Kurtz and colleagues¹⁸³ reported that age younger than 32 years imparted an increased local rate of recurrence (34% at 8.5 years).

In one prospective randomized series, older age (over 55 years) in patients undergoing quadrantectomy was associated with a lower risk for recurrence.¹⁶⁶

Does family history of breast cancer or detection of genetic mutation preclude breast-conserving therapy and increase local recurrence?

Neither a family history of breast or ovarian carcinoma nor the detection of a *BRCA1* or *BRCA2* deleterious mutation precludes breast-conserving surgery and radiation therapy.^{163,183,217,261-266} However, genetic carriers, while obtaining similar local control rates²⁶⁶ as patients who do not express a *BRCA1* or *BRCA2* mutation, are at increased risk for subsequent, new breast tumors in the ipsilateral or contralateral breast.²⁶⁷

For these patients, we recommend genetic counseling, testing, and breast MRI before radiation therapy and, ideally, before surgery. Many *BRCA1* and *BRCA2* carriers, once they understand their risk for a second ipsilateral or contralateral breast cancer, opt for unilateral mastectomy or bilateral mastectomies with or without reconstruction.

Does tumor size influence local recurrence?

Local recurrence rates are not increased for T2 lesions as compared with T1 lesions when controlled for final margin status.^{51,177,192,194} Rosen and colleagues¹⁹⁵ assessed microscopic residual disease in mastectomy specimens in patients with T1 and T2 tumors after reproducing a wide excision. No statistically significant difference paralleling clinical results was found in the literature.

Does the location of the primary lesion influence local recurrence?

The location of the index carcinoma per se is not predictive of local recurrence^{195,268} when controlled for other factors. On the other hand, tumors within 2 cm of the nipple–areolar complex^{157,158,193} and those involving the nipple^{196,269} have a higher incidence of multicentricity than do tumors distant from the nipple–areolar complex.¹⁷⁷ Therefore, specimens from central lesions should be reviewed particularly carefully and re-excision employed, if necessary, to obtain microscopically free margins.

Does histopathologic subtype influence local recurrence?

Invasive lobular, medullary, colloid, and tubular carcinoma all can be effectively treated with conservative surgery and radiation therapy.^{197–200} The principles of mammographic-pathologic correlation are especially important in invasive lobular carcinoma, which frequently presents as a vague thickening, and often is more extensive microscopically than mammographically.

Does lymph node status influence local recurrence?

As shown in prospective randomized trials^{51–56} and retrospective reports,^{177,194} involvement of the axillary lymph nodes does not increase the risk for ipsilateral breast cancer recurrence after conservative surgery and radiation therapy. In the NSABP series, radiation therapy improved the rate of local control in both patients with uninvolved (12% vs. 32%) and patients with involved (5% vs. 41%) axillary lymph nodes. Patients who had involved lymph nodes actually had a lower local failure rate with radiation therapy than those who had uninvolved lymph nodes and received radiation therapy. The improved local control rate likely reflects synergy between the radiation therapy and the chemotherapy that was delivered to patients who had involved axillary lymph nodes. If radiation therapy to the breast is withheld, involvement of the axillary nodes is prognostic for ipsilateral breast tumor recurrence.^{144,203}

Does regional nodal irradiation affect local and regional control?

Regional nodal irradiation has been shown to lower regional nodal failure but not ipsilateral breast tumor recurrence.⁵⁵ As with all medical therapy, the potential benefits (in this case, regional nodal control) are compared to the potential side effects of treatment. In an unselected population suitable for conservative surgery and radiation therapy, regional nodal failures (axillary, supraclavicular, and internal mammary) may be as low as 2% to 5% without regional nodal irradiation.^{51,52,225,270,271} However, for selected patients who are at increased risk of disease recurrence (see later) in the regional lymph nodes, regional nodal irradiation becomes appropriate.

Recurrent disease in the supraclavicular region occurs in 10% to 26% of patients who have pathologically involved axillary lymph nodes.^{225,271–273} Regional nodal irradiation should primarily be reserved for patients at substantial risk for developing a supraclavicular recurrence—that is, patients with four or more involved axillary lymph nodes or involved apical (level III) lymph nodes. It is not yet clear whether the survival benefits seen in premenopausal women undergoing regional nodal and chest wall irradiation after mastectomy^{274,275} will apply to postmenopausal women or women undergoing breast-conserving therapy (see section on postmastectomy radiation therapy).

Irradiation of the dissected axilla is indicated less often because of the low incidence of axillary recurrence after dissection and the risk for arm edema after axillary dissection and full axillary irradiation.^{225,276,277} Indications for axillary irradiation include lack of an axillary dissection (unless the risk for involvement is less than 10% to 15%) and gross residual axillary tumor after dissection. Microscopic extranodal extension and involvement of more than four axillary lymph nodes are more controversial indications for axillary irradiation.²⁷⁸ Pierce and colleagues²⁰¹ have suggested that it is not necessary to irradiate the axilla in patients who have extracapsular microscopic extension of axillary nodal disease. They observed only a 5% rate of axillary recurrence in such patients, but caution in uniformly adopting this policy seems warranted given the small number of patients studied.

Indications for irradiation of the internal mammary chain are controversial. The risk for recurrence in the internal mammary lymph nodes is as low as 0% to 2% in some series.^{270–273,277} The incidence of toxicity from treatment (hematologic suppression, pneumonitis, and cardiotoxicity), although minimized with modern radiotherapeutic technique, may be greater than the incidence of recurrence.

Using electrons or a combination of electrons and photons, symptomatic pneumonitis can be lowered to 2%, but some amount of lung must be irradiated to treat the internal mammary lymph nodes.^{278,279} Irradiation of the internal mammary lymph nodes generally is recommended for patients with known microscopic involvement of the internal mammary lymph nodes and for patients who require total regional nodal irradiation (i.e., for bone marrow or stem cell transplantation protocols). For patients at high risk—those with inner quadrant or central lesions and involved axillary lymph nodes—positron emission tomography (PET) scan may be used before chemotherapy to evaluate the internal mammary chain. The role of adjuvant internal mammary nodal irradiation for women with stage II or III carcinoma of the breast undergoing breast conservation is not clearly delineated. In the two randomized trials of regional nodal irradiation after mastectomy, internal mammary nodal (IMN) irradiation was not randomized, and the impact of the IMN field versus the chest wall/supraclavicular fields is not clear. Given the toxicity, especially with increased use of anthracyclines and Herceptin and the potentially synergistic effects, extrapolation from the postmastectomy series^{274,275} should be undertaken with caution until further data are available.

Summary

Most patients with stage I or II invasive carcinoma of the breast are candidates for conservative surgery and

radiotherapy. With optimal radiation therapy technique and appropriate patient selection, the overall survival is comparable to that achieved by mastectomy, and 85% to 90% of patients have preserved their breast 10 to 15 years after therapy.

ACUTE AND LATE EFFECTS OF RADIATION THERAPY TO THE BREAST

What are the effects of radiation therapy during the course of treatment?

The acute and late effects of radiation therapy vary with the volume treated (breast, chest wall, regional lymph nodes); the radiation therapy technique; the surgical technique, including placement of the incision; the extent of axillary dissection; the size and shape of the breast; and the use of chemotherapy.

Radiation therapy of the intact breast is well tolerated. The most common acute effects—fatigue, erythema, edema, and hyperpigmentation—develop at the end of the second or the beginning of the third week of treatment. The chance of developing breast edema is greater in patients who underwent an axillary dissection and is proportional to the extent of the dissection.^{254,280} Pruritus and breast discomfort occur in about 30% of patients. Ten to 15% of patients notice temporary nipple hypersensitivity. In most patients, the effects peak about 10 days to 2 weeks after completion of treatment and begin to improve shortly thereafter. Fatigue has resolved in most patients by 6 weeks after treatment. The skin changes have subsided and reached their new baseline by 3 months after treatment. Large-breasted patients, patients with a pendulous breast, and those requiring a breast ring or mold may develop moist desquamation. The desquamation most commonly occurs in the moist inframammary fold and can be exacerbated by use of a bra. Continuous aeration, discontinuation of a bra, and cornstarch to absorb moisture reduce the incidence and severity of moist desquamation. If desquamation does occur, it generally develops toward the end of whole-breast radiotherapy (at 4000 to 4600 cGy) and persists for 7 to 10 days. It typically resolves with the use of topical preparations such as Xeroform gauze or silver sulfadiazine (Silvadene) ointment. In patients receiving chemotherapy, the acute effects may develop sooner, have greater intensity, and resolve more slowly. A hemogram (with differential) generally should be checked weekly in patients who have received chemotherapy, especially when treating the left breast (because of the dose to the blood volume passing through the heart) or regional lymph nodes. Mild cytopenias, most commonly leukopenia, are seen. Rarely, administration of filgrastim (Neupogen) or interruption of treatment is necessary.

Irradiation of the regional lymphatics alters the type and range of acute effects. In addition to the effects seen with breast radiotherapy, irradiation of the supraclavicular fossa can result in a dry cough, sore throat, or both. Similarly, irradiation of the internal mammary lymph node chain may result in leukopenia, esophagitis, or both. As discussed previously, the hemogram should be monitored weekly because most patients receiving regional nodal irradiation have had or are receiving chemotherapy.

Irradiation of the axilla results in hyperpigmentation, epilation of axillary hair, and, occasionally, dry or moist

desquamation in the skin fold. Topical preparations, as described earlier, are prescribed. Rarely, interruption of treatment is required.

What are the effects of radiation therapy after treatment is completed?

Mild skin changes—that is, residual hyperpigmentation—occur in most patients undergoing radiotherapy. Change in size, shape, and texture of the breast is also common. The breast may end up slightly smaller or larger than its pretreatment size. If the resultant size is larger, mild edema and a heavy sensation may accompany the size increase. The breast texture after radiotherapy is frequently firmer. With optimal radiotherapy technique using a linear accelerator and minimizing inhomogeneity of dose, long-term effects are usually very mild. The most common undesirable effect is development of ipsilateral arm edema. About 2% to 10% of patients develop arm edema after breast surgery and axillary dissection independent of the radiotherapy.^{281–283} When radiation therapy is added to conservative surgery and axillary dissection, arm edema develops in 4% to 13% of patients.^{194,276,281,284–290} The incidence increases with the extent of the axillary dissection,^{276,281,291,292} irradiation of the full axilla,^{276,281,282,289–292} obesity,^{282,293} and chemotherapy.^{91,252,276,294–297} The risk for lymphedema may be less following sentinel lymphadenectomy.^{276,292} Factors that can be adjusted to minimize arm edema include treatment position during radiotherapy and choice of the superior field border. Ideally, abducting the arm so that the axilla is above the superior aspect of the breast, placing the patient on a slant board so that the superior aspect of the breast tissue is forced inferiorly, and placement of the superior aspect of the whole-breast treatment portal as low as possible (yet still covering the breast tissue with a margin) minimize unnecessary irradiation of the axilla. Lesions high in the tail of the breast may mandate irradiation of a larger portion of the axilla to adequately treat the tumor bed. If arm edema develops, physical therapy is the treatment of choice.

Symptomatic pneumonitis develops in less than 5% of patients after radiotherapy to the breast or regional lymphatics.^{194,284–288,290} Factors that increase the likelihood of development include irradiation of the supraclavicular region,²⁹⁸ an increased volume of lung included in the breast tangent fields,^{298–301} and chemotherapy (concomitant more so than sequential).^{195,253,295–297,302–304} The symptoms include a dry cough, dyspnea, and low-grade fever. Symptoms typically develop 2 to 3 months after radiation therapy. Chemotherapy may accelerate the onset of symptoms. Pneumonitis usually resolves spontaneously. Rarely, steroids may be required.

Whether or not symptomatic pneumonitis develops, fibrosis and pleural thickening in the irradiated lung volume may be seen on subsequent CT scans or chest films.³⁰⁴ Pulmonary function testing in asymptomatic patients generally reveals a transient decrease in carbon monoxide diffusing capacity after radiation therapy. Normalization occurs spontaneously within 2 years.³⁰¹

Soft tissue ulceration or bone necrosis is reported in 0% to 1% of patients overall.^{189,284,288,290} However, in a series from the University of Texas M. D. Anderson Hospital, 75% (three of four) of patients with preexisting collagen-vascular disease

developed severe soft tissue ulceration or necrosis.^{32–34} In patients who do not have collagen-vascular disease, rib fracture and soft tissue complications are rarely seen with optimal radiation therapy technique.^{194,284–288} Inhomogeneity of the dose distribution, resulting in hot spots in the chest wall and ribs that are more likely to lead to late normal-tissue toxicity, can be seen with lower-energy (i.e., cobalt 60 and, occasionally, 4-MV) therapy. The inhomogeneity of dose is increased in patients with a wide chest wall separation (i.e., the distance between the medial and lateral borders of the field) or a large breast. If the inhomogeneity would be greater than 10% with standard techniques, a higher-energy beam or an intensity-modulated-type technique with more than two fields should be used to compensate.

Brachial plexopathy is not a consequence of irradiation of the breast because the brachial plexus is not in the field. After irradiation of the breast and supraclavicular region, brachial plexopathy is seen in less than 1% of cases.^{194,284,288,290} The risk is increased with larger daily fraction size,³⁰⁶ higher total dose,³⁰⁷ and chemotherapy.^{194,253,295–297} Symptoms may be transient or permanent. If the patient has shoulder or upper extremity pain in addition to signs of plexopathy, recurrent disease should be suspected.

Does irradiation induce second malignancies?

All patients having had one breast cancer are at increased risk for a second contralateral cancer. Factors such as lobular histology, young age, family history, and possession of a deleterious *BRCA1* or *BRCA2* mutation increase the risk. The precise incidence of radiation-related malignancies is difficult to calculate as it appears to be a small fraction of the non-radiation-related second malignancies that act as “background noise.” Perhaps the reader will find it odd that radiobiologic data suggest that low-dose radiation to the breast (<1000 cGy) appears most likely to induce subsequent breast malignancies.^{308–310} A linear dose-response relationship for carcinogenesis exists only for doses up to 1000 cGy; as the dose increases further, the risk for carcinogenesis levels off.^{308,309} It is believed that following low doses of radiation, nonlethal mutations that can be carcinogenic may occur. At higher doses, however, cell death predominates, and these dead cells cannot become neoplastic. Clinically, this parallels the low incidence of second malignancies seen after radiation therapy.

If there is an increased risk for contralateral breast cancer after conservative surgery and radiation therapy, the risk is small. The six prospective randomized trials of breast preservation have thus far found no increased risk for contralateral breast cancer after conservative surgery plus irradiation of the ipsilateral breast as compared with mastectomy.^{51,55,311,312} Horn and Thompson³¹³ and Storm and Jensen³¹⁴ in case-control studies reported no increase in risk. Gao and colleagues, using the Surveillance, Epidemiology, and End Results (SEER) database, found no increase in contralateral breast cancers after ipsilateral breast-conserving surgery and radiotherapy.³¹⁵ Boice and associates,³¹⁶ using the Connecticut Tumor Registry, reported a small increase in the relative risk (RR) of a contralateral breast cancer after breast irradiation in women younger than 45 years at the time of treatment (RR, 1.59) compared with older women (RR, 1.01). The increase in

contralateral breast malignancies became apparent only 10 years or more after the radiation exposure and was greatest if the radiation exposure occurred during adolescence.³¹⁴ Fowle and coworkers, in a non-case-controlled series, also found young age (and family history) to increase the risk for contralateral breast cancer.³¹⁷

Unfortunately, application of the findings of Boice and associates³¹⁶ is difficult because histology and family history were not considered. In addition, most patients received post-mastectomy chest wall or regional nodal radiation therapy with suboptimal (by current standards) machinery and techniques. It is probably inaccurate to extrapolate the authors’ conclusions to patients receiving modern breast radiotherapy alone with optimal technique, in whom the contralateral breast dose can be kept below 250 cGy.⁴⁷

Thus, if definitive radiation therapy to the involved breast increases the risk for a contralateral breast cancer, the risk is small and should not prohibit a patient from pursuing breast preservation. However, optimal radiation therapy technique should be employed to minimize the dose to the contralateral breast.

An increased risk for ipsilateral lung cancer has been reported after locoregional radiation therapy for breast cancer.^{318–321} Again, there is a latency period of 10 years. Most of the data are based on older postmastectomy series using obsolete techniques. Important details regarding radiation therapy (regional nodal treatment, actual doses delivered to the lung) and smoking history are incomplete. However, for the sake of completeness, it is probably fair to observe that in three series, the RR for nonsmokers was 1.9 to 3.0. No risk estimates are available, at present, for patients treated with modern linear accelerators and optimal technique. After breast-conserving surgery and radiation therapy to the breast, an increased risk for cancer in the ipsilateral lung has not been shown.^{320,321} The risk for ipsilateral lung cancer after conservative surgery and radiation therapy in one series revealed a 0.09% incidence at 10 years.³¹⁹ Although longer follow-up is needed, it is advisable to minimize the volume of lung treated.

Rarely (i.e., in about 0.2% of cases), a sarcoma may develop in the treatment field.^{322–324} Ten to 25 years are required before an increase in solid tumors (compared with the normal non-irradiated population) appears.

The risk for leukemia is increased after chemotherapy with alkylating agents, topoisomerase II inhibitors, doxorubicin, and epirubicin.^{325–328} The risk for leukemia is not increased after breast radiotherapy alone but rarely may be increased after radiation therapy to the breast or chest wall *and* regional nodes.^{325–328} The risk increases as the amount of bone marrow irradiated increases. Leukemia may develop 5 to 7 years after treatment. In the NSABP B-06 trial, the incidence of leukemia after radiation to the breast *and* regional nodes was 1.37%.³²⁸ It is likely that the risk is even lower when only the breast (and not the regional lymph nodes) is irradiated.

Modern radiotherapeutic technique should yield an even lower risk for second malignancies using megavoltage (as opposed to cobalt or orthovoltage) equipment and with less leakage from the head of the machine. However, with increasing sophistication and now the use of IMRT, more fields and longer treatment times may paradoxically expose the surrounding normal tissues to a higher dose than treatment with two standard tangential fields. Use of IMRT, although potentially improving cosmetic result or allowing delivery of a

higher dose to the tumor bed with acceptable acute and late toxicity to the breast, could paradoxically result in an increase in second malignancies in the surrounding normal structures.³²⁹

What kind of cosmetic result is likely?

Overall, more than 85% of patients and their physicians rate the final cosmetic result as good to excellent^{27,58,66,246,330} (Fig. 26–20). The outcome is a result of a multidisciplinary effort and is contributed to by specific attention to the details of surgery and radiation therapy. As discussed later, chemotherapy also can have an impact on the cosmetic result.

How can the surgeon help?

The size of the tumor, the necessary amount of tissue resected to obtain free margins, the location of the tumor, the location and size of the scar, and the patient's preoperative

breast size affect the postoperative, preradiotherapy cosmetic result.^{60,150,220,221,331,332} For example, in a small-breasted woman, resection of a 3.5-cm lesion (with free margins) may affect cosmesis more than the identical resection in a large-breasted woman. Because there is generally less breast tissue in the upper inner quadrant, resection of a lesion from this region may leave a more noticeable defect than an identical resection from the upper outer quadrant. Resection of a lesion inferior to the nipple may cause more disparity between the levels of the ipsilateral and contralateral nipples and yield poorer cosmesis.²²⁰ Although the size and location of the lesion cannot be controlled by the surgeon, the placement of the incision and the additional volume of tissue resected (beyond that required for free margins) are within the surgeon's control and are important for cosmesis. Although a quadrantectomy, as opposed to a segmental excision, seemed to result in a small improvement in local control in the Milan QUART-TART trial,¹⁵⁰ it also resulted in a statistically significant decrease in a satisfactory cosmetic result.^{26,29} If the patient does not have an optimal cosmetic result before radiation therapy, the long-term cosmesis is unlikely to improve after radiation therapy.

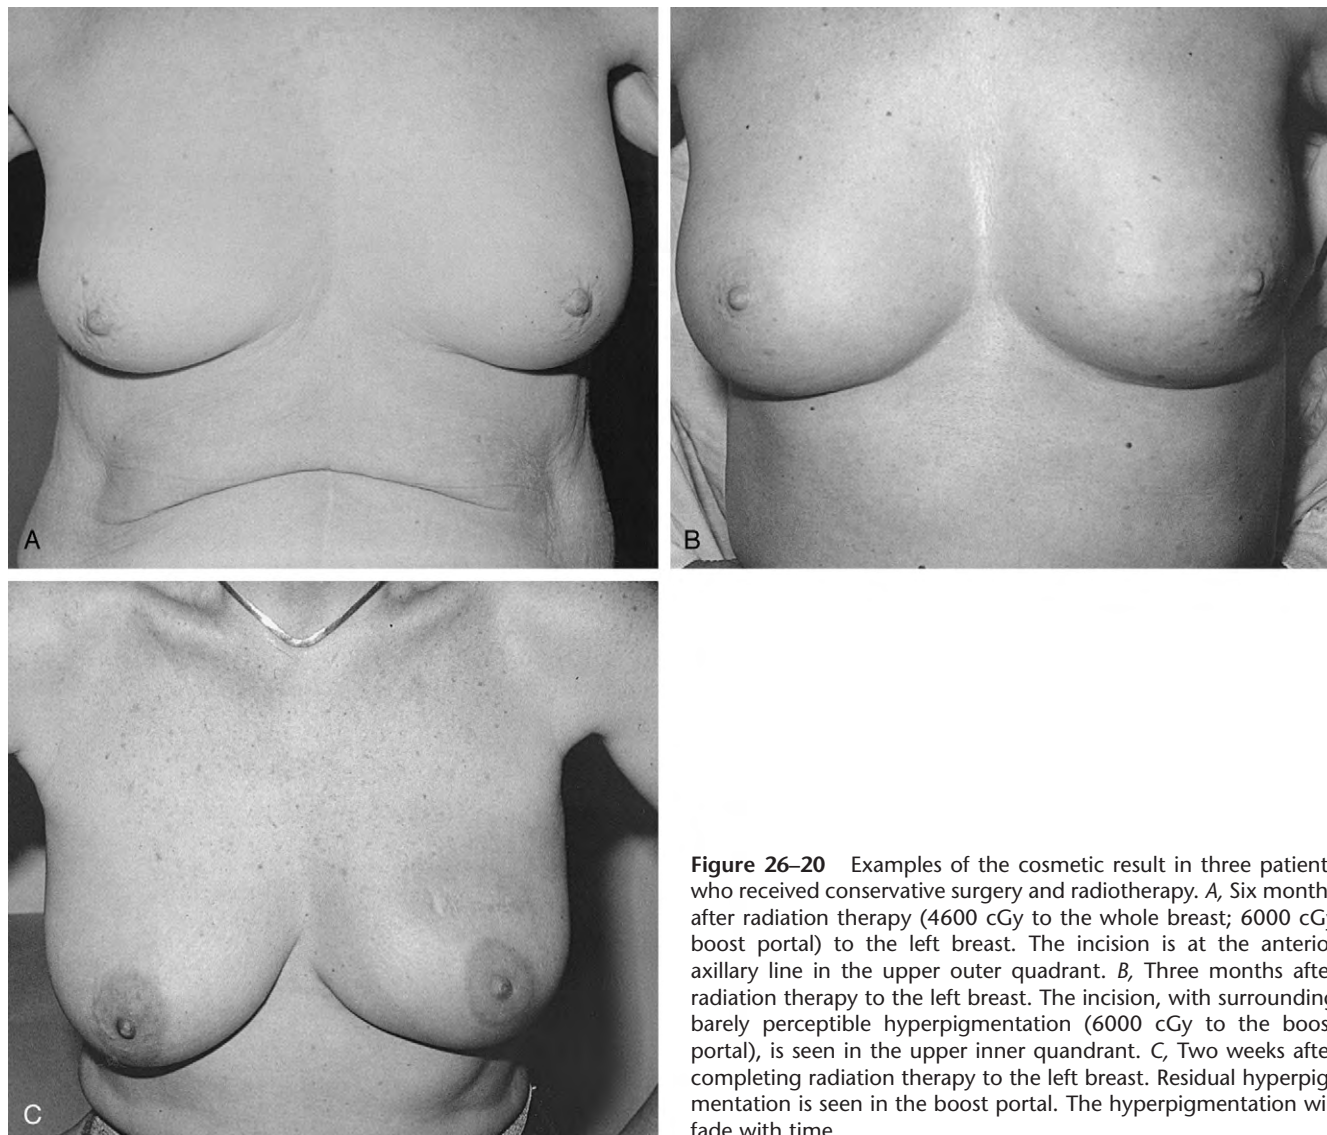

Figure 26–20 Examples of the cosmetic result in three patients who received conservative surgery and radiotherapy. *A*, Six months after radiation therapy (4600 cGy to the whole breast; 6000 cGy boost portal) to the left breast. The incision is at the anterior axillary line in the upper outer quadrant. *B*, Three months after radiation therapy to the left breast. The incision, with surrounding barely perceptible hyperpigmentation (6000 cGy to the boost portal), is seen in the upper inner quadrant. *C*, Two weeks after completing radiation therapy to the left breast. Residual hyperpigmentation is seen in the boost portal. The hyperpigmentation will fade with time.

Finally, the surgeon can aid the radiation oncologist by placing radiopaque clips in the tumor bed at the time of segmental excision. This enables the radiation oncologist to accurately place the boost, while minimizing its amount. The placement of surgical clips in the tumor bed is extremely helpful to the radiation oncologist and to the accuracy of the boost field placement when a reconstructive procedure is performed with the lumpectomy. Because treating a larger volume of tissue with a higher total dose may impair cosmesis, the smaller-volume boost is desirable.

What can the radiation oncologist do to maximize the cosmetic result?

The radiation oncologist can optimize the cosmetic outcome by choosing the proper machinery, energy of the beam, dose per fraction, total dose, and optimal treatment plan with the use of wedged compensators individually chosen for the patient. Inhomogeneity of dose across the breast and resultant hot spots may be seen with use of low-energy and nonlinear accelerator equipment and a beam energy that is too low for the patient's breast width. The resultant inhomogeneity increases the possibility of compromised cosmesis. As mentioned previously, the use of IMRT and additional fields may decrease inhomogeneity and improve cosmesis in selected patients.

Delivery of conventional fractionation of 180 to 200 cGy per fraction, as compared with doses above 250 cGy per fraction, minimizes reaction of the skin and breast tissue and optimizes the possibility of a good cosmetic result while effectively eradicating residual neoplastic cells.^{24,25,58,60} A higher dose per treatment may be delivered with acceptable toxicity when the volume is small. Therefore, when treatment encompasses the tumor bed only or "partial breast," a shorter fractionation schema (fewer treatments, larger dose per treatment) may result in satisfactory cosmesis. However, when larger doses per fraction are delivered to the entire breast, patient selection is critical. The factors shown to lower the ultimate cosmetic outcome (i.e. large breast, large separation, width of chest wall) may result in a decline in cosmesis. If future or salvage mastectomy with reconstruction is performed and there has been an increase in fibrosis or subclinical cutaneous or vascular damage because of the larger dose per fraction, the reconstruction may be suboptimal. If the dose to the whole breast surpasses 5000 to 6000 cGy, an increased rate of long-term breast edema and compromised cosmesis are risked.⁵⁸ At doses above 7000 cGy, fibrosis, pain, and retraction may be seen.

The radiation oncologist should also keep the boost volume to the minimum required to encompass the tumor bed and, if using electron-beam therapy, should choose the appropriate energy. Using the clips placed in the tumor bed at surgery or using a CT scan or ultrasound⁶⁹ to localize the tumor bed, the radiation oncologist can accurately localize the volume and avoid excessive margins that may be required when the tumor bed is estimated from mammography and placement of the incision. If clips have not been placed and CT scan or ultrasound is not available or did not delineate the surgical bed, a 3-cm margin is placed around the incision. In comparisons of the two methods, placement of clips resulted in a smaller and more accurate boost volume.⁷¹⁻⁷³ Again directed by

radiopaque surgical clips, the radiation oncologist can choose the optimal electron energy required to reach the tumor bed while minimizing dose to the overlying (skin) and underlying (chest wall and lung) anatomy.⁷⁰ Using an iridium (brachytherapy) boost has resulted in worsened cosmesis in a few reports.^{66,67,70} Intraoperative radiotherapy and balloon catheter brachytherapy have also been used to deliver the boost treatment.

Can systemic therapy recommendations affect cosmesis?

Chemotherapy may worsen the cosmetic result after conservative surgery and radiation therapy.^{77,188,251-255} Both the timing of chemotherapy in relation to radiation therapy and the specific chemotherapeutic agents delivered affect the ultimate result.^{26,333-335} General, concurrent chemoradiotherapy results in a worse cosmetic result than sequential therapy.^{252,255} Impaired cosmesis has been documented with concurrent CMF.^{252,255} Cytosine and 5-fluorouracil concurrent with radiation therapy, in several series, did not affect the appearance of the breast.^{26,333-335} Doxorubicin sensitizes the skin and, when given concurrently with radiation therapy, can result in an unacceptably brisk erythema. Paclitaxel and docetaxel arrest cells in mitosis (an extremely radiosensitive phase of the cell cycle) and increase the reaction to radiation therapy if given concurrently.^{333,336} Gemcitabine is also a potent radiosensitizer and, when delivered concurrently with chest wall radiotherapy, commonly results in skin desquamation.³³⁷

The medical oncologist and radiation oncologist should work together to minimize the risk for relapse and toxicity while maximizing the cosmetic result.

What is the role of radiation therapy after mastectomy?

The goals of postmastectomy radiotherapy are to prevent locoregional recurrence and improve survival. Premenopausal or postmenopausal patients at substantial (i.e., greater than 10%) risk for locoregional recurrence (after mastectomy) should be considered. Patients who may have a survival benefit after postmastectomy radiation therapy are discussed next.

Is there any value to postmastectomy radiotherapy?

Radiation therapy may be delivered in the postmastectomy setting, usually in addition to chemotherapy, to eradicate micrometastatic deposits and thereby improve local control and survival. Because of the relationship of dose and tumor volume, radiotherapy delivered after development of a locoregional recurrence results in a complete response rate in only 50% of patients.³³⁸ The morbidity from an uncontrolled recurrence has been well documented and includes ulceration, bleeding, pain, infection, lymphedema, and brachial plexopathy. Given the severity of symptoms and difficulty achieving palliation, the best treatment is prevention of the recurrence. Moreover, if recurrence is prevented in

a patient with a low risk for distant failure, survival could potentially be improved.

Which patients are at high risk of locoregional recurrence?

Patients who have disease in their axillary lymph nodes have a relatively high risk for locoregional recurrence. Within this subset, the risk for recurrence rises with increasing numbers of involved lymph nodes.^{141,339} To estimate the risk for locoregional recurrence and the value of postmastectomy radiation therapy, the axillary dissection should contain at least 10 lymph nodes. When an adequate axillary dissection has been performed, the risk for recurrence increases with increasing numbers of involved axillary nodes. In patients who do not receive radiation therapy after mastectomy and axillary dissection, the incidence of chest wall recurrence rises from 5% in patients who do not have involvement of their axillary lymph nodes, to 9% in those with one to three involved lymph nodes, to at least 20% in those with four or more involved nodes.^{268,272,277,340–343}

The risk for locoregional recurrence also rises with enlarging primary tumor size from less than 10% in patients having tumors larger than 2 cm to 25% to 35% in patients having tumors larger than 5 cm.^{268,277,340,344,345,346}

The risk for a supraclavicular lymph node recurrence also rises as the number of involved axillary nodes increases and may predict for distant dissemination.³³⁹ The supraclavicular and infraclavicular regions should be included when postmastectomy radiation therapy is delivered.

Other factors that *may* be associated with locoregional recurrence include an involved surgical margin, high histologic grade,^{347,348} age younger than 40 years,^{268,349,350} pectoralis major fascia involvement,³⁴⁵ ER-negative tumor,^{345,351} and presence of tumor necrosis.³⁴⁵

The risk for an axillary recurrence is generally low, and the toxicity of irradiation to the full axilla is not justified when an adequate axillary dissection is performed.³³⁹ If a more limited axillary dissection is performed and less than 10 lymph nodes are removed in a patient with axillary lymph node involvement, several studies have reported an increased risk for axillary recurrence.^{275,339} Therefore, when an axillary dissection (and not sentinel lymphadenectomy) is indicated, an adequate dissection should be intended to avoid an increased risk for recurrence or the morbidity of axillary radiation therapy superimposed on the surgical morbidity.

Does chemotherapy prevent local recurrence and obviate the need for radiation therapy?

In most studies, chemotherapy does not significantly reduce the risk for locoregional failure.^{345,347,352,353} Despite therapy with CMF, for example, patients who have primary tumors 5 cm or larger *and* four to seven involved axillary lymph nodes have a 20% to 30% risk for locoregional failure.^{345,352,353} In one series of patients who had 10 or more lymph nodes involved and received high-dose chemotherapy and bone marrow transplantation, Marks and colleagues³⁵⁴ reported a 30% chest wall recurrence rate. Although there are no prospective

randomized data investigating postmastectomy radiation therapy after adjuvant chemotherapy with anthracyclines or taxanes, the available data and ongoing adjuvant chemotherapeutic trials continue to use postmastectomy radiation therapy if the risk for locoregional recurrence is about 20% or greater.

Can radiation therapy decrease locoregional recurrence?

Radiation therapy clearly decreases the rate of locoregional recurrence, whether or not chemotherapy is used.^{277,340,354–358} In most prospective and retrospective series, with or without chemotherapy, radiation therapy reduces the risk for locoregional failure from between 20% and 30% to less than 10%.^{278,351,358–367}

Should the role of postmastectomy radiotherapy in the modern era be reassessed?

Several prospective randomized series that failed to find a benefit were conducted in the 1950s and 1960s and must be viewed in their proper perspective because they were done before the development of modern linear accelerators, electron therapy, and the current understanding of dose-response relationships in tumor and normal tissues.^{272,368–370} Although locoregional recurrences were lowered, toxicity compromised the benefit. The lessons learned from these early studies are as follows:

1. Orthovoltage therapy (250 kV) increases complications in the skin, soft tissue, and heart because of relatively poor depth-dose profiles and resulting inhomogeneity of dose. In at least two trials, orthovoltage therapy likely contributed to increased mortality.^{371,372}
2. The amount of heart and lung in the treatment portals should be kept to the minimum amount possible.^{324,343,373–375}
3. Omission of postmastectomy radiation therapy to the chest wall (treating peripheral lymphatics only) results in an increased risk for chest wall recurrence and lower survival rates.^{272,368,370}
4. Doses below 4500 cGy are not adequate to sterilize microscopic disease and result in increased recurrence rates.^{272,368,370}
5. Increasing the daily dose per fraction increases long-term complications. A daily fraction size of 180 to 200 cGy is recommended.^{368–370}
6. Patients who have uninvolved axillary lymph nodes and primary tumor size of less than 5 cm have a low risk for locoregional recurrence.^{277,370}
7. If internal mammary lymph nodes are to be treated, direct photon fields should be avoided because of increased dose to the heart and increased cardiotoxicity.^{369,370,372–376}

With modern technology and meticulous technique, optimal treatment to the desired sites (chest wall with or without regional lymph nodes) can be delivered, keeping the dose to normal tissues to a minimum. In summary, patients who should receive radiation therapy after mastectomy are (1)

those with a tumor size of 5 cm or greater or four or more involved axillary lymph nodes and (2) those who have locally advanced disease undergoing up-front chemotherapy followed by surgery. Possible indications include involved surgical margins, suboptimal axillary dissection in a patient with stage II disease (i.e., three of a total of six lymph nodes involved), multiple risk factors that individually do not yield a 15% risk for locoregional recurrence (i.e., gross multicentric disease, extensive lymphovascular invasion, ER negativity), and microscopic disease in an internal mammary lymph node.

Does postmastectomy radiation therapy affect survival?

This has been and remains a difficult question to answer. Certainly, patients who have a high risk for distant failure (in general, 10 or more involved axillary lymph nodes) or a low (less than 10%) risk for locoregional recurrence (e.g., no involved axillary lymph nodes and tumor size less than 5 cm) would not be expected to have a survival benefit. Clinical experience verifies this.

In the early trials of regional radiation following mastectomy, all patients, regardless of tumor size and axillary nodal status, received postmastectomy radiation therapy.^{272,368–370,373} These results were not analyzed by lymph node status or tumor size, and combined with the poor technique (by modern standards), resultant excessive morbidity, and small sample size, no difference in overall survival was seen. Two series reported a benefit in disease-free survival at 10 years.^{378,379} On subset analysis of two additional trials, the Stockholm^{142,365} and Oslo trials,³⁶⁸ a benefit in disease-free survival at 10 years was noted for stage II patients.

In contrast, more recent studies^{274,380,384} of radiation therapy in selected subsets of patients who had mastectomies have shown improved disease-free survival. Ragaz and colleagues^{274,380,381} reported a study of premenopausal women who had involved axillary nodes and were randomized after mastectomy to CMF either with or without radiation therapy to the chest wall and regional lymph nodes. At 15 years, survival was improved in the women who received radiation therapy in addition to chemotherapy. The largest benefit was seen in the patients who had four or more lymph nodes involved, although given the small sample size and the 29% reduction in mortality from breast cancer, all groups experienced benefit from the addition of radiation therapy. The women who received radiation therapy also had a statistically significant 33% reduction in recurrence.

The Danish Breast Cancer Group has also shown improved survival attributable to the use of postmastectomy radiation therapy in patients who had T3 or T4 tumors or involved lymph nodes.^{370,383} At 10 years, with the addition of radiation therapy, overall survival (54% vs. 45%; $P < .001$), disease-free survival (48% vs. 34%; $P < .001$), and locoregional recurrence (9% vs. 32%; $P < .001$) were all improved. Postmenopausal women received tamoxifen with or without radiation therapy, and at 5 years they experienced a statistically significant improvement in disease-free survival related to radiation therapy. Both premenopausal and postmenopausal groups had marked reductions in local recurrence rates with

radiation therapy (28% vs. 9% premenopausal [$P < .0001$]; 36% to 5% postmenopausal [$P < .0001$]). Van der Hage and colleagues, in a retrospective series of 3648 patients, also found a survival benefit for postmastectomy radiation therapy in women with one to three positive lymph nodes.³⁵⁹

Although many other series show no improvement in survival, these experiences raise the possibility of improved survival from radiation therapy when appropriate patient selection is employed. A North American intergroup trial was designed to better answer this question but was not completed. As increasingly effective cytotoxic and biologic therapies are employed, the role of locoregional recurrence and its potential contribution to overall survival may be increasingly meaningful. Premenopausal women with one to three involved axillary lymph nodes should consult with a radiation therapist. Until more data are available, selected premenopausal patients with one to three positive lymph nodes should be evaluated for radiation therapy. Factors that will influence the decision for or against radiation include tumor size, number of lymph nodes removed, the presence or absence of lymphovascular invasion, ER status, and possibly *HER-2* status.

In addition to the chest wall, should regional lymph nodes be irradiated?

It is my belief that, in general, patients who have T3 or T4 lesions and four or more involved lymph nodes should receive radiation therapy not only to the chest wall but also to the supraclavicular lymph nodes. As described earlier, the risk for recurrence in the chest wall and supraclavicular regions with a primary carcinoma larger than 5 cm and four or more axillary lymph nodes involved ranges from 10% to 45%. In addition, using meticulous technique, treatment of these sites is accomplished with acceptable toxicity (see earlier discussions of technique and late effects).

Because axillary recurrences are rare following adequate dissection, and because irradiation of the dissected axilla increases the risk for lymphedema, treatment of the axilla is generally reserved for patients who have suspected gross residual disease or an undissected axilla.^{201,384,385}

Treatment of the internal mammary region remains controversial. The series reporting benefits in disease-free and overall survival included the internal mammary lymph nodes in the irradiated volume; however, it is not at all clear that treatment of the internal mammary region per se is critical. Surgical series document the greatest likelihood of microscopic involvement of the internal mammary chain in patients who have inner quadrant tumors and involved axillary lymph nodes. The data of Tubiana and associates³⁸⁶ support a survival benefit for chest wall and regional lymph node irradiation (including the internal mammary nodes) in patients with central inner quadrant lesions and involved axillary nodes. However, the development of an internal mammary recurrence is rare after mastectomy (with or without chemotherapy), and given the synergistic cardiotoxicity of doxorubicin and irradiation,^{274,387} when undertaken, irradiation of the internal mammary region should be performed with meticulous technique to minimize short- and long-term morbidity.

Systemic Treatment for Stage I and Stage II Breast Cancer

Clifford A. Hudis and Larry Norton

Breast cancer presents as two interrelated problems. First is the problem of local disease in the breast and axillary lymph nodes, and second is the problem of metastatic disease in distant sites. Local disease is better controlled now than in the past because of advances in surgery and, more recently, radiotherapy. In addition, heightened public awareness and the more widespread use of mammography have led to the more frequent detection of small cancers with better prognosis. Despite these gains, the problem of distant recurrence, which leads almost inevitably to death, persists. Based on the demonstrated activity of systemic therapy against distant recurrences, this modality has been explored as treatment for the presumed micrometastatic disease that remains after surgery for early-stage breast cancer. The effectiveness of systemic therapy as an adjunct to local control procedures has now been confirmed by long-term follow-up of the seminal trials and by a crucial series of meta-analyses showing that both hormonal therapy and chemotherapy prolong disease-free and overall survival in nearly all groups of patients. Although the relative and absolute influences of drug therapies are modest and vary among patient subgroups, the proper application of these treatments to the hundreds of thousands of patients diagnosed worldwide per year would yield a major impact on public health. For the near future, clinical trials will likely lead to improved outcomes using conventional drugs through the application of novel dosing and scheduling strategies. In the long term, recent laboratory advances and clinical trial data indicate the potential of newer modalities aimed at novel biochemical targets to provide even greater results in treatment of occult disseminated disease.

INTRODUCTION

Modern methods of detection and treatment lead to cure for most women in the developed world who are diagnosed with breast cancer. Yet, its position as the most common primary life-threatening malignancy in American and European women means that despite effective treatment, it remains the second most common cause of cancer-related death, after primary lung cancer.¹ In contrast, for most of recorded history,

breast cancer was almost universally fatal, and treatment, when provided, was intended to be palliative.²

Perhaps the first cause for optimism arose in the late 19th century with the popularization of a theory of cancer spread that suggested a curative role for local surgery.^{3,4} This then-novel theory proposed that breast cancer spread first by direct extension into contiguous tissues and next by an orderly progression through the lymphatic circulation to the rest of the body. This theory led to the prediction that total resection of the primary cancer and the immediate lymphatic drainage could cure the patient if the disease had not yet spread beyond this local region. At about the same time, improvements in surgical technique made it possible to resect local disease with wide margins and inclusion of the draining axillary lymph nodes, which were presumed to act as a filter against more distant spread. The resulting radical mastectomy was the surgical technique popularized by Halsted.

Long-term follow-up has confirmed that Halsted's radical mastectomy does reduce distant failure rates compared with historical series.⁴ Although this observation has largely been regarded as consistent with the motivating theory, there are many other observations that are inconsistent with the hypothesis. For example, because they can experience distant recurrence, some patients with node-negative breast cancer must have micrometastatic disease at the time of primary surgery. Similarly, some patients develop recurrence locally in the breast or chest wall despite macroscopically and microscopically negative margins of resection. Explaining these observations requires a more complex model than the one proposed by Halsted.

Another aspect of this complexity is the seeming randomness of metastatic growth. The best and simplest explanation is that metastases are a consequence of three events: the development of cells with metastatic growth potential; anatomic access by these cells to distant sites; and a "fertile field" effect in which local conditions, including growth factors, are conducive to cancer cell viability. In all cases of operable breast cancer, we now believe that anatomic access or metastases can occur so early in the life history of the disease that the concept of the axillary filter is at best irrelevant if it is true at all. Seminal trials alone or as included in a recent meta-analysis of all randomized trials on the subject show that efforts to

decrease local recurrence by, for example, adding radiotherapy to surgery are effective but fail to have a major beneficial impact on the occurrence of distant metastases.⁵⁻⁹ The limited impact of more intensive local control therapies on distant relapse suggests that further improvements in survival will require better methods of obtaining systemic control over the unseen micrometastases that must be present even after “curative” surgery.

This focus on the issue of micrometastases motivated the development of the entire field of systemic adjuvant therapy. With the recognition that further improvements in survival require even better methods of systemic control, effective drug therapy became the goal of investigators worldwide, and many clinical trials have tested drugs as an adjunct to local control obtained through surgery, with or without radiotherapy. Yet, one should not forget that each of the three major modalities (surgery, drug therapy, and radiotherapy when appropriate) offers a distinct and valuable contribution toward our goal of cure and that adjuvant therapy, now considered an integral component of the management of most patients with primary breast cancer, is but one of these contributors. For the best possible results, each of these modalities should be applied optimally because compromise in the rigor with which any one is employed might easily offset gains made in other treatment areas.

What are the fundamental principles of systemic adjuvant therapy for breast cancer?

From the beginning of the study of systemic adjuvant therapy, drugs have been chosen for study and use based on their demonstrated activity against disseminated (stage IV) disease. Oophorectomy, the first effective systemic therapy for stage IV breast cancer, was thus the first therapeutic manipulation tried in the adjuvant setting.¹⁰ Although the experiments with oophorectomy pre-dated the laboratory studies of cytokinetics, which argued for adjuvant therapy, this hormonal manipulation was predicted to work against occult disease precisely because of its activity against demonstrable disease. The demonstration of an effect in the series of studies undertaken in the 1940s and 1950s served as the first “proof of principle” that adjuvant therapy might be effective, and it motivated all subsequent trials.^{11,12}

In terms of chemotherapy, many of the early trials of adjuvant drug therapy violated the concept that the same therapy effective in advanced disease should be applied when only occult disease is presumed to be present. Instead, these trials used what would now be considered inadequate schedules and doses.¹³ Part of the reason for this miscalculation was an erroneous extrapolation from the observation that in transplantable mouse leukemia, chemotherapy kills cells by first-order kinetics. In this case, a constant fraction of cells are killed, not a constant number.¹⁴ Because this laboratory model used an exponentially growing leukemia cell line, cell kill caused by cell cycle-specific agents was thought to be proportional to the fraction of cells undergoing mitosis. This presents a conceptual difficulty because, although exponentially growing tumors like experimental leukemia have the same growth fraction regardless of tumor size, nonexponentially growing tumors do not. Moreover, for breast cancer and other so-called solid tumors, the exponential model does not fit any

available clinical data, and it is now believed that the growth fraction of subclinical tumors is larger than it is for more advanced tumors. The nonexponential model that best describes this growth pattern is the gompertzian one.¹⁵ Tumors that grow in this fashion have an ever-decreasing growth rate (on a percentage basis), so that although they may always be enlarging, the relative time for each doubling of cell number continually lengthens. To the extent that this more complex model of growth is correct, the micrometastatic disease should then be predisposed to have a larger fraction of cells killed from a single treatment than would more advanced disease, and less treatment would be needed to achieve the desired result of cancer eradication. This optimistic prediction is neither fully supported nor refuted by the available evidence, as discussed subsequently.

What are the pitfalls in interpreting trials of adjuvant chemotherapy?

The earliest trials of chemotherapy, although retrospectively judged to be less than ideal in design, nonetheless did support the hypothesis that adjuvant chemotherapy would improve disease-free and overall survival. Presently, more than 100 individual properly randomized, prospective clinical trials and many hundreds of additional nonrandomized studies have been conducted or are still underway. Because many of these trials have been reported several times, either while they were still being conducted or afterward, accurate interpretation or even determination of the results can be difficult. Multiple analyses and replications of experiments will produce some “positive” and some “negative” findings merely by random chance, particularly when the true difference between the experimental arms is modest or even nonexistent. Contributing to this difficulty is the frequent problem of inadequately sized trials that, combined with random fluctuations in the results, can allow true differences to be obscured. For all of these reasons, much confusion has reigned in the field, and discrete schools of opinion centered on bodies of data generated by one or another cooperative group or major institution have emerged. To correct this unacceptable situation, a comprehensive conceptual framework is needed to serve as a context for the interpretation of individual trial results and to identify the most critical questions to be addressed in newer studies. Just such a framework has been provided by the meta-analyses performed at regular intervals by an organization called the Early Breast Cancer Trialists’ Collaborative Group.

What does the overview analysis of randomized trials accomplish?

On a regular basis, currently every 5 years, this group examines in overview all mature and properly randomized trials performed anywhere in the world that are concerned with the treatment of primary breast cancer.¹⁶⁻¹⁸ Although they study all aspects of care for early-stage breast cancer, a significant portion of their work focuses on adjuvant drug therapy. To date, this effort has resulted in three published meta-analyses of nearly all of the world’s prospective randomized experience with adjuvant therapy, and a fourth overview (2000) has been commenced but is not yet fully published.

For inclusion in the overview, eligible trials must have a minimum of 5 years of follow-up. However, 10 years of follow-up were available for most studies as of the 1990 meeting, 15 years of follow-up were available for many studies at the 1995 meeting of collaborators in Oxford, and up to 20 years of data were presented at the 2000 meeting. In addition, compared with the 1995 overview, there were increased numbers of patients in studies concerned with most of the main questions. Because the results of the 2000 meeting are not yet published, we focus on the 1995 overview even as we await the additional information and clarification that the updated data set will likely yield. Given the maturity of the 1995 data, there is little expectation of significant changes in results for the main questions examined in future analyses.

Regardless of the possibly subtle differences to emerge from the as-yet-unpublished 2000 proceedings and the anticipated 2005 meeting, the overview remains conceptually important for what it demonstrates regarding treatment effect. Specifically, only through the overview have the following simple but unanticipated effects been convincingly demonstrated: first, that treatment has a consistent effect in all risk groups, and second, that the treatment effect persists well beyond the time of actual treatment.

What are the strengths and weaknesses of overview analysis?

Understanding these basic conclusions requires that we first understand the strengths and the weaknesses of the overview methodology. For each study included in the analysis, the control arm is analyzed to provide an expected number of events—usually relapse and death. This number is then compared with the number of events that were observed in the experimental arm, and an odds ratio is calculated for the end point. This allows the result for each study to be reduced to one number that expresses the percentage reduction (or increase!) in the yearly odds of the event in question for

treated versus untreated patients. Trials of similar, although rarely identical, design are then grouped together, and an overall odds ratio is calculated. Within each group, trials are weighted by their relative size, so that large studies count more than smaller ones. The final result of this method of analysis is a number reflecting the change in the chances that an event (relapse or death) will occur as a consequence of a certain type of treatment. By multiplying this percentage change in odds with the absolute annual odds that the event will occur without the manipulation, one can estimate the absolute benefit offered by the intervention. Hence, we can consider the overall impact of a treatment either as the percentage change in odds of an event or as an absolute benefit. As discussed later, it is both a strength and a weakness of this approach that it takes into account all of the randomized evidence available. However, it is certainly true that by including in a fair and unbiased way all of the available evidence, we can be confident that the observations are real.

The powerful conclusions of the overview—that treatment durably changes the overall chances of an occurrence and that the impact of a treatment in terms of altering odds is independent of the absolute odds of that event's occurring in the absence of treatment—are provocative ones. In this case, if an event is more likely to occur in the unperturbed situation—for example, a recurrence with metastatic disease in a patient with many involved axillary lymph nodes at the time of surgery—then the absolute impact of adjuvant therapy will be greater than if the event is less likely to occur in the unperturbed situation.

A simple biologic explanation for this observation is not obvious. Nonetheless, the observation is real and should inform standard practices even outside of clinical trials. In actuality, the clinical application of these results remains quite difficult because a fixed reduction of the annual odds of an event in two settings does not translate into the same overall proportional change in the number of the events. In Figure 27-1, we have simulated the impact of an intervention that reduces the annual odds of an event by one third in two

Figure 27-1 The percentage of patients free of recurrence at the end of each year following local therapy is dependent on both the risk for recurrence and the impact of therapy. In this model, therapy reduces the annual odds of recurrence by one third in all treatment groups. The annual odds of recurrence in the low-risk population therefore decrease from 1.5% per year (*line B*) to 1% per year (*line A*) and in the high-risk population from 15% per year (*line D*) to 10% per year (*line C*). The absolute impact at every time point is smaller in the low-risk group than in the high-risk group. At 10 years of follow-up, 4 fewer recurrences are predicted among 100 treated patients, compared with 15 fewer among 100 treated high-risk patients.

situations. In situation A, untreated patients experience recurrence at a high rate (15% per year), so that at the end of 10 years, only about 20% of patients are free of disease. If we treated this group of patients with therapy that reduces the annual odds of recurrence by one third, we would lower the odds of recurrence from 15% per year to 10% per year. After 10 years, 35% of patients would be free of disease. Thus, treatment will have prevented 15% of the treated patients from experiencing relapse and will have prevented 19% of the expected recurrences. Thus, in the setting of a high rate of recurrence, a reduction in the annual odds of recurrence by one third does not reduce the overall proportion or absolute number of recurrences by one third. In contrast, consider the exact same therapy applied to a group of patients with a better prognosis. In this case, we see that by reducing the annual odds of relapse by one third from 1.5% to 1.0% per year, we change the percentage of patients with recurrence from 14% to 10% at 10 years. In this lower-risk circumstance, only about 4 patients in 100 have their recurrence prevented, but almost one third of the expected recurrences have been avoided. Explaining these benefits in a simple and accurate way to patients represents a difficult and time-consuming challenge for all clinicians concerned with standard adjuvant therapy.

A second issue is that the previous paragraphs make sense only if the odds of recurrence are about the same each year and if the reduction in these odds by therapy applies evenly for each year after the therapy is started. The earlier meta-analyses showed that both adjuvant hormonal therapy and adjuvant chemotherapy do work approximately this way because there was a nearly consistent impact each year for the first 10 years after local therapy of the breast cancer. If the effect of adjuvant drug therapy is reduced after 10 years, then the previous method of analysis will be less accurate when considering the longest-term impact. Nevertheless, the absolute influence of therapy, particularly in the first decade, would hold, and we will still have confidence in the fact the therapy works or does not work to some roughly specifiable degree.

Before drawing specific and detailed treatment conclusions from the results of the overview, it is important to keep one major weakness of the meta-analysis firmly in mind: the fact that the method is essentially a form of homogenization and was never intended to supplant the examination of individual trials. This homogenization is manifested in several ways. First, the methodology excludes newer trials, which through therapeutic refinements might possibly have larger impact because prolonged follow-up is required for inclusion in the meta-analysis. Additionally, and in contrast to the older and more mature studies, these newer trials have all (appropriately) used some form of conventional therapy as the control arm. Hence, the newer studies are not interpretable as regards the impact of the experimental manipulation on recurrence or survival compared with no adjuvant treatment. As we look toward the 1995 analyses and beyond, the most innovative programs may be sufficiently unique that they are not easily grouped with other studies. If they are inappropriately grouped with less efficacious regimens, the impact of their individual treatment innovation may be lost in the “noise” of data from other, not quite relevant treatments. A related concern is that large or even small differences in the agents employed, doses and schedules, and precise methods of follow-up and evaluation will not be reflected in any overview.

For these reasons, accurate interpretation of the vast and growing body of data related to adjuvant therapy must incorporate both the overview and the results of individual trials. Certainly, and as predicted by the methodology, for the major questions (Does chemotherapy work? Does hormone therapy work?), the two approaches give quite concordant outcomes. Although to a certain extent a self-fulfilling prophecy, the corroboration by the overview of individual trial results lends more confidence to the conclusions of both. On the other hand, for subtle questions (higher- or lower-dose chemotherapy, timing of chemotherapy and hormone therapy), the overview is less useful, and individual trials must be relied on to provide the best available guidance. This is why we use both the overview and individual trial results to design studies and to guide routine patient care.

THE MAJOR QUESTIONS ADDRESSED BY THE OVERVIEW

As noted, the largest groups of patients included in the overview are available to answer only the most basic questions concerning the use of chemotherapy and hormone therapy. In some parts of the world, the resulting conclusions are viewed as common knowledge and have been incorporated into standard practice for years. In other regions, these conclusions have provided the impetus needed to increase the use of adjuvant systemic therapy. We discuss these specific conclusions next.

What is the impact of adjuvant tamoxifen?

The single largest group of patients included in the 1995 overview numbers about 37,000 and was included in studies that asked if tamoxifen is active (Table 27–1). For all such treated patients, tamoxifen therapy resulted in a 26% reduction in the annual odds of recurrence and a 15% reduction in the annual odds of death. In recognition of the very limited impact of tamoxifen among women with hormone-unresponsive tumors, about 8000 such patients were not included in the detailed analysis, discussed later, which was limited to patients with tumors either known to be estrogen receptor (ER) positive or ER-positivity unknown—the latter included based on the assumption that the simple majority could be expected to be hormone responsive.¹⁷

The dose of tamoxifen generally used was 20 to 40 mg per day, with the lower dose typical of most of the larger trials. Because there is to date no evidence of a dose-response relationship within this range, and because most patients were treated at the lower dose, we consider a dose of 20 mg orally per day to be standard.¹⁹

What is the appropriate duration of adjuvant tamoxifen therapy?

In terms of duration, there was overwhelming evidence that at least about 5 years of therapy with tamoxifen has a beneficial ratio of advantages to disadvantages and that longer durations are no better. In four large trials testing the duration of

Table 27-1 Percentage Reduction in the Annual Odds of Either Recurrence of Breast Cancer or Death from Any Cause in Various Subsets by Type of Therapy for Which Sample Size Was Adequate*

Age (yr)	Type of Therapy [†]	Recurrence [‡]	Death [‡]
<50	Tamoxifen versus no drug	45 ± 8	32 ± 10
	CC versus no drug	35 ± 4	27 ± 5
	CC + tamoxifen versus CC	52 ± 8	47 ± 9
>50	Tamoxifen versus no drug	(37–54) ± (5–13)	
	CC versus no drug	(11–34) ± (5–13)	
	CC versus no drug	22 ± 4	12 ± 4
	CC + tamoxifen versus tamoxifen	19 ± 3	11 ± 4

CC, chemotherapy.

*Tamoxifen therapy was limited to subsets of patients in whom 5 years of therapy was planned.

[†]Tamoxifen therapy averaged 2 years of use; CC equates to 6 months of CMF (cyclophosphamide, methotrexate, 5-fluorouracil) but includes other combinations as well.

[‡]Plus-minus values are the mean plus the standard deviation.

Data from Early Breast Cancer Trialists' Collaborative Group. Tamoxifen for early breast cancer: An overview of the randomised trials. *Lancet* 1998;351(9114):1451–1467.

tamoxifen, 5 years seemed optimal, and this is confirmed in the overview, in which there was a 42% reduction in annual odds of recurrence, compared with 25% and 18% for 2 years or 1 year of therapy, respectively (see Table 27-1). The largest individual trials were from Sweden and Britain, and both showed an advantage for 5 years over 2 years.²⁰ The next largest trial, the National Surgical Adjuvant Breast and Bowel Project (NSABP) Protocol B-14, suggested no additional benefit for tamoxifen when it is continued beyond 5 years, whereas a relatively smaller trial from the Eastern Cooperative Oncology Group (ECOG) does suggest a benefit.²¹ Although exactly 5 years appears to be a reasonable target duration for tamoxifen therapy, additional studies addressing the emerging role of aromatase inhibitors (discussed later) require that we carefully reconsider this issue in the near future.^{22–25}

Is there a role for tamoxifen in patients with receptor-negative disease?

As predicted by preclinical experiments, tamoxifen is most convincingly active in patients whose tumors are receptor positive. As in metastatic disease, the benefits of tamoxifen for patients with truly ER-negative disease are essentially nil.^{26,27} Although a small benefit could be seen for patients with receptor-poor tumors in the overview, this was quite modest compared with the benefit seen in hormone receptor-positive tumors. The terms “receptor poor” and “receptor rich” used in the overview deserve definition and comment in this context. For both technical and practical reasons, the overview did not previously have a receptor-negative classification. This was necessary because many individual trials included in the analysis did not test for the progesterone receptor (PR), because of the era when they began. As is well demonstrated in metastatic disease, tamoxifen and other endocrine

therapies are nearly as effective in ER-negative but PR-positive cases as they are in cases that are positive for ER.²⁸ The biologic reasons for this are less important than the clinical implication, which is that an “ER-poor” tumor may well be hormone responsive. In addition, the now-recognized problem of inadequate specimen handling (receptors in resected tissues degrade rapidly at room temperature, as in the operating room and pathology laboratory) with resulting false-negative ER assay results, could add to the incidence of false-negative findings in the older trials included in the overview. For all these reasons, some historical cases in the receptor-poor category must have been truly low or even markedly receptor positive. This would allow for a positive, if weak, biologic effect of tamoxifen in patients included as having receptor-poor tumors. Thus, although there is evidence of benefit from tamoxifen in the older studies enrolling receptor-negative cases, we can be sure that the magnitude of the benefit increases with increasing levels of ER expression, and with modern testing, there is little reason to expect that cases with true negatives (for both receptors) will derive a meaningful benefit.

Is there a role for tamoxifen in younger patients?

Until the mid-1990s, accrual to adjuvant tamoxifen trials has favored older patients, an imbalance reflected by the overview.²⁹ Furthermore, within the overview, an age of 50 years was used as a surrogate for the allocation of patients to menopausal status categories. This was necessary because actual menopausal states for enrolled patients were frequently unavailable. As noted earlier, postmenopausal patients whose tumors were positive for ER benefited the most from tamoxifen in this analysis. For patients younger than 50 years, the reduction in the annual odds of recurrence is now known to be quite similar to the benefit found in older patients, assuming they are in the receptor-rich or unknown category, but not in the receptor-poor group.¹⁷ In recent years, tamoxifen has been shown effective at preventing breast cancer among patients with no personal history of the disease and at preventing in-breast recurrences in patients with ductal carcinoma in situ.^{30,31} Yet the benefit of tamoxifen, particularly in considering the treatment of lower-risk patients and those in whom the expected improvement in outcome is extremely modest, must be balanced against the slight, but clear, effect of tamoxifen in increasing the rate of diagnosis of endometrial carcinoma. At present, the exact incidence of endometrial cancer in women treated with tamoxifen is imprecisely defined but appears to be in the range of 1 in 300 to 1 in 1000 women per year of use.^{32,33} Finally, future studies (discussed later) will address the possible advantages of ovarian ablation and aromatase inhibition in lieu of tamoxifen possibly obviating this concern.

Is there any value in combining adjuvant tamoxifen with oophorectomy?

Because of the potential for reactive hyperestrodiolema in response to tamoxifen in younger (premenopausal) patients, ovarian ablation, in addition to tamoxifen, is biologically

appealing. Temporary or permanent removal of this source of estrogen production might allow premenopausal patients to reap the same benefits of tamoxifen as do postmenopausal patients. This would be true only if the lower activity of tamoxifen were due primarily to competition for the receptor from endogenous estradiol. Certainly, ovarian ablation alone was effective treatment in early adjuvant trials and more recently has been equivalent to chemotherapy in some cases.³⁴ However, the overview provides no convincing evidence of additivity for these two modalities. Within the overview, the impact of ovarian ablation in addition to chemotherapy is modest and statistically unconvincing because there were only five trials, a 10% reduction in annual odds of recurrence, and (relevant in terms of statistical significance) a 9% standard deviation. Furthermore, permanent ablation, as tested in earlier clinical trials, could be reasonably expected to result in premature osteoporosis and coronary artery disease—two illnesses with greater public health impact in the United States than breast cancer.³⁵ Hence, the assumption that this intervention is less toxic than chemotherapy is a dubious one. In fact, it may be less toxic but chronically more so.

To address these and related questions, several studies were undertaken to pursue whether concurrent or sequential tamoxifen adds to chemotherapy in premenopausal patients and whether ovarian suppression by goserelin augments tamoxifen's effects; these studies have been completed but not yet fully reported. An ECOG study compared (1) chemotherapy (cyclophosphamide, doxorubicin [Adriamycin], 5-fluorouracil [CAF]) alone, (2) CAF with ovarian ablation, or CAF with both tamoxifen and ovarian ablation; the study suggested the possibility of a benefit only in very young women with high baseline serum estradiol levels.³⁶ If castration turns out to be important in ensuring optimal tamoxifen effect, the use of luteinizing hormone–releasing hormone (LHRH) analogues might be preferable to surgical or radiotherapy-induced ovarian ablation because the chemically induced menopause would be reversible and might therefore limit the deleterious long-term effects. This would be especially relevant if ovarian ablation, like chemotherapy and tamoxifen, exerted a prolonged effect on tumor recurrence following a time-limited exposure. At the same time, the possibility that aromatase inhibitors could be effective in young patients with ovarian ablation makes this an important issue for the near term.

Is there a value to tamoxifen added to chemotherapy?

As with any other systemic treatment evaluated using the meta-analysis technique, the benefits of tamoxifen are easiest to determine in comparison with those of wholly untreated control populations. However, the relevant question for many physicians and patients does not concern the use of tamoxifen versus no treatment but instead its use in addition to systemic chemotherapy. This is particularly critical in the treatment of younger postmenopausal patients with higher-risk disease, such as those with multiple positive lymph nodes. Despite an absence of additive benefit in several individual trials, within the overview, tamoxifen does significantly add to the benefits of chemotherapy in postmenopausal patients.^{5,16,37,38} The indirect estimates from the 1995 meeting were that the effect

in particular of 5 years of tamoxifen was independent of the use of chemotherapy and of age. The key conclusion to be drawn is that because tamoxifen is considerably less toxic than chemotherapy, it is the adjuvant drug of first choice for postmenopausal patients with hormonally responsive tumors who would benefit from drug therapy. However, it is also reasonable to treat patients who have considerable risk for recurrence with both modalities—chemotherapy plus tamoxifen—because this will further reduce their absolute risks for recurrence and death. The best means of combining chemotherapy and hormonal therapy is not yet defined and is the subject of ongoing clinical trials.

Are there any other benefits to adjuvant tamoxifen?

In addition to its indicated use, which is the prevention of systemic relapse, there are other potential benefits associated with tamoxifen use. Probably because of its estrogen-like effects, it has been associated with reductions in the rate of progression of osteopenia in postmenopausal women.^{39–41} Tamoxifen has been shown to change lipid profiles in a favorable direction and may reduce the risk for coronary artery disease, although there is no evidence, one way or the other, of an effect on cardiac events. In terms of primary breast cancer, several adjuvant therapy trials suggested a protective effect against second primary breast cancers, and a large randomized trial (NSABP P-1) has demonstrated that among women without a prior history of breast cancer but with a high risk for developing it, tamoxifen is effective.³⁰

What newer agents appear to be effective for adjuvant therapy of breast cancer?

In parallel with explorations of newer indications for tamoxifen, there are also newer agents to consider. One such drug is raloxifene, which may be an effective antimitogen for breast cells without the endometrial mitogenetic action of tamoxifen.⁴² It also preserves osteoblastic stimulation, thereby providing the same protection against osteoporosis as does tamoxifen.⁴³ Indeed, the current NSABP prevention study, P-2, compares tamoxifen against raloxifene for the prevention of breast cancer. However, there is no direct evidence to support the use of raloxifene to treat breast cancer in any setting, but particularly as adjuvant hormone therapy.

In the 1990s, the treatment of advanced breast cancer was improved with the availability of selective aromatase inhibitors that block the production of estradiol and estrone sulfate but do not inhibit the production of most other hormones. Because these newer agents do not appear likely to convey any estrogen-like effects, including thrombophlebitis and endometrial cancer, they have been studied in the adjuvant setting among postmenopausal women.⁴⁴ In the three adjuvant trials published as of early 2004, these agents were used instead of tamoxifen (anastrozole), after 5 years of tamoxifen (letrozole), and instead of the last 2 to 3 years of 5 years of tamoxifen (exemestane). None demonstrated a survival difference, but all three showed improved event-free survival in comparison with tamoxifen or placebo, along with acceptable toxicity profiles^{23–25} (Table 27–2). Hence, these

Table 27–2 Summary Results of the Available Aromatase Inhibitor Trials

Study	N	Setting	Treatment Arms	Results
ATAC ²³	9366	Postoperative	5 yr of tamoxifen 5 yr of anastrozole 5 yr of both	— ↑ EFS No benefit
NCIC MA-17 ²⁴	5187	After 4.5–6 yr of tamoxifen therapy	5 yr of placebo 5 yr of letrozole	— ↑ EFS
IES ²⁵	4742	After 2–3 yr of tamoxifen therapy	2–3 yr of tamoxifen (total 5 yr) 2–3 yr of exemestane (total 5 yr)	— ↑ EFS

ATAC, Anastrozole, tamoxifen, and combination; EFS, event-free survival; IES, International Exemestane Study; NCIC, National Cancer Institute of Canada.

agents are likely to be accepted as standard adjuvant therapy even while their optimal timing, duration, and long-term toxicities remain uncertain. In addition, several trials will test them in the presence of ovarian ablation among premenopausal women, but as of this writing there is no evidence for this approach outside of clinical trials.

What is the overall impact of adjuvant chemotherapy?

Overall, patients treated with chemotherapy had a 24% reduction in the annual odds of recurrence (see Table 27–1). The benefits were somewhat age dependent, so that the absolute benefit was 10.4%/15.4% (node negative/node positive) in women younger than 50 years and 5.7%/5.4% in older women at 10 years of follow-up. As with tamoxifen, the benefits in overall survival were less striking but were significant. Overall, treated patients experienced a 15% reduction in their annual risk for death, again with larger absolute gains among younger patients. In the overview, and consistent with the published results of selected individual trials, combinations of chemotherapy agents were unquestionably superior to single agents.¹⁶ The chemotherapy regimen most well represented in the overview was cyclophosphamide, methotrexate, and 5-fluorouracil (CMF). Although additional agents such as vincristine and prednisone were used in some of the included trials, they are largely of historical interest because they were included in the earliest versions of CMF administered continuously for 2 years.⁴⁵ Later modifications, in line with the MOPP (Mustargen [nitrogen mustard], Oncovin [vincristine], procarbazine, prednisone) regimen shown to be effective against Hodgkin's disease, included the intravenous administration of methotrexate and 5-fluorouracil on days 1 and 8, and oral cyclophosphamide on days 1 through 14, in 28-day cycles (14 days without chemotherapy).⁴⁶ This version, and the all-intravenous every-21-day version, are the two most standard regimens currently used. Hence, we refer to this category as CMF because, in most studies, these three drugs are the most conserved components.

What is the optimal adjuvant CMF regimen?

An ongoing effort concerning CMF has been the attempt to minimize its toxicity without compromising its proven efficacy. Lowering the individual drug doses, shortening the

overall duration of treatment, and omitting unnecessary component agents have all been tried in numerous studies. Lowering the drug dose appears to be detrimental because dose correlates with outcome. A retrospective analysis by Hryniuk and Levine⁴⁷ compared a variety of chemotherapy combinations containing an alkylating agent (generally cyclophosphamide) and antimetabolites (generally methotrexate and 5-fluorouracil) using a mathematical transformation to describe the relative dose intensities of each of the regimens. There was a significant trend suggesting improved relapse-free survival in stage II breast cancer when the higher-dose-intensity regimens were employed. Interestingly, these data are also consistent with the hypothesis that more drugs are better than fewer because the single-drug regimens were associated with the lowest probability of remaining disease free, whereas the two- and three-drug regimens had better outcomes.

Because this was a retrospective analysis across multiple studies, and because the planned rather than the delivered dose intensity was used, one could be skeptical regarding any conclusions. However, two subsequent studies support Hryniuk's conclusion. First, the group from Milan analyzed their results at 20 years of follow-up from their initial CMF trial. In this analysis, patients receiving under 85% of the planned dose intensity had a worse outcome.⁴⁸ This conclusion more strongly supports the delivery of the planned dose intensity, as close as possible. A second study, and one that was prospective and randomized, compared three dose levels of CAF and demonstrated superiority for the highest dose levels.⁴⁹ In node-positive breast cancer, there was a trend favoring the highest dose-intensity arm and a statistically significant benefit for the two higher-dose arms, as compared with the lower-dose arm.⁵⁰ Based on this mix of retrospective and prospective data, it now appears unwise to reduce the standard doses of standard chemotherapy combinations such as CMF and CAF in the effort to reduce toxicity because such intervention is very likely to reduce efficacy. On the other hand, extraordinary dose escalation remains an unproved experimental approach, as discussed later.

What is the appropriate duration of adjuvant chemotherapy?

The ideal duration for combination chemotherapy in general, or for CMF in particular, is not precisely known. The earliest studies of combination therapy, based on the current hypotheses regarding tumor growth kinetics, delivered

chemotherapy for as long as 2 years in some cases. A series of trials from Milan demonstrated that 12 months of therapy was equivalent to 24 months and later that 6 months of therapy was equivalent to 12 months.⁵¹ Other trials supported the use of the shorter durations of treatment as well. An NSABP trial (B-15) randomized patients with node-positive disease to receive 3 months (four cycles) of AC (Adriamycin [doxorubicin] and cyclophosphamide) or to receive 6 months (six cycles) of CMF with a second randomization for patients on the AC arm for “reinduction” treatment with an additional 6 months of CMF. The additional CMF added nothing, again supporting the conclusion that 6 months of CMF is adequate. The question is whether an even shorter treatment period would be as efficacious. Although it has been shown that a single cycle of treatment is inadequate, it is also clear that 3 months (four cycles) of AC is equivalent to 6 months of CMF.⁵² The possibility that 3 months of CMF might be equivalent to 6 months is the subject of ongoing and recently completed trials.⁵³ These trials, coupled with the overview method, are required to further clarify this important issue because the issue of statistical power means that negative results in studies of small size lend little confidence. For now, 6 months of treatment (six cycles of day 1 and day 8 every-28-days CMF or eight cycles of every-21-days all-intravenous CMF) appears most reasonable. At the same time, a clear demonstration that 3 or 4 months of CMF is adequate would have significant economic implications and would serve to further minimize the toxicity of standard treatment.

What are the alternatives to CMF?

The establishment of CMF as a gold standard does not preclude the existence of better regimens. The effort to increase efficacy has been the major goal of most recent trials, although some have instead sought to identify less toxic but equally active regimens. As noted earlier, the overview is not the ideal means of sorting out the ideal version of CMF to use because it groups studies that may be different in subtle but important ways. For example, all versions of CMF appear about equal in the overview, suggesting that the least toxic version might be preferred. However, in stage IV disease, the oral and intravenous day 1 and 8 administration prolonged progression-free survival, compared with the all-intravenous version administered at 21-day intervals.⁵⁴ Could this difference in efficacy in stage IV disease translate to a significant difference in earlier stages? Although one might hypothesize that a small difference in efficacy in stage IV disease is unlikely to translate into a significant difference in the adjuvant setting, this possibility is not tested and remains unanswerable within the overview.

Within the overview, trials incorporating anthracyclines (doxorubicin or epirubicin) appear to offer advantages over CMF. Yet, many of these anthracycline-containing regimens vary significantly in terms of dose and schedule for all of the component drugs, and lumping them together may lead to either overestimation or underestimation of the true impact of adding this drug. Stated another way, if there is only one best way to incorporate doxorubicin, then the overview will most likely fail to identify it because many of the trials used possibly suboptimal doses or schedules that dilute and obscure this effect. As an example, individual trials suggest

that a three-drug regimen, such as CEF (E for epirubicin) is superior to CMF, whereas several NSABP trials demonstrate equivalence for AC (four cycles) compared with CMF.^{55,56} Combining both types of trials in the overview could obscure the possible benefits associated with the “better” regimen.

Is there a role for methotrexate and 5-fluorouracil alone?

To limit the toxicity of CMF, its most noxious component—cyclophosphamide—has been omitted in some studies. That methotrexate and 5-fluorouracil (MF) is as effective as CMF was suggested by a small randomized trial conducted in stage II breast cancer.⁵⁷ However, a larger prospective randomized trial involving more than 1000 women with node-negative disease found an advantage for 6 months of CMF over 6 months of MF alone.⁵⁸ While suggesting that MF is appropriate therapy for patients judged too frail to tolerate cyclophosphamide, this study clearly showed that the omission of this agent compromises efficacy. Hence, for patients deemed appropriate for conventional chemotherapy, 6 months of CMF is the most defensible standard approach.⁵⁹ At the same time, it is important to emphasize the relative rarity of any significant long-term toxicities and to contrast this with the relative frequency of metastatic breast cancer even among the lowest-risk treatment groups. Thus, there is no reason to avoid standard CMF among otherwise healthy women with resectable breast cancer who, based on histopathology, are appropriate candidates for chemotherapy.

The previous arguments for considering CMF as the gold standard are most supportable when considering the treatment of the lowest-risk patients who should be treated with chemotherapy, such as those with negative axillary nodes and infiltrating ductal or lobular disease exceeding 1 cm in maximal diameter. In this group, the modest potential differences between regimens are most likely to be obscured against a background of relatively few events. Hence, a treatment that is detectably better in higher-risk patients who are more likely to experience an end point (relapse or death) may appear equal or nearly so in lower-risk patients. This is not, however, a good argument for generalized use of the “better” regimen because if the difference is too slight to detect reliably, then the increased toxicity of the “better” regimen may easily outweigh its benefit. The use of doxorubicin provides an example of this phenomenon. This agent has long been considered the best single agent for metastatic disease, motivating its extensive study in the adjuvant setting. Yet clear demonstrations of its advantages as adjuvant therapy have been few in comparison with the many studies finding no difference. Accepting the assumption that including this drug does improve outcome, but only by a numerically small amount among low-risk patients, most of whom never experience relapse, then the about 1% risk for congestive heart failure and acute leukemia and the guarantee of alopecia may exceed any obtainable benefit.⁶⁰⁻⁶² The point is not that adding the drug fails to improve outcome—perhaps among 100,000 such patients, a benefit would be statistically significant—but that the modest size of the benefit prevents us from reliably detecting it in the usual studies, and the risk for an untoward or even fatal complication outweighs any obtainable benefit. At the same time, this analysis by no means rules out the existence of an effective

unique non-CMF regimen. Instead, it merely indicates that the simple expedient of polychemotherapy beyond CMF does not automatically improve results in a meaningful way.

Chemotherapy plus ovarian ablation: Is the chemotherapy effect due to chemical castration?

Although the overview clearly demonstrated that chemotherapy was effective in all risk groups with adequate patient numbers (patients younger than 70 years), premenopausal patients clearly demonstrated the largest improvement in outcome. Decade by decade, there was a decrease in the relative input. This rekindled speculation that some or all of the chemotherapy effect was achieved simply through the known impact of chemotherapy on ovarian function (in some cases, a chemical castration). This is an unlikely explanation, however, given the greater impact of CMF in very young patients, in whom the rate of drug-induced amenorrhea is least; the modest but clearly additive impact of ovarian ablation in such patients; and the convincing evidence of similar benefit in postmenopausal women. In fact, although the numbers are too small to allow full confidence, there is some evidence that the impact of ovarian ablation is nearly the same in patients treated with chemotherapy as it is in untreated women.³⁴ Thus, the chemotherapy effect appears to be independent and additive to whatever benefit ovarian ablation obtains.

This very critical issue has been addressed in a recently completed but not yet reported intergroup trial. In this study, premenopausal patients treated with chemotherapy were randomized for ovarian ablation and for the addition of tamoxifen. As noted earlier in the chapter, these data are needed before we can consider ovarian ablation for standard use. It remains very possible that the long-term detrimental effects of surgical ovarian ablation, particularly if broadly applied to young lower-risk (i.e., node-negative) patients, could outweigh any gain in breast cancer outcome. Moreover, the demonstration that a temporary ablation, achieved hormonally, could provide long-term benefit but without the sequelae of premature menopause would be exciting indeed. Yet for now, there is no clear evidence to support the routine substitution of ovarian ablation for chemotherapy, nor for the addition of these two modalities, even in high-risk patients.

Is adjuvant chemotherapy of benefit in older patients?

In all patients, the benefits from tamoxifen and chemotherapy appear independent, meaning that each contributes to disease-free and overall survival. In older patients, the estimates of effectiveness for chemotherapy decline to an annual risk reduction of 20%, as opposed to 35% in those younger than 50 years. This specific result provides a nice example of the value of the technique of meta-analysis because the relatively weak but real effect of chemotherapy in postmenopausal patients was not apparent in many of the individual trials, particularly those comparing CMF plus tamoxifen with tamoxifen alone.^{38,63} The NSABP conducted the largest trial of chemotherapy plus tamoxifen versus tamoxifen alone in postmenopausal patients with receptor-

positive, node-positive disease. After more than 8 years of follow-up, this trial continues to provide clear evidence of an additive effect.⁶⁴ Similarly, the extensive experience of the National Cancer Institute in Milan confirms an impact of CMF independent of patient age, at least when the planned dose intensity is maintained.⁴⁸ On the other hand, there does appear to be a decade-by-decade decline in the impact of chemotherapy in the overview, and it remains puzzling that this modality has a relatively weaker impact in older than younger patients, particularly because in advanced disease, it is equally effective in these two groups.⁶⁵ A biologic explanation is not obvious, and it remains possible that the age effect seen in the overview is due to patient selection, purely statistical issues related to sample sizes, or perhaps a consistent trend toward underdosing as age rises. This latter possibility, that in some negative trials dose adjustments for actual or anticipated toxicity in older patients are biased against a chemotherapy response, cannot be determined without review of individual patient records, which is well beyond the limits of the overview. At the same time, it is possible that tamoxifen confounded the results in some trials, particularly among relatively lower-risk patients. For example, if there was a profound tamoxifen effect in patients with very ER-positive tumors, this could have diminished the possibility of detecting a chemotherapy effect because the already low underlying risk for recurrence was significantly further reduced. This situation could pertain to patients with low degrees of nodal involvement. If true, then a statistically important benefit for higher-risk patients could be missed. Despite this possibly confounding circumstance, it is clear from the overview that there is a chemotherapy effect in the postmenopausal setting, and clinicians should exploit this benefit in defined circumstances such as in higher-risk postmenopausal patients, as discussed later. At the same time, an increasing number of clinical trials are underway to develop better and safer regimens in particular for older patients with hormone receptor-negative tumors.

What are the results of clinical trials with taxanes?

Based on extensive trials demonstrating significant activity for taxanes in the treatment of advanced disease, thousands of patients have been treated in adjuvant studies testing these agents. Clinical trial results too late for inclusion even in the 2000 overview clearly show that patients with node-positive disease benefit from the inclusion of taxanes either following conventional AC or replacing 5-fluorouracil as part of an FAC (5-fluorouracil, doxorubicin [Adriamycin], cyclophosphamide) regimen.^{66,67} These trials, unlike the earlier-generation studies included in the overview, are large, with thousands of randomized patients. In fact, the first three positive adjuvant trials testing taxanes enrolled almost as many patients (about 7500) as were ever randomized in the more than one dozen trials comparing anthracycline-containing regimens against CMF (13,800). All three of these first adjuvant taxane studies enrolled patients with node-positive disease, and all allowed hormonal and radiotherapy therapy where appropriate. In all three studies, a benefit in disease-free survival was seen, and in two of the studies, overall survival was also improved. Taken together, these studies provide

ample justification for the routine use of taxanes following one of these approaches in appropriate patients. Direct comparisons between the taxanes have not been reported, but one large study (ECOG 1199) is fully accrued.

Are dose-dense regimens better than conventional dosing schedules?

Dose intensity is a way of quantifying the total amount of drug administered over a specified period of time. Increases in dose intensity are therefore possible not only by increasing dose size (dose escalation) but also by decreasing the interval between treatments (shortening the time period). The latter method of dose intensification, first proposed by Norton,⁶⁸ can be labeled *dose-dense treatment* to distinguish it from all other dose-intensification schemes (Fig. 27–2). However, it can be tested only when other variables, such as dose size and number, are controlled. A trial conducted in Milan and enrolling women with four or more involved nodes was one of the first tests of dose-dense therapy.⁶⁹ Treatment consisted of alternating (less dose-dense) versus sequential (more dose-dense) regimens using single-agent doxorubicin (A) and CMF, and over more than 33 weeks of treatment, every patient in the study received four doses of doxorubicin and eight of CMF. At 10 years of follow-up, sequential administration (four cycles of A followed by eight of CMF) remained significantly better in disease-free and overall survival than the alternating plan. Based on these results, as well as those of several promising pilot trials, the intergroup has now conducted several trials in which dose density is a critical question. One study compared concurrent AC with sequential (more dose-dense) administration of the same cumulative doses of these drugs (Southwest Oncology Group [SWOG] 9313). However, the numbers of cycles of administration for each agent vary in this trial. Coupled with the lack of a dose-response relationship in the supernormal range for these two drugs, one has to recognize that rather than testing dose density in isolation, this trial tests fewer cycles of higher-dose treatment against more cycles of lower-dose therapy.^{66,70,71} If the low and high doses are equally effective, this trial could be interpreted as showing that dose-dense administration of

cyclophosphamide compensates for the administration of fewer cycles.⁷²

In terms of dose density, the key testing the concept was the Cancer and Leukemia Group B (CALGB) 9741 trial. In this study, every-other-week chemotherapy was compared with every-third-week treatment, demonstrating a significant improvement in both disease-free and overall survival for the more dose-dense approach.⁷³ This latter trial is particularly important because the shortened interval (from 3 to 2 weeks) not only was superior but also was unassociated with significantly increased toxicity. A planned NSABP study may compare this dose-dense regimen of AC followed by paclitaxel (all given at 2-week intervals) against a more “conventional” TAC (docetaxel [Taxotere], doxorubicin [Adriamycin], cyclophosphamide) regimen using docetaxel and AC together at 3-week intervals. Until this study is reported, either regimen can be appropriate for higher-risk patients.

How does risk assessment influence the choice of adjuvant therapy?

The proceeding discussion shows that the absolute benefit of therapy is only indirectly linked to the relative benefit and is always numerically less. Hence, it is not sufficient to conclude that a 20% reduction in the risk for annual recurrence does or does not justify treatment. In the lowest-risk patients, this benefit will, in absolute terms, be nearly zero, whereas in those with higher risk, the same therapeutic impact is far more significant. Although this rationale seems self-evident, the overview provides welcome confirmation. Because of the widespread assumption that risk for relapse and treatment benefit are always linked, we have historically dichotomized patients both for allocation into trials and for rendering recommendations regarding choice of therapy. This has resulted in fairly discrete but somewhat arbitrary categories of risk, and these have, in turn, become integral to our standard clinical lexicon. The simplest dichotomy—node positivity versus node negativity—provides demonstration of the limits of this approach because it implies that the magnitude of nodal involvement is unimportant, whereas a patient with one or two positive axillary lymph nodes and a small tumor has a

Figure 27–2 Schematic comparison of dose escalation and dose density. In this example, the dose-response relationship is relatively flat between dose A and dose B (A). However, the higher-dose level of dose B is associated with greater toxicity, whereas the lower dose, A, is sufficiently nontoxic that it can be repeated multiple times at short intervals. The theoretical result is greater overall cell kill, as shown in parts B and C.

prognosis more similar to that of a patient with negative nodes than to that of a patient with more than 20 involved nodes.^{74,75} Similarly, ER status is more likely a continuum, not merely a dichotomous “positive” or “negative,” as our classifications would specify. Even menopausal status is less precise than our earlier discussion would imply. The youngest premenopausal patients benefit the least from tamoxifen, whereas those who are still menstruating but are approaching menopause may gain almost as much from the use of tamoxifen as do frankly menopausal women. The underlying biology of this continuum could be due to the relative drop in estrogen levels with approaching menopause or, perhaps more importantly, the relative lack of a hyperestrogenic response to the administration of tamoxifen as women age. Regardless, the biologic continuum argues against an over-reliance on strict dichotomous descriptors when considering the management of patients in the clinic.

Despite the limitations that the “pigeon-holing” of patients entails, we still need a means of assessing risk so that we can determine the relative risks and benefits of specific therapeutic interventions, such as chemotherapy or tamoxifen. Specifically, because the impact of adjuvant drug therapy is on the rate of recurrence or death from cancer, in order to determine whether we should use tamoxifen or chemotherapy, we need to assess that rate in the unperturbed situation, know the degree of perturbation in that rate that we can expect from a specific treatment, estimate the impact of that rate reduction on absolute risk for recurrence or death, and balance that absolute benefit against the toxicities, expense, and inconvenience of treatment. In daily clinical practice, this is a challenging task made even more so by uncertainties regarding drug interactions in some patient subgroups and by unknown predictive factors that might play a role in determining the benefits of specific treatments in individual patients.

The complexity of this topic is such that only general recommendations can be offered. Furthermore, it is probably counterproductive to strive for broad and absolute recommendations given that the risks for treatment evolve over time (presumably toward greater safety) and the benefits of therapy continue to be more clearly identified. Instead, one should strive to consistently apply classic clinical medical principles, emphasizing the avoidance of unwarranted harm and the maximizing of benefits. To guide clinical decision making, Table 27–1 lists a published reanalysis of the 1990 overview, giving estimates of the recurrence rate reductions in various dichotomous categories. For younger patients, chemotherapy is the modality of choice if the risk for recurrence is high enough to justify any adjuvant treatment at all. A role for tamoxifen alone might be considered in older premenopausal patients with ER-rich tumors who qualify for treatment but still have a relatively low risk for recurrence, but this approach is less firmly supportable. In younger postmenopausal patients, tamoxifen might also be added to chemotherapy if the tumor is ER rich and the residual risk for recurrence is estimated to be high even after chemotherapy. This strategy may be especially reasonable in older premenopausal patients if the chemotherapy has induced menopause, as it frequently does in this subgroup. However, it must be kept in mind that the 1995 overview, which is not yet published, will be scrutinized for the additional advantage of tamoxifen plus chemotherapy over chemotherapy alone in younger patients, so that recommendations in this regard may change rapidly.

For postmenopausal patients, tamoxifen is clearly advantageous in the treatment of ER-positive disease. However, independent of age, many postmenopausal patients will still have a significant chance of recurrence even after tamoxifen use because of tumor size or high degrees of nodal involvement. Because chemotherapy does have activity in the older patient, its use cannot and should not be ignored in making treatment decisions, especially in those cases in which the tumor is ER and PR poor.

How is the risk for recurrence estimated?

The previous discussion and the rational use of adjuvant therapy pivot on the issue of risk assessment. By far, the most time-tested and most accurate estimator of risk is the degree of metastatic involvement of the ipsilateral axillary lymph nodes.⁷⁶ Importantly, this assessment is simply based on the absolute number of involved nodes and not the percentage of nodes involved or the size of individual metastatic nodes. Of course, an adequate lymph node examination is required to assess this involvement, and historically, a minimal standard was that at least 10 individual nodes be made available for pathologic study. Statistically, 10 of 10 nodes found to be free of cancer by light microscopy is a reliable indicator of “true” node-negative status.⁷⁷ On the other hand, there certainly are circumstances in which excellent surgeons are unable to provide this minimal number of nodes, and in these cases, the proportion of involved nodes may be a reasonable relative guide to risk—for example, a patient with 3 of 5 axillary nodes found to contain breast cancer is most likely at a similarly high risk as a patient with 8 involved nodes out of 21 examined. Because a patient with even one involved node generally has a risk for relapse in excess of 30%, any adjuvant therapy that reduces the odds of recurrence by at least 20% should improve her chances of being free of cancer after 10 years by at least 5% and should be considered. Now that sentinel lymph node dissection has been broadly accepted as adequate demonstration of node-negative status, the historical standards in terms of nodal examination no longer apply. However, newer techniques, such as cytokeratin staining or molecular studies, used to confirm that no positive nodes are missed, may increase the identification of involved nodes, making reassessment of the meaning of “positive” necessary.⁷⁸

How is the risk for recurrence assessed in node-negative patients?

The situation regarding treatment is less clear in patients without axillary lymph node involvement than it is in node-positive patients. Overall, about one third of node-negative patients will eventually manifest stage IV disease; thus, nodal negativity cannot be considered tantamount to cure by local control alone. In this group, risk can be stratified most simply by examining the maximal tumor size. For example, patients with node-negative disease but whose tumors exceed 2 cm have a risk for recurrence very similar to that of patients with one or two involved axillary nodes.^{74,75} As in the previous paragraph, adjuvant treatment is easily justified if it can reduce the annual odds of recurrence by 30% (it can) and the absolute risk for developing recurrence at 10 years by 5% (it

also can). More troubling at the moment is how to treat the growing number of patients with often only mammographically detected node-negative breast cancer less than 2 cm in size. The critical issue is whether the patients in this “low-risk” group, or even those previously discussed who have higher risk and are destined to experience recurrence, can be picked out by some reliable method and targeted for systemic therapy. Obviously, this would also allow us to spare other patients unnecessary treatment while perhaps more effectively treating those who need it most. Efforts in this direction have been ongoing, and a large body of investigation has pointed to many potential prognostic factors assessable in the resected surgical specimen at the time of primary local control.

On the assumption that some factors intrinsic to individual tumors are associated with greater or lesser risk for distant spread, great effort has been made to identify useful prognostic markers. An interesting common ground shared by many of these factors is the hypothesis that they are in some way directly and functionally related to the “aggressiveness” of the tumor. If proven effective as prognostic factors, these could be used in addition to tumor size and histopathology to aid in clinical decision making. An ideal marker would serve to separate patients with virtually no risk for distant recurrence from those with greater risk or, conversely, those with certain risk of recurrence from those with lesser risk. Of the many potentially useful factors, some of the most popular and widely used clinically are steroid hormone receptor status, S-phase fraction, DNA ploidy, cathepsin D levels by biochemical assay or immunohistochemistry, and *HER-2/neu* overexpression.^{79–83} For these and other markers, such as *p53* overexpression (a marker of mutated *p53* gene), retrospective analyses suggest that these determinations do convey some prognostic information, but in all cases except the steroid receptor assays, prospective studies demonstrating that prior knowledge of these results leads to improved therapeutic choices and outcomes are not available. Another limitation on the utility of these prognostic factors is that they often correlate with more easily measured variables such as tumor size and degree of differentiation. In addition, these prognostic factors mostly exert their influence within pathologic subgroups already defined by virtue of size, histology, and nodal status. Furthermore, within individual studies, this information is frequently confounded because of the lack of standardization between and even within laboratories. A final obstacle to routine use is that even if reliable results were available, there is no simple system for integrating the multiple, often conflicting, prognostic factor data. Indeed, some workers have gone so far as to develop so-called neural networks and web-based computer programs that incorporate the “effect” of this growing list of prognostic factors to arrive at individualized risk assessment.^{84,85} Because of their complexity and lack of reliability, these newer factors have rightly not entered routine clinical practice, and the safest course in the clinic at present is to rely on established histopathologic measures alone in assessing prognosis.⁸⁶

At present, a significant effort is underway to develop molecular profiling, primarily through the use of tissue microarrays, to identify patterns of gene expression associated with greater or lesser risks for recurrence.⁸⁷ Although promising, these methods are still to be prospectively validated.

Among node-negative patients, the simplest and most accurate determinant of recurrence is tumor size. The best

evidence to date comes from Memorial Sloan-Kettering Cancer Center, where 767 women with node-negative disease and no adjuvant systemic therapy were followed for more than 2 decades after undergoing local treatment.⁸⁸ Those who had infiltrating ductal carcinomas, not otherwise specified, or infiltrating lobular carcinomas, in either case measuring up to 1 cm in diameter, had a 13% actuarial risk for relapse at 21 years. In this series, the small number of patients with special histologic types of node-negative cancer—tubular, papillary, true medullary, mucinous, or adenoid cystic—had the same low risk for recurrence with tumor diameters of up to 3 cm as was seen in the more common histologic subtypes with tumor diameters less than 1 cm. The low risk for recurrence in this category of node-negative patients has a critical clinical implication. If, as described earlier, a systemic treatment (be it chemotherapy or tamoxifen) results in at least a one-third reduction in the annual odds of recurrence, then an extrapolation to these low-risk patients suggests that they might gain no more than 4 percentage points in benefit distributed over 2 decades. At 10 years, there might be only a 2% difference in the absolute risk for relapse, and unless benefits continue to accrue for a lifetime (an unlikely assumption), this might be the total size of the benefit ever seen. An additional argument against the routine use of any systemic therapy for this low-risk group is based on the simple fact that there are no properly randomized data obtained in such patients, although the pooled NSABP data do suggest a similar relative risk reduction in patients with subcentimeter node-negative tumors.⁸⁹ For these reasons, the National Cancer Institute issued a clinical alert in 1990 suggesting that such patients may not be good candidates for systemic therapy because all drug therapies are associated with a small but real risk for serious untoward effects, and benefit in these low-risk patients is not proved or suggested by any available data.⁹⁰ The 2000 update was less specific in this regard and could be interpreted as supporting chemotherapy in high-risk subsets.⁹¹

What is the appropriate timing of chemotherapy in relation to surgery?

Given the modest effectiveness of each of the three standard interventions (surgery, radiation therapy, and systemic therapy) available to patients with early-stage disease, a part of our clinical effort is directed at optimizing the delivery of each modality. In addition, the most beneficial means of applying and integrating surgery, radiation therapy, and systemic therapy has been sought but is not yet certain.

The first issue to consider is the timing of systemic therapy and surgery. Because chemotherapy has been used successfully to shrink locally advanced breast cancers before local control surgery (so-called neoadjuvant therapy), there has been enthusiasm for broader use of this approach. The arguments in favor of routine neoadjuvant chemotherapy are twofold. First, it would allow for increased use of breast-conserving surgery. Second, it might be theoretically better because it would result in the earliest possible application of systemic therapy and might, therefore, improve the chances of ultimate cure.

The first argument, that it increases the chances for breast conservation, has been substantiated in one prospective randomized trial. In a study conducted by the NSABP (B-18),

patients with initially operable breast cancer were randomly assigned to receive standard treatment with AC for four cycles either before or after standard surgery. Limited excisions were performed in 81% of cases in the preoperative treatment group, as compared with 57% in the postoperative group.⁹² Based on this result, it does appear reasonable to consider standard chemotherapy in the preoperative setting, especially for patients who might refuse to undergo mastectomy but for whom a limited excision and radiation therapy would be acceptable. At the same time, neither this nor any other study demonstrates that earlier therapy provides any advantages in terms of disease-free or overall survival, meaning that unless lumpectomy is facilitated in a specific situation, there is little justification for preoperative therapy outside of the clinical trial setting for resectable breast cancer.

There are several additional reasons to resist the temptation simply to treat all patients with neoadjuvant therapy. First, if an anthracycline-containing regimen were used, then many low-risk patients for whom this acutely more toxic drug does not offer proven advantage would be overtreated and subjected to increased risk for chronic toxicities, including cardiomyopathy and perhaps leukemia. Similarly, low-risk patients with resectable node-negative disease who might be appropriate candidates for tamoxifen alone would also be overtreated because they would not benefit significantly from the application of chemotherapy. At the other end of the local disease spectrum, there could be some patients with marginally resectable breast cancer treated in this fashion who might have progression of disease during chemotherapy to the point of unresectability. This rare outcome is particularly tragic because local control still offers a tremendous improvement in quality of life for many patients even when their disease is incurable. Finally, because of the unpredictability of downstaging, patients could no longer be as accurately staged, with the result that those patients who might benefit from more innovative treatment strategies might not be identified and referred for study or even standard therapy, such as postmastectomy radiation therapy.

What is the appropriate timing of chemotherapy in relation to radiotherapy?

On the assumption that definitive breast cancer surgery will be followed by systemic therapy, the timing of radiotherapy (when it is indicated) remains an issue. On theoretical grounds, all permutations (i.e., chemotherapy, then radiation therapy; radiation therapy, then chemotherapy; and more complex interdigitations) have been hypothesized as superior to other permutations. At the same time, it is established by prospective randomized trial that at least 5 weeks may relapse from definitive breast surgery before the initiation of chemotherapy with no loss of efficacy.⁵² Hence, in a quest to minimize the risk for a local recurrence in patients treated with breast conservation, many radiotherapists have opted for radiation before chemotherapy, especially in the low-risk setting of node-negative disease when fears of rapid systemic recurrence are justifiably low. In support of this approach, a retrospective report from the Joint Center for Radiotherapy in Boston, soon followed by supportive historical information from the University of Washington, suggested that patients receiving all of their chemotherapy before undergoing breast

irradiation had an unacceptable incidence of local recurrence.^{93,94} Although provocative, these findings were not conclusive because they were not based on randomized prospective trials. Furthermore, retrospective data from other centers were not corroborating.^{95,96} To their credit, investigators at the Joint Center performed a prospective clinical trial comparing the sequence of chemotherapy followed by radiation therapy against the reverse. In this relatively small study, patients randomized to receive radiation first had a lower incidence of local recurrence compared with those receiving a 16-week course of chemotherapy first, but they had a higher incidence of systemic recurrence, and the difference was most significant among those with positive axillary lymph nodes.⁹⁷ Because it is systemic failure rather than ipsilateral breast recurrence that is more life-threatening, and because the only prospective randomized trial suggests that the early delivery of chemotherapy is advantageous in terms of overall survival, this is the most defensible strategy to employ in routine clinical practice. Hence, for most patients with operable breast cancer, the most appropriate sequence of treatments appears to be surgery, then chemotherapy (if indicated), and then radiotherapy (if indicated).

NEW DIRECTIONS IN CHEMOTHERAPY

As described earlier, both individual trial results and the overview have clearly established that prolonged polychemotherapy such as CMF in the adjuvant setting prolongs disease-free and overall survival and is superior in this regard to single-agent chemotherapy. Within the overview, CMF alone is no worse than the CMF variants that simply add or substitute pharmacologic components and is also equivalent to other multiagent combinations. Although the degree of reduction in the odds of relapse and death observed to date from combination chemotherapy are respectable, they are far from satisfactory, and the toxicities of chemotherapy remain significant. Hence, a great deal of attention is focused on the development of new and better agents or regimens and clinical trials testing vinorelbine, gemcitabine, capecitabine, and other recently developed drugs. In addition, new studies are exploring the choice of taxanes and their schedule of administration.

What newer modalities have been introduced for adjuvant therapy of breast cancer?

Theoretical considerations and clinical trials data that support the use of dose density and sequential chemotherapy are also consistent with a somewhat more pessimistic possibility—that is, if the small volumes of residual breast cancer left after local care and systemic drug therapy can regrow so rapidly that the impact of adjuvant therapy is modest, then perhaps any improvement in the effectiveness of chemotherapy will be undetectable unless complete eradication of all malignant cells is achieved. Neither the fractional cell kill model nor the refinement of gompertzian growth curves predicts this happy result. In this case, further advances in treatment will lead to greater cell killing but little actual clinical benefit in disease-free or overall survival.

To overcome this obstacle, clinical scientists have turned their attention to the translation of laboratory concepts of growth control to the problem of growth inhibition of refractory cancer cells. Recent laboratory evidence has shown that receptors with both intracellular and extracellular domains may act as controls on cell growth. The family of molecules best studied in this regard includes both *HER-2/neu* and epidermal growth factor receptors. Although a preliminary result, the possibility of interfering with the normal function of these receptors and thereby altering the growth of malignant cells is suggested by the demonstration that monoclonal antibodies to the *HER-2/neu* putative growth factor receptor can cause prolonged regression of *HER-2*-positive advanced breast cancer.^{98,99} This result has been confirmed in larger randomized trials in more narrowly defined subpopulations of women with metastatic breast cancer.^{100,101} As a consequence, several trials are testing the incorporation of trastuzumab into an AC-taxane-based adjuvant chemotherapy approach.

Another immunologic treatment that targets unique antigens overexpressed on breast cancer cells is vaccination. Vaccines against antigens commonly expressed in adenocarcinomas, like MUC-1, are being studied in advanced disease, but efficacy is not yet established.¹⁰² Again, tumor heterogeneity represents a challenge to the successful use of this technique, but polyvalent vaccines may overcome this difficulty. The list of potential biologic therapies for use in the adjuvant setting grows yearly and includes polyelectrolytes to absorb growth factors, radioisotopes or toxins conjugated to growth factors or monoclonal antibodies, retinoids to induce differentiation, and inhibitors of protein kinases, signal transduction, and angiogenesis.¹⁰³⁻¹⁰⁷ Although it is premature to consider these agents for use as adjuvant therapy, their development is predicated on the possibility that they may be useful after optimized cytoreduction with chemotherapy to get beyond the limits of conventional treatment.

What is the potential role of bisphosphonates as adjuvant therapy?

A new and unexplored approach to treating early-stage breast cancer involves the use of stromal-altering agents that work, not by direct effect on tumor cells, but instead through changes in the underlying tissues in which the cells grow. An early example of one such agent was pamidronate. This antihypercalcemia agent exerts its effect through the inhibition of osteoclasts. Interestingly, randomized trials have demonstrated a modest but real impact on the rate of progression of lytic bone metastases in treated patients.¹⁰⁸ It is intriguing to note that this observation was the first to suggest that an agent acting only on the stroma can change the growth pattern of a malignancy. The exact mechanism of this effect is not defined but should be explored so as to suggest perhaps better means of exploiting this potential. In addition to pamidronate and zoledronate, there are other antiosteoporosis products available that also selectively inhibit bone resorption. These agents are intriguing for the prevention of osteoporosis, because, of course, they lack any of the endocrine effects of tamoxifen. At present, the role of these agents either alone or combined with other active cytotoxic or cytotoxic agents as adjuvant therapy is completely unknown, but a future role is a distinct possibility warranting randomized study. Several adjuvant

therapy trials testing oral and intravenous bisphosphonates are underway.

How aggressively should a patient's extent of disease be evaluated before and after adjuvant therapy?

For patients with early-stage breast cancer, the use of staging studies and follow-up testing, including all diagnostic interventions performed after local control surgery and radiotherapy and after the conclusion of adjuvant systemic chemotherapy, has been controversial for many years. Because testing may be expensive, time-consuming, and of uncertain benefit, and because recent changes in the treatment paradigm for early-stage breast cancer have increased the number of patients who are potentially cured, this issue is receiving more attention.

On the assumption that mammography, chest radiography, and selected liver function tests have been obtained in all patients at baseline, the first question concerns the use of additional baseline studies. Serum markers, such as carcinoembryonic antigen (CEA) and CA-15-3, and nuclear bone scans are reasonable additional studies for high-risk groups (i.e., four or more involved nodes or large primary tumors) and for those with increased serum alkaline phosphatase or any skeletal symptoms. The routine use of computed tomography (CT) scans of the chest and abdomen is not justifiable for lower-risk patients but might be for those with 10 or more positive nodes.¹⁰⁹ After this phase of treatment and evaluation, the question now raised concerns the utility of repeating these tests at specific intervals.¹¹⁰

The answer to this question requires that we first consider the goals of follow-up testing, the most critical being the identification of curable disease and the secondary one being the early diagnosis of presymptomatic disease so as to facilitate preemptive palliation. Curable disease can include new primary ipsilateral or contralateral breast cancer, other primary malignancies such as colorectal or cervical cancer, and other routine medical illnesses. In addition, endometrial carcinoma is a particular concern in patients taking tamoxifen.³³ These objectives are considered separately.

Patients with a history of breast cancer are at increased risk for the development of new primary breast neoplasms and, among patients treated with breast conservation, for recurrence within the breast.¹¹¹ Therefore, they are appropriate targets for intensified screening for early detection of disease within the breast. As with other defined high-risk groups, screening should consist of regular history and physical examinations and mammography. Although retrospective study has established the worth of regular physical examinations combined with yearly mammographic screening, the ideal frequency for office visits is not known. In one series, the incidence of in situ and stage I carcinomas combined rose from 58% to 74% after mammographic screening was added to the routine follow-up of patients with early-stage disease.¹¹² Because second primary breast cancers, like first primary cancers, are more likely to be cured if they are diagnosed earlier, mammography should be included as a routine part of follow-up testing. Although local relapse within the breast is a poor prognostic factor, many such patients will be cured by salvage surgery, and their risk for locally advanced disease will

clearly be reduced.¹¹³ In line with the recommendations for screening the general population, patients with a history of breast cancer should be followed with at least a yearly history and physical examination and mammography. More frequent office visits may be justifiable, but more frequent screening mammograms are probably not.¹¹⁴ More recently, a possible role for magnetic resonance imaging (MRI), particularly among very high-risk patients and as a tool for treatment planning, has been suggested, and many clinicians have adopted this approach, recognizing the challenges inherent in conducting convincing large-scale screening studies, as was required for mammography.^{115,116}

Although patients with a history of breast cancer may be at increased risk for other malignancies, there are no data supporting more intensive screening for them. They should be offered screening in accordance with standard guidelines, including stool hemocult testing and pelvic examination on a yearly basis or as appropriate for the patient's age. Sigmoidoscopy should be performed at regular intervals following standard screening guidelines as well. Even for patients on tamoxifen, the role of uterine ultrasonography or biopsy as screening tests for endometrial cancer is unproved, and these tests cannot now be routinely recommended. Routine CA-125 determinations as a screening test for ovarian cancer have likewise not been shown to be useful in the general population.³²

The second and more controversial goal of follow-up testing is the detection of metastatic disease, the goals being improved palliation, delayed onset of symptoms, and possibly increased odds of cure. Clinicians may also be motivated by the need to obtain accurate results for clinical trials of adjuvant therapy and the desire to reassure patients that there is no evidence of disease. To achieve these goals, testing can include history and physical examination, serum liver function assays, complete blood counts, serum marker assays (CEA, CA-15-3, and possibly others), and imaging studies, including chest radiography, nuclear bone scans, ultrasonography, CT, and MRI at regular intervals.

Multiple retrospective studies have found that history and physical examinations detect 50% to 90% of all recurrences.¹¹⁷ Even among intensively tested patients, most recurrences are discovered only after a specific problem or complaint is noted during or between scheduled office visits. Recognizing these data, and based on historical procedures, most investigators have recommended 3- to 6-month intervals between physician visits for the first 1 to 5 years after diagnosis. One motive for this frequent follow-up schedule is that some patients may not report problems between visits but will save them for weeks or months until a regularly scheduled appointment. These patients could benefit from more frequent opportunities to note their complaints and thereby might have better palliation of symptoms. In addition, this schedule allows physicians ample opportunity for general medical testing for hypertension, diabetes, coronary artery disease, and other common medical illnesses.

In addition to the history, physical examination, and mammography, many clinicians rely on blood testing to detect metastatic disease. At present, there are no data on the usefulness of frequent complete blood counts. This test can detect anemia and cytopenia secondary to medical ailments or metastatic breast cancer, and for patients treated in investigational studies, the detection of secondary leukemias may be

important. Hence, most investigators recommend at least a yearly complete blood count, but many clinicians obtain this inexpensive test far more often. Serum liver function tests, including alkaline phosphatase and aspartate aminotransferase (AST), can be early indicators of liver or bone metastases and have long-established positions in most clinicians' follow-up schemas. Retrospective study has shown the sensitivity and specificity of two serial elevations of these assays for recurrence.¹¹⁸ These studies can serve as screening tests to trigger more intensive imaging studies in patients who are asymptomatic, with the goal of implementing therapy before symptoms appear. The recommended frequency of such testing is not established. Currently available serum marker assays include CEA and the CA-15-3 (and analogues), but others are under development. Numerous authors have reported that the probability of finding clinically detectable metastatic breast cancer in patients with rising serial CEA determinations is between 15% and 68%.¹¹⁹ False-positive rates for elevation range from 10% to 27%. The median lead time between detection of an elevated CEA and clinically detectable evidence of metastatic disease has ranged from 5 to 7 months. Thus, in patients whose CEA elevation does predict stage IV disease, there could often be as much as a 6-month advance warning before other signs and symptoms of disease appear. The CA-15-3 is an assay for circulating levels of polymorphic epithelial mucin studied extensively as an aid in the management of patients with advanced disease. As with CEA, there is evidence that rising serial CA-15-3 determinations predict recurrent disease with a median lead time of 9 months.¹²⁰

Chest radiography is one of the least expensive and most widely available imaging studies. Among smokers, it may be useful as a screening test for primary lung cancer, but in patients with a history of breast cancer, it is used to screen for distant metastases.¹²¹ In one large retrospective study, high-risk patients (T3, T4, or node positive) underwent chest radiography 6 months after diagnosis, 1 year after diagnosis, and then yearly for 6 years.¹²² In this series, chest radiography was successful at finding presymptomatic disease with a true-positive rate of 1 of 76 examinations performed. The obvious question is whether presymptomatic detection of such metastases is helpful.

Because bone is a frequent site for recurrent breast cancer and may be the most frequent site of single metastases, and because most lesions are osteolytic or mixed osteolytic and osteoblastic, the nuclear bone scan is a sensitive means of detection. In patients with bone metastases, symptoms are generally attributed to periosteal involvement, which can occur late. Thus, these lesions can remain clinically silent for prolonged periods. Because many patients with early-stage disease will develop bone metastases, and because early treatment with radiation therapy or orthopedic surgery may prevent pathologic fractures and subsequent pain, many clinicians advocate the routine use of nuclear bone scans in asymptomatic patients. One study demonstrated that the eventual bone scan conversion rates for stage I and II breast cancer were 7% and 45%, respectively, and that most conversions occurred in the first 24 months after diagnosis. Based on these data, some investigators recommend bone scans every 6 months for 2 years after diagnosis but subsequently only in symptomatic patients.¹²³ Evidence against this sort of routine use was provided by a retrospective review that noted that the chance of finding metastatic disease on a bone scan was less

than 1% if the patient was asymptomatic and had a normal chest radiograph and alkaline phosphatase and no other evidence of metastases.¹²⁴ Because most high-risk patients experience relapse in the first 2 or 3 years after diagnosis, some cooperative groups have not been recommending that this test be performed on any asymptomatic patients beyond 3 years from diagnosis.¹²⁵

Considering the various methods for detecting recurrent stage IV breast cancer, Schapira and Urban in 1991 noted that patients found 70.6% of all recurrent disease, physical examinations found 15.4%, nuclear bone scans detected 3.4%, chest radiographs 2.7%, and serum blood tests 5.9%.¹²⁶ Mammography found an additional 2%, but this subset presumably does not have metastatic disease. Similarly, Loprinzi summarized the results of multiple reports of follow-up screening studies and also found that history and physical examination detected 75% to 85% of all metastases, serum and liver function tests found 1% to 12%, chest radiography 0% to 5%, and nuclear bone scans 0% to 8%.¹²⁴ For markers such as CEA and CA-15-3, there were no data.

In 1994, two prospective randomized trials from Italy comparing intensive and nonintensive follow-up were reported. In the first trial, 1243 patients younger than 70 years who were free of cancer were followed at 12 centers. All patients underwent annual mammography and 3-month follow-up visits for 2 years, then 6-month follow-up visits for 2 years, and then 6-month follow-up visits for 3 years. Patients were randomly assigned so that 621 underwent no additional screening and 622 underwent chest radiography and bone scans at 6-month intervals. The end points of this trial were disease-free survival and overall survival. There were slightly more distant metastases noted in the intensive follow-up group, and there was increased detection of isolated intrathoracic and bone involvement (18% versus 11.4%), in particular. However, at 5 years of follow-up, there was no difference in the overall survival, nor in the subsequent therapeutic interventions for each group. Thus, early detection did not change survival. Importantly, the style of treatment for metastases was similarly unaffected by the increased detection.¹²⁷ This could explain the lack of difference in outcome because it is likely that early identification of isolated stage IV breast cancer will not improve outcome unless the therapeutic interventions are altered and improved as compared with a more minimally followed group of patients.

A second trial, the Interdisciplinary Group for Cancer Care Evaluation (GIVIO) study, followed 1320 patients younger than 70 years at 26 treatment centers. Six-hundred sixty-five patients were randomly assigned to undergo yearly mammography as well as history of physical at 3-month intervals for 2 years and then at 6-month intervals for 3 years. The other 655 patients were, in addition, screened with chest radiographs every 6 months, yearly bone scans, liver sonograms, and laboratory testing, including serum liver function tests. In addition to overall and disease-free survival, quality of life was also assessed using a panel of standard tools. There were no differences in any of these three end points.¹²⁸ This is important because one concern regarding intensive testing has been that the stress of testing and pursuing positive results outweighs any potential benefits. This study suggests that this stress is not appreciable or is equaled by the heightened sense of security among patients who are found to be free of cancer.

Based on these two trials, it appears that there is no survival advantage for intensively tested patients who are subsequently treated in the same fashion as routinely screened patients. Hence, these investigators recommend that asymptomatic patients should not be tested except as part of clinical trials. However, more intensive testing could be justified for patients who might consider participation on clinical trials if metastases were found.

For patients and their physicians, there is no simple or single answer to the question "How much is enough?" Institutions, practices, and cooperative groups have internal standards and protocols for patients both on and off study. The rationales in each of these settings may be very different. For patients who are very elderly or for whom systemic therapy or prophylactic palliative therapy is not contemplated, a minimalist approach can be recommended.¹²⁹ In this setting, a history and physical examination should be performed every 3 to 4 months for 3 years, then every 4 to 6 months in years 4 and 5, and then yearly. Importantly, an annual mammogram and routine surveillance for other curable malignancies must be incorporated as appropriate. At the same time, physicians and other health care providers must be vigilant and compulsive in pursuing vague and possibly early signs or symptoms of metastatic disease so as to avoid an occasional catastrophic presentation of metastases.

If a patient is potentially interested in pursuing investigational therapies, a more intensive follow-up program may be justified. In this case, in addition to the routine follow-up described earlier, a chest radiograph should be obtained yearly. The justification for this test is that it is relatively inexpensive and may increase the chance of finding the isolated intrathoracic metastasis that may be better treated when smaller. Similarly, serum studies with alkaline phosphatase, AST, and markers should be obtained at every clinic visit, and a confirmed elevated serum test should trigger a more intensive diagnostic evaluation. In high-risk patients it is tempting to recommend nuclear bone scans at regular intervals. However, if the liver function studies and chest radiographs are normal and the patient has no skeletal complaints, the yield for routine bone scans is probably too low to justify the expense. There is at present no defined group of patients outside of those participating in clinical trials for whom routine CT scanning should be employed.

The most widely used argument against extensive testing, as described earlier, is the fact that stage IV breast cancer has been historically incurable and that testing therefore only serves to increase the time during which patients must live with the knowledge that they have a fatal disease.¹³⁰ Furthermore, because palliation implies the presence of symptoms, testing for asymptomatic metastases appears irrational to some.¹³¹ Finally, it is often assumed that testing is stressful to both the patient and the physician, with no clear benefit to outweigh this risk. The GIVIO study suggests that this latter concern is unwarranted.

For the future, we need to answer several questions before we can provide more firm recommendations for follow-up. Specifically, we need to know whether intensive screening can increase the fraction of patients cured with novel therapeutics and whether early treatment can truly alter the natural history of this disease. It is possible that new classes of agents applied in the investigational setting for these subsets of patients will

have such an effect, but if we fail to accurately identify such patients, we will never have the opportunity to know.

CONCLUSION

The mortality rate for breast cancer has been falling in the United States for more than a decade owing no doubt to better use of every available treatment modality, including early detection.¹ Certainly, the use of drugs as systemic therapy in conjunction with surgery and radiation as local therapy is one of the unique contributions of this century to breast cancer management, and one of the most productive. Already, an impact on public health is being appreciated when comparing survival among women with similar stages of disease but treated in different decades.¹³² At the same time, the moderate toxicities associated with standard treatment options make careful assessment of risk and benefit crucial in routine clinical practice. The decision to use hormonal therapy (5 years of tamoxifen), 6 months of combination chemotherapy, or both is often complex and time-consuming despite the guidance afforded by the Early Breast Cancer Trialists' Collaborative Group. Recommendations depend on the estimated risk for recurrence without the specific treatment in question, the ER status of the tumor, patient age, and comorbidity. Furthermore, despite the emergence of so-called standards, many issues remain unresolved and are the subjects of ongoing investigations. These trials deserve the support of the oncologic community, including professional, lay, and advocacy groups, so that the greatest number of patients may benefit in the shortest possible time. By testing the many new ideas, largely based on laboratory science, that are now influencing the design of innovative trials, these current and future investigations promise to refine and improve our management of early breast cancer and move us closer to the cure for this common malignancy.

Treatment of Bilateral Breast Cancer

Alexander J. Swistel and Peter I. Pressman

The breasts are paired organs, and whatever pathologic processes have resulted in a malignancy in one breast are likely to be underway in the other breast as well. Just as all the cells of the body share an identical genetic code, the cells of the glandular epithelium of both breasts are similar, so that an inherited genetic mutation, such as the *BRCA1* or *BRCA2* gene, can be identified in all of the breast epithelium. Benign breast disease or premalignant changes are often found to be present bilaterally. Whatever it is that enables, permits, or stimulates a breast cancer to grow in one breast may also act on the other. The term *bilateral breast cancer* implies that in a patient with a known cancer in one breast, a malignancy has also been discovered in the second breast.

How is bilateral breast cancer defined?

Bilateral primary breast cancers are described as either synchronous (occurring simultaneously) or metachronous (appearing at another point in time, not coincident with the first cancer diagnosis and treatment). These are arbitrary designations of time rather than truly significant biologic distinctions. A second breast cancer that occurs 2 years or more after the initial malignancy can probably be called metachronous. If women are followed for long periods, more cancers do become apparent. In our experience, 22% of patients with second breast cancers had initially been treated 25 years earlier. These events were certainly separated in time (metachronous). Many of these women, as longtime survivors, have outlived the original surgeons' statistics.

Most opposite breast cancers occur within the first few years after treatment of the initial malignancy. In fact, a second cancer diagnosed several months or even a year after the first, although clinically and mammographically occult, was certainly present earlier and probably should be considered a synchronous lesion. As more sensitive diagnostic techniques, such as screening ultrasound, digital mammography, and magnetic resonance imaging (MRI), become more widely available, the proportion of synchronously diagnosed cancers should increase. Because management of the initial cancer would have been initiated or completed, however, the second breast malignancy must be treated as an entirely new, independent event.

What is the incidence of bilateral breast cancer?

A 0.7% per year risk for developing a clinically evident contralateral breast cancer is a reasonable estimate.¹ Autopsy studies have shown that 68% of women who have been treated for a unilateral breast cancer harbor a malignancy in their contralateral breast.² Because the treatment of a patient with breast cancer is appropriately focused on the presenting unilateral malignancy, most contralateral breast lesions remain occult in their lifetime. There are probably several reasons for this. First, in situ cancers may remain occult for many years. Second, many women with infiltrating breast cancer do not live long enough to develop a clinically evident cancer in their other breast.

The reported incidence of bilateral breast cancer, whether synchronous or metachronous, varies according to the method of diagnosis and the length of follow-up.³⁻⁶ When the initial diagnosis of the second cancer is established by clinical examination, the incidence is 0.2% to 2.0%.⁷ The addition of mammography increases this to 2% to 5%,⁸⁻¹⁰ and by performing a selective biopsy of the opposite breast, the yield can be increased to 16.7%.¹¹ MRI can increase this diagnosis up to 30.8%.^{12,13} When prophylactic contralateral mastectomies were performed at the time of reconstructive surgery for known unilateral breast cancer, extensive histologic examination of the tissues has shown that a range of 15% to 42.5% of the contralateral breasts contained invasive or in situ carcinomas.^{14,15} This percentage increases substantially in the genetically positive *BRCA* population.¹⁶ The highest incidence of bilaterality (68%) was reported in an autopsy study.²

How is a second breast cancer differentiated from a metastasis?

Appropriate management of the patient depends on whether the second breast cancer is an independent primary or a metastasis from the initial breast lesion. Although early investigators considered all second breast cancers to be metastatic, in fact, metastases are much less common than new primary lesions. Even rarer are metastatic tumors to the breast from extramammary sites.^{17,18}

Differentiating a primary from a metastatic cancer in the second breast is not difficult if each cancer has an entirely different histology, as with pure ductal and pure lobular carcinomas. However, most breast cancers are of ductal origin and contain mixed patterns or areas where the tumor exhibits lobular features. Studies have shown that up to 70% of breast carcinomas exhibit multicentricity, so that the focality of the lesion and the histology alone cannot be considered exclusively diagnostic.¹⁹⁻²¹ Morphologic and immunohistochemical techniques have shown that these second cancers are distinctly different from the primary tumor.²²⁻²⁴ Nor is time alone a reliable means of differentiating between primary and metastatic tumors.^{3,25} Also, a secondary primary malignancy may have been present when the initial breast cancer was treated (synchronous) but may have been unapparent because of a slower growth rate.

It is also incorrect to consider all second breast tumors as metastatic if detected in the setting of known metastatic disease.²⁶ A high incidence of contralateral primary carcinomas has been reported in detailed autopsy studies of women dying with known ipsilateral breast carcinoma.² The opposite breast is frequently forgotten in the management of a patient with metastatic breast carcinoma and sometimes may actually harbor the malignancy responsible for the metastases.²⁷

The gross characteristics of the tumor are not always reliable in differentiating metastases from metachronous disease. Although metastatic tumors are frequently rounded and appear solitary in the fatty tissues of the medial or lateral (axillary tail) regions of the breast, they may sometimes be flat and firm and cause overlying skin retraction in the breast, exactly as can be seen with subcutaneous lesions in the abdominal wall, neck, scalp, and chest wall. In the breast, this skin retraction can mimic a primary carcinoma. Because this spectrum of gross findings is reflected by imaging studies, mammography is not as helpful in differentiated metastases, as has been described.²⁸ Spread across the midline is one of the more common features of metastatic or in-continuity extension of a breast cancer. This is commonly seen in inflammatory breast cancer either initially or at some point in its course. As with stage III breast cancers that have been treated aggressively with chemotherapy, mastectomy, and radiation therapy, the presence of edema or a parasternal breast mass in the opposite breast is frequently a focal manifestation of recurrence outside of the radiation and operative fields.

A precise distinction between metastatic and primary tumors is not always possible, but the constellation of criteria that may help to distinguish between the two is present in Table 28-1.

What is the significance of contralateral axillary lymph node metastasis?

One clinical situation that can be vexing is the discovery of a carcinoma in the lymph nodes of the opposite axilla without an apparent ipsilateral breast lesion after prior treatment for breast cancer. Whether this is present at the time of discovery of the initial breast cancer or found later, the differential diagnosis is the same:

- A new primary breast carcinoma (occult) and metastasis to the ipsilateral axillary lymph nodes

Table 28-1 Criteria for Differentiating Primary from Metastatic Carcinomas in the Contralateral Breast

<p>Primary Lesions</p> <ul style="list-style-type: none"> Presence of two distinctly different histologic types of invasive breast cancer In situ ductal or lobular carcinoma continuous with infiltrating lesions Pure carcinoma in situ Presence of multicentricity Nuclear grade differentiation better in the second breast lesion (particularly helpful when the primary lesion is fairly homogenous)²⁶ Histology in the second breast that exhibits features of epithelial hyperplasia, cellular atypia, and ductal premalignant changes that were absent in the first breast
<p>Metastatic Lesions</p> <ul style="list-style-type: none"> Clearly located in the fatty tissues that surround the breast, medially near the sternum, or in the fatty tissue of the tail In a superficial location, as intracutaneous or subcutaneous lesions that may exhibit skin retraction Within the breast parenchyma, but without any of the features described and associated with primary lesions Clear extension across the sternum of the primary lesion into the other breast As part of a picture of hematogenous dissemination

- Metastasis from the contralateral original breast carcinoma
- Metastasis from an extramammary site

In elderly patients, in whom concurrent disease is not unusual, a contralateral axillary lesion may be a manifestation of lymphoma. Although a new occult breast cancer on that contralateral side may present initially as a metastasis in the axilla, this is uncommon.²⁹ Recent experience with lymphatic mapping has shown the occasional bilateral pathways to both axillary nodal basins. Most frequently, such lesions are metastatic from the opposite breast. When there is evidence of disseminated carcinoma, there is no dilemma. But when axillary adenopathy is an isolated finding, the origin must be sought.³⁰ If there is no compelling evidence of recurrent or metastatic carcinoma, treatment of the breast may be indicated, with acknowledgment that this lesion may represent a first metastatic site.

How is bilateral carcinoma diagnosed?

The opposite breast of any woman being treated for a breast cancer should be critically examined because minor abnormalities either on clinical palpation by a physician or by imaging studies may prove to be significant.

Breast Palpation

Clinical palpation is particularly important in lobular disease. These infiltrating carcinomas do not usually produce the desmoplastic reaction of ductal carcinomas, frequently are not visualized on mammography, and may be large when detected. With an initial diagnosis of lobular carcinoma, thickening in the opposite breast that might otherwise be followed should undergo biopsy because this has led to further curative surgery.³¹⁻³³

It has become commonplace to denigrate the value of breast self-examination (BSE) because a study from China found little value.³⁴ However, women frequently find their

Figure 28–1 A 61-year-old woman with simultaneous bilateral infiltrating breast cancers detected by mammography—one clinically evident (*left*), the opposite detected by mammography (*right*).

Table 28–2 Synchronous Versus Metachronous Second Breast Cancer*

	Synchronous	Metachronous
I (BEM)	15.2%	84.8%
II (AEM)	28.1%	71.9%

BEM, before effective mammography; AEM, after effective mammography. Data from Senofsky GM, Wanebo HW, Wilhem MC, et al. Has monitoring of the contralateral breast improved the prognosis in patients treated for primary breast cancer? *Cancer* 1986;57:597–607.

second breast cancers themselves because they have become sensitized by their initial experience and are very worried about developing that second breast cancer.¹⁰ BSE, therefore, becomes particularly important in surveillance of the opposite breast.

Diagnostic Imaging

Monitoring the second breast with mammography does not increase the incidence of bilateral breast cancer but does make it possible to detect these cancers at an earlier stage (Fig. 28–1). In a study comparing a premammographic era with contemporary practice, it was demonstrated that with mammography, more second breast cancers are diagnosed synchronously, with a resulting decrease in the number of metachronous tumors²⁷ (Table 28–2). Although mammography was the major method of detecting second breast cancers in this population, clinical examination and contralateral biopsy made it possible to diagnose 26% of the second cancers that were missed by mammography. In critically reviewing the value of regular follow-up of women who have been treated for a breast cancer, the detection of early breast cancers with mammography is probably the most significant contribution to improved survival.³⁵ The addition of sonography has enhanced detection in the radiographically dense breast by as

much as 42%,^{36–37} but in other studies, the benefit is not clear.³⁸ MRI has improved on this as well.^{12,13} Recent work suggests that there will be a significant role for MRI in preoperative evaluation. One group showed that MRI could detect cancers significantly better than mammography and that the amount of intraductal spread within the breast was more clearly visualized.³⁹ MRI screening of high-risk populations has shown a 4% incidence of otherwise occult malignancies.⁴⁰ More recently, with the increase in screening for *BRCA* gene carriers, higher levels of synchronous disease are being found containing high-grade lesions.^{41,42}

Surgical Biopsies

Contralateral breast biopsy, reduction mammoplasty of the opposite breast, and prophylactic mastectomy are three other means by which carcinomas that are not suspected on either clinical examination or mammography are discovered in the opposite breast.

Contralateral Breast Biopsy. Biopsy of the opposite breast has been assessed in several series.^{4,5,26,33,43,44} Experiences with biopsy of the opposite breast have shown that the yield of true random biopsy is about 12.5%.⁵ The bilaterality rate can be raised to 16.7% or higher by selecting patients only with stage I or stage II breast cancer, without known axillary node metastases, who are younger than 65 years. Contralateral breast biopsy experience also includes biopsies of areas of clinical or radiologic concern (Table 28–3). In a series of 610 patients treated for a unilateral breast carcinoma, 258 met the above criteria.¹⁰ Thirty-two lesions were found by true random biopsy, a yield of 14.2%. However, only 4 were infiltrating cancers, and of the remainder, 19 of the 28 were lobular carcinoma in situ (LCIS). In four instances, LCIS and ductal carcinoma in situ (DCIS) coexisted. Others also reported that most lesions found on contralateral biopsies were mostly non-invasive carcinomas.⁴⁵

Table 28-3 Cancers Detected by Selective Biopsy of the Opposite Breast in 258 Patients

Biopsy	No.	Pathologic Findings (No.)
Clinical or radiographic suspicion	11	Infiltrating (11)
Random biopsy	32	Infiltrating (4) Noninfiltrating (28)
Patients eligible for biopsy	258	
Total cancers detected	43	

Data from Pressman PI. Selective biopsy of the opposite breast. *Cancer* 1986;57:577-580.

Generally, the technique of contralateral biopsy is to be discouraged. On the other hand, if biopsy of the opposite breast is to be tried, the most productive area is tissue from the central or upper outer quadrants of the breast because these are the most common sites of carcinoma. It is for this reason that a mirror-image biopsy can be productive. However, if the presenting malignancy is in the medial or inferior quadrants, biopsy is not performed only in the mirror image because breast parenchyma is relatively sparse in these areas. The random biopsy is carried out to include tissue from the central or upper outer quadrants and is designated as a contralateral biopsy. Because the findings will mainly be benign, circum-areolar, or laterally placed, incisions in skin lines are used to procure suitable specimens (at least 2 cm) while avoiding breast deformity. Occasionally, depending on breast volume, a triangular segment of tissue can be obtained to include central ducts in a radial orientation as well as tissue of the upper outer quadrant.

Reduction Mammoplasty with Primary Cancer (Opposite Breast). To achieve symmetry after unilateral breast reconstruction, reduction mammoplasty is sometimes carried out. An incidence of unsuspected carcinoma of 34% has been reported in the tissues removed at reduction surgery of the opposite breast in a series of 41 patients.⁴⁶ Another group showed analysis of reduction mammoplasty tissue to have a 0.7% rate of clinically occult malignancy in a random series of patients with an otherwise negative workup.⁴⁷

Prophylactic Mastectomy. In a study in which prophylactic contralateral mastectomies were performed in a series of 126 patients selected because they were considered to be at high risk, the yield was 19.7%, of which 56% were LCIS or DCIS and 44% were invasive carcinomas.²⁰ In an older study, in which subcutaneous contralateral mastectomies were carried out as a part of breast reconstruction to achieve symmetry, 42.5% of the specimens examined in 3- to 5-mm serial sections contained either invasive carcinoma or in situ carcinoma.¹⁴ Other studies have not supported these findings, but there is no question that concurrent malignancies or atypical lesions can be found with closer scrutiny of the tissues. It is also clear that with high-risk groups such as genetically positive patients, higher rates of contralateral disease can be found. These topics, as well as technical considerations of prophylactic mastectomy, are discussed later in this chapter.

Table 28-4 Calculated Cumulative Risk for Bilateral Disease by Age at First Diagnosis

Age at First Diagnosis (yr)	Incidence		Cumulative Risk (%)
	Unilateral	Bilateral	
<40	52	5	9.6
40-49	166	24	14.5
50-59	243	10	4.1
60-69	347	16	4.6
70-79	319	8	2.5
80+	158	3	5.9
Total	1285	66	5.1

Data from Adami HO, Bergstron R, Hansen J. Age at first primary as a determinant of the incidence of bilateral breast cancer. *Cancer* 1995;55:643-647.

What are the risk factors for contralateral breast cancer?

It is estimated that women who have had a breast cancer have a lifetime risk for a second primary tumor about five times that of women who have not had a first breast cancer.⁴⁸ This is therefore the single most important risk factor, but there are other major risk factors, as discussed subsequently.

Age

Age at time of the initial diagnosis of breast cancer is a major determinant of the risk of developing a second, metachronous breast cancer. Long-term survival presumably provides a longer exposure to pathogenic factors. In an epidemiologic study, it was calculated that the cumulative risk for a second, metachronous lesion in women younger than 50 years is 13.3% and in women older than 50 years is 3.5%, with an overall estimated 5% to 6% lifetime risk for both groups⁴⁹ (Table 28-4). For women with premenopausal familial breast cancer, there is a cumulative risk of 37% for the development of a new primary cancer in the contralateral breast over a 20-year period of survival.⁵⁰

Family History

In all series, the risk for developing bilateral breast cancer is higher among women with a family history of the disease,^{50,51} and this is typically expressed at an early age.⁵² In addition, the yield of contralateral biopsies is twofold greater in women with a family history of breast cancer. The relative risk is reported as a fivefold increase in the lifetime incidence of bilateral breast cancer in familial versus nonfamilial patients.⁵³

Genetics

Among *BRCA1* and *BRCA2* gene carriers, the cumulative lifetime risk for developing breast cancer by age 70 years is estimated to be 87%. For these women, there are only three approaches:^{54,55} (1) intensified screening, (2) chemoprevention, and (3) prophylactic mastectomy.

Regular clinical examinations, mammography, sonography, and MRI for women in their 20s and 30s aids in early detection. The only available chemopreventive agent that has

undergone long-term trials is tamoxifen. It reduces the occurrence of secondary primary breast cancers in the opposite breasts of postmenopausal woman.⁵⁶ Its value for such prophylaxis in younger women has also been demonstrated in a randomized trial.⁵⁷ Recently, other hormonal agents have shown similar and, in some cases, improved prophylaxis and may eventually supplant tamoxifen.⁵⁸ Women with *BRCA* mutation who undergo bilateral prophylactic oophorectomy decrease their risk for developing breast cancer.^{59,60} Previously, bilateral prophylactic mastectomy was the only truly preventive strategy available for these women, but the true predictive risk for bilaterality based on having a defective gene is yet to be determined. The incidence of simultaneous occult carcinoma in the prophylactically removed breasts of these *BRCA*-positive women has yet to be reported.

The *p53* gene is probably one of the genes responsible for an inherited susceptibility to various cancers. Abnormalities of *p53* have been detected in 50% of bilateral and 25.8% of unilateral cases studied. The percentage of patients with a *p53* gene abnormality and positive family history was higher for those with bilateral than with unilateral breast cancer, and in metachronous cases the incidence of *p53* gene abnormalities was particularly high. These findings may suggest that the genetic changes and the mechanism of carcinogenesis in bilateral and unilateral breast cancer may be different.⁶¹

Recent work with other genetic factors, such as the ataxia-telangiectasia mutation (*ATM*), has looked at the incidence of both synchronous and metachronous breast cancer without showing any increase.⁶²

Previous Radiation Therapy

There is no apparent risk to the contralateral breast in women whose breast cancer is treated by quadrantectomy, axillary dissection, and radiation therapy when compared with women treated by the Halsted radical mastectomy and no radiation therapy.⁶³ This is fortunate because breast conservation using radiation therapy has become the treatment of choice for early breast cancer.

There is considerable risk, however, for the development of bilateral breast cancer in young female patients successfully treated with mantle irradiation for Hodgkin's disease. Tumors tend to be bilateral and medially located within 10 years of initial radiation exposure.^{64,65} In these patients, the actuarial incidence of developing breast cancer approaches 35% by 40 years. In children, older age (10 to 16 years vs. less than 10 years) at the time of radiation treatment and higher dose are associated with even higher risks.⁶⁶ In adults, younger age at time of treatment for Hodgkin's disease was associated with high risk. This risk decreased to average if the radiation was given over the age of 30 years.^{67,68} This suggests that radiation exposure on the adolescent's developing breast tissue poses a significantly greater risk. Bilateral breast cancer has also been reported after whole-lung irradiation in osteosarcoma treatment.⁶⁹ We have personally observed bilateral breast cancers in patients whose skin had been irradiated for childhood acne and in those who had mastitis associated with breast-feeding.

Identification of High-Risk (Pathologic) Features in the Ipsilateral Breast

According to Foote and Stewart, "the most frequent antecedent of cancer in one breast is the history of having had

cancer in the opposite breast."⁷⁰ The predictive value of examining the first breast histologically has been studied exhaustively, and as many as 38 pathologic factors have been assessed.^{44,71,72} There is no correlation of bilateral breast cancer with tumor size, histologic differentiation, hormone receptor content, or the magnitude of lymph node involvement, except as these factors affect survival after the initial breast malignancy. However, there are a few truly predictive pathologic factors.

Lobular Carcinoma in Situ. LCIS has a bilaterality rate as high as 30% to 40%.⁷³ The highest incidences are reported when elective contralateral breast biopsy is performed. Investigators generally agree that patients who have histologic evidence of LCIS alone have a 25% chance of developing an infiltrating carcinoma, usually of the ductal type, in either breast within a period of 25 years. Patients with coexisting invasive lobular carcinoma have an even higher risk of developing a second breast cancer.⁷⁴ When LCIS coexists with infiltrating ductal cell carcinoma, the bilaterality rate has been reported to be as high as 57%.⁷⁵ The finding of LCIS alone in a breast biopsy is correctly called a marker of risk for the future development of an infiltrating breast carcinoma—a risk shared equally by both breasts. When it is found in association with an infiltrating carcinoma, it confers an even greater risk on the opposite breast. Recently, a high-grade pleomorphic variant of LCIS that has a higher incidence of both coexistent and subsequent development of invasive disease has been identified.^{76,77}

Ductal Carcinoma in Situ. Mammographically detected DCIS now accounts for more than 20% of the breast cancers treated today, and there are no long-term statistics comparable to those for LCIS as regards the long-term risk for bilaterality. It is clear that, unlike LCIS, bilateral synchronous presentation is uncommon with DCIS, with an incidence of less than 5%.⁷⁸ In a carefully studied series of 1140 patients with pure DCIS, there was a 7.9% incidence of subsequent contralateral cancers with a median follow-up time of 78 months.⁷⁹ These findings are highly significant, and DCIS may be more important than LCIS as a marker of risk for the development of a metachronous contralateral breast carcinoma.

Infiltrating Lobular Carcinoma. Infiltrating lobular carcinomas are frequently large when detected clinically and account for many false-negative mammograms because they tend not to incite the desmoplastic reactions of ductal carcinomas. Although they may be isolated and discrete and behave like ductal cancers, they are frequently multicentric, particularly when associated with LCIS. A 25% incidence of either synchronous or metachronous carcinomas in the contralateral breast of patients with infiltrating lobular carcinoma has been reported.⁸⁰ In 419 patients with infiltrating lobular carcinoma, the incidence was 10%.⁸¹ As previously noted, however, the incidences in association with LCIS are considerably higher.⁷⁴

Multicentricity. A common denominator in the growth patterns of most of the high-risk histologic diagnoses discussed—LCIS, DCIS, and infiltrating lobular carcinoma—is multicentricity.⁷⁵ In an analysis of all the possible variables, the only factor with a statistically significant association with bilateral breast cancer was a histologic diagnosis characterized

by multicentricity.^{82,83} It is pertinent to repeat the initial premise of this chapter—that the breasts are paired organs and that whatever pathologic processes evolve in one breast are likely to be reflected in the other.

What is the prognosis of bilateral breast cancer?

Survival of women with bilateral breast carcinoma is determined by the more advanced of the two malignancies. A clear example is a woman who has an invasive carcinoma in one breast and carcinoma in situ in the other. It is the invasive carcinoma that will determine the prognosis. When both of the carcinomas are at an in situ stage, the chance of cure is close to 100%. When both carcinomas are invasive, however, the patient is at an unpredictable risk with regard to survival. It has been reported that patients with metachronous breast cancer have a poorer prognosis than those with unilateral disease.^{84–90} It is likely that this poorer prognosis depends on the impact of the stage of the second carcinoma rather than any influence of the first malignancy. On the other hand, patients with synchronous disease have been identified to overexpress high levels of *HER-2/neu*, raising the possibility that this may be the cause of higher mortality.⁹¹ With vigilant follow-up of the opposite breast, the second cancers are discovered at an earlier stage than the first, and the prognosis can be highly favorable.⁹²

It was observed in the National Surgical Adjuvant Breast Project (NSABP) Protocol B-04 that women with contralateral carcinomas presenting within 2 years of the first fared much worse than those whose tumors were discovered later.⁵¹ This has been confirmed in another study in which it is clear that the interval between the discovery of the carcinomas is important. The recurrence-free survival rate of patients with second carcinomas diagnosed within 5 years was 58%, compared with 95% for patients diagnosed more than 5 years after the first carcinoma.⁹³

The second lesions that occur within a 2-year period are probably synchronous, and these bilateral carcinomas have a poorer prognosis because the cancers are frequently more advanced. An exception is opposite cancers that are detected by true random biopsy on new diagnostic imaging. These are more likely to be at an in situ stage and theoretically should have a better prognosis by avoiding the risk of development of an invasive carcinoma.

Is there a role for contralateral prophylactic mastectomy?

A clinically and radiographically apparent unilateral carcinoma is investigated and treated according to the known pathologic findings. Contralateral biopsies, reduction mammoplasty, and opposite prophylactic mastectomy are elective means by which a second cancer may be discovered. Although it is natural to focus on the presenting unilateral problem, it is important to consider bilaterality and to carefully examine the opposite breast clinically just as the radiologist scrutinizes the mammogram. Pursuing subtle abnormalities with stereotactically, ultrasound-, or MRI-guided biopsy may provide useful information about the opposite breast.⁹⁴

With the advent of breast-conserving therapy, there is a reluctance to recommend a true random biopsy of the opposite breast. As we have previously seen, a positive biopsy usually discovers LCIS, a lesion for which additional treatment is not mandated.

With an increased awareness of risk factors and the availability of good breast reconstruction, opposite prophylactic mastectomy is being offered in specific instances. Although there has not been a randomized or convincing nonrandomized trial to prove that contralateral prophylactic mastectomy improves survival, the issue may be compelling in certain situations. Because the malignancies encountered in the opposite breasts are mainly at an in situ or early invasive stage, in these women this procedure reduces the risk to that of the stage of the initial unilateral breast cancer and can improve survival.

Women who might be considered for contralateral prophylactic mastectomy may be those who have a constellation of factors, which include the following:

- Young age
- Hereditary breast carcinoma
- First-degree relatives with bilateral carcinoma
- LCIS in addition to infiltrating ductal or lobular carcinoma
- Multicentric lobular carcinoma
- Cancerphobia
- A planned transverse rectus abdominis muscle (TRAM) flap reconstruction
- *BRCA1* and *BRCA2* gene mutation

Other than having a known genetic abnormality, none of the above is an absolute indication. Together, the risks may seem acceptable to a woman who has a justified fear about developing a cancer in her opposite breast, particularly when surveillance has failed in her own case or with family members or friends. These women who elect to have a contralateral prophylactic mastectomy are extremely grateful and relieved.

Another consideration (not a risk factor) is the type of breast reconstruction planned for the initial mastectomy. An implant can always be matched at a future date with a second implant with the expectation of accomplishing good symmetry (Fig. 28–2). However, when a unilateral TRAM flap reconstruction has been used and a second mastectomy needs to be reconstructed (for a metachronous carcinoma), an entirely different technique is required, and the appearance is usually poor (Fig. 28–3). Because it cannot be repeated, whenever a TRAM flap reconstruction is planned, the risk for developing a second breast cancer needs to be evaluated and the role of a contralateral (prophylactic) mastectomy considered.⁹⁵ The best cosmetic result can be accomplished when the TRAM flap is used to reconstruct both breasts following simultaneous bilateral mastectomy (Fig. 28–4).

Prophylactic mastectomy can successfully prevent the development of a breast cancer.⁹⁶ A central ellipse of skin including the nipple–areolar complex is removed. This is an excellent setting for skin-sparing mastectomy (SSM). The incision can be planned with cosmetic intent and can be preservative of skin.⁹⁷ This is not a subcutaneous mastectomy that is performed through an inframammary incision and in which the nipple–areolar complex remains intact, which would virtually imply that residual breast parenchyma will remain on superficial deep planes. Recently, a modification of this original SSM has shown that the areolar skin can be preserved as well.^{98,99}

Figure 28-2 Bilateral tissue expander reconstruction. A 51-year-old woman initially underwent a right modified radical mastectomy for an invasive ductal carcinoma and breast reconstruction with an expander. An invasive carcinoma of the opposite breast was detected by random biopsy, and a second mastectomy with a similar reconstruction was subsequently carried out.

Figure 28-3 At age 42 years, a transverse rectus abdominis muscle flap reconstruction was used to reconstruct a right modified radical mastectomy. Five years later, a carcinoma in the left breast required a modified radical mastectomy and reconstruction with a tissue expander and saline implant.

This results in a more satisfactory cosmetic outcome, with a nipple reconstruction carried out secondarily. It must be stressed that the skin flaps should be developed with the same factors as for invasive disease with oncologic intent. In similar fashion, because the intent is to remove all underlying breast tissue, the nipple must be removed.

What are the treatment options for synchronous bilateral breast cancers?

Each breast cancer ideally should be treated according to its individual characteristics; however, the presence of a second cancer may dictate different priorities. The stage of the more advanced cancer (usually the presenting lesion) has greater

Figure 28-4 A 52-year-old woman with bilateral infiltrating breast carcinoma underwent modified radical mastectomies and immediate transverse rectus abdominis flap reconstruction.

impact on the choice of treatment. When synchronous cancers are detected, it is necessary to make decisions about both breasts. Patients have been likely to have had treatment consistent with the approach preferred at the time. This would have been bilateral radical mastectomy in the 1960s or bilateral modified radical mastectomy in the 1970s. The option of implant breast reconstruction was added to the modified radical mastectomy in the 1980s, and myocutaneous flaps are now more frequently being used. Presently, breast-conserving surgery and radiation therapy have become the preferred approach. Some patients, however, are not candidates for breast conservation. Whether the cancers are infiltrating or at an in situ stage, a mastectomy can be performed with or without reconstruction. The necessity for an axillary dissection is based on sentinel lymph node biopsy. More recently, sentinel lymph node biopsy has also been used at the time of prophylactic surgery because the morbidity is low, and the possibility of finding invasive disease in the prophylactically removed breast tissue provides valuable information about the need for subsequent full axillary dissection.

Breast-conserving therapy is a successful and preferred approach to treating unilateral breast cancer. When bilateral synchronous infiltrating cancers are each amenable to breast conservation, this is also successful and can be advised.^{100,101}

It is reasonable to use the same approach for both breasts to provide the best possible symmetry. Considerations in selection of management approaches include some of the following:

- The prolonged treatment (10 to 12 weeks) required for bilateral radiation therapy may motivate mastectomy, particularly in elderly women.
- Bilateral breast reconstruction may not be an option because of age or concurrent medical problems.
- Younger women may feel more secure with bilateral mastectomy and reconstruction because the risk for recurrence, which is acceptable with unilateral breast conservation (radiotherapy), is increased with two breasts treated. Also, a breast recurrence after radiation therapy usually mandates myocutaneous flap reconstruction, and this does not remain an option if the recurrence appears at an older age.

- Although radiation therapy may be optimal for an infiltrating cancer of one breast, it may not be appropriate for an in situ cancer of the opposite breast such as diffuse DCIS.
- Radiation therapy cannot be used where prior irradiation may have played an etiologic role.

What are the treatment options for metachronous contralateral cancer?

When the second cancer has been detected in the opposite breast in the follow-up of a woman who previously had a breast cancer, the treatment is inevitably influenced by a constellation of factors:

- The interval between the discovery of the new cancer and the first breast cancer
- The treatment approach used for the initial malignancy
- The success of the first breast cancer treatment and the stage of the new carcinoma
- The age of the patient at the time of the second diagnosis
- The method to accomplish the best symmetry
- Concurrent medical conditions
- The patient's personal choice

Reduction mammoplasty of the opposite breast is frequently performed as a secondary operation to improve symmetry after mastectomy when implant reconstruction has been carried out in the site of the initial cancer. Carcinoma may be found in the tissues removed.³⁷ If it is an infiltrating carcinoma, mastectomy with a lymph node dissection and expander reconstruction is usually indicated. If the malignancy encountered is LCIS, a simple mastectomy with similar reconstruction can be carried out. The option of observation without additional surgery also exists. The reduced breast, however, is more difficult to follow mammographically. If the finding is DCIS, the same considerations may apply as with LCIS.

The major problem with an unexpected finding of malignancy in the tissues removed during a reduction mammoplasty is that the exact location of the carcinoma in the breast is usually uncertain. Performing a mastectomy obviates the need to know the location of the malignancy, which would be important if radiation therapy were to be employed. The use of an implant can often accomplish better symmetry than the reduction procedure.

When the second breast cancer occurs many years later, the patient's perception of the outcome of the first cancer treatment has an impact on how the second malignancy will be managed. For example, a woman who was successfully treated 25 years earlier with a radical mastectomy with skin grafting and a 10-day hospitalization may feel secure only with another mastectomy, so that a modified radical mastectomy without reconstruction and 1 to 2 days in the hospital is an improved approach for her. Yet, with an identical prior history of treatment and outcome, another woman may be emphatic about saving her remaining breast and not mind the several weeks of radiation therapy involved following excision and axillary surgery. A woman with a metachronous cancer frequently has acquired more knowledge than when she was first treated, and a newer modality may be an option (Fig. 28–5).

When the first breast cancer was treated conservatively using lumpectomy and radiation therapy, it is appropriate for

Figure 28–5 A 65-year-old woman underwent a right radical mastectomy when she was 35 years old. She elected to treat her second breast carcinoma with radiation therapy following a lumpectomy and axillary dissection.

Figure 28–6 A 50-year-old woman who underwent bilateral skin-sparing mastectomies with bilateral free transverse rectus abdominis flap reconstruction—one therapeutic and one prophylactic.

the metachronous malignancy to be similarly treated using radiation therapy because the results are as good with unilateral as with bilateral disease.¹⁰² Some women facing a second cancer are very happy to proceed with this similar approach. However, others may opt for bilateral mastectomy, removing the initially conservatively treated breast so as not to be concerned about the potential additional risks for bilateral local recurrence (Fig. 28–6).

SUMMARY

Most women treated for a unilateral breast carcinoma will not develop a malignancy of the opposite breast, and routine clinical and mammographic follow-up surveillance is appropriate. However, the possibility of bilaterality must always be considered. Because younger women are diagnosed more frequently with early-stage disease, the lifetime risk for developing a second breast cancer is greater. An awareness of genetic

and pathologic risk factors makes it possible to make recommendations prospectively for appropriate investigative biopsies. This affects decisions regarding therapeutic and prophylactic mastectomy, reconstruction, and breast conservation. For the many reasons described, mastectomy is more frequently used for treating bilateral breast cancer. Although the risk of developing a contralateral primary carcinoma diminishes as women get older, new cancers continue to occur. There are special problems in management because some choices are not available related to age. A woman who develops a second breast cancer has acquired more information based on her experience and may be more proactive in making decisions about her care.

Treatment of Locally Advanced Breast Cancer

Matthew Volm and Silvia Formenti

How is locally advanced breast cancer defined?

The definition of locally advanced breast cancer (LABC) has evolved during the past 50 years. Historically, the definition of LABC was based on work by Haagensen and Stout published in 1943 that described physical tumor characteristics associated with local and distant failure rates so high that surgery was strictly contraindicated: fixation of the tumor to skin or chest wall, skin edema (peau d'orange), skin ulceration, satellite nodules, fixed or matted axillary lymph nodes, supraclavicular lymphadenopathy, or arm edema.¹ Before Haagensen and Stout identified criteria of inoperability, en bloc radical mastectomy was the standard treatment for locally advanced breast cancer. After their publication, the term *locally advanced breast cancer* was associated with disease deemed inoperable based on their criteria.

Haagensen and Stout's work has withstood the test of time, and their observations remain the basis of the T4 and N2-3 categories in the current clinical staging system of the American Joint Committee on Cancer (AJCC), as shown in Table 29–1. The criteria of inoperability they identified are still used to select patients who are not candidates for surgery unless the local tumor burden can be successfully decreased with chemotherapy or radiation, as described later.

In the 1970s and 1980s, clinical practice progressed to include the option of breast-conserving surgery, lumpectomy, or segmental excision, followed by radiation as primary treatment for most patients with breast cancer. At the same time, the average tumor size decreased because of improved mammographic detection. As less extensive surgery became commonplace, the definition of *locally advanced disease* evolved to include tumors that are operable by the criteria of Haagensen and Stout, but that require mastectomy for a successful surgical outcome. Thus, an expanded definition of LABC now commonly includes large operable breast cancers, often those larger than 5.0 cm (T3 tumors in the AJCC system), in addition to inoperable T4 disease. This has led to a heterogeneous population of patients in many reported series of LABC, with many series including both T3 and T4 tumors.

The definition of LABC continues to evolve. In the past, ipsilateral infraclavicular or supraclavicular nodal involvement was considered to be distant metastatic disease (M1, stage IV), and patients were treated with largely palliative intent. More recently, however, the AJCC recognized clinical

data showing that some of these patients achieve long disease-free survival and are possibly cured with contemporary multimodality therapy.^{2,3} These patients are now classified as having N3 disease and are now often included in clinical trials for patients with LABC.

Some series in the LABC literature include patients with inflammatory breast cancer (IBC), an unusual, aggressive form of breast cancer presenting with inflammatory skin changes that reflect dermal lymphatic involvement (AJCC T4d tumors). IBC has a distinct biologic behavior that warrants considering it separately from other forms of locally advanced disease.⁴ This chapter first discusses the approach to patients with noninflammatory LABC and then reviews the unique features and management of IBC.

Who gets locally advanced breast cancer?

LABC is the most common presentation of breast cancer worldwide. This is because of the high percentage of patients who present with locally advanced disease throughout the developing world. In India, for example, 50% to 70% of all breast cancer patients present with locally advanced disease.⁵ Although LABC is less common in the developed world, where there is access to mammography and where breast cancer awareness in the medical community and general population is high, it remains a significant medical problem. In the United States, about 5% to 6% of patients present with locally advanced disease.⁶ As expected, LABC is more common in poor, minority, and immigrant communities; in some medically underserved areas in the United States, up to one third of breast cancer patients present with LABC.⁷

How is locally advanced breast cancer diagnosed?

The diagnosis of LABC is usually straightforward in that most patients present with a large, firm, palpable breast mass. The differential diagnosis includes benign cysts, hematomas, fat necrosis, fibroadenomas, and phyllodes tumors. Diagnostic mammography, ultrasound, and magnetic resonance imaging (MRI) can assist in the diagnosis and help to delineate the extent of disease, but ultimately a suspicious lesion requires tissue sampling. A fine-needle aspirate can demonstrate the

Table 29–1 Primary Tumor (T) and Clinical Regional Lymph Node (N) Categories Comprising Locally Advanced Breast Cancer in the Current American Joint Committee on Cancer Classification System*

T3: Tumor more than 5 cm in greatest diameter
T4: Tumor of any size, with direct extension to chest wall or skin, as described below
T4a: Extension to chest wall, not including pectoralis muscle
T4b: Edema (including peau d'orange) or ulceration of the skin of the breast or satellite nodules confined to same breast
T4c: Both Ta and Tb
T4d: Inflammatory carcinoma
N2: Metastasis in ipsilateral axillary nodes fixed or matted, or in clinically apparent ipsilateral internal mammary nodes in the absence of clinically evident axillary node metastases
N3: Metastasis in ipsilateral infraclavicular or supraclavicular lymph nodes or in clinically apparent internal mammary nodes in the presence of clinically evident axillary node metastases

*In earlier editions of the American Joint Committee on Cancer Staging Handbook, stage III was confined to T4 or N2-3 disease (i.e., locally advanced, inoperable tumors). In the current system, in addition to locally advanced breast cancer, stage III includes tumors at high risk for systemic relapse because of involvement of four or more axillary nodes.

From Greene FL, Page DL, Fleming ID, et al. AJCC Cancer Staging Manual, 6th ed. New York, Springer-Verlag, 2002.

presence of malignant cells but does not provide information about the architecture of the lesion (intraductal versus invasive carcinoma). A core biopsy, performed with local anesthesia, is usually sufficient to document the presence of invasive carcinoma and provides adequate tissue for assays for hormone receptors and *HER-2*, which may help to guide therapy.

Before therapy is initiated, an evaluation for metastatic disease is appropriate. At our institution, this includes laboratory work, computed tomography (CT) scans of the chest and abdomen, and a bone scan. An MRI of the brain is indicated when there are symptoms of central nervous system involvement. Despite the presence of locally extensive disease, it is unusual for patients to have clinically detectable metastases at presentation.

How is locally advanced breast cancer treated?

Contemporary management of LABC is a collaborative effort involving surgical, medical, and radiation oncologists. In order to be successful, the treatment of LABC must both achieve local control and eradicate any disseminated microscopic metastases. Although chemotherapy alone results in high overall response rates, it rarely eradicates the tumor in the breast and axilla. Radiation and surgery, on the other hand, improve local control but do not treat distant microscopic metastases. An outline of the contemporary multimodality treatment for patients with LABC is shown in Table 29–2. Treatment is initiated with chemotherapy, which provides early treatment of microscopic metastases and facilitates subsequent local therapy, which is usually surgery followed by radiation.

The importance of multimodality therapy is underscored by the historical experience demonstrating that the use of single-modality treatment results in poor local control and inferior survival.

Table 29–2 Summary of the Management of Locally Advanced Breast Cancer

Clinical Diagnosis Physical examination, mammogram, ultrasound
Pathologic Diagnosis Core biopsy to confirm diagnosis of invasive carcinoma and to obtain estrogen receptor, progesterone receptor, and <i>HER-2</i> status
Staging Bone scan, computed tomography scans, routine laboratory studies
Neoadjuvant Chemotherapy Use of an anthracycline and a taxane is recommended, e.g., four cycles of AC (doxorubicin, cyclophosphamide) followed by four cycles of paclitaxel or docetaxel; patients who would not tolerate chemotherapy and have hormone receptor–positive disease may be considered for treatment with tamoxifen or an aromatase inhibitor
Local Therapy For patients who are surgical candidates after neoadjuvant chemotherapy, surgery (lumpectomy or mastectomy) followed by radiation For patients who are not surgical candidates after neoadjuvant chemotherapy, radiation alone
Adjuvant Therapy All patients with hormone receptor–positive disease should receive adjuvant hormonal therapy for 5 years or longer

What is the role of chemotherapy in the treatment of locally advanced breast cancer?

In the setting of LABC, systemic chemotherapy is given before local therapy and is referred to as *primary, induction, or neoadjuvant* therapy. Neoadjuvant chemotherapy has response rates in the primary tumor substantially higher than those seen when chemotherapy is given for metastatic disease, and it provides early systemic treatment for disseminated microscopic metastases. In addition, the downstaging achieved with neoadjuvant chemotherapy can often allow tumors that were inoperable at presentation to be removed by mastectomy and can allow breast-conserving surgery for some tumors that would otherwise have required mastectomy.

How does the response to neoadjuvant chemotherapy affect outcome?

Important prognostic information can be obtained by assessing the tumor's response to neoadjuvant therapy. The *clinical assessment* of response to neoadjuvant chemotherapy can be difficult: tumor measurements based on physical examination often overestimate or underestimate the degree of response and are less reliable than either mammographic or ultrasound measurements.⁸ The ultimate *pathologic assessment* of treatment effect is determined after surgery. Clinical evidence indicates that the degree of pathologic response after primary chemotherapy can be used as a surrogate end point for survival. Despite differences in the methods used to measure and report the pathologic findings after neoadjuvant chemotherapy, all investigators have reported a similar correlation between the amount of residual disease found at surgery and

patient outcome.^{9–12} As expected, patients with complete clearance of tumor from the breast and axilla have the best outcome, and the degree of nodal involvement after neoadjuvant chemotherapy retains significant prognostic importance.

What are the results of multimodality treatment with neoadjuvant doxorubicin-based chemotherapy?

Although there is not a standard neoadjuvant chemotherapy regimen for LABC, it is possible to draw conclusions about the regimens that appear to be most effective. Results from anthracycline-based regimens are shown in Table 29–3. Several conclusions can be drawn about induction chemotherapy with an anthracycline-containing regimen. First, the response rates achieved with neoadjuvant chemotherapy for LABC are substantially higher than when similar regimens are given to treat metastatic disease. Second, although disease progression on chemotherapy is common in the setting of metastatic disease, it is rare for the patient on neoadjuvant chemotherapy, less than 5% in all reported series. Third, despite the high response rates achieved with conventional anthracycline-based neoadjuvant therapy, a pathologic complete response (i.e., no residual invasive tumor

in the breast or axilla) is unusual, occurring in 10% to 15% of patients in most series, and prolonged survival remains limited to about 50% of patients. Although it is difficult to make comparisons among trials with varied eligibility requirements and treatments, longer duration of neoadjuvant therapy appears to result in higher pathologic complete response rates.

How has the experience with neoadjuvant chemotherapy for locally advanced breast cancer affected the treatment of smaller tumors?

The safety and high response rates observed when neoadjuvant chemotherapy has been administered for LABC have encouraged the investigation of the neoadjuvant approach in patients with smaller operable tumors. To test the hypothesis that the administration of chemotherapy before surgery could improve relapse-free survival in patients with palpable, operable breast tumors, the National Surgical Adjuvant Breast and Bowel Project (NSABP) (B-18) conducted a large randomized trial comparing four cycles of neoadjuvant doxorubicin and cyclophosphamide (AC) to the same treatment provided after surgery.

Table 29–3 Anthracycline-Based Chemotherapy for Locally Advanced Breast Cancer

Study	No. of Patients and Tumor Characteristics	Treatment Regimen	Response	Breast Conservation	Survival
Schwartz et al., 1994 ³⁵	158 patients with tumor > 5 cm	Doxorubicin-based chemotherapy given until response plateau → surgery → RT	Overall RR 85%; pCR in 10%	Breast-conserving surgery in 36% of responding patients	5-yr OS 69% for responding patients (67% for mastectomy patients; 80% for lumpectomy patients)
Merajver et al., 1997 ³⁶	89 patients with 1997 AJCC stage III (tumor > 5 cm or N2 disease)	27 weeks of anthracycline-based chemohormonal therapy → patients with negative biopsy had RT only; all others had mastectomy followed by RT → additional chemohormonal therapy	Overall RR 97%; pCR in 28%	28% of patients with no tumor after neoadjuvant therapy had RT alone	5-yr DFS 44%, OS 54%; local control 82% in RT patients and 78% in patients with mastectomy and RT
Morrell et al., 1998 ³⁷	55 patients with LABC or IBC	MVAC chemotherapy until maximal clinical response → surgery → MVAC × 6 cycles RT	Overall RR 89%; pCR in 27%	All patients had mastectomy	5-yr DFS 51%; 5-yr OS 63%
Kuerer et al., 1999 ³⁸	372 patients with tumor > 4 cm	4 cycles of doxorubicin-based chemotherapy → surgery → additional chemotherapy → RT	pCR in 12%	Breast conservation in 29% of patients	5-yr DFS 89% for patients with pCR, 64% for patients with residual tumor
Zambetti et al., 1999 ³⁹	88 patients with LABC (1997 AJCC T3 or T4a-c)	3 cycles of doxorubicin or epirubicin → surgery → CMF → RT	Overall RR 70%; pCR in only 2%	Breast conservation in 32% of patients	At 52 mo, DFS 52%, OS 62%
Therasse et al., 2003 ⁴⁰	448 patients with T4 tumors	Patients randomized to 6 cycles of CEF or 6 cycles of dose-intense EC → surgery ± RT	Overall RR >90% in both groups; pCR in 14% for CEF and 10% for EC	Not reported	5-yr OS 51% for CEF, 53% for EC

AJCC, American Joint Committee on Cancer; CEF, cyclophosphamide, epirubicin, 5-fluorouracil; DFS, disease-free survival; EC, epirubicin, cyclophosphamide; IBC, inflammatory breast cancer; LABC, locally advanced breast cancer; MVAC, methotrexate, vinblastine, doxorubicin, cisplatin; RR, response rate; RT, radiation therapy; OS, overall survival; pCR, pathologic complete response.

The study demonstrated a high response rate for neoadjuvant chemotherapy (80%) but few pathologic complete responses (9%).¹³ Although there was no difference in disease-free or overall survival between the two groups, the neoadjuvant group achieved a higher rate of breast conservation (67% vs. 60%). Neoadjuvant therapy has been incorporated into more clinical trials of systemic therapy for patients with operable breast cancer, in whom differences in response rates and especially pathologic complete response rates can provide useful information before survival data are available.

What is the effect of adding a taxane to the neoadjuvant therapy regimen?

The taxanes have recently become a part of standard postoperative adjuvant therapy for many patients with node-positive breast cancer. Their use has been investigated as neoadjuvant therapy in a more limited fashion in patients with LABC, as shown in Table 29–4. The results of these trials indicate that the taxanes, especially docetaxel, have good activity in patients with LABC. Although the NSABP B-27¹⁴ and the German Preoperative Adriamycin Docetaxel Study Group (GEPAR-DUO)¹⁵ studies were not limited to patients with LABC, the average tumor size was large in these randomized trials, and along with results of the study from the Aberdeen group,¹⁶ the results support the use of four cycles of anthracycline-based therapy followed by four cycles of a taxane as a reasonable neoadjuvant regimen for LABC.

How are hormonal agents integrated into the treatment of locally advanced breast cancer?

Hormonal therapy with 5 years of tamoxifen was typically given to patients with hormone receptor-positive LABC after

completion of all other treatment, including chemotherapy, surgery, and radiation. This practice is based on extensive data from adjuvant (i.e., postoperative) trials in the general breast cancer population that demonstrated an approximate 50% reduction in the annual odds of relapse for patients receiving tamoxifen. In the neoadjuvant setting, responses to tamoxifen appear to be slower and less complete than those achieved with chemotherapy, and tamoxifen has most often been administered to postmenopausal women considered poor candidates for chemotherapy.

More recently, with the development of a new class of hormonal agents, the aromatase inhibitors, there has been increased interest in neoadjuvant hormonal therapy. These agents, anastrozole (Arimidex), letrozole (Femara), and exemestane (Aromasin), inhibit the aromatase-dependent production of estrogen in postmenopausal women. They have largely replaced tamoxifen as front-line therapy for hormone receptor-positive disease in postmenopausal women with metastatic breast cancer and are being incorporated into the adjuvant setting. Several studies have investigated the use of an aromatase inhibitor in postmenopausal women with LABC. In the largest study, Ellis and associates randomized 250 postmenopausal patients with hormone receptor-positive breast cancer deemed ineligible for breast-conserving surgery to either tamoxifen or letrozole for 4 months before surgery.¹⁷ The clinical response rate favored letrozole (60% vs. 41%), as did the rate of breast-conserving surgery (48% vs. 36%). A planned subset analysis showed a striking difference between the two treatments when tumors with *HER-2* gene amplification were identified: the response rate was 88% for letrozole versus 21% for tamoxifen. This finding supports retrospective data from several adjuvant trials indicating that *HER-2* amplification is associated with tamoxifen resistance. Of note, only 1% of patients in this study achieved a pathologic complete response, a rate significantly lower than is usually achieved with neoadjuvant chemotherapy regimens. In addition,

Table 29–4 Taxanes in the Neoadjuvant Treatment of Breast Cancer

Study	No. of Patients and Tumor Characteristics	Treatment Regimen	Response	Survival
Swain, 2003 ⁴¹	45 patients with tumor > 5 cm (median size, 9 cm)	DOC × 4 → surgery → AC × 4	Overall RR 58%; pCR 10%, residual disease < 5 mm 7%	5-yr OS 80%
Smith, 2002; ⁴² Hutcheon et al., 2003 (Aberdeen study) ¹⁶	162 patients with tumor > 3 cm	Randomized to CVAP × 8 vs. sequential CVAP × 4 → DOC × 4	Clearance of tumor from the breast: 16% for CVAP vs 34% for CVAP → DOC	OS 78% for CVAP vs. 93% for CVAP → DOC (<i>P</i> = 0.04)
Ezzat et al., 2000 ⁴³	72 patients with tumor > 4 cm	Paclitaxel and cisplatin for 3–4 cycles before surgery	Overall RR 90%, pCR in 22%	Projected DFS 74% at 3 yr
Bear et al., 2003 (NSABP B-27) ¹⁴	2411 patients with palpable tumor > 1 cm (mean, 4.5 cm)	Randomized to AC × 4 vs. AC → DOC × 4	Clinical CR 40.1% for AC vs. 63.6% for AC → docetaxel; pCR in the breast 14% for AC vs. 26% for AC → DOC	Not available
von Minckwitz et al., 2002 (GEPAR-DUO) ¹⁵	913 patients with tumor > 2 cm (median, 4 cm)	Randomized to dose-dense ADOC × 4 (8 wk) vs. AC × 4 → 4 DOC × 4 (24 wk)	Overall RR for ADOC 77% vs. 87% for AC → DOC; pCR for ADOC 11% vs. 22% for AC → DOC	Not available

AC, doxorubicin, cyclophosphamide; ADOC, doxorubicin, docetaxel; CVAP, cyclophosphamide, vincristine, doxorubicin, prednisone; DFS, disease-free survival; DOC, docetaxel; OS, overall survival; pCR, pathologic complete response; RR, response rate.

disease progression was observed in 8% of patients taking letrozole and in 12% of patients taking tamoxifen (no statistically significant difference), a rate higher than is observed in neoadjuvant chemotherapy trials.

Although the effectiveness of adjuvant hormonal therapy is well established for hormone receptor–positive breast cancers of all stages, the role of neoadjuvant hormonal therapy for patients with LABC remains to be better defined. At present, neoadjuvant hormonal therapy can be considered a standard only for patients with hormone receptor–positive disease and relative or absolute contraindications to chemotherapy.

What is the best local therapy for patients with locally advanced breast cancer: radiation, surgery, or both?

Historically, after Haagensen and Stout's article defining inoperable breast cancers, radiation was used for palliation. In the absence of surgery or systemic therapy, standard doses of radiation provided poor local control for patients with inoperable disease, with local relapse rates of 30% to 70% and 5-year survival rates of 10% to 40%.^{18,19} Higher doses of radiation could improve local control, but with increased toxicity.^{20,21} As reports of high response rates and improved survival with chemotherapy were presented in the literature, neoadjuvant chemotherapy became the standard primary treatment for patients with LABC, and the question became, what is the optimal local therapy—surgery, radiation, or both? This question pertains to large operable tumors and to inoperable tumors that become technically resectable after responding to neoadjuvant chemotherapy. Patients with inoperable disease and a limited response to chemotherapy are treated with radiation.

Surgery Versus Radiation

Two clinical trials have compared radiation with surgery following neoadjuvant chemotherapy. The Cancer and Leukemia Group B (CALGB) treated 113 patients with LABC or IBC with three cycles of induction CAFVP (cyclophosphamide, doxorubicin [Adriamycin], 5-FU, vincristine, and prednisone).²² Of the 113 patients, 91 (81%) were judged to have operable disease following neoadjuvant chemotherapy and were randomized to either mastectomy or radiotherapy. Of the initial disease relapses in each treatment arm, about half were local (27% in the radiotherapy arm and 19% in the surgery arm). Median survival for both groups was about 39 months. Similarly, an Italian study comparing radiation with mastectomy after three cycles of doxorubicin-based chemotherapy showed local control in about 70% of patients in both groups and equivalent survival.²³

Surgery Followed by Radiation

There are no randomized studies comparing triple-modality therapy (neoadjuvant chemotherapy, surgery, and radiation) with dual-modality therapy (chemotherapy plus surgery or radiation). The current standard practice of incorporating surgery into multimodality treatment plans for LABC is based on retrospective data and indirect comparisons indicating higher local failure rates when surgery is omitted. Radiotherapy alone following neoadjuvant chemotherapy is

associated with local recurrence rates of about 30% to 50%; when both modalities are used, the rate of local failure is reduced to about 10% to 20%.

Can patients with locally advanced breast cancer safely undergo breast-conserving surgery?

Data on breast-conserving surgery for patients with LABC come from a variety of nonrandomized clinical trials that differ significantly in tumor characteristics and treatment regimens. These studies support the concept that selected patients with LABC can safely forgo mastectomy in favor of less extensive surgery. Investigators at University of Texas M. D. Anderson Cancer Center systematically studied patients with LABC to answer this question. They first reviewed histologic findings in mastectomy specimens from LABC patients who received neoadjuvant chemotherapy to identify factors associated with multiquadrant involvement that would preclude breast conservation.²⁴ They established the following criteria for breast conservation and applied them to 362 patients who had received neoadjuvant anthracycline-based chemotherapy:

- No skin or chest wall involvement
- Lack of multicentric disease or extensive microcalcifications
- Tumor smaller than 5.0 cm
- Ability to localize primary tumor
- No contraindications to radiation
- Patient desire to preserve breast

The outcome of these patients has been reported.²⁵ At presentation, about one fourth of the patients had tumors smaller than 5.0 cm; the remaining three fourths had tumors greater than 5.0 cm or were otherwise locally advanced. With a median follow-up of 65 months, survival rates without local regional recurrence, with breast tumor recurrence, and with distant metastases were 91%, 94%, and 86%, respectively. Notably, the pretreatment tumor size did not predict for local recurrence, whereas pretreatment clinical N2 or N3 node status was associated with a higher rate of local failure. Pathologic findings at surgery associated with an increased risk for local failure included residual tumor mass greater than 2.0 cm, a multifocal pattern of residual disease, and lymphovascular space invasion.

Other groups have reported their experience with breast conservation for patients treated with neoadjuvant chemotherapy. The largest reported experience is that of Bonadonna and colleagues in Milan.¹¹ They reported their institution's experience with 536 patients considered ineligible for breast conservation because of tumor size greater than 2.5 cm. (The threshold for recommending mastectomy is frequently lower in Europe than in the United States.) After neoadjuvant chemotherapy, 85% of patients were able to have breast-conserving surgery. With a median follow-up of 65 months, 6.8% of patients have experienced an isolated local relapse.

Although these series support the safety of breast conservation for patients following successful neoadjuvant chemotherapy for LABC, they are not randomized, and the decision to proceed with mastectomy versus breast conservation may be subject to considerable selection bias, with more favorable tumors treated with breast conservation.

Could some patients with locally advanced breast cancer be treated effectively without surgery?

Based on nonrandomized, retrospective reviews of data, several investigators have questioned the need for surgery, especially when neoadjuvant chemotherapy achieves a complete clinical response. Ring and coworkers recently reported on 136 patients with operable breast cancers greater than 3.0 cm who achieved a clinical complete response following neoadjuvant chemotherapy.²⁶ Patients were offered the option of radiation alone or radiation and surgery. With a median follow-up of 7 years, disease-free and overall survival rates are the same for the two groups, which appeared to be well matched in terms of tumor characteristics. In the 69 patients who elected not to have surgery, there have been 16 local-only relapses, whereas of the 67 patients who had surgery (10 mastectomy, 57 breast conservation), 7 patients have had local-only relapses. In a similar retrospective review, Favret and colleagues reported on a group of 64 patients with IBC or LABC treated with neoadjuvant chemotherapy followed by either radiation alone or surgery and radiation, depending on the response of the tumor to chemotherapy and the patient's preference.²⁷ Forty-four patients received radiation alone, and 20 patients received radiation followed by surgery. With a mean follow-up of 51 months, no difference in local control, disease-free survival, or overall survival has been observed. Note that both of these series are nonrandomized and may be subject to substantial selection bias, with patients with more favorable tumors or better responses to neoadjuvant chemotherapy forgoing surgery.

What new approaches to locally advanced breast cancer are being investigated?

A variety of investigational approaches to the treatment of LABC are the subject of clinical trials and may lead to more effective treatments for LABC in the future. Experience from the treatment of locally advanced cancers in other anatomic sites suggests that combining chemotherapy and radiation currently may provide better local control and improved survival than providing the treatments in sequence. In breast cancer, concurrent chemotherapy and radiation has been investigated with 5-fluorouracil (5-FU) and paclitaxel. Formenti and associates reported a pathologic response rate (defined as fewer than 10 microscopic foci of disease in the resected breast) of 34% and a 5-year disease-free survival of 58% in patients with inoperable LABC treated with concurrent 5-FU and radiation.²⁸ A follow-up study using concurrent chemotherapy with paclitaxel and radiation also achieved a pathologic response rate of 34%.²⁹

In addition to looking at novel ways of combining chemotherapy and radiation, new agents are being incorporated into the treatment of LABC. The most important of these is trastuzumab (Herceptin), a humanized monoclonal antibody directed at the membrane-bound *HER-2* growth factor receptor, which is overexpressed in about one fourth of breast cancers. A phase II study of trastuzumab given in combination with paclitaxel for four cycles before surgery for tumors greater than 2.0 cm with *HER-2* overexpression

yielded a pathologic complete response rate of 18% in a group of patients that included many patients with large tumors.³⁰

What is inflammatory breast cancer?

The classic presentation of inflammatory breast cancer is that of a younger patient who presents with recent onset of diffuse erythema and edema of the breast, frequently with peau d'orange skin changes and the absence of a palpable mass. The condition is often first treated as mastitis and recognized as IBC after antibiotics have failed and a biopsy demonstrates tumor emboli in dermal lymphatics. In the AJCC classification system, IBC comprises T4d tumors, a subset of stage III disease. The AJCC manual points out that IBC is a clinical rather than a pathologic entity: involvement of dermal lymphatics alone does not define IBC in the absence of the clinical syndrome, and a neglected noninflammatory LABC that has progressed to create edema and erythema should not be considered IBC. Although some cases may be difficult to classify as IBC versus an aggressive LABC, a recent review of data from the Surveillance, Epidemiology, and End Results (SEER) breast cancer registry confirmed that IBC is a distinct clinicopathologic entity with average age of onset 10 years before that for LABC, a lower rate of hormone receptor positivity, and a markedly poorer survival.³¹ Laboratory evidence suggests that the diffuse involvement of dermal lymphatics and aggressive course of IBC may be related to overexpression of genes involved in angiogenesis: interleukin-8 (*IL-8*), vascular endothelial growth factor (*VEGF*), basic fibroblast growth factor (*b-FGF*), and others.³² These mechanisms could be therapeutic targets for the treatment of IBC in the future.

How is inflammatory breast cancer treated?

Although IBC is a distinct clinical entity, it is treated in much the same manner as noninflammatory LABC: induction chemotherapy followed by local therapy with radiation and surgery. As with noninflammatory LABC, response rates to neoadjuvant anthracycline-based chemotherapy are high, on the order of 70% to 90%,^{32,33} and rapid resolution of erythema and edema are commonly seen in the clinic. Despite high response rates to chemotherapy, however, survival remains poor, with median survival only 3 to 4 years. Investigators at M. D. Anderson Cancer Center have retrospectively reviewed the effect of adding paclitaxel to the neoadjuvant regimen in IBC and found significantly improved survival for patients with hormone receptor–negative disease.³⁴

Emerging Local Treatment Modalities for Breast Cancer

Tara L. Huston and Rache M. Simmons

As biologic therapies for breast cancer evolve, the need for minimally invasive surgical intervention as part of a multidisciplinary approach to its treatment grows. This chapter discusses a number of ablative and percutaneous techniques for the treatment of breast cancer, including radiofrequency ablation, cryoablation, interstitial laser therapy, microwave thermotherapy, focused ultrasound ablation, stereotactic excision, and vacuum-assisted core biopsy. These modalities are guided by ultrasound, stereotactic mammography, or magnetic resonance imaging (MRI) and can be performed in the office or ambulatory surgery setting.

ABLATIVE TECHNIQUES

For many years, ablative techniques have been successfully used to treat metastatic hepatic tumors. More recently, they have been applied to malignancies in the breast, lung, bone, central nervous system, kidney, and prostate.¹ The breast is an ideal model for ablative therapies owing to its superficial location on the thorax and lack of intervening organs between it and the skin.

Most current and historical studies of breast cancer ablation include postprocedure resection of the specimen in order to evaluate the level of pathologic tumor destruction. A standard prerequisite, for any of the ablative techniques, is a core biopsy of the breast tumor to determine the presence of estrogen and progesterone receptors, *HER-2/neu*, and markers of proliferation, apoptosis, differentiation, and cell regulation. Once the tumor has been destroyed, none of these markers can be reliably assessed.²

Radiofrequency Ablation

How does radiofrequency ablation work?

Radiofrequency (RF) ablation accomplishes tissue destruction through heat. High-frequency alternating current flows from an electrode on the tip of the RF probe into surrounding tissue. This results in ions in close proximity oscillating at applied frequencies and creating friction. Cell death occurs at sustained temperatures above 40°C to 50°C.³

How is radiofrequency ablation performed?

In order to perform RF ablation on a breast cancer, the tumor must be identifiable by stereotactic mammography or ultrasound imaging.^{4,5} The skin overlying the tumor is injected with local anesthetic, and then an insulated 15-gauge probe is inserted. Once the probe is in proper position, a starlike array of prongs is deployed to allow even distribution of the thermal energy^{2,6} (Fig. 30–1). Temperature sensors are located within the prongs to monitor the temperature of the surrounding breast tissue. The usual RF ablation procedure achieves a target temperature of 95°C within 5 to 7 minutes; the temperature is maintained for 15 minutes and is followed by a 1-minute cool-down period.²

With varying deployment of the starlike array of prongs, a spherical ablation zone anywhere between 3 and 5 cm in diameter can be created.⁵ To protect the patient from an electrical shock, a grounding pad must be applied to the patient's skin.^{2,6} Most RF ablation procedures have been performed under monitored sedation or general anesthesia in the operating room and followed by previously planned standard surgical resection.^{7,8}

What effect does radiofrequency ablation have on breast tissue?

Microscopically, RF ablation induces coagulative necrosis and protein denaturation.⁴ Even though the basic architecture of the ablated tumor can be discerned, the assessment of tumor grade and lymphovascular invasion is hindered by the heat destruction.⁹ At gross sectioning, the ablated region exhibits a firm, chalky, yellow-white center surrounded by a hyperemic red ring marking the edge of tissue destruction (Fig. 30–2). The tissues often do not show these changes for 48 hours; thus, examining a sample that was resected immediately after ablation may not reveal this characteristic pattern. To evaluate cell viability, nicotinamide adenine dinucleotide-diaphorase (NADH) staining is used in addition to the hematoxylin and eosin (H&E). With the NADH stain, an oxidation reaction in the cytoplasm of viable tissue stains dark blue, and the nonviable tissue stains pale gray.^{1,2}

Figure 30-1 Radiofrequency ablation demonstrating deployment of the prongs within a breast tumor and even distribution of thermal energy. (From Simmons R. Ablative techniques in the treatment of benign and malignant breast disease. *J Am Coll Surg* 2003;197[2]:334–338.)

Figure 30-2 Gross sectioning of a tumor after radiofrequency ablation. The ablated region exhibits a firm, chalky, yellow-white center and is surrounded by a hyperemic red ring, which marks the edge of tissue destruction. (From Simmons R. Ablative techniques in the treatment of benign and malignant breast disease. *J Am Coll Surg* 2003;197[2]:334–338.)

What are the data to support radiofrequency ablation?

In 1999, a pilot study to evaluate RF ablation as a treatment for breast cancer was undertaken by Jeffrey and colleagues.⁸ Five women with locally advanced breast cancer, and tumors ranging from 4 to 7 cm, underwent RF ablation in the operating room immediately before planned mastectomy. Histologically, all tumors showed some degree of cell death. The ablated zone extended between 0.8 and 1.8 cm around the tip of RF probe. NADH staining revealed complete cell death within the ablated zone in four of the patients. The fifth tumor harbored a single focus of viable cells smaller than 1 mm

partially lining a cyst. There were no perioperative complications related to the RF ablation.

Ultrasound-guided RF ablation was successfully performed on 26 women with needle core biopsy-proven T1 and T2 invasive breast cancers. The tumor size ranged between 0.7 and 3.0 cm, with a mean of 1.8 cm. All of the participants had RF ablation followed immediately by resection of the primary tumor. NADH staining revealed cell viability in only one of the 26 patients (4%). One woman sustained a full-thickness burn in the skin overlying the treatment zone, which was excised during the subsequent mastectomy without further complication.¹⁰

Another series of RF ablation of breast cancer in 17 women demonstrated that 94% of patients had complete tumor cell death at microscopic examination of the resected specimen. The single unsuccessful ablation was in a patient who had undergone neoadjuvant chemotherapy before ablation, which had resulted in nonconcentric tumor regression.^{2,7}

Hayashi and associates studied 22 postmenopausal women with clinical T1N0 breast cancers and tumors smaller than 3 cm.⁹ Tumors were initially thermally ablated and then surgically resected within the following 2 weeks. In three cases, residual disease was found at the ablation zone margin. One patient had dense breast tissue that bent the probe tips, another's tumor was too close to the chest wall, and in the third, ultrasound had significantly underestimated the size of the tumor. In five patients, the tumor was found to be multifocal distant to the ablation zone. A retrospective review of these five preprocedure mammograms had failed to identify the sites of multifocal disease. RF ablation alone would have been insufficient and would have led to a high rate of local failure in these five cases, equaling 23% of this study group. Overall, patient satisfaction was high, with minimal pain noted during the procedure itself, and 95% of women said they would be willing to have RF ablation again.

RF ablation has been successfully performed with the assistance of stereotactic guidance. A 71-year-old woman with a 1.6-cm infiltrating ductal carcinoma, diagnosed by stereotactic core needle biopsy, underwent RF ablation with an average temperature of 75°C for 20 minutes, after which a metallic clip was left in place. One month later, needle-localized surgical resection was performed with successful retrieval of the clip. The patient tolerated the procedure well, and no viable tumor was found. This case highlights a promising use for RF ablation in early breast cancers mammographically detected and then diagnosed with stereotactic core needle biopsy.¹¹

As a result of these successful treatments with RF ablation, a few trials are now investigating the use of RF alone, not followed by resection. These protocols will likely exclude patients with large tumors or those with a high likelihood of harboring multifocal disease. The natural history of RF-treated breast tumors without resection remains unknown and justifies further evaluation.

Cryoablation

How does cryoablation work?

With cryoablation, tissue is destroyed through localized freezing. Cryoablation involves multiple freeze–thaw cycles to

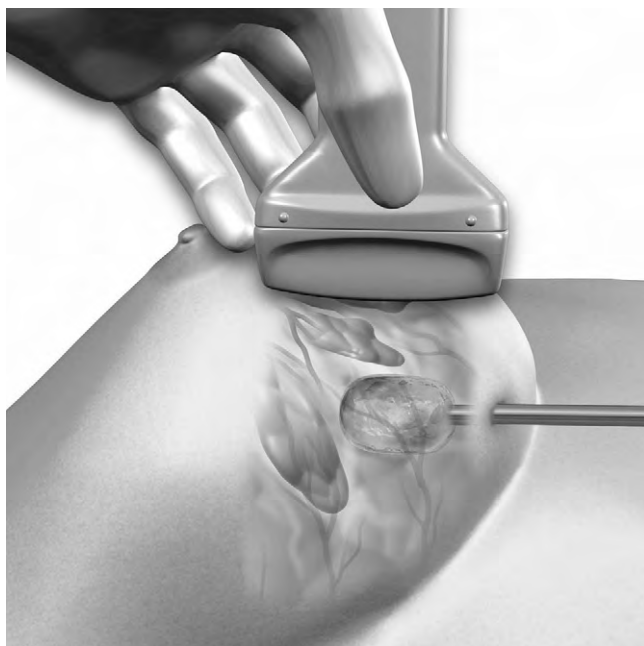

Figure 30-3 Demonstration of cryoablation showing sonographic probe placement and frozen ablation zone. (From Simmons R. Ablative techniques in the treatment of benign and malignant breast disease. *J Am Coll Surg* 2003;197[2]:334–338.)

achieve maximum tissue destruction. The size of the tumor determines the number of cycles that will be necessary.^{2,4,12–14} The target temperature has been shown to be between -160°C and -190°C .^{2,12,13} Gross determination of tissue destruction is very difficult for up to 1 week after cryoablation; thus, a delay is recommended before resection for adequate resection margins and histologic analysis.²

How is cryoablation performed?

The tumor is located by ultrasound probe and the overlying skin numbed with a local anesthetic. A small skin incision is then created through which the cryoprobe is inserted. No anesthesia is needed for the remainder of the procedure, as the freezing procedure itself acts as an anesthetic on the breast tissue. Patients stay completely awake for the procedure, and many view their procedure on the ultrasound monitor.⁴

The cryoprobe itself is entirely insulated except for a small area at the tip that is placed directly into the tumor (Fig. 30-3). While observing the ultrasound, one can visualize the generation of a sonographic freezeball from the liquid nitrogen or argon gas. With real-time ultrasound, the freezeball can be seen encompassing the tumor because a highly echogenic interface exists between frozen and unfrozen tissue (Fig. 30-4). The skin can sustain a thermal burn if the freezeball is too close. Therefore, to maintain a suitable distance, saline can be injected into the breast tissue between tumor and skin to create a separation. Alternatively, room-temperature saline or water can be dripped directly onto the skin's surface to protect it.⁴

Figure 30-4 Image of sonographic freezeball during cryoablation. (From Simmons R. Ablative techniques in the treatment of benign and malignant breast disease. *J Am Coll Surg* 2003;197[2]:334–338.)

Are there data to support cryoablation?

In 1985, Rand and colleagues produced one of the first pilot studies using cryoablation to treat breast cancer. The initial patient was a 77-year-old woman with a 1×2 cm palpable mass, which had malignant characteristics on mammogram. Using sonographic guidance aided by direct vision, a 5-mm cryoprobe was inserted into the lesion. The tumor underwent five freeze cycles and was then resected. No viable tumor cells were identified in the pathologic specimen. The patient had an uneventful recovery and, at a 2-year follow-up, was clinically and mammographically disease free.¹⁵

More recently, Staren and colleagues used cryoablation to treat a 76-year-old woman with two foci of infiltrating lobular carcinoma (0.5 and 0.8 cm) in the same quadrant, diagnosed by ultrasound-guided core needle biopsy. Cryoablation was performed separately on both tumors using sonographic guidance, and the masses were not resected. Core needle biopsy at 4 weeks and 12 weeks postablation revealed tissue necrosis, inflammatory cells, and cellular debris but were negative for persistent tumor. Shortly after the procedure, the patient developed a vague 2-cm firmness in the area between the two cryoablation zones, but this spontaneously resolved within 12 weeks.¹³

Stocks and associates¹⁶ performed cryoablation on 11 women with core needle biopsy-proven breast cancer and then resected the specimens within 1 to 3 weeks. The mean tumor size was 13 mm, with a range of 7 to 22 mm. The sonographic freezeball was generated to surround the tumor as well as a 1-cm margin of normal-appearing breast parenchyma. Ten of the tumors showed complete ablation. The one tumor with residual malignant cells revealed ductal carcinoma in situ (DCIS) at the border of the ablation zone. Two of the women sustained minor dermal injuries before the use of saline injection for tumors near the skin.

Pfleiderer and coworkers¹⁷ studied 15 women with 16 breast tumors, averaging 21 mm, to further investigate the potential of ultrasound-guided cryotherapy in breast cancer. Under ultrasound guidance, a 3-mm cryoprobe was inserted into each tumor. Two freeze–thaw cycles of 7 to 10 minutes and 5 minutes, respectively, were performed. Within 5 days after the cryoablation, all tumors were resected. The mean diameter of the freezeball was 28 mm. No severe side effects were observed. The five tumors smaller than 16 mm had no evidence of invasive cancer after treatment. However, two of these five had DCIS in the surrounding tissue. In the 11 tumors 23 mm or larger, histologic examination revealed incomplete necrosis. These authors concluded that the invasive components of small tumors can be treated using cryotherapy, but DCIS components that may not be detected before ablation represent a challenging problem.

The previously described studies indicate that cryoablation of breast cancers is a promising technique; however, more research needs to be done. In two of the studies, the presence of DCIS at the margin of the ablation zone resulted in incomplete tumor necrosis; thus, patients with DCIS may not be good candidates for cryotherapy. Major advantages to this technique are the obviation of anesthesia because the freezing numbs the breast, and the ability to perform this procedure in the office under real-time ultrasound guidance. Prospective randomized trials are needed to determine the long-term effectiveness of cryotherapy on breast cancer.

Interstitial Laser Ablation

How does interstitial laser ablation work?

Interstitial laser ablation (ILA) uses heat to destroy tissue. To perform the procedure, the lesion must be visualized by mammogram, MRI, or ultrasound. Mammographic guidance is used for microcalcifications or tumors seen solely on mammogram, whereas MRI tends to be used for other lesions. Ideally, the lesion should be well circumscribed and measure less than 1.5 cm in diameter.¹⁸

How is interstitial laser ablation performed?

No general anesthetic is necessary, but the skin overlying the cancer is numbed and a field block is performed directly at the site.^{5,19} A small skin incision is made, through which a hollow stereotactic needle is inserted. Through the stereotactic needle, a 16- to 18-gauge laser-emitting optic fiber is deposited.^{2,19} Parallel to the stereotactic needle, about 1 cm away, a multi-sensing probe is placed to monitor the temperature of the surrounding breast tissue. Laser coagulation cannot be monitored by real-time digital images, although continuous recording of the temperature grids can guide adequacy of treatment. The target temperature at the center is between 80°C and 100°C, which correlates to about 60°C registered on the probes at the periphery.¹⁹ Contrast-enhanced Doppler can be used to see the loss of blood flow to the ablated area.¹⁸

Within 20 minutes, about 1400 joules of laser energy per cubic centimeter of calculated tissue are delivered at a rate of 5 to 7 watts/second.^{5,18} The volume of tissue sphere encom-

passing the entire ablation zone is calculated by $V = 4/3\pi(\text{radius})^3$; thus, for the average 1-cm tumor with 0.5 cm surrounding cover of parenchyma, the volume is 4 cm³, and 5600 joules of laser energy are needed for its complete ablation. Saline is continuously dripped from the tip of the laser to prevent overheating.⁵ Using MRI, detailed temperature grids can be generated to outline the area of ablation and help to monitor the temperature of the surrounding breast tissue.²⁰

What does interstitial laser ablation do to tissue?

Bloom and colleagues²¹ reported a series of 40 patients with mammographically detectable T1 breast cancers treated by interstitial laser therapy. All tumors were excised within 5 to 42 days and examined to detail the pathologic changes induced by interstitial laser therapy. Upon evaluation, all revealed a characteristic series of concentric rings surrounding the laser needle tip cavity. Zone 1 was charred tissue within the cavity; zone 2 was coagulated with “wind-swept” nuclei similar to those seen in cautery artifact; zone 3 was a gray-tan ring that histologically showed recognizable tumor but did not express cytokeratin 8/18 (a viability marker) and was thus not viable; zone 4 was a ring of red-tan tissue in which the tumor architecture was evident but the cytoplasm and nuclear characteristics had been erased; and zone 5 was grossly hyperemic while histologically consisting of a rim of vascular proliferation with fat necrosis interspersed with aggregates of inflammatory cells and macrophages (Fig. 30–5). The classic zones were present in all patients regardless of the time that had elapsed between ablation and resection. Thus, it is the outer zone of fat necrosis that delineates the actual area of effective ablation.

Figure 30–5 Resected tissue specimen following interstitial laser ablation. Box highlights pseudoviability zone, which is structurally and histologically intact but is composed of nonviable cells. (Courtesy of Dr. Kombiz Dowlatshahi.)

What are the data to support interstitial laser ablation?

Dowlatshahi and colleagues¹⁹ studied the effect of laser therapy on 56 women with breast cancers smaller than 23 mm. Within 8 weeks of the ablation, the tissue was resected in all but 2 of these patients, both of whom were treated outside of the protocol. Sixteen of the 54 patients harbored residual tumor following ablation: 4 cases were early (learning phase) and not given sufficient laser energy; 2 patients were overestimated and moved involuntarily; 4 cases failed because of technical problems with the equipment; 5 cases had suboptimal target visualization because of excessive fluid infusion or needle biopsy hematomas; and 1 patient had a tumor larger than 2 cm. Difficult target visualization was overcome by inserting metallic markers around the tumor after numbing the skin but before the infusion of peritumoral anesthesia. The 2 patients who did not undergo resection were monitored by mammogram, ultrasound, and needle core biopsy for 2 years. This is of note because it is one of the only human demonstrations of the short-term natural history of interstitial therapy. In both patients, the laser-treated tumors first became smaller and were then replaced by a 2- to 3-cm oil cyst. After resolution of the cysts, fibrosis was identified on core biopsies.¹⁸

Laser ablation of breast cancers can also be done with MRI guidance. When compared with traditional MRI, rotating delivery of excitation off-resonance (RODEO) breast MRI affords higher contrast and improved spatial resolution in visualizing breast cancers. Using gadolinium further helps to locate the lesion. With RODEO MRI, an MRI-compatible needle is stereotactically placed within the lesion. The laser ablative therapy is then interactively controlled by continuous MRI with energy delivery correlated to tumor dimensions. The appearance of a hypointense zone on the image correlates with the effectiveness of the treatment.²⁰

Harms and associates²² performed MRI-guided laser ablation on 22 invasive cancers in 12 patients to test the feasibility of this approach. In 3 patients with tumors smaller than 3 cm, the goal was total ablation, whereas in the other 9 patients, only portions of large tumors were ablated. The laser-treated area was resected in all patients. The zone of ablation was measured as the greatest distance between two points on the hyperemic ring and was subjected to standard H&E as well as proliferation cell nuclear antigen (PCNA) staining for tumor viability. Pathologic analysis confirmed complete destruction in tumors smaller than 3 cm. The most frequent complaint, discomfort from compression of the MRI coils, was not related to the laser itself. An advantage of MRI-guided laser ablation is the ability to determine lesion margins precisely.

Microwave Ablation

How does microwave ablation work?

Microwave ablation involves thermal tissue destruction through two microwave phased array wave guide applicators. Because breast cancers have higher water content than surrounding normal breast tissue, the cancer should heat more rapidly than healthy tissue during microwave ablation. During the procedure, the breast is compressed between two acrylic

plates to allow penetration of microwave energy and to minimize patient movement. The microwaves are focused at the center of the tumor, where a temperature probe is placed to regulate the target temperature of 43°C. To avoid heat injury to the overlying skin, noninvasive skin surface temperature probes are applied to the skin, and fans provide constant air cooling.²³

What are the data to support the use of microwave ablation?

Gardner and colleagues²³ performed a pilot study using focused microwaves to achieve breast cancer thermoablation in 10 women planning to undergo mastectomy. The microwave treatment time averaged 34.7 minutes, with a range of 12 to 40 minutes. The mean peak temperature was 44.9°C and varied between 43.3°C and 47.7°C. All of the specimens were surgically resected as mastectomy specimens within 18 days. These data showed tumor size reduction averaging 41% (29% to 60%) on the basis of sonographic measurements before and after microwave therapy. On pathologic analysis, tumor necrosis was noted in 4 of 10 specimens and apoptosis was seen in 6. Three of the 10 women suffered flap necrosis following mastectomy that may have been associated with the elevated skin temperature during the laser therapy.

Can microwave ablation be used as a preoperative adjunct?

A group of nine patients with advanced breast carcinoma underwent hyperthermic tumor ablation (HTA) as a preoperative adjunct to determine whether tumor volume could be decreased. An 8-MHz radiofrequency heating device (Thermotron RF-8, Yamamoto Vinita, Japan) was combined with a grounded needle electrode to achieve a target temperature above 50°C. Tumor size was decreased from a mean of 122 cm³ to 82.2 cm³. Histologic examination of the primary focus showed total coagulation necrosis encompassing a sphere between 3.5 and 5.0 cm in diameter. The authors concluded that preoperative HTA is safe and well tolerated and results in a large volume of destruction of breast cancer tissue.²⁴

Can microwave ablation be used with chemotherapy?

Heat treatment can be used alone to kill tumor cells but has also been shown to enhance chemotherapy's tumoricidal effects. An ongoing phase II trial of focused microwave thermotherapy in women with locally advanced breast cancer is comparing neoadjuvant chemotherapy to neoadjuvant thermochemotherapy. Specifically, this two-armed randomized trial is comparing neoadjuvant focused 915-mHz microwave energy treatment with neoadjuvant doxorubicin (Adriamycin) plus cyclophosphamide (Cytosan) chemotherapy. By examining the thermal cell kill in resulting lumpectomy specimens, researchers hope to assess the added benefit of microwave thermotherapy to neoadjuvant chemotherapy.²⁵

Focused Ultrasound Ablation

What is focused ultrasound ablation?

Focused ultrasound (FUS) ablates tumor tissue with heat, resulting in protein denaturation and tissue necrosis. The ultrasound beams penetrate soft tissue and can be directed at tissue volumes as small as a few cubic millimeters. The absorbed energy causes an elevated temperature in the breast tissue with such a high thermal gradient that the boundaries of the treatment area are sharply demarcated without damage to the surrounding parenchyma. In seconds, a target temperature between 55°C and 90°C is attained. MRI is ideal for guiding FUS ablation because it yields excellent anatomic resolution, is highly accurate in the detection of tumors, and allows the physician to monitor the ultrasound ablation in real time.²⁶ Dose calculations are based on tumor size and the length of the ultrasound pathway as measured by MRI.²⁷

How is focused ultrasound ablation performed?

The patient is placed prone on a FUS table inside an MRI magnet. An anxiolytic is administered to reduce movement inside the MRI tube, and an analgesic is given to reduce the associated discomfort. No skin incision is needed. The transducer is positioned such that the ultrasound beam is focused directly on specific points within the tumor. At these focal points, the beam produces temperature elevations and coagulation necrosis. The treatment consists of a series of sonications throughout these points within the tumor itself plus a surrounding margin. At histologic assessment of resected specimens, the treated areas show a yellow-white area of central necrosis surrounded by a red hemorrhagic ring.²⁶

What are the data to support focused ultrasound ablation?

In a pilot study of MRI-guided focused ultrasound ablation, Gianfelice and associates²⁶ treated 12 women with invasive breast cancer consisting of tumors smaller than 3.5 cm. The treatment was composed of multiple sonications at targeted points, which were monitored with temperature-sensitive MRI followed by surgical resection. The effectiveness was determined by comparing the volumes of necrosed and residual tumor in the resected specimen. The procedure was well tolerated, with two minor skin burns as the sole complications. In three patients treated with the first ultrasound system (InSightec-TxSonics Mark 1 InSightec TxSonics, Dallas, TX), a mean of 46.7% of the tumor was within the targeted zone, and a mean of 43.3% of the cancer tissue was necrosed. In nine patients treated with the more advanced second ultrasound system (InSightec-TxSonics Mark 2), a mean of 95.6% of the tumor was within the targeted zone, and a mean of 88.3% of the cancer tissue was necrosed. Residual tumor was identified predominantly at the periphery of the tumor mass. By increasing the total targeted area, such as with an increased number of sonications, a greater tumor volume could be destroyed. The authors' conclusion was that thermal

coagulation of small breast tumors by means of MRI-guided focused ultrasound is a promising noninvasive ablation procedure for which further study is warranted.

Huber and colleagues performed a single-patient pilot study of a woman with a 2.2-cm centrally located invasive ductal carcinoma. The therapy involved 80 single ultrasound pulses of 9 seconds each at 30 to 50 watts of acoustic power. Immediately after the treatment, the patient was evaluated with gadolinium-enhanced MRI to determine the extent of tissue destruction. The images demonstrated a zone without contrast in the targeted area, suggesting a complete interruption of the blood supply. No anesthesia was needed, and the patient did not note any discomfort during the procedure. A lumpectomy was performed 5 days after the focused ultrasound ablation procedure. Histologic examination revealed both lethal and sublethal damage to the tumor. The authors concluded that noninvasive MRI-guided therapy of breast cancer is feasible and effective and that MRI-guided FUS may represent a new strategy for the neoadjuvant, adjuvant, or palliative treatment in selected breast cancer patients.²⁷

Advantages of focused ultrasound ablation include the fact that no skin incision needs to be made, the focal point is continually changeable throughout the treatment, and there is great flexibility in matching the size of the treatment zone to the targeted volume of the tumor in three dimensions.²⁶

PERCUTANEOUS TUMOR EXCISION: STEREOTACTIC EXCISION AND VACUUM-ASSISTED CORE BIOPSY

How does stereotactic excision work?

Stereotactic excision of small breast cancers is possible using the Advanced Breast Biopsy Instrumentation system (ABBI, U.S. Surgical Corporation, Norwalk, CT). It was originally introduced in 1996 as a diagnostic tool that incorporates large-bore cannulas within the stereotactic table and can remove mammographic breast tumors as a nonfragmented single-core specimen. A surgical cannula, up to 20 mm wide, is inserted along a stereotactically positioned axial wire in the center of the tumor. Tissue cylinders encompassing the entire tumor are then extracted in amounts significantly larger than those obtained by core biopsy.

What are the data on the use of stereotactic excision?

In 50 patients with in situ and invasive breast cancer, positive margins and residual tumor rates were similar to those seen with needle-localized excisional biopsy when compared by mammographic lesion size and ABBI cannula size.^{28,29} As expected, there was a higher rate of positive margins when larger lesions were excised with smaller cannulas. Even though small tumors can be successfully excised with negative margins, there are limitations regarding incision placement and an increased incidence of wound hematoma compared with other methods.

How does the vacuum-assisted core biopsy work?

The two vacuum-assisted systems currently in use are the Mammotome (Biopsy Medical, Cincinnati, OH) and the Minimally Invasive Breast Biopsy (MIBB, U.S. Surgical Corporation, Norwalk, CT). Both techniques use a vacuum to pull tissue into a sampling chamber, where it is removed with high-speed rotating knives and then suctioned into an external chamber for harvest. This method avoids multiple passes, compared with a standard core biopsy, and allows the retrieval of contiguous samples. The Mammotome functions with internally rotating knives. The MIBB uses an externally oscillating knife that is capable of sampling larger specimens.^{30,31}

What are the data to support the use of the vacuum-assisted core biopsy?

Fine and coworkers³² published a multicenter nonrandomized study evaluating 124 women with low-risk palpable breast lesions resected using the Mammotome under ultrasound guidance. The 75 lesions 1.5 cm or smaller were removed with an 11-gauge probe, whereas the 49 lesions between 1.5 and 3.0 cm were removed using an 8-gauge probe. Follow-up evaluation was performed 10 days after the biopsy. Complete removal of the imaged lesion was similar between groups: 99% with the 8-gauge and 96% with the 11-gauge. Most complications were mild and anticipated. Ninety-seven percent of patients were satisfied with the appearance of the incision, and 98% would recommend the procedure to others. Thus, percutaneous removal of palpable benign breast masses using the Mammotome system is feasible, is safe, and yields high patient satisfaction.

The complete removal of small lesions under ultrasonographic guidance in an outpatient setting using the multidirectional hand-held vacuum-assisted biopsy device was also demonstrated by Johnson and associates.³³ One hundred one breast lesions in 81 patients were excised through 3-mm incisions using a hand-held 8-gauge or 11-gauge Mammotome. The average lesion size was 1.15 cm. Ninety-four (93%) of the lesions were benign, five (5%) were malignant, and two (2%) showed atypical hyperplasia. At subsequent excisional biopsy of the malignant lesions, only one was found to harbor residual disease. Of the two lesions with atypical hyperplasia, no evidence of malignant disease was noted in either excisional biopsy specimen. This study concluded that vacuum-assisted excisional breast biopsy under ultrasound guidance is an effective technique for the management of benign lesions.

CONCLUSION

Numerous methods of image-guided percutaneous breast cancer ablation and percutaneous tumor excision are currently being investigated in clinical trials. Long-term follow-up data regarding local effects on the surrounding breast tissue or recurrence rates are not yet available. There are limited data suggesting the possibility of fat necrosis within the unresected tissue.² Local breast changes may pose diagnostic

dilemmas in future ablation-only trials, making it difficult to distinguish recurrent cancer from scar or fat necrosis.

We are cautiously optimistic that ablative and percutaneous excisional therapies will be used as a routine adjunct in the future to treat selected breast cancers. The challenge in the success of these techniques will lie in the ability to identify multifocal disease and to ensure complete and effective eradication of the breast cancer.

Surveillance Following Breast Cancer Treatment

Tracey O'Connor and Stephen B. Edge

In the United States, there were more than 200,000 new cases of invasive breast cancer in 2003, with an additional 55,000 cases of carcinoma in situ,¹ making breast cancer the most common malignancy in American women. The increased incidence and improved mortality rate have resulted in a large population of breast cancer survivors who require regular follow-up, probably exceeding 2 million women. A rational plan for breast cancer follow-up takes into consideration the natural history of the disease and the influence of various therapies. This plan should account for the likely sites and timing of recurrences as well as the ability of treatment to effectively influence disease outcome. Women with breast cancer also require regular follow-up to detect and manage complications and side effects of therapy, such as lymphedema and premature menopause and its consequences. This chapter reviews the pertinent data and explains the recent shift from intensive medical surveillance to a less aggressive approach.

What are the goals of breast cancer follow-up?

There are several goals of medical surveillance following primary breast cancer therapy. One reason for continued follow-up is contribution to research and accumulation of data.² Another is the detection of new primary breast cancers in the contralateral breast at an early stage. Studies have demonstrated that women with a history of invasive breast cancer have a greater risk for developing a contralateral breast cancer. Other goals include the detection of recurrent disease in patients who may benefit from therapy, patient rehabilitation and psychological support, evaluation of treatment effects, and risk counseling for the patient and family.³ Because most women survive breast cancer, it is also important for them to continue routine primary care and preventive health practices and to maintain a relationship with their primary care providers.

FOLLOW-UP OF IN SITU BREAST DISEASE

How is the patient with in situ breast disease followed?

Before the widespread use of screening mammography, ductal carcinoma in situ (DCIS) was an infrequently encountered

problem routinely treated with mastectomy. Thus, there is a limited amount of information regarding the natural history of this disease.⁴ In recent years, coinciding with the use of screening mammography, there has been a marked increase in the incidence of DCIS in asymptomatic women. In one series, DCIS represented 20% of all screen-detected breast cancers, and the overall rate of DCIS detection by screening mammography was 0.78 per 1000 mammograms, with the rate increasing with age. Therefore, about 1 case of DCIS is detected for every 1300 mammograms performed.⁵

Depending on the individual circumstances, patients with DCIS generally undergo surgery (lumpectomy or mastectomy) and may also receive radiation therapy, tamoxifen, or both. Patients with DCIS are at a very low risk for systemic disease but have a substantial risk for developing recurrence in the conserved breast that may be invasive breast cancer or a recurrent in situ lesion, and they are also at risk for a contralateral breast cancer. The estimates of recurrence risk after breast conservation therapy vary across studies and are influenced by factors such as tumor grade, tumor size, margin width, patient age, and treatment. In one large clinical trial, after a mean follow-up of 90 months, the incidence of ipsilateral invasive breast cancer in patients treated with lumpectomy alone was 13.4%.⁶ The addition of radiation to lumpectomy reduced the rate of invasive recurrence to 3.9% and the rate of recurrent DCIS to 8.2%. A more recent study cited high nuclear grade as the factor most strongly associated with recurrence in women treated with lumpectomy alone, although this variable was not able to predict an invasive versus noninvasive recurrence. Women with DCIS of high nuclear grade had high 5-year recurrence rates for invasive cancer of 11.8% and for DCIS of 17.1%, whereas women with low-nuclear-grade tumors had relatively low 5-year recurrence rates for invasive cancer of 4.8% and for DCIS of 4.8%.⁷ Women with high-nuclear-grade DCIS or DCIS treated with lumpectomy alone had relatively high rates of invasive breast cancer recurrence when compared with patients diagnosed with DCIS of low nuclear grade and treated with radiotherapy.⁷

The National Surgical Adjuvant Breast and Bowel Project (NSABP) Protocol B-24 examined the role of tamoxifen in women treated for DCIS with breast-conserving surgery and radiation. After completing radiotherapy, women were randomized to placebo or tamoxifen. The women treated with tamoxifen had an 8.2% incidence of ipsilateral breast cancer (4.1% invasive and 4.2% noninvasive) compared with 13.4% of the placebo group (7.2% invasive and 6.2% noninvasive) at

Table 31-1 Follow-up after Treatment for Ductal Carcinoma In Situ

- Interval history and physical exam every 6 mo for 5 yr, then annually
- Mammogram every 12 mo
- If tamoxifen is given:
 - Annual pelvic exam with Pap smear if appropriate
 - Ophthalmology exam if cataracts or vision problems
 - Consider monitoring for bone density loss if premenopausal

Data from Writing Committee. NCCN breast cancer clinical practice guidelines. JNCCN 2003;1:148–188.

a median follow-up of 74 months.⁸ In addition, tamoxifen reduced the risk for contralateral breast cancer.

The goal of follow-up after DCIS is therefore to screen for a new or recurrent cancer in the conserved breast or in the contralateral breast. Screening for distant metastases has no role. Follow-up for women with DCIS involves a history and physical examination every 6 to 12 months for 5 years. Postexcision mammogram should be performed after surgery, and before radiation, to ensure completeness of resection and is especially important for cancers manifested by microcalcifications. The first postradiation mammogram should be performed 6 months after the completion of radiation to record the new baseline breast appearance.⁹ Mammograms performed before this 6-month interval may be suboptimal because of edema and skin changes. Mammography is then recommended annually and should be performed on both breasts (Table 31-1).

Although the incidence of DCIS continues to rise, the incidence of lobular carcinoma in situ (LCIS), which accounts for 13% of in situ breast carcinomas, has been stable since 1988.¹⁰ The true incidence of LCIS in the general population is unknown because there are no specific clinical or mammographic signs. LCIS is thought to represent a transitional intraepithelial, or in situ, stage in the evolution of breast cancer, and it is assumed to be distributed throughout breast tissue, having close to a 100% incidence of bilaterality and multicentricity.¹¹ The presence of LCIS is a marker of future risk for breast cancer development. About 0.5% to 1% of women with LCIS develop invasive breast cancer annually.¹² The risk is bilateral and not limited to the breast in which LCIS was found.

The management of LCIS is conceptually different from the management of other breast cancers, reflecting the view that LCIS is a precancerous lesion and not a true cancer. The goal of treatment is prevention of an invasive lesion or early detection while the invasive lesion remains confined to the breast. Consensus now supports observation alone as the most appropriate treatment for LCIS.¹³ Bilateral mastectomy, with or without reconstruction, is considered for women with a strong family history or genetic susceptibility, and for those who view their personal risk for breast cancer as unacceptably high.

Surgical excision to achieve negative margins is not needed at the initiation of surveillance. Similarly, radiation therapy has no currently established role in the treatment of this disease. Treatments that do not account for the bilaterality of this process (i.e., unilateral mastectomy) are not logical.

Tamoxifen decreases the risk for a subsequent invasive breast cancer in women with LCIS. The NSABP P-01 breast

Table 31-2 Follow-up after Treatment for LCIS

- Interval history and physical exam every 6–12 mo
- Mammogram every 12 mo unless after bilateral mastectomy
- If tamoxifen is given:
 - Annual pelvic exam with Pap smear if appropriate
 - Ophthalmology exam if cataracts or vision problems
 - Consider monitoring for bone density loss if premenopausal

Data from Writing Committee. NCCN breast cancer clinical practice guidelines. JNCCN 2003;1:148–188.

cancer prevention trial included 826 women with LCIS. Among women with LCIS who received no treatment, the average annual rate of invasive cancer was 12.99 per 1000 women. Tamoxifen decreased the annual rate per 1000 to 5.69, a risk reduction of 56%.¹⁴

Patients with LCIS treated with observation alone or bilateral mastectomy share a good prognosis. Consensus follow-up recommendations include history and physical examinations every 6 to 12 months for 5 years and annually thereafter in conjunction with yearly mammography for those being followed by observation (Table 31-2).

FOLLOW-UP OF INVASIVE BREAST CANCER

About one third of patients with a history of breast cancer will experience a recurrence and ultimately die of their disease. Recurrence rates increase with the size of the primary tumor and lymph node involvement, whereas adequate surgical treatment and adjuvant therapy are associated with lower recurrence rates.

Women with a history of breast cancer remain at risk for recurrence for the rest of their lives. As will be detailed, although most recurrences occur within 5 years of diagnosis, the hazard of recurrence decreases slowly through year 12, and very late recurrences are not uncommon.¹⁵ However, most relapses occur during the first decade, with the rate of relapse peaking between years 2 and 5 after diagnosis. Late mortality estimates are less than 2% per year beginning 15 years after primary treatment.¹⁶

In women with a history of invasive breast cancer, a yearly mammogram of the remaining breast tissue is indicated. Mammography of the reconstructed breast or of the chest wall has a low yield and is not recommended.¹⁷ As noted, for cases of mammographically detected breast cancer, a postexcision mammogram may be performed before radiation to ensure completeness of resection and is especially important for DCIS diagnosed by radiographic microcalcifications. The first postradiation mammogram should be performed 6 months after the completion of radiation to record the new baseline breast appearance.⁹ Mammograms performed before this 6-month interval may be suboptimal owing to edema and skin changes. Mammography is then recommended annually and should be performed on both breasts.

Consensus recommendations for follow-up of invasive breast cancer include history and physical examinations every 3 to 6 months for the first 3 years, then every 6 to 12 months for 2 years, then annually. Pelvic examination and cervical cytology should be continued annually for patients with an intact uterus. Prompt evaluation of new signs and symptoms,

Table 31-3 Follow-up after Treatment for Invasive Breast Cancer

- Interval history and physical every 4–6 mo for 5 yr, then every 12 mo
- Mammogram every 12 mo (and 6 mo after radiation if breast conservation is performed)
- Pelvic examination every 12 mo if uterus is present and patient is taking tamoxifen
- Prompt evaluation of new signs and symptoms
- Osteoporosis screening and appropriate treatment (see text) for high-risk women
 - All women older than 65 yr
 - Women aged 60–64 yr with:
 - a. Family history
 - b. Body weight > 70 kg
 - c. Prior nontraumatic fracture
 - d. Other risk factors
- Postmenopausal women of any age receiving aromatase inhibitors
- Premenopausal women with therapy-associated menopause

ongoing patient education, continued coordination of care, and psychosocial support should also be maintained (Table 31–3).

What is the timing of breast cancer recurrence?

The timing of breast cancer recurrence affects the frequency of follow-up examinations and testing. Because breast cancer may recur at any time following treatment, all patients must continue on surveillance throughout life. A large series from Milan examining the risk for locoregional and distant recurrence rates over 12 years of follow-up in 2233 patients following breast-conserving therapy consisting of quadrantectomy, axillary dissection, and radiotherapy was published in 1995.¹⁸ This series reported 119 local recurrences, 32 new ipsilateral cancers, and 414 distant metastases as first events. Distant metastases occurred in up to 5% of patients per year for the first 2 years after therapy, after which the recurrence rates declined sharply. In contrast, locoregional recurrence rates did not show a peak of incidence, instead remaining constant for the 12-year follow-up period, at about 1% per year.

Another large study analyzing the clinical course of 3585 patients enrolled in seven Eastern Cooperative Oncology Group (ECOG) adjuvant trials was reported in 1996.¹⁵ This study included both premenopausal and postmenopausal women in its analysis, and most women had positive lymph nodes at the time of diagnosis. Forty-five percent (1625) of patients experienced a recurrence during the median follow-up of 8.1 years. One hundred eighty-two patients (5%) died without recurrence and were censored for recurrence at the time of death. The hazard of recurrence was greatest between 1 and 2 years after surgery (13.3%), then decreased consistently from 2 to 5 years. Beyond 5 years, the hazard of recurrence decreased slowly. Between years 5 and 8, the hazard of recurrence was 4.7%, and between years 8 and 12, it was 3.4% ($P = .01$). Higher-risk subsets (patients with more than three positive nodes) had a higher hazard of recurrence at all time intervals but demonstrated the same temporal pattern of recurrence as the lower-risk subsets.

Estrogen receptor (ER) status affected the timing of recurrence in this study. Overall, the hazard of recurrence was increased for the ER-negative patients compared with the ER-positive patients. However, the increased hazard associated with ER negativity reflected the higher hazard of recurrence in years 0 to 5. Between years 3 and 4, the hazards for ER-negative and ER-positive patients crossed, and beyond 5 years, the hazard was greater for ER-positive patients. There is therefore no definable point at which a woman may be considered cured of her disease, nor free from risk for the development of a new primary breast tumor.

What is the rate of locoregional recurrence following mastectomy?

Local recurrence following mastectomy most commonly presents as nodularity in or under the skin of the chest wall, usually in or near the mastectomy scar. Regional recurrence presents as palpable adenopathy in the previously treated axilla or supraclavicular or infraclavicular nodes. The rate of isolated locoregional failure after mastectomy ranges from 2% to 20% depending on the tumor size, lymph node involvement, and length of follow-up.³ Many of the data regarding locoregional recurrences in patients treated with mastectomy were generated from the time period before widespread use of adjuvant systemic therapy and regional radiation. However, 20-year follow-up of NSABP B-06 showed a local and regional recurrence rate of 14.8% in patients treated with total mastectomy.¹⁹ The size of the primary tumor, lymph node involvement, and use of adjuvant radiation all can influence the rate of locoregional recurrence following mastectomy. A meta-analysis of randomized trials conducted by the Early Breast Cancer Trialists' Collaborative Group demonstrated that adjuvant chest wall irradiation can decrease local recurrence but did not impact survival, likely reflecting the increased likelihood of occult distant disease in women presenting with locoregional failure after mastectomy.²⁰

Almost all patients with an isolated local recurrence following mastectomy develop distant disease, despite local therapy. In one series of patients treated for local or regional recurrence after mastectomy from 1968 to 1978, the 5- and 10-year actuarial rates of freedom from distant metastasis were 30% and 7%, with overall survival only 26% at 10 years.²¹ Because locoregional recurrence following mastectomy is frequently associated with distant disease, a metastatic assessment is indicated before any aggressive local therapy is employed.

What is the risk for locoregional recurrence following breast-conserving therapy?

Ipsilateral recurrence after lumpectomy and radiotherapy occurs at a rate of 0.5% to 1% per year and generally presents in a fashion similar to that of primary breast cancer.²² Abnormalities on mammogram, palpable masses, and suspicious nipple discharge must be evaluated as potential signs of recurrent disease. The risk for locoregional recurrence increases with positive margins of resection, multifocal disease, young age at diagnosis, and the absence of radiotherapy. The rate of recurrent cancer in the ipsilateral breast among women with negative nodes treated with breast-conserving

therapy, systemic therapy, and radiation is about 6% at 10 years of follow-up.¹⁹ Trials with broader inclusion criteria have reported ipsilateral failure rates from 8.8% in the Milan trial, reported at 20 years,²³ to 22% in the National Cancer Institute study,²⁴ reported at a median follow-up of 18.4 years. In contrast to locoregional recurrence after mastectomy, an in-breast recurrence is associated with synchronous distant metastases in only 10% of cases, and most patients will be effectively treated and not experience further recurrence.²⁵ Therefore, the overall survival of patients after primary treatment with mastectomy or with breast-conserving therapy is equivalent at 20 years. When radiotherapy is omitted from breast-conserving therapy, the locoregional recurrence rate increases significantly (39.2% in the NSABP series) but without a corresponding decrement in overall survival. As already noted, it is essential to follow the conserved breast with periodic physical examinations and annual mammography.

What are the most common sites of distant disease relapse?

It is important to understand the pattern of distant breast cancer recurrence because this knowledge can be used to focus the history and physical examinations during surveillance visits. Distant recurrence rates in women with a history of invasive breast cancer vary from 5% to 80%, depending on stage and other prognostic factors.³ Current data on the patterns of breast cancer recurrence reflect a period of time before the widespread use of breast conservation and systemic therapy; nonetheless, they are important to our understanding of the disease.

The skeletal system represents the most common site of distant relapse, followed by lung or pleura and liver. Kamby and colleagues reported a series of 415 patients with first recurrence and found the most common sites of distant metastatic disease were bone (31%), lung (19%), and liver (15%).²⁶ The central nervous system is the first distant site of metastasis in less than 5% of patients who develop distant metastasis.²⁷ Between 10% and 15% of patients have disease at multiple sites at the time of presentation with distant metastatic disease.

Should women with a history of breast cancer have routine chest radiographs or imaging studies?

Most patients with metastatic disease are diagnosed with distant disease following symptoms or abnormality detected on physical exam. A number of trials have examined the potential role of radiographic modalities to screen for asymptomatic breast cancer recurrence. Reflecting the fact that the skeleton is the most common site of initial distant relapse, most studies have examined the potential role of nuclear medicine bone scanning.

The NSABP performed a prospective study of 2697 women with a history of stage II breast cancer followed with routine bone scans. Only 0.6% of scans detected metastasis in asymptomatic patients.²⁸ In a trial reported by Pedrazzini and associates, routine bone scanning done at baseline and repeated at 1 year could provide early detection of a recurrence for 2.4%

of the population studied.²⁹ These clinical trials fail to support routine radionuclide scintigraphy in the follow-up of the asymptomatic patient.

The performance of routine chest radiographs as a method of detecting recurrence has also been examined. Intrathoracic recurrence can present as lung metastases, pleural recurrence with associated effusion, and mediastinal disease. A review of retrospective studies of chest radiographs as a method of detection reported that first recurrence was detected by chest films in 2.7%, with a range of 0% to 5.1%.³⁰ Another study followed 241 patients with routine chest radiographs and bone scans during the first 2 years after surgical treatment.³¹ Twelve patients (5%) were discovered to have pulmonary metastasis on routine sequential chest radiography. Four of these 12 patients were symptomatic. Overall, 1091 chest radiographs in 241 patients were required to detect occult metastases in 8 cases. Based on these and similar studies, routine chest radiography is not recommended.

Computed tomography (CT), magnetic resonance imaging (MRI), and positron emission technology (PET) are newer imaging modalities potentially able to screen patients for asymptomatic first recurrence. Large prospective trials addressing the potential utility of these techniques have not been reported, and the routine use of these tests in the asymptomatic patient is not recommended.

Should routine blood work be performed during breast cancer follow-up?

There are insufficient data to suggest that patients should receive routine complete blood counts as part of a surveillance program. Similarly, chemistry profiles have not been found to be helpful in detecting recurrences in the asymptomatic patient. In one retrospective review, chemistry studies detected initial recurrence in only 5.9% of cases (range, 1.2% to 12.0%).³⁰ However, in a study of 6.3% of patients who did develop liver metastases, only 1.3% were asymptomatic.³²

Are there data available to support the use of tumor markers in surveillance of the breast cancer patient?

The serial measurement of tumor markers represents a newer approach to screening for breast cancer recurrence. Carcinoembryonic antigen (CEA), CA-15-3, and CA-27.29 are three commonly measured markers. Compared with conventional disease assessment tools, biochemical markers assess the total-body burden of disease rather than the size of a single lesion, making them potentially more sensitive for early detection.

The serum markers CA-15-3 and CA-27.29 measure a class of glycoproteins secreted by breast cancer cells. CA-15-3 was the first available test. It can be measured in the sera radioimmunologically with the monoclonal antibodies DF3 and 115-D8. Multiple studies have reported that the incidence of CA-15-3 elevation increases with the stage of disease, with incidences of elevation from 5% to 30%, 15% to 50%, 60% to 70%, and 65% to 90% in stages I, II, III, and IV, respectively.³³ Large tumor burden correlates with high marker values.³⁴ Despite this correlation with extent of disease, low CA-15-3

levels do not exclude metastatic disease, and a given level does not predict stage of disease. In addition, CA-15-3 is elevated in 5% to 6% of healthy people, and more often in individuals with benign diseases of the liver and biliary system or with benign mastopathic disease of the breast.³⁴ There are few studies examining the value of CA-15-3 in prospective trials of the follow-up of breast cancer patients after primary treatment. A recently reported prospective trial by Kokko and associates of CA-15-3 levels measured regularly in 243 patients with primary breast cancer for a median follow-up of 4.3 years demonstrated a mean lead time to diagnosis of 3 months. Other studies have reported mean lead times varying from 9.5 months,³⁵ 4.2 months,³⁶ and 64 days.³⁷ Despite these findings, there is no evidence that lead time affects the benefit and outcome of treatment for metastatic disease. A large prospective randomized trial is required to examine this question.

CA-27.29 has been compared with CA-15-3 in a retrospective trial of 275 patients. This study found CA-27.29 to be more sensitive in the patient populations studied, with incidences of elevation of 29%, 36%, and 59% in stages I, II, and III, respectively. In contrast, CA-15-3 measured in the same samples was elevated 15%, 23%, and 54%, respectively.³⁸ Chan and coworkers conducted a study to determine the ability of CA-27.29 to predict relapse and lead time from the marker elevation to clinical evidence of disease.³⁹ The study reported a sensitivity of CA-27.29 positivity of 57.7% and a lead time of 5.3 months.

CEA belongs to a family of cell surface glycoproteins with increased expression in breast cancer as well as other malignancies. The level of CEA is elevated in 10% to 60% of patients with breast cancer, with the likelihood and degree of elevation related to the stage of disease.³ The false-positive rate in patients without disease recurrence has varied from 0% to 11%, depending on the study. In patients in whom elevated CEA levels precede clinical evidence, the lead time varies between 3 and 7 months.⁴⁰

The American Society of Clinical Oncology (ASCO) Tumor Markers Panel evaluated the available evidence to assess the value of using CEA, CA-27.29, and CA-15-3 as markers of asymptomatic recurrence. They found insufficient evidence to support the routine use of these markers in the screening, diagnosis, staging, or follow-up of breast cancer.⁴¹ Although a rising marker can detect a recurrence after primary treatment, there is no established clinical benefit to this detection, and options for therapy remain essentially unchanged. The ASCO Guidelines state that “there has been no demonstrated impact on the most significant outcomes (improved disease-free or overall survival, better quality of life, lesser toxicity, or improved cost-effectiveness).”⁴¹

The overall strategy of intensive surveillance after breast cancer has been tested in controlled trials. Two large prospective randomized controlled trials involving more than 2500 early-stage breast cancer patients compared intensive surveillance (serial bone scans, liver ultrasounds, chest radiographs, and laboratory testing) with routine surveillance.^{42,43} Both studies determined that most patients with metastatic disease presented with symptoms rather than findings on the screening examinations. Neither study was able to detect a survival benefit or improvement in quality of life related to intensive surveillance, concluding that such surveillance is not indicated in the follow-up of early-stage breast cancer patients. There are not randomized data of this quality to assess the value of

tumor markers in this setting, but the available uncontrolled data cited earlier do not suggest that the use of markers would lead to a survival benefit.

What is the risk for developing a second primary breast cancer?

Patients with breast cancer are at risk for a second primary breast cancer. Ten years after treatment, the risk for developing a new breast cancer is equal to or greater than the risk for developing a disease recurrence.⁴⁴ Patients who develop bilateral breast cancer, synchronously or asynchronously, may have a strong family history of breast cancer and are at risk for carrying a *BRCA1* or *BRCA2* mutation. Second primary breast cancers are curable, especially if detected early. Women with a history of invasive breast cancer have a greater risk for developing a contralateral breast cancer. The magnitude of this risk is about 0.5% to 1% per year of follow-up. In a large series of patients followed at Memorial Sloan-Kettering for a median of 18.2 years, the average annual incidence was 8 per 1000 per year of follow-up (0.8%). This risk was age dependent: women younger than 45 years at the time of diagnosis have an average annual rate of contralateral breast cancer of about 1%, whereas those older than 50 years at diagnosis face a risk of about 0.5% per year.⁴⁵ The incidence of contralateral breast cancer was about 9% at 20 years and 25 years in the NSABP B-06 and B-04 studies, respectively.^{19,46} Other studies have demonstrated that contralateral breast cancer exhibits a prognosis similar to that of the first breast, making early detection and treatment valuable.⁴⁷ The primary source of overall mortality is largely determined by the risk for distant disease from the first primary cancer, although the risk for a new primary or recurrence is real.⁴⁵ These data provide further support for the need for annual mammography after breast cancer treatment.

COMPLICATIONS OF THERAPY

What complications of local therapy may be seen in follow-up?

The current therapy for breast cancer often includes one or more local treatments associated with complications. In general, women are treated with either mastectomy or breast-conserving therapy followed by radiation. Axillary lymph nodes are generally evaluated with a sentinel node biopsy, a level 1 and 2 axillary nodal dissection, or both. The risk for local complications can increase with systemic therapy and with the degree of local therapy required.⁴⁸

Axillary surgery can result in persistent numbness or discomfort, swelling (lymphedema), and decreased range of motion of the arm. Mild symptoms are common and have been reported in about one third of women 2 to 5 years after axillary node dissection.⁴⁹ The increasing use of sentinel lymph node procedures is hoped to decrease the likelihood of local morbidity. One study by Schijven and colleagues compared morbidity in 213 patients treated with axillary lymph node dissection (ALND) with 180 patients treated with

sentinel node biopsy (SNB) using a disease-specific quality-of-life questionnaire.⁵⁰ Patients having SNB had a 3.2-fold lower risk for pain, a 5-fold lower risk for lymphedema, a 7.7-fold lower risk for numbness, a 7.1-fold lower risk for loss of strength in the affected arm, and a 2.9-fold lower risk for impaired use of the arm. Axillary radiotherapy added to the risk for lymphedema by 2.4-fold and enhanced the impaired use of the arm by 2.6-fold.

Although most cases of lymphedema are mild, it can have a significant impact on a woman's quality of life. Identified risk factors include axillary radiation, extent of axillary surgery, obesity, and weight gain.⁵¹ Before any treatment for lymphedema is started, a cancer recurrence involving the axilla or brachial plexus, axillary vein thrombosis, or infection should be considered and treated if present. Recommendations for treatment are limited by the lack of prospective randomized trials on therapy options but may include compression garments and comprehensive physical therapy (manual lymphatic drainage).⁵² Surgery, diuretics, and compression pumps are ineffective.

What are the long-term side effects of chemotherapy?

An increasing number of women receive adjuvant systemic chemotherapy for breast cancer. These treatments may be associated with weight gain, infertility, chemotherapy-induced premature menopause, and neuropathy.⁵³ Women with chemotherapy-induced ovarian failure may be at increased risk for osteoporosis and should consider bone density monitoring. Less common side effects include cardiac dysfunction from anthracycline-based chemotherapy and leukemia-myelodysplastic syndromes. The potential for development of these complications should be considered during follow-up if a woman presents with concerning symptoms. As discussed earlier, there are no data to support the use of complete blood counts to screen for bone marrow relapse or myelodysplasia or serial echocardiography, or of multigated acquisition scanning to screen for cardiac dysfunction.¹⁶

How should women on hormonal therapy be followed?

Antiestrogen hormonal therapies are frequently used in the treatment of women with early-stage breast cancer and are highly effective for patients with hormone receptor-positive disease. Although they are generally well tolerated as compared with chemotherapy, hormonal treatments are associated with significant side effects, and because of the duration of treatment, these effects may persist for years.

Tamoxifen and anastrozole are the most commonly used agents in the adjuvant setting for early-stage breast cancer. Both are associated with vasomotor symptoms and vaginal atrophy and dryness. The major serious side effects of tamoxifen are rare and related to its weak estrogen agonist properties. These include thromboembolic disease (deep vein thrombosis, pulmonary embolism, and stroke), cataracts, and endometrial carcinoma. Uterine cancer occurs at a rate of 0.2% per year in women receiving adjuvant tamoxifen therapy.¹⁴ Relative to tamoxifen, anastrozole has a better

Table 31–4 Incidence of Predefined Adverse Events at the First and Updated Analyses of the ATAC Trial

ATAC, Arimidex, Tamoxifen, Alone or in Combination.
Data from Winer EP, Hudis C, Burstein HJ, et al. American Society of Clinical Oncology Technology Assessment Working Group update: Use of aromatase inhibitors in the adjuvant setting. *J Clin Oncol* 2003;21:2597–2599.

side-effect profile in terms of hot flashes, vaginal bleeding, endometrial cancer, stroke, and thrombotic events; however, increases in musculoskeletal symptoms and fractures are reported.⁵⁴

The best comparison of side effects of tamoxifen and anastrozole is the recently reported Arimidex, Tamoxifen, Alone or in Combination (ATAC) adjuvant breast cancer trial.⁵⁵ Selected side effects reported in this study are shown in Table 31–4.

Vasomotor symptoms (or hot flashes) are one of the most common complaints of breast cancer patients. In randomized placebo-controlled trials, a reduction of 20% to 30% in hot flash frequency and severity is noted with placebo alone, demonstrating the importance of well-designed trials to address treatment options for this bothersome complaint.⁵⁶ Scientifically designed clinical trials have reported that treatments such as black cohosh and vitamin E are not more effective than placebo.^{57,58} Likewise, studies have also reported that soy products are only marginally or no more effective than placebo for treatment of menopausal symptoms.⁵⁹ Bothersome symptoms of hot flashes may be treated with serotonin-reuptake inhibitors such as venlafaxine; Loprinzi and associates reported a placebo-controlled study showing up to a 61% reduction in hot flash score in treated women.⁶⁰ Other possible agents include clonidine and gabapentin.

Two prospective trials have evaluated potential clinical benefit of screening for endometrial cancer in patients receiving adjuvant tamoxifen. Barakat and coworkers⁶¹ examined the potential benefit of screening with endometrial biopsy. In this study of premenopausal and postmenopausal breast cancer patients with a median age of 50 years, 111 women had a total of 635 endometrial biopsies, with a mean number of 5.8 samplings per patient. Of the biopsies, 544 (86%) revealed benign

endometrium and 82 (12.6%) were insufficient for diagnosis. In 9 (1.4%), biopsy results were abnormal, leading to further evaluation. In total, 14 patients underwent a dilation and curettage (D&C). Although 3 of the 111 patients (2.7%) were ultimately treated with hysterectomy, only 1 of the 111 (0.9%) had pathology detected by screening endometrial biopsy.

Gerber and colleagues⁶² addressed the role of transvaginal sonography (TVS) in 247 postmenopausal women with breast cancer and compared them with 98 women with breast cancer not eligible for tamoxifen therapy. The mean age of the patients was 60 years in both groups. They performed TVS every 6 months for up to 5 years. Fifty-two asymptomatic women with morphologically suspect or thickened endometrium (10 mm) underwent hysteroscopy or D&C. This resulted in four uterine perforations. Histology demonstrated atrophy in 38 patients, polyps in 9, hyperplasia in 4, and endometrial cancer in 1. Twenty screened patients reported vaginal bleeding. Five had atrophy, 5 had polyps, and 4 had hyperplasia. Two women had endometrial cancer identified by bleeding only despite having screening TVS. Overall, 1265 TVS procedures detected 1 asymptomatic cancer.

These two studies and others support the guidelines that routine endometrial surveillance of women treated with adjuvant tamoxifen is not warranted.⁶³ Women receiving tamoxifen should have annual gynecologic examination. Endometrial biopsy, with or without transvaginal ultrasound, should be used in patients with abnormal vaginal bleeding or discharge. There is no current role for screening endometrial biopsy or transvaginal⁶⁴ ultrasound in asymptomatic women off a clinical trial, and such screening attempts may be associated with significant morbidity.

How should bone density be followed in women treated for breast cancer?

Osteopenia and osteoporosis are common and important issues in women with breast cancer. Most women with a newly diagnosed breast cancer are at risk related either to age or breast cancer therapy. One of the most common side effects of adjuvant chemotherapy is permanent ovarian failure, occurring in 63% to 85% of premenopausal patients treated with cyclophosphamide, methotrexate, and fluorouracil and in 50% or more of women treated with anthracyclines.⁶⁵ Age is an important determinant of ovarian failure, with women older than 40 years developing menopause more frequently and after a shorter duration of chemotherapy.⁶⁶ There is a growing interest in the United States in the use of ovarian suppression or ablation as an adjuvant breast cancer therapy in premenopausal women, and this has been an established practice in Europe.⁶⁷

Ovarian suppression results in a decrease in estrogen levels and is associated with an increased risk for osteoporosis and fracture.⁴⁸ Chemotherapy-induced ovarian failure causes rapid and significant bone loss in the spine and femur, detectable within 6 months of starting chemotherapy. Shapiro and colleagues⁶⁵ reported highly significant bone loss in the lumbar spine by 6 months, with further increase at 12 months, in 35 women with chemotherapy-induced ovarian failure. The median decreases of bone mineral density (BMD) in the spine from 0 to 6 months and 6 to 12 months were -4.0% and -3.7% , respectively. Fourteen patients who retained ovarian

function had no significant decreases in BMD during the same time period.

Tamoxifen also has important effects on bone density. Tamoxifen acts as an estrogen agonist in bone. This results in a preservation of BMD in postmenopausal women; however, in premenopausal women, tamoxifen has been associated with bone loss.⁶⁸ The antiresorptive properties of tamoxifen are modest: Although tamoxifen preserves BMD in postmenopausal patients, there is no reduction in vertebral and femoral fractures in women receiving tamoxifen.⁶⁹

Anastrozole recently received approval for the adjuvant treatment of postmenopausal women with early-stage ER-positive breast cancer based on the results of the ATAC trial.⁷⁰ Although the combination of drugs was not superior to tamoxifen alone, anastrozole alone improved disease-free survival and reduced contralateral breast cancers. The most serious adverse event was the fracture rate in the anastrozole group as compared with the tamoxifen group. In a recent update with a median follow-up of 37 months, the fracture rate in the anastrozole arm was 7.1%, as compared with 4.4% in the tamoxifen arm.⁵⁴ Indirect evidence suggests that roughly one third of the excess fracture risk seen with anastrozole is related to an absence of tamoxifen effect.⁷¹ Data from three large studies show a consistent improvement in disease-free survival among postmenopausal women treated in the adjuvant setting with aromatase inhibitors. Optimal adjuvant hormonal therapy for a postmenopausal woman with hormone receptor-positive breast cancer includes an aromatase inhibitor as initial therapy or after treatment with tamoxifen.⁷² Tamoxifen continues to be the optimal adjuvant hormonal therapy for premenopausal women with receptor-positive breast cancer.

In part reflecting the approval of anastrozole in the adjuvant setting and concern that this trend in adjuvant hormonal therapy would make osteoporosis a greater health problem in the future, an ASCO panel updated the recommendations on bone health in women with a history of breast cancer in 2003.⁷¹ The panel recommended “in otherwise healthy women, a strong body of evidence supports a strategy of early detection and therapy of osteoporosis.” Breast cancer patients determined to be at high risk (older than 65 years, 60 to 64 years of age with other risk factors, any woman taking aromatase inhibitors, and premenopausal women with therapy-induced menopause) should have annual bone densitometry, and as in women without breast cancer, subsequent treatments are guided by BMD result. Basic measures include adequate calcium intake (1200 mg/day) with vitamin D (400 to 800 IU), exercise, and smoking cessation. Breast cancer patients with osteoporosis (T score, -2.5 or lower) should initiate pharmacologic therapy (i.e., oral bisphosphonates) and continue annual BMD screening. Breast cancer patients with osteopenia (T score, -1 to -2.5) should have basic measures instituted in conjunction with annual BMD screening, but the panel concluded that current evidence does not support use of bisphosphonates for this group.

Who should conduct breast cancer surveillance?

The initial breast cancer surveillance guidelines stated, “Cancer patients should have the right to treatment by an

oncologist indefinitely after a cancer diagnosis in accordance with ASCO policy.⁷³ Since the time the original guidelines were published, questions have been raised about the evidence available to support this statement.

Because breast cancer is a disease treated by multiple subspecialists, patients have often scheduled regular follow-up visits with surgeons, radiation oncologists, and medical oncologists. Coordination of care is important to avoid a burdensome and expensive redundancy of effort for the first 5 years following primary therapy. A randomized trial involving 296 breast cancer patients in England was reported in 1996.⁷⁴ The patients were randomized to follow-up with a general practitioner or in a multidisciplinary breast clinic. They were followed in both settings with regular scheduled history and physical examinations and yearly mammograms. This trial was designed to assess effects on time to diagnosis of recurrence and quality of life when responsibility of follow-up was shifted to the primary care provider. Although the follow-up period reported was short (18 months), the results did not detect a difference in time to diagnosis, increase in anxiety, or deterioration in health-related quality of life in women receiving care from generalists. Most recurrences detected by the patients occurred in the interval between follow-up exams, and almost half (7 of 16; 44%) of the recurrences in the specialist follow-up group presented first to a general practitioner. Although generalization of these data is limited in terms of sample size, follow-up time, and cultural factors, they suggest that effective follow-up may occur in various settings. It is recommended that follow-up of breast cancer patients be performed in a setting in which continuity of care is possible and in which an individual experienced in the care and examination of cancer patients performs the surveillance. These findings support the assertion that women should be well educated about symptoms of recurrence because most recurrences become symptomatic during the interval between follow-up visits.

The goals of breast cancer surveillance include medical assessment for disease recurrence, sharing information regarding advances in treatment, ensuring compliance with surveillance guidelines, providing psychological support, and managing side effects and complications of therapy. Patients are best served by a coordinated multidisciplinary follow-up effort between generalists and specialists. The development of a strong doctor-patient relationship and careful attention to history and physical examination deserve emphasis over diagnostic testing and best serve the unique health concerns of the breast cancer survivor.

Management of Metastatic Breast Cancer

Introduction and Principles of Treatment

Ruth Oratz

What is the scope of the problem?

Despite advances in screening and early diagnosis of breast cancer, many women still develop and die from metastatic disease. Adjuvant systemic therapy has increased the survival of women who present with early-stage disease but has certainly not completely eradicated the risk for recurrence. Relapse rates following standard current adjuvant therapy for patients presenting at the various stages is as follows: stage I, 10% to 30%; stage II, 40% to 60%; and stage III, greater than 90%.¹

The annual incidence of all newly diagnosed cases of breast cancer is greater than 200,000, and more than 50,000 women will die of breast cancer this year. Most women present with early-stage disease. Although fewer than 10% of patients in the United States present with stage IV disease, this represents a significant number of women: 10,000 to 15,000 with metastatic disease.²

At this time, metastatic breast cancer is rarely cured. Median survival after development of metastatic disease is 2 to 3 years.³⁻⁵ Treatment may be effective for palliating symptoms, with responders enjoying not only an enhanced quality but also, in some cases, prolongation of life. Nonetheless, cure is not an expectation, and research efforts both at the basic science and at the clinical levels must be directed at defining better and more effective therapies that may offer the possibility of cure for patients with metastatic disease.

NATURAL HISTORY AND CLINICAL PATTERNS OF METASTASES

When do metastases appear?

Although up to 75% of recurrences occur within the first 5 years of diagnosis, metastatic disease continues to appear after this time and has been well documented as long as 25 or 30 years after first presentation.⁵

What are the sites of metastatic disease?

The most common sites of metastasis are bone, lungs, liver, chest wall, and central nervous system (CNS). Less common sites are the adrenals, ovaries, pericardium, thyroid, and bone marrow.¹ Factors that may determine the site of relapse include the disease-free interval, histologic subtype of the primary lesion, estrogen receptor (ER) status of the primary tumor, and possibly, the type of adjuvant therapy. In patients with short disease-free intervals, visceral disease predominates, whereas if the disease-free interval is longer, bone metastases are more likely. Invasive lobular carcinoma is more likely to spread to peritoneum, pleura, adrenal glands, uterus, and ovaries. Invasive ductal carcinoma is more likely to spread to liver, lung, and bone⁶⁻⁹ (Table 32-1).

What are the important prognostic factors in metastatic breast cancer?

ER status is an important prognostic factor. Estrogen stimulates the growth of many breast tumors. About 30% of unselected breast cancers are ER positive. In general, patients with ER-positive tumors who are postmenopausal have a more favorable prognosis once recurrence develops. These patients are more likely to develop osseous metastases than visceral metastases, and there may be a longer disease-free interval from the time of primary diagnosis until the development of metastatic disease. Once metastatic disease is diagnosed, patients with ER-positive tumors may have a more indolent clinical course, with slower progression of disease and longer survival. Some patients have survived in excess of 10 years with ER-positive osseous metastases. In contrast, patients with ER-negative tumors may have more aggressive disease, with a

Table 32-1 Common Sites of Metastatic Breast Cancer

Bone
Liver
Lung
Central nervous system

shorter disease-free interval, more rapid spread and growth of metastases, a higher incidence of visceral metastases, and shorter long-term survival.¹⁰⁻¹²

Postmenopausal patients are more likely than premenopausal patients to have ER-positive disease. In addition, expression of hormone receptors may correlate with other prognostic factors, including *HER-2/neu*. Tumors that overexpress *HER-2/neu* are more likely to be ER negative and to be associated with more aggressive disease. There are also data suggesting that the ER and *HER-2/neu* interact. Overexpression or amplification of *HER-2/neu* may be associated with relative tamoxifen resistance in tumors that are ER positive.¹³⁻²⁰ It has also been noted that hormone receptors may be less frequently expressed in tumors arising in patients with genetic mutations in *BRCA1*. This may affect prognosis as well.^{21,22}

Survival from the time of diagnosis of recurrent disease may also depend on the site of metastasis. Patients with bone-only metastases may have a longer median survival than do those with extraskelatal metastases. In some studies, survival was almost twice as long if bone metastases rather than visceral metastases were present.¹⁰⁻¹² In one study, median survival of patients with skeletal involvement was 48 months, with one third of patients living longer than 5 years. Patients with visceral disease have a median survival of 6 months.¹² Also, in patients with local chest wall recurrence alone, survival is longer than in those with visceral disease.

Some preliminary data suggest that adjuvant therapy may have an impact on sites of recurrence. A retrospective review of adjuvant therapy clinical trials by the International Breast Cancer Study Group compared relapse rates and sites of relapse. Women who had received a full course of adjuvant chemotherapy were compared with those followed by observation alone after surgery or who had only one cycle of perioperative chemotherapy. Similar rates of relapse were observed in both groups, but there was a significant difference in locoregional and soft tissue relapse between the two groups. Those who had received the more effective chemotherapy had only an 18% relapse rate in soft tissue, compared with a 36% relapse rate in locoregional and soft tissue sites in women who had received the less effective adjuvant treatment. There were no differences in the incidence of visceral or bony metastases. This information is inconclusive as to the effect of adjuvant therapy on site of relapse and has not been confirmed in other large studies²³ (Table 32-2).

How does metastatic disease progress?

In some instances, metastatic disease follows a rather indolent course, with little in the way of symptoms or complications. This pattern of metastatic disease is most often

Table 32-2 Important Prognostic Factors in Metastatic Breast Cancer

Disease-free interval—length of time from diagnosis of primary lesion until development of metastatic disease
Number of metastatic sites
Skeletal vs. visceral metastases
Estrogen/progesterone receptor expression
<i>HER-2-neu</i> expression

associated with older age at diagnosis, postmenopausal status, longer disease-free interval, smaller tumor burden, ER-positive tumors, and bony rather than visceral sites of metastases.

In other instances, disease is rapidly progressive, causing a great deal of morbidity, pain, and discomfort. This pattern of metastasis is more commonly seen in patients who have widespread visceral disease, who are premenopausal, or who have multiple sites of involvement with greater tumor burden and ER-negative and *HER-2/neu*-positive tumors.

DIAGNOSIS AND WORKUP OF METASTATIC DISEASE

How is metastatic disease diagnosed?

Less than 10% of patients present with stage IV disease, but this is only a small fraction of all women who will ultimately develop advanced breast cancer. Most patients are diagnosed with metastatic breast cancer after having been treated for stage I, II, or III disease.

Patients should be followed after initial diagnosis for the possibilities of both local and distant recurrence. Careful history and physical examination should be performed at regular intervals. Mammographic surveillance is indicated for patients who have had breast-conserving surgery. Chest radiographs may detect asymptomatic pulmonary metastases and may be indicated for patients at risk. Although many patients will develop osseous metastases, routine use of nuclear bone scans or radiographic bone surveys has not proved cost-effective and is not routinely recommended for patients who present with early-stage disease. Serum chemistries (aspartate aminotransferase [AST], alanine aminotransferase [ALT], lactate dehydrogenase [LDH], and alkaline phosphatase) may be helpful in screening for liver or bone metastases. It is unclear, however, whether there is a survival advantage for regular, intensive testing.

Two large studies have addressed the impact of intensive surveillance on survival of patients following diagnosis of breast cancer. In both trials, women were randomly assigned to either intensive follow-up (defined as physician visits, blood tests, bone scans, and chest radiographs on a scheduled basis) or routine follow-up (defined as physician visits and testing only as clinically indicated). Screening mammography was conducted in both arms of each study. Once metastatic disease was diagnosed, therapy was initiated. The reported results were strikingly similar in the two studies. There was a small increase in the frequency of detection

of metastases in the intensively followed group but no survival difference.^{24,25}

Furthermore, the dollar cost of routine testing for the asymptomatic patient must be considered. One financial analysis published in 1990 found that the direct cost of intensive follow-up (with physician visits, blood tests, mammography, nuclear bone scans, and chest films) would be at least five times higher than for less intensive follow-up (physician visits, mammography). The range of cost was from about \$1000 per patient over 5 years for the routine follow-up to more than \$5000 per patient for the intensively followed group. Given the number of women to be followed, the estimated difference in cost for the two follow-up approaches over a 5-year period in the United States could exceed \$800 million.²⁶

Positron emission tomography (PET) scanning is a new diagnostic modality that offers several advantages over anatomically oriented imaging such as radiography, computed tomography (CT) scanning, ultrasound, and conventional nuclear imaging. PET most commonly uses the radiotracer ¹⁸F-fluorodeoxyglucose (FDG), which is actively transported into cells through the glucose transport mechanism and then undergoes phosphorylation in the initial step of glycolysis. FDG-6P (phosphorylated FDG), however, is not a substrate for additional phosphorylation and is blocked from further metabolism. Most malignant cells lack the phosphatase enzymes necessary for dephosphorylation of FDG-6P, allowing high levels of this compound to accumulate. The amount of FDG uptake in the cells reflects the overall metabolic activity and identifies cells that are more active. This correlates with malignancy and with biologic behavior of certain tumor types. Higher-grade tumors tend to accumulate higher levels of FDG than lower-grade tumors. This may be helpful in detecting areas of involvement by metastatic tumor and in differentiating rapidly growing from more indolent tumors.²⁷⁻³⁰

PET scanning may be useful in staging and in serial evaluations after diagnosis of breast cancer. PET scanning has been used in breast cancer. It has been reported to detect metastases in axillary lymph nodes with high sensitivity and specificity. However, some series also report significant numbers of false-positive and false-negative results.³¹⁻³⁴ Distant sites of disease, including pulmonary, osseous, and distant nodal sites, are more reliably detected by PET.³⁵⁻³⁶ There may be an increasing role for PET imaging in the early detection of metastatic disease and in monitoring response to therapy. PET is costly but may be a more efficient imaging method than more conventional anatomically based studies.

Serum cancer markers, such as carcinoembryonic antigen (CEA) and CA-15-3, may have some utility in detecting early metastases. CA-15-3 has been shown to have a high degree of both sensitivity (81.5%) and specificity (66%) and a high predictive value (92%) in the detection of osseous metastases.³⁷ CEA may be elevated in metastatic breast cancer but is also increased in a number of other malignancies, including lung cancer, gastrointestinal tract carcinomas (stomach, colon, rectum, pancreas), and ovarian cancer. In addition, patients who smoke cigarettes, have benign liver disease, or have inflammatory diseases of the breast or liver may also have elevated serum CEA. CA-15-3 may be somewhat more specific and may be predictive of recurrence.³⁸⁻⁴² The usefulness of monitoring these serum markers has not

yet been clearly established, and the financial cost is not insignificant.

It is clear that follow-up is necessary after the diagnosis of breast cancer, but the degree to which routine use of invasive or costly testing is indicated needs further definition. To date, no survival advantage has been demonstrated following the use of intensive follow-up screening for metastatic disease. Careful history and physical examination at regular intervals are recommended. Surveillance mammography is indicated, as discussed elsewhere. Until clearcut data defining the utility of other tests emerge, the routine use of screening radiographs, scans, and serum markers cannot be recommended. These tests may be helpful in detecting early recurrence, and their use will be determined by the treating physician, regional standards of care, and third-party payers.

What is the workup for a newly diagnosed stage IV patient?

Metastatic disease may be diagnosed because either the patient presents with a new clinical sign or symptom, or a routine screening test demonstrates an abnormality suspicious of recurrence. If a patient presents with a symptom indicative of metastatic involvement, an appropriately directed workup to confirm the diagnosis is indicated. For example, a complaint of pain may lead to a radiograph or bone scan; cough or shortness of breath may direct one to order a chest film or CT scan. On the other hand, an abnormality on a routine screening test may trigger other diagnostic interventions. For example, elevated serum markers and liver function tests in an asymptomatic patient may prompt a request for an abdominal CT scan looking for liver metastases, or a PET scan for a more generalized examination.

After a patient is identified as having metastatic disease, a complete staging workup to define the extent of disease should be undertaken. This begins with a thorough history and physical examination. Laboratory tests include a complete blood count (CBC) with differential; clinical chemistries including electrolytes, transaminases (ALT, AST), alkaline phosphatase, albumin, calcium, LDH, and possibly serum markers (CEA and CA-15-3). Imaging studies should be used as indicated to define the anatomic sites of involvement. It is important to know the full extent of disease when embarking on treatment in order to define optimal therapy, determine response, and define progression.

The first site of recurrent disease should be documented histologically, whenever technically feasible, given lesions that can undergo biopsy with acceptable risk. The differential diagnosis of a new lesion in a patient with a history of breast cancer includes metastases from primary breast cancer, benign lesions, and other primary or metastatic malignancies. It is imperative to confirm the histologic nature of the lesion as recurrent or metastatic breast cancer for diagnostic and prognostic purposes and before beginning toxic and costly therapies. Biopsy should be performed on the site that is most accessible and that would render an adequate tissue sample with the least morbidity for the patient. Often, a fine-needle aspiration biopsy with radiologic guidance can be performed on pulmonary, hepatic, soft tissue, or osseous sites. Sometimes, a surgical biopsy is required. Again, it must

Table 32-3 Workup of the Patient with Newly Diagnosed Metastatic Disease

Complete medical history
Comprehensive physical examination (including neurologic evaluation and gynecologic examination)
Histologic confirmation of metastatic disease—fine-needle aspiration biopsy, core biopsy, excisional biopsy
Routine chemistries, including electrolytes, liver function tests and enzymes (transaminases), serum albumin, calcium, alkaline phosphatase
Complete blood count and differential
Chest film
Nuclear bone scan
CT/MRI scan(s), as clinically indicated
Serum markers—CEA, CA-15-3
Pretreatment testing (nuclear-gated heart pool scan or echocardiogram for measurement of ejection fraction before anthracyclines; creatinine clearance before platinum analogues)

CT, computed tomography; MRI, magnetic resonance imaging; CEA, carcinoembryonic antigen.

be emphasized that documentation of the recurrence is essential before further therapeutic interventions. Pathologic confirmation of diagnosis is required, and definition of molecular characteristics, including expression of ER and progesterone receptor and *HER-2/neu*, will affect treatment decisions (Table 32-3).

SYSTEMIC TREATMENT OF METASTATIC DISEASE

What are the basic principles of treatment of metastatic disease?

Patients with either distant recurrence of breast cancer or advanced locoregional recurrence following primary treatment have an often lethal disease. Treatment is rarely curative, and median survival after diagnosis of metastasis is 2 to 3 years. Systemic treatment of metastatic breast cancer may prolong the median survival in a small number of patients. Therefore, the goal of therapy remains palliation, with the hope of providing the best response with the best quality of life for the longest time possible. With available approaches, up to two thirds of patients may respond to and benefit from treatment. Complete responses are observed in no more than 10% to 15% of patients, and the median duration of these responses is 6 to 12 months. Nonetheless, as many as 10% of patients may survive longer than 10 years after the diagnosis of metastatic disease. Treatment for metastatic disease is indicated in that it may enhance quality of life and prolong life. To determine the optimal treatment strategy in metastatic disease, it is essential to confirm that the diagnosis is metastatic breast cancer (and not another malignancy or disease process), estimate the prognosis and median survival, and predict the likelihood of response to treatment. Treatment modalities are both systemic and local. Systemic treatments, including hormonal, chemotherapeutic, and biologic interventions, are aimed at achieving a response in all sites of

disease. Local modalities, including radiation therapy, surgery, and regional instillation of chemotherapeutic agents, are directed at palliating specific complications in defined anatomic locations. These approaches are discussed in greater detail later in this chapter.

Treatment selections must be made on an individual basis and should be guided by the patient's symptoms and performance status, biologic characteristics of the tumor, and both long-term and short-term clinical goals. Treatment should be tailored to the needs of the individual patient. Decision making should be a shared process in which patients make informed choices with their physician's guidance.

Specific clinical syndromes may require that locoregional therapy be instituted before or in addition to systemic treatment. For example, a lytic bone metastasis with risk for impending fracture (explained later) may require orthopedic surgical intervention and radiation therapy as well as systemic treatment. Space-occupying CNS or spinal metastases may require surgical debulking to prevent potential neurologic complications. Thoracentesis and pleurodesis may be indicated for control of malignant pleural effusions. Pericardiocentesis and formation of a pericardial window is the treatment of choice for cardiac tamponade caused by malignant pericardial effusion. Management of symptoms with analgesics, antihypercalcemic agents, bisphosphonates, anxiolytics, and antiemetics should also be initiated as clinically required.

Choice of systemic treatment will be influenced by a number of factors. ER status is an important predictor of response to hormonal therapy. In patients with ER-positive tumors, hormonal therapy should be considered for initial treatment. Hormonal treatment is particularly effective in patients who are postmenopausal, patients with osseous or soft tissue disease as opposed to visceral disease, and those who have a longer disease-free interval—perhaps indicating more indolent disease. The time to response to hormonal therapy may be 2 months or longer. Although hormonal therapy also has a role in the treatment of the premenopausal patient with metastatic disease, it is generally more effective if there is less visceral involvement and less aggressive progression of disease. Hormonal therapy may also have fewer side effects and may be more easily tolerated than chemotherapy in the elderly or debilitated patient.

In patients with ER-negative tumors and *HER-2/neu*-positive tumors, rapid tumor growth, extensive visceral involvement, and multiple sites of metastases, chemotherapy (with trastuzumab if indicated), rather than hormonal therapy, is usually indicated as the first systemic modality. There are a number of active agents and regimens, as discussed later. The choice of which regimen to use should be made by the physician and the patient. Options, including participation in clinical trials, should be discussed with the patient. Many factors influence the choice of chemotherapy program, including efficacy, toxicity, frequency, ease and cost of administration, requirements for adjunctive treatments necessitating hospitalization, and patient preference. These issues should be taken into consideration during discussion of therapeutic recommendations.

Chronologic age alone should not determine treatment selection. The extent and nature of the metastases and the patient's physiologic condition are more important factors in

choosing appropriate therapy. Comorbidity, concomitant medications, performance status, and psychosocial support should all be considered before initiating treatment. Chemotherapy may be administered safely and effectively to older women as long as attention is paid to appropriate dosing and management of potential toxicity. Supportive care with antiemetics, intravenous (IV) hydration, and bone marrow growth factors, as indicated, is warranted. A number of investigators have reported on the efficacy of chemotherapy in this cohort of patients.^{43–50} A greater experience is available for hormonal treatment than for chemotherapy in the elderly.⁴⁶ Because breast cancer is statistically a disease of older women, these concerns are especially relevant. The average life expectancy of a healthy 85-year-old woman is 6.5 years.⁴⁷ Treatment should be directed at maximum palliation with acceptable toxicity.

The Eastern Cooperative Oncology Group (ECOG) reported that no difference in toxicity was seen in women aged 60 to 65 years compared with those younger than 60 years in clinical trials using chemotherapy.⁴⁸ Other investigators reported on chemotherapy response rates and toxicity in women older than 70 years. In a series of five clinical trials, all using doxorubicin (Adriamycin)-containing regimens, no differences in time to progression or overall survival were seen in cohorts of women who were younger than 50 years, 50 to 69 years, and older than 70 years. Toxicity was similar in all groups, except that the youngest patients experienced the greatest degree of nausea and vomiting. Performance status was the most important factor determining response. Age itself was not a prognostic factor.^{45,46,49}

Participation in clinical trials testing new regimens or comparing various protocols is always encouraged. The toxicity, ease of administration, and efficacy of the chosen regimen must be considered in making therapeutic recommendations. Patients should directly participate in treatment decisions through the process of informed consent. After careful delineation of treatment goals and expectations and discussion of the risks and benefits of therapeutic options, patients and physicians together should decide on a course of action.

What is the importance of stable disease for patients with metastatic breast cancer?

“Overall clinical benefit” including “stable disease” has emerged as an important concept in the evaluation of the efficacy of therapy for metastatic disease. Although quantifiable responses, whether complete response (CR), defined as complete disappearance of all measurable disease for at least 4 weeks’ duration, or partial response (PR), defined as at least 50% reduction in all measurable lesions for at least 4 weeks’ duration, are admirable goals of treatment, palliation of symptoms, freedom from progression, and stable disease (SD) are meaningful and clinically relevant end points for treatment regimens. This notion is self-evident to the experienced clinician and has been documented in a study designed to assess survival based on remission criteria.⁵⁰ In patients receiving endocrine therapy for metastatic breast cancer, durable stable disease was meaningful, and no overall survival advantage was detected for patients who had achieved CR or PR as first response to treatment. Many studies now report overall

clinical benefit as CR + PR + SD, where SD is defined as no progression for at least 6 months.

Chemotherapy for Metastatic Breast Cancer

*Amy D. Tiersten and
Shalini Mulaparathi*

Metastatic breast cancer is a heterogenous entity with complex manifestations. The primary goal of treatment for metastatic breast cancer is palliation. In 2005, about 211,240 new cases of breast cancer will be diagnosed in the United States, and 40,440 women can be expected to die of metastatic disease.¹ Perhaps partially because of advances in supportive care and the development of numerous active chemotherapy regimens and hormone therapies, breast cancer mortality rates have been declining. From 1990 to 2000, breast cancer death rates decreased slightly.¹ This improvement may also reflect the greater proportion of patients who were diagnosed with early-stage disease and the incremental improvements in and increased application of adjuvant therapies. Chemotherapy for metastatic breast cancer provides systemic treatment for disease that is hormone unresponsive. Chemotherapy may also palliate disease in patients with extensive visceral or rapidly growing metastases more effectively than hormonal therapy. Up to two thirds of patients with breast cancer will respond to chemotherapy for advanced disease, although complete remissions are seen in less than 10% of patients. Patients with disease refractory to first-line chemotherapy often do not respond to second- and third-line regimens.

What is the historical background of modern-day chemotherapy?

Before 1970, virtually all reported chemotherapy trials were based on the use of single-agent therapy with one of the available agents—alkylators, vinca alkaloids, or antimetabolites. Livingston and Carter analyzed a series of 1590 patients with breast cancer treated with single-agent chemotherapy.² There was one complete remission, and the overall response rate was 30%. Remission durations were reported in the range of 3 to 4 months. Time to progression was not frequently reported.²

Skipper³ and Pittillo and colleagues⁴ proposed combination chemotherapy based on its effect on hematologic malignancies. These investigators used *in vitro* models with cancer cell lines to demonstrate that dose and dose rate may be critical to the success of chemotherapy. They also predicted that after obtaining maximal benefit from one combination, but before relapse due to the emergence of drug-resistant cell proliferation, the introduction of a non-cross-resistant combination of drugs would enhance cure rates.

In 1969, Cooper developed a prototype combination regimen consisting of cyclophosphamide, methotrexate, fluorouracil, vincristine, and prednisone (CMFVP).⁵ This combination was reported to produce responses in more than 90% of patients, although confirmatory studies suggested activity in the 40% to 60% range. Over the subsequent 20 years, CMFVP was the most commonly used regimen for metastatic breast cancer. Almost simultaneously with the development of CMF, Jones and associates developed doxorubicin-containing combinations.^{6,7} The FAC (fluorouracil, doxorubicin, and cyclophosphamide) and AC (doxorubicin [Adriamycin] and cyclophosphamide) regimens were compared with CMF in large randomized trials, with CMF producing fewer responses than doxorubicin-based regimens.^{8–11}

The introduction of taxanes in the early 1990s added significantly to our armamentarium for the management of metastatic breast cancer. Paclitaxel and docetaxel were found to have superior activity compared with previously used single agents, producing response rates and time to progression rates comparable to two- and three-drug regimens used previously.^{12–14}

What systemic chemotherapeutic agents are used for metastatic breast cancer?

Most antitumor agents have some degree of efficacy against breast cancer. The activities of agents commonly used for metastatic breast cancer are listed in Table 32–4.

Although the taxanes and anthracyclines are among the most active agents for the treatment of advanced disease, the activity of any agent is most dependent on the characteristics of the patient population, particularly the extent of prior chemotherapy. The precise order in which treatments are

administered is unlikely to affect overall survival. Toxicity considerations are of paramount importance in treatment considerations, given the overall goals of therapy. The median duration of response with most first-line chemotherapy regimens is in the range of 6 to 12 months. A shorter duration of response is seen in patients who are treated in the second- and third-line settings.

Anthracyclines

Anthracyclines were previously more commonly used as first-line chemotherapy for metastatic breast cancer.¹⁵ Because more recently anthracyclines have been commonly administered in the adjuvant setting, and because there is a plethora of new drugs with fewer toxicities, anthracyclines are now used less frequently in the treatment of metastatic breast cancer, although they are among the most active agents in the treatment of this disease.

Doxorubicin. The cytotoxic effect of doxorubicin on malignant cells and its toxic effects on various organs are thought to be related to nucleotide base intercalation and cell membrane lipid-binding activities of doxorubicin. Intercalation inhibits nucleotide replication and action of DNA and RNA polymerases.¹⁶ The interaction of doxorubicin with topoisomerase II to form DNA-cleavable complexes appears to be an important mechanism of doxorubicin cytotoxic activity. Dose-limiting toxicities of therapy are myelosuppression and cardiotoxicity. Single-agent doxorubicin produces response rates of 35% to 50% given as front-line therapy.¹⁶ Doxorubicin combinations as front-line therapy produce responses in the 50% to 80% range.⁸ Several randomized clinical trials showed higher response rates and improvements in disease-free survival for patients treated with FAC compared with CMF regimens.^{10,17–19} Although more efficacious in the metastatic setting, doxorubicin-containing regimens are generally more toxic than CMF-type regimens. Almost all patients treated with doxorubicin develop alopecia and some degree of nausea and vomiting. About 2% to 4% of patients develop congestive heart failure (CHF). Cardiotoxicity is more likely in adults receiving total cumulative doses of doxorubicin greater than 450 to 550 mg/m² and may occur months or even years after administration. Extravasation of doxorubicin may cause severe skin and subcutaneous damage. Conventional first-line regimens include AC and FAC.

Epirubicin. Epirubicin is a doxorubicin analogue that has been shown to have similar efficacy and somewhat less toxicity than doxorubicin at equipotent therapeutic doses.²⁰ It has been suggested that the pharmacokinetic characteristics of doxorubicin and epirubicin are responsible for their different toxicity profiles. A randomized clinical trial compared FAC with fluorouracil, epirubicin, and cyclophosphamide (FEC) at equimolar doses of doxorubicin and epirubicin.²¹ In this study, FEC was as effective as FAC in terms of response rate, time to progression, and survival and was associated with less gastrointestinal, hematologic, and cardiac toxicity.

Liposomal Anthracyclines. Liposomal anthracyclines were developed with the goal of increasing the therapeutic index of conventional anthracyclines. To date, three liposomal anthracycline formulations have been developed: liposomal daunorubicin (DaunoXome), liposomal doxorubicin (D-99,

Table 32–4 Agents Used for Metastatic Breast Cancer

Drug	Response Rate (%)	Range (%)
Alkylating		
Cisplatin	21	0–54
Carboplatin	15	0–30

Mitomycin	22	5–37

Myocet), and pegylated liposomal doxorubicin (Doxil, Caelyx).²²⁻²⁴ Some important differences exist among these agents. First, there is a substantial difference in half-life, ranging from about 2 to 4 hours for liposomal daunorubicin and liposomal doxorubicin formulations to more than 55 hours for pegylated liposomal doxorubicin. In addition, pegylated liposomal doxorubicin is the only liposomal anthracycline that exhibits drastically lower uptake by the mononuclear phagocyte system, owing to an additional polyethylene glycol layer that surrounds the doxorubicin-containing liposome, thereby resulting in a longer plasma half-life relative to other liposomal anthracyclines. The size of these drug-containing vesicles allows the liposomes to extravasate through the leaky tumor vasculature. This property, combined with the longer half-life, promotes targeted drug delivery to the tumor site.²⁵

Pegylated Liposomal Doxorubicin. Pegylated liposomal doxorubicin (Doxil, Caelyx) has been evaluated as single-agent therapy in metastatic breast cancer with response rates between 30% and 35% in phase II trials.^{26,27} The development of stomatitis was dose related and occurred at a higher frequency in patients receiving doses greater than 60 mg/m². The incidence of palmar-plantar erythrodysesthesia was schedule dependent, with shorter dosing intervals leading to a greater frequency and severity of skin manifestations.

Wigler and associates reported a multicenter phase III trial comparing the cardiac safety and efficacy of pegylated liposomal doxorubicin with that of conventional doxorubicin as first-line therapy for metastatic breast cancer patients.²⁸ The primary end points were progression-free survival and cardiac toxicity. The median progression-free and overall survival rates were similar in both treatment groups, whereas the incidences of alopecia, myelosuppression, nausea, and vomiting were lower in patients treated with liposomal doxorubicin than in patients treated with conventional doxorubicin. Most important, pegylated liposomal doxorubicin was associated with a significantly lower incidence of cardiotoxicity, even at higher cumulative doses. Only 10 patients who received pegylated liposomal doxorubicin developed left ventricular ejection fraction (LVEF)-defined cardiotoxicity, compared with 48 patients who received conventional doxorubicin ($P < .001$). In addition, no patients treated with pegylated liposomal doxorubicin developed cardiotoxicity with signs and symptoms of CHF, compared with 10 patients treated with conventional doxorubicin. Among patients who received pegylated liposomal doxorubicin, cumulative doses that exceeded 450 mg/m² were not associated with a significant decrease in LVEF from baseline.

Liposomal Doxorubicin. Liposomal doxorubicin (D-99, Myocet) is approved in Europe as a first-line treatment for metastatic breast cancer. Two studies compared this liposomal formulation with conventional doxorubicin and produced similar results.^{29,30}

In a phase III study conducted by Harris and colleagues,²⁹ 224 patients were randomized to receive either liposomal doxorubicin at 75 mg/m² or conventional doxorubicin at 75 mg/m² every 3 weeks. Response rates were 26% in both treatment groups, with less toxicity in patients receiving the liposomal formulation. Patients who received liposomal doxorubicin had fewer total cardiac events than those

receiving conventional doxorubicin (13% vs. 29%, respectively; $P = .0001$), and significantly fewer patients treated with liposomal doxorubicin developed CHF (2% vs. 8% of patients receiving conventional doxorubicin; $P = .0001$). The median cumulative doxorubicin dose at the onset of cardiotoxicity was significantly higher in patients treated with liposomal doxorubicin, 785 mg/m², compared with 570 mg/m² in patients receiving conventional doxorubicin ($P = .0001$).

Batist and colleagues compared the activity of liposomal doxorubicin 60 mg/m² with that of conventional doxorubicin 60 mg/m² when combined with cyclophosphamide in 279 patients with metastatic breast cancer.³⁰ Study results revealed identical response rates in both arms, with the liposomal doxorubicin again demonstrating better cardiac safety than conventional doxorubicin. Cardiotoxicity was noted in 6% of patients treated with liposomal doxorubicin, compared with 21% of patients treated with conventional doxorubicin ($P = .0001$). Although none of the patients receiving liposomal doxorubicin developed CHF, it was documented in five patients who received conventional doxorubicin ($P = .02$). The onset of cardiotoxicity was also identified to occur at significantly higher median cumulative doses with liposomal doxorubicin (estimated at >2200 mg/m²) than with conventional doxorubicin (480 mg/m²; $P = .0001$).

In conclusion, these agents exhibit comparable efficacy with conventional anthracyclines with a better safety profile. There is growing evidence to support the use of these drugs in the treatment of metastatic breast cancer, and they may play an expanding role in our future adjuvant therapies.

Taxanes

Paclitaxel. Paclitaxel is a natural product isolated from the bark of the Pacific yew tree, *Taxus brevifolia*. Its mechanism of action is to promote polymerization of tubulin monomers and prevent normal assembly of the microtubule apparatus. This excessive stabilization of the microtubules prevents cell division. When it is used as front-line therapy, response rates are 32% to 62%.³¹⁻³³ In patients with anthracycline-resistant disease, paclitaxel produces response rates of 36% to 48%. Several different doses and schedules of paclitaxel have been investigated, and the optimal administration regimen has yet to be determined.^{34,35}

Smith and colleagues randomized 563 women with metastatic breast cancer to receive 3-hour paclitaxel versus 24-hour paclitaxel.³⁶ Although a significantly higher rate of tumor response occurred in the first four cycles of therapy in patients who received the 24-hour infusion of paclitaxel (51% vs. 41%, respectively; $P = .025$), there were no significant differences in event-free or overall survival between the two arms of the study. Paclitaxel as a 24-hour infusion resulted, in this study and in multiple other studies, in increased hematologic toxicity and decreased neurosensory toxicity as compared with 3-hour paclitaxel.

Weekly paclitaxel has more recently been evaluated in several phase II studies and has been found to have a favorable toxicity profile in pretreated metastatic breast cancer patients.^{13,36} Although no head-to-head comparisons have been made in patients with metastatic breast cancer of weekly regimens versus every-3-week therapy, there is a suggestion that there may be less alopecia, myelosuppression, and

neuropathy using a weekly schedule. Response rates have been reported in the 40% to 50% range.

Paridaens and colleagues failed to prove the superiority of paclitaxel (175 mg/m² as a 3-hour infusion) when compared with doxorubicin, as first-line chemotherapy for 331 metastatic breast cancer patients.³⁷ In this study, the response rate was significantly higher with doxorubicin than with paclitaxel (41% vs. 25%; $P = .003$). A longer median progression-free survival (7.5 vs. 3.9 months; $P < .001$) was reported for doxorubicin-treated patients as well. Toxicities reflected the expected side effects of each drug (more hematologic, gastrointestinal, and cardiac side effects with doxorubicin, and more neurotoxicity and arthralgia or myalgia with paclitaxel). Interestingly, a detailed quality-of-life analysis showed that the greater toxicity of doxorubicin was compensated for by better symptom control, particularly pain control, with doxorubicin than with paclitaxel.

In 2001, Jassem and colleagues reported a phase III trial demonstrating the superiority of a combination of doxorubicin and paclitaxel over FAC as first-line therapy in 267 metastatic breast cancer patients.³⁸ Time to progression was the primary end point, with secondary end points of response rate, overall survival, toxicity, and quality of life. Median time to progression, response rates, and overall survival (23.3 vs. 18.3 months; $P = .013$) were significantly better for doxorubicin-paclitaxel compared with FAC. Grade 3/4 neutropenia was more frequent with doxorubicin-paclitaxel than with FAC (89% vs. 65%; $P < .001$), but there was no difference in the incidence of febrile neutropenia. Nonhematologic toxicities were generally reflective of the expected toxicity profiles of each of the regimens: grade 3/4 arthralgia and myalgia, peripheral neuropathy, and diarrhea were more common with doxorubicin-paclitaxel, whereas nausea and vomiting were more common with FAC. The incidence of cardiotoxicity was low in both arms in this study. Quality of life was also similar with the two regimens.

The European Organisation for the Research and Treatment of Cancer (EORTC) performed a multicenter phase III trial comparing a doxorubicin-paclitaxel combination to the standard doxorubicin-cyclophosphamide regimen as first-line chemotherapy for 275 anthracycline-naïve metastatic breast cancer patients.³⁹ The primary end point was progression-free survival, and secondary end points were response rate, overall survival, safety, and quality of life. No significant differences in the study end points were observed between the two treatment arms, but treatment-related toxicity compromised the doxorubicin dose intensity in the paclitaxel-based regimen. The incidence of grade 4 neutropenia was similar in the two treatment arms, but neutropenic fever occurred more frequently in patients treated with doxorubicin-paclitaxel (32% vs. 9%; $P < .001$). LVEF decreases were documented in 27% of patients receiving doxorubicin-paclitaxel and in 14% of the doxorubicin-cyclophosphamide patients.

In two similar phase III trials,^{40,41} epirubicin combined with paclitaxel was compared with epirubicin-cyclophosphamide as first-line treatment for metastatic breast cancer. Despite large sample sizes, results failed to show superiority of the paclitaxel-based regimens.

The first interim analysis of the AGO Breast Cancer Group study was reported at the 2000 American Society of Clinical

Oncology (ASCO) meeting comprising data from 429 of the 560 randomized patients, at a median follow-up of 36 weeks.⁴⁰ The combination of epirubicin and paclitaxel was as active as epirubicin-cyclophosphamide (overall response rate, 46% vs. 41%), and there was no significant difference in median progression-free survival (39 vs. 33 weeks). Grade 3/4 neutropenia was observed in 34% of patients using epirubicin-paclitaxel and 45% of patients using epirubicin-cyclophosphamide, and the incidence of febrile neutropenia was the same in both arms. Two patients, both in the paclitaxel-based arm, developed grade 3 cardiotoxicity. Final results of this trial are awaited.

The UK Coordinating Committee on Cancer Research (UKCCCR) ABO1 trial compared the same two regimens as first-line treatment of 705 metastatic breast cancer patients.⁴¹ Epirubicin dose intensity was equivalent in both arms. A greater proportion of paclitaxel-treated patients achieved objective remissions as best response to treatment (67% vs. 56%). However, differences in median progression-free survival and overall survival were not statistically significant. Quality of life during treatment was similar in both arms.

The initial results of a 460-patient trial comparing standard-formulation paclitaxel with the investigational nanoparticle albumin-bound paclitaxel Abraxane (ABI-007) were presented at the San Antonio Breast Cancer Symposium in 2003.⁴² The response rate of 33% seen with ABI-007 was significantly higher than the 19% seen with paclitaxel ($P < .001$). Time to progression was also significantly higher with Abraxane compared with paclitaxel (21.9 weeks vs. 16.1 weeks; $P = .01$). In contrast to paclitaxel, whereby the active ingredient is delivered through a Cremophor-based solvent known to cause hypersensitivity reactions, Abraxane binds paclitaxel to albumin in a solvent-free nanoparticle. This formulation may allow for higher doses of active drug delivered and greater intratumoral paclitaxel concentrations. Although grade 4 neutropenia was more common with paclitaxel than with Abraxane and no patients taking Abraxane experienced hypersensitivity reactions, neuropathy was significantly more common in Abraxane-treated patients than in paclitaxel-treated patients.⁴²

Docetaxel. Docetaxel is a second-generation taxane, purified from the needles of the European yew tree, *Taxus baccata*.^{43,44} Docetaxel is a highly effective agent for metastatic breast cancer. In previously untreated patients, response rates range from 40% to 68%.⁴⁵ Docetaxel is also active in patients with anthracycline-resistant breast cancer. In two studies published simultaneously, the objective response rates to docetaxel in patients with breast cancer resistant to anthracyclines were 53%⁴⁶ and 57%.⁴⁷

Docetaxel monotherapy has been compared with doxorubicin monotherapy in 326 anthracycline-naïve metastatic breast cancer patients who had previously received alkylating agent-containing chemotherapy.⁴⁸ The primary end point in this study was time to progression. Docetaxel yielded a significantly higher overall response rate of 47.8%, compared with 33.3% ($P = .008$), but the median time to progression ($P = .45$) and median overall survival ($P = .39$) were not significantly different between the treatment arms in this study. The incidence of toxic deaths (cardiac) was higher in the anthracycline-treated group (3%) than in the docetaxel

group (1.2%; $P < .001$). Grade 4 neutropenia was similar in both groups, but the incidence of severe neutropenic complications was significantly higher with doxorubicin ($P = .02$).

In 1999, Nabholz and colleagues published the results of a randomized phase III trial comparing docetaxel monotherapy to the combination mitomycin-vinblastine in 392 metastatic breast cancer patients whose cancer had progressed on prior anthracycline.⁴⁹ The primary end point was time to progression. In an intent-to-treat analysis, docetaxel was significantly superior to the combination arm in terms of response rate (30% vs. 11.6%; $P < .0001$), median time to progression (19 weeks vs. 1 week; $P = .0001$), and overall survival (11.4 months vs. 8.7 months; $P = .0097$). The incidences of febrile neutropenia, grade 3/4 infections, and grade 3/4 neutropenia were significantly higher in the docetaxel-treated group, as were most nonhematologic adverse events such as stomatitis, diarrhea, skin toxicity, asthenia, neurotoxicity, and nail disorders. Conversely, grade 3/4 thrombocytopenia and constipation were significantly more frequent in the mitomycin-vinblastine arm. Toxic deaths and the quality-of-life analysis were similar in both arms.

Nabholz and colleagues presented a phase III trial comparing a combination of doxorubicin and docetaxel (AD) to the standard combination doxorubicin and cyclophosphamide (AC) as first-line therapy for 429 metastatic breast cancer patients in 1999.⁵⁰ AD showed a significantly higher response rate than AC (60% vs. 47%) and a longer time to progression (37 vs. 32 months). Grade 3/4 neutropenia was frequent in both groups, although febrile neutropenia and infections were more frequent for patients receiving AD (33% vs. 10%, $P < .001$; 8% vs. 2%, $P = .01$). Severe nonhematologic toxicity was infrequent in both groups, including grade 3/4 cardiac events.

The same investigators subsequently performed a phase III comparison of the three-drug combination of docetaxel, doxorubicin, and cyclophosphamide (DAC) to the standard three-drug combination of FAC (5-fluorouracil, doxorubicin, and cyclophosphamide) as first-line treatment in 484 metastatic breast cancer patients.⁵¹ DAC was superior to FAC in terms of response rate (55% vs. 44%), but no difference was found in time to progression or overall survival. Grade 3/4 toxicities (both hematologic and nonhematologic) were more common with DAC than with FAC.

A long-awaited head-to-head comparison of docetaxel and paclitaxel was reported at the San Antonio Breast Cancer Symposium in 2003. In this study, 449 patients with metastatic breast cancer who had failed anthracycline-based chemotherapy were randomized to paclitaxel 175 mg/m² every 3 weeks or docetaxel 100 mg/m² every 3 weeks.⁴² The primary end point of the study was overall response rate, and secondary end points were time to progression and overall survival. The patients treated with docetaxel had improved survival (15.4 months vs. 12.7 months; $P = .03$) and a longer median time to progression (5.7 months vs. 3.6 months; $P < .001$). The docetaxel arm was also associated with greater toxicity compared with the paclitaxel. Grade 3/4 neutropenia (93.3% vs. 54.5%), asthenia (23.9% vs. 6.8%), edema (11.3% vs. 4.5%), and stomatitis (10.4% vs. 0.5%) all were more common with docetaxel therapy.

As with paclitaxel, several phase III studies of weekly docetaxel have provided encouraging data indicating that there is generally less myelosuppression than with the 3-week schedule in patients with a variety of advanced malignancies.^{51a,52} At

least five studies of weekly docetaxel have been reported in patients with metastatic breast cancer, resulting in responses ranging from 32% to 41% using 25 to 40 mg/m² of docetaxel in pretreated patients. Myelosuppression was mild, but fatigue was common and was the most common reason for dose reduction.

Antimetabolites

Gemcitabine. Gemcitabine (2',2'-difluorodeoxycytidine, dFdC) is a novel nucleoside antimetabolite that has proven activity in a variety of human solid tumors, including pancreatic, non-small cell lung, bladder, ovarian, and breast cancer.^{53,54} The parent compound is phosphorylated intracellularly by deoxycytidine kinase to the active metabolites, gemcitabine diphosphate and triphosphate. Gemcitabine triphosphate competes with deoxycytidine triphosphate (dCTP) for incorporation into DNA as a fraudulent base, which results in masked chain termination and inhibition of further DNA synthesis.^{55,56} Gemcitabine diphosphate inhibits ribonucleotide reductase, an enzyme responsible for catalyzing dCTP. The subsequent decrease in dCTP potentiates the incorporation of gemcitabine triphosphate into DNA and enhances phosphorylation of gemcitabine because there is less dCTP to inhibit deoxycytidine kinase. These self-potentiating mechanisms prolong the retention of active gemcitabine in tumor cells.^{53,54}

At least nine studies have been reported that provide an initial assessment of the single-agent activity and tolerability of gemcitabine in advanced breast cancer.⁵⁷⁻⁶⁵ Comparability among the studies is limited by different gemcitabine regimens and conditions of pretreatment. The most frequently applied regimens were doses of 1000 or 1200 mg/m² administered over 4-week cycles.⁶⁶

As a single agent, gemcitabine is moderately active and well tolerated as first-line and salvage therapy of advanced breast cancer. Single-agent therapy in chemo-naïve patients has achieved overall response rates of 25% to 55%, which may be improved further with combinations. Median durations of response have been in the range of 6 to 12 months in most studies. As second-line treatment, single-agent therapy has produced response rates of 20% to 40% and response durations of 2 to 8 months. Toxicity generally consists of mild to moderate myelosuppression with minimal clinical consequences, and minimal nonhematologic toxicity, including hepatic and cutaneous toxicity and flu-like syndrome.⁶⁷

In 2004, a study comparing gemcitabine and paclitaxel (GT) with paclitaxel (T) alone in 529 patients with metastatic breast cancer was reported.⁶⁸ Median time to progression was 5.4 months for GT and 3.5 months for T ($P = .0013$). Progression-free survival and overall response rates were also significantly higher in the GT arm. In addition, improvement in analgesic level, pain relief, and global quality of life was higher in the GT arm. Grade 4 hematologic toxicity was more pronounced in the GT arm, and preliminary analysis also suggested a survival benefit for this combination.

Capecitabine. Capecitabine is an orally administered prodrug of fluorouracil. It is metabolically activated preferentially at the tumor site. Bioavailability after oral administration is close to 100%.^{69,70} In patients with pretreated advanced breast cancer, capecitabine is effective as monotherapy and in

combination with other agents. The most common adverse effects occurring in patients receiving capecitabine monotherapy include lymphopenia, anemia, diarrhea, hand-foot syndrome, nausea, fatigue, hyperbilirubinemia, dermatitis, and vomiting (all >25% incidence). A pivotal phase II trial was conducted in women with paclitaxel-refractory metastatic breast cancer at 24 medical centers in North America.⁷¹ Oral capecitabine was administered at 1250 mg/m² twice daily for 14 days, followed by a 7-day rest period. Of the 163 patients who entered the study, 162 received capecitabine and were included in the analyses of efficacy and safety. The study population represented a poor prognostic group: 75% of patients had more than two metastatic sites at baseline, and visceral metastases were present in 68% of patients. All patients were heavily pretreated: 100% had received prior paclitaxel, 91% had received prior anthracyclines, and 82% had received prior 5-fluorouracil-containing therapy (usually as an intravenous bolus). Capecitabine demonstrated activity in this heavily pretreated population, with an overall response rate of 20%.⁷² In addition to the patients who had an objective response, 43% of patients achieved stable disease, giving a disease control rate (complete or partial response or stable disease) of 63%. The median duration of response was 7.9 months, and the median time to disease progression was 3.0 months. Median survival as reported in a recently presented update of this study was 11.6 months.⁷¹ A subgroup analysis demonstrated that overall survival in patients with stable disease was similar to that in patients achieving an objective response, indicating that stable disease may be a clinically meaningful outcome. Among the 51 patients with significant pain at baseline, 47% experienced durable pain relief.

A number of confirmatory studies have evaluated single-agent capecitabine in patients whose disease has progressed during or following treatment with either paclitaxel or docetaxel.⁷³⁻⁷⁵ The patients in these studies, as in the pivotal study, were heavily pretreated and similar in terms of age, performance status, and distribution of metastatic sites. Efficacy data in these studies confirm the high activity of capecitabine in taxane-pretreated patients.^{54,76,77} More recent data suggest that the response rate is not lessened at a lower starting dose of capecitabine.

O'Shaughnessy and colleagues performed a phase III trial of docetaxel as monotherapy compared with docetaxel in combination with capecitabine in 511 patients with anthracycline-refractory metastatic breast cancer.⁵² The combination arm was superior in terms of time to progression (6.1 vs. 4.2 months; $P = .0001$) and overall survival (14.5 vs. 11.5 months; $P = .0126$). About two thirds of patients (65%) in the combination arm required a dose reduction of capecitabine (4%), docetaxel (10%), or both drugs (51%) for adverse events, whereas in the docetaxel arm, 36% of patients required a dose reduction. Premature withdrawal for adverse events or intercurrent illness was significantly more common in the combination arm. Gastrointestinal side effects and hand-foot syndrome were more common with the combination therapy, whereas myalgia, arthralgia, and neutropenic sepsis were more common with single-agent docetaxel. No difference was noted in quality of life. Of note, the use of poststudy chemotherapy was high in both arms (70% in the combination arm and 63% in the single-agent arm). Because only 27% of patients who received poststudy chemotherapy in the single-agent docetaxel arm received poststudy capecitabine, it

is unclear whether combination capecitabine-docetaxel provides a survival benefit compared with sequential administration of the same agents.

Vinca Alkaloids

Vinorelbine. Vinorelbine is a cell cycle-specific microtubule inhibitor. In contrast to the taxanes, which cause excessive microtubule stabilization, vinorelbine acts by destabilizing the microtubule. In vitro studies showed a selective effect on non-neuronal microtubules, which may explain the decreased neurotoxicity of vinorelbine compared to other vinca alkaloids.⁷⁸

Vinorelbine produces responses in 30% to 50% of patients with metastatic breast cancer in the first-line setting. Garcia-Conde and colleagues treated 54 patients with locally advanced or metastatic breast cancer who had received no prior chemotherapy with vinorelbine given as a weekly infusion of 30 mg/m².⁷⁹ The overall response rate was 50% (complete response, 2%; partial response, 48%). The median duration of response was 9 months, median time to treatment failure was 5 months, and median survival was 15 months. At least one episode of World Health Organization (WHO) grade 3/4 granulocytopenia was seen in 71% of the patients. Significant nausea and vomiting (WHO grade 3) were seen in less than 1% of cycles, and other side effects were uncommon.

Twelves and associates showed similar results with vinorelbine given as a 25-mg/m² weekly infusion to metastatic breast cancer patients as first-line therapy.⁸⁰ In this study, fatigue was the most common side effect, and the main reason for dose adjustments was myelosuppression. In previously treated patients, vinorelbine had demonstrated a response rate of 50%. The median time to progression was 18 weeks in this study. The drug was active in patients pretreated with cyclophosphamide, methotrexate, and fluorouracil (CMF) or anthracyclines.

Jones and colleagues performed a randomized comparison of vinorelbine versus melphalan in anthracycline-refractory metastatic breast cancer.⁸¹ Efficacy end points included time to progression, time to treatment failure, survival, response rates, quality of life, and relief of cancer-related symptoms. Time to progression was significantly longer with vinorelbine than with melphalan, with a median of 12 weeks versus 8 weeks, respectively ($P < .001$). More importantly, vinorelbine had a beneficial effect on survival, which reached statistical significance. One-year survival rates were 35.7% with vinorelbine and 21.7% for patients treated with melphalan ($P = .034$).

A recent phase II trial was performed to evaluate the efficacy, tolerance, and pharmacokinetic profiles of oral vinorelbine.⁸⁵ Sixty-four patients received oral vinorelbine on a weekly basis for a total of 8 weeks unless progression or toxicity occurred. Oral vinorelbine was given at 60 mg/m² weekly for the first three administrations and was increased to 80 mg/m² for the subsequent administrations if there was no grade 4 neutropenia or no more than one episode of grade 3 neutropenia. Fifty-eight evaluable patients were included for front-line therapy. Four patients (6.9%) had complete responses, and 14 (24.1%) had partial responses, for an overall response rate of 31% (95% confidence interval, 19%–43%). Median progression-free survival was 17.4 weeks. The most common toxicity was neutropenia. Grades 3 and 4 nausea or vomiting was noted in less than 5% of the patients, with no significant alterations in the baseline quality of

life. This study shows promise for another oral therapy for metastatic breast cancer patients. Additional studies are ongoing.

What is known about the optimal duration of chemotherapy?

The optimal duration of chemotherapy administration in the management of metastatic breast cancer is poorly defined. A meta-analysis of three trials including 666 women examining chemotherapy duration suggested a survival advantage for women randomized to longer durations of chemotherapy ($P = .01$).^{83–85} Coates and coworkers conducted a randomized trial comparing continuous chemotherapy (administered until disease progression) with intermittent therapy (treatment was stopped after three cycles and then repeated for three more cycles only when there was evidence of disease progression).⁸³ Each approach was tested with doxorubicin combined with cyclophosphamide or with cyclophosphamide combined with methotrexate, fluorouracil, and prednisone. Intermittent therapy resulted in a significantly worse response ($P = .02$ by Mann-Whitney test), a significantly shorter time to disease progression (relative risk based on proportional-hazards model, 1.8; 95% confidence interval, 1.4%–2.4%), and a trend toward shorter survival. Quality of life was expressed as linear-analogue self-assessment scores for physical well-being, mood, pain, and appetite. It improved significantly during the first three cycles, when all patients received treatment. Thereafter, intermittent therapy was associated with worse scores for physical well-being, appetite, and overall quality-of-life index as indicated by the patient and the physician. The authors concluded that, as tested in this study, continuous chemotherapy is better than intermittent chemotherapy for advanced breast cancer.

Ejlertson and associates asked a related question by comparing FEC (fluorouracil, epirubicin, and cyclophosphamide) for 24 cycles followed by tamoxifen with FEC for 8 cycles with tamoxifen in 318 women with metastatic breast cancer.⁸⁴ Median survival was higher in the longer-treatment group (23 vs. 18 months; $P = .03$).

Gregory and colleagues conducted a randomized trial to assess the survival of patients receiving up to six extra courses of chemotherapy compared with those who stopped after six courses.⁸⁵ The patients received VAC, VEC (vincristine, doxorubicin or epirubicin, and cyclophosphamide), or MMM (mitoxantrone, methotrexate, and mitomycin C) therapy. Patients who had stable disease or were responding after six courses of chemotherapy were randomized to either stop or continue treatment for another six courses. Those patients receiving maintenance therapy had a significantly longer duration of response ($P < .02$) and a significantly longer progression-free survival ($P < .01$). There was, however, no survival difference between the two groups in this study. Furthermore, treatment toxicity, which was similar in the two groups, persisted for longer in the maintenance group.

A fourth trial compared continuous mitoxantrone with mitoxantrone for four cycles in 43 patients with metastatic breast cancer and showed no statistically significant difference in overall survival.⁸⁶

Although survival benefits seen are modest, these increments may be valued highly by women with metastatic breast

cancer. Quality of life was also generally better for those who received more cycles of chemotherapy than fewer cycles, suggesting that the negative effects of ongoing chemotherapy may be offset by a reduction in cancer-related symptoms.⁸⁷ The combined evidence supports a policy of continuing chemotherapy in the absence of disease progression or prohibitive toxicity. Of course, treatment decisions must be individualized in practice.

What is the comparative efficacy of combination versus sequential or single-agent chemotherapy?

Goldie and Coldman hypothesized that the use of non-cross-resistant alternating combination chemotherapy would be a better way to eliminate the risk for drug resistance.⁸⁸ They also proposed that many drugs should be used early on, when the tumor burden is small. A contrasting cytokinetic concept is the Norton-Simon model, which takes into account multiple populations of cells within a tumor that have variable sensitivity to chemotherapy drugs, variable growth of these populations, and variable response rates to application of chemotherapy. This Norton-Simon model was the foundation for the important hypothesis that using intensive chemotherapy for a shorter time (for the fast-growing cellular population), followed by a non-cross-resistant regimen over a longer period for the slower-growing population, is the most effective approach to tumors.⁸⁹ Sequential therapy allows for dose-intense administration of individual cytotoxic agents and avoids overlapping toxicities seen with combinations. Results of studies in metastatic breast cancer have frequently shown higher overall response rates with combinations, but it is unusual to see an impact on survival in individual studies.

A meta-analysis by Fossati and colleagues reviewed randomized clinical trials in metastatic breast cancer between 1975 and 1997 and showed an increase in overall survival favoring combination chemotherapy over single-agent chemotherapy.⁸⁷ The absolute survival benefit was 9% at 1 year, 5% at 2 years, and 3% at 5 years and thereafter. Of note, the regimens used in this study were not modern chemotherapy drugs (Table 32–5).

Chlebowski and associates in 1989 randomized 222 patients with advanced breast cancer in two separate trials of similar design to either concomitant combination treatment or sequential use of the same drugs given as single agents changed only at disease progression.⁹⁰ Both trials used cyclophosphamide, methotrexate, 5-fluorouracil, and prednisone—the Western Cancer Study Group (WCSG) using triiodothyronine and the South Eastern Cancer Study Group (SECSG) using vincristine as the remaining agent. A common database was generated for these trials for combined analysis. Combination treatment was associated with a significantly increased response rate (46% vs. 26%; $P < .05$) but no survival improvement, suggesting that sequential single-agent therapy can result in survival comparable to combination treatment.

Joensuu and colleagues in 1998 compared epirubicin followed by mitomycin at disease progression with FEC followed by mitomycin and vinblastine (MiV).⁹¹ Response rates were 48% in the epirubicin plus mitomycin arm and 55% in the FEC-MiV arm. There was no difference in overall survival or time to disease progression. In this study, quality of life was

Table 32-5 Randomized Trials with Single-Agent Compared with Combination Chemotherapy

Study	n	Chemotherapy Regimen	Response Rate (%)	Survival
Chlebowski phase III ⁹⁰	129	CMFP ± V	68	MS not significant
	93	F → M → P or V → C → P	55	
Joensuu phase III ⁹¹	153	E → Mi	48 → 16	MS not significant
	150	FEC → MiVi	55 → 6	
Bishop phase III ⁹³	107	CMFP	29	MS 17.3 for P vs. 13.9 for MN
	102	Paclitaxel	35	
Heidemann phase III ⁹⁴	119	FEC	36	QoL significant with Mi arm
	119	MN	25	
Norris et al. (2000), phase III ⁹⁵	151	Doxorubicin vs.	30	MS not significant
	149	Dox/vinorelbine	38	
Nabholtz phase III ⁴⁹	392	Docetaxel vs.	30	MS 11.4 vs. 8.7 MN (<i>P</i> < .001)
		MN/vinblastine	11.5	
Sjostrom et al. (1999), phase III ¹⁷²	283	Docetaxel vs.	42	MS not significant
		MF	21	
Bonnetterre, phase III ¹⁷³	176	Docetaxel vs.	43	MS not significant
		F/vinorelbine	38.8	
O'Shaughnessy, phase III ^{94a}	511	Docetaxel vs.	29.7	MS 11.5 vs. 14.5 MN (<i>P</i> < .001)
		doce/capecitabine	41.6	
Sledge phase III ⁹²	245	Doxorubicin	36	MS not significant
	242	Paclitaxel	34	
	244	Dox + Pac + G-CSF	47	

RR, response rate; MS, median survival; QoL, quality of life; P, prednisone; C, cytoxan; M, methotrexate; V, vincristine; F, 5-fluorouracil; E, epirubicin; Mi, mitomycin; Vi, vinblastine; MN, mitoxantrone; G-CSF, growth factor; Dox, doxorubicin; Pac, paclitaxel.

assessed and was found to be better in the single-agent sequential therapy group.

A landmark Eastern Cooperative Oncology Group (ECOG) study published in 2003 randomized 739 patients to doxorubicin (60 mg/m²), paclitaxel (175 mg/m²/24 h), or the combination of doxorubicin and paclitaxel (AT, 50 mg/m² and 150 mg/m²/24 h, plus granulocyte colony-stimulating factor, 5 mg/kg) as first-line therapy for metastatic breast cancer.⁹² Patients receiving single-agent doxorubicin or paclitaxel were crossed over to the other single agent at the time of progression. Responses were seen in 36% of doxorubicin, 34% of paclitaxel, and 47% of AT patients (*P* = .84 for doxorubicin vs. paclitaxel; *P* = .007 for doxorubicin vs. AT, *P* = .004 for paclitaxel vs. AT). Median times to treatment failure were 5.8, 6.0, and 8.0 months for doxorubicin, paclitaxel, and AT, respectively (*P* = .68 for doxorubicin vs. paclitaxel; *P* = .003 for doxorubicin vs. AT; *P* = .009 for paclitaxel vs. AT). Median survival times were not significantly different: 18.9 months for patients randomized to doxorubicin, 22.2 months for paclitaxel, and 22.0 months for AT. Responses were seen in 20% of patients crossing from doxorubicin to paclitaxel and in 22% of patients crossing from paclitaxel to doxorubicin.

In 1999, Bishop and coworkers reported a study in which patients with previously untreated metastatic breast cancer were randomized to receive either paclitaxel 200 mg/m² intravenously over 3 hours for eight cycles (24 weeks) or standard (CMFP) for six cycles (24 weeks) with epirubicin recommended as second-line therapy.⁹³ A total of 209 eligible patients were randomized with a median survival duration of 17.3 months for paclitaxel and 13.9 months for CMFP (*P* = .068). Paclitaxel produced significantly less severe leukopenia, thrombocytopenia, mucositis, infections, nausea, or vomiting

but more alopecia, peripheral neuropathy, and myalgia or arthralgia. Overall, quality of life was similar for both treatments (*P* ≥ .07).

Heidemann and associates performed a study that evaluated quality of life by using a modified Brunners score to measure the effects of disease, quality of life, and toxicity.⁹⁴ In this study, FEC produced a slightly higher response rate than single-agent mitoxantrone, but again, no difference was observed in time to disease progression or overall survival. The single-agent group demonstrated better quality of life using the modified Brunner score.

One of the few studies that did show a survival advantage for combination over single-agent chemotherapy was the study of O'Shaughnessy^{94a} comparing capecitabine and docetaxel with docetaxel alone. At this time, the comparative efficacy of sequential use of docetaxel and capecitabine versus combination is not known because only 27% of the patients who received single-agent docetaxel crossed over to capecitabine as subsequent therapy. Likewise, in the study of Albain,⁶⁸ only 14% of patients on the single-agent paclitaxel arm went on to receive gemcitabine. This raises a similar question with regard to whether these drugs might have had the same benefit if given sequentially rather than in combination.

Taken together, evidence would support the use of sequential single-agent chemotherapy in an effort to optimize toxicity and tumor control. In most breast cancer patients, sequential single-agent therapy can result in survival comparable to combination treatment. In addition, sole consideration of response frequency does not represent the optimal criterion to compare therapeutic approaches in advanced breast cancer. An exception to this might include patients with

highly symptomatic metastatic breast cancer in whom immediate response is an important end point. The choice of single-agent versus combination chemotherapy needs to be analyzed with respect to both efficacy and quality of life for an individual patient.^{51,95}

What is the efficacy of high-dose chemotherapy with hematopoietic support?

Retrospective analyses initially suggested a clinical correlation between dose of chemotherapy and outcome in patients with metastatic breast cancer. The use of high-dose chemotherapy with stem cell rescue is based on the hypothesis that major dose escalations are needed to overcome drug resistance and produce meaningful clinical outcomes. In the late 1980s and early 1990s, several phase II trials of highly selected patients reported promising results for high-dose chemotherapy in metastatic breast cancer patients.⁹⁶⁻¹¹⁰ We now have data from seven randomized trials comparing high-dose chemotherapy to standard chemotherapy in women with metastatic breast cancer.¹¹¹⁻¹¹⁷

In 1996, a study from Duke University was reported at ASCO.¹¹¹ This was a crossover trial in which 100 metastatic breast cancer patients in complete response with conventional dose of AFM (doxorubicin, 5-fluorouracil, methotrexate) were randomized to (1) immediate high-dose chemotherapy with CPB (cyclophosphamide, cisplatin, carmustine) with stem cell rescue or (2) high-dose chemotherapy at the time of relapse. A significant disease-free survival benefit was demonstrated in patients undergoing intensive therapy at first complete remission, but there was no difference in overall survival.

In another study conducted at Duke, 69 patients with bone-only disease received induction chemotherapy with a maximum of four cycles of AFM.¹¹² Patients were then randomized to receive immediate consolidation with CPB with stem cell rescue or observation with CPB at the time of disease progression. Disease-free survival was again significantly better in the immediate high-dose chemotherapy arm, but no differences were seen in survival.

In the Philadelphia Intergroup study, metastatic breast cancer patients received induction therapy with four to six cycles of CAF or CMF and then were randomized to receive high-dose chemotherapy using the STAMP V regimen (carboplatin, 800 mg/m²; cyclophosphamide, 6000 mg/m²; and thiotepa, 500 mg/m²) with stem cell rescue or maintenance CMF continued until progression or for up to 24 cycles.¹¹³ The median overall survival times were 25.8 and 26.1 months for the high-dose chemotherapy and CMF groups, respectively, and median times to progression were 9.6 months for high-dose chemotherapy and 9.1 months for CMF.

In the PEGASE 04 study, patients responding to induction chemotherapy were randomized to receive intensified-dose cyclophosphamide, melphalan, and mitoxantrone with autologous stem cells or continuation of conventional treatment (two to four cycles).¹¹⁴ There was no difference in time to progression and 5-year overall survival rates between the two groups.

A phase III National Cancer Institute of Canada (NCIC) trial was presented by Crump and colleagues at the ASCO in 2001.¹¹⁵ In this study, 219 patients with metastatic breast cancer responding after four cycles of a first-line therapy

were randomized to receive two to four additional cycles of standard chemotherapy or one or two cycles of standard chemotherapy followed by high-dose chemotherapy (cyclophosphamide, mitoxantrone, carboplatin) with stem cells. Disease-free survival was significantly improved in the high-dose chemotherapy arm, whereas no difference was seen in 3-year survival between groups. There was a 20% dropout rate, and transplant-related mortality was high in this study at 7.7%.

The PEGASE 03 study randomized 180 patients with metastatic breast cancer with an objective response after four cycles of FEC (5-FU, epirubicin, and cytoxan) to high-dose chemotherapy (thiotepa, cyclophosphamide) with stem cells versus no further treatment.¹¹⁶ The 1-year disease-free survival rates were 19% and 46%, favoring the high-dose arm; but again, overall survival was not statistically different (38% in the high-dose chemotherapy arm vs. 30% in the observation arm).

Schmidt and associates randomized 92 metastatic breast cancer patients to six to nine courses of chemotherapy with doxorubicin and paclitaxel versus double high-dose chemotherapy (cyclophosphamide, mitoxantrone, etoposide) with stem cell rescue.¹¹⁷ Crossover high-dose chemotherapy was planned at relapse for patients showing a complete response to AT. In this study, high-dose chemotherapy was associated with a significantly longer progression-free survival (PFS). No difference was seen in overall survival between the arms at 14 months of follow-up.

It is notable that in six of the seven trials, disease-free survival was improved in the high-dose chemotherapy group. The delay in relapse for patients with metastatic disease may represent an important end point because it is associated with a longer off-therapy survival and a better quality of life during that off-therapy period at the cost of the greater toxicity of the high-dose therapy.

The lack of any positive impact on survival using this approach would argue against a role for high-dose chemotherapy as part of standard management for metastatic breast cancer. Whether there is a role for the use of high-dose chemotherapy as a platform on which novel molecular targeted therapy can be added remains to be seen.

What is the role of biologic therapy in the management of metastatic breast cancer?

Trastuzumab

The *HER-2/neu* gene, which encodes the transmembrane receptor p185HER-2/neu, has partial homology with the epidermal growth factor receptor, and both share the same tyrosine kinase activity. *HER-2* is amplified in 25% to 30% of breast cancers, and women with *HER-2*-overexpressing breast cancer have shortened relapse-free and overall survival.^{118,119} Trastuzumab is a humanized monoclonal antihuman epidermal growth factor receptor-2 (*HER-2*) antibody that has proven efficacy in *HER-2*-overexpressing breast cancer. Trastuzumab monotherapy has been evaluated in previously treated and untreated patients with metastatic breast cancer, with overall response rates of 15% to 26%.^{120,121} Although patients were enrolled in initial trials based on their level of *HER-2* overexpression as assessed by immunohistochemistry, subsequent retrospective analyses using fluorescence in situ

hybridization (FISH) of archival tumor tissue from the same patients showed that the efficacy was higher in patients who tested positive on FISH for amplification of the *HER-2/neu/c-erbB-2* locus (19% to 34%) and was nonexistent to low in patients who tested negative (0% to 7%).^{121,122} It has subsequently been shown that 3+ specimens by immunohistochemistry provide reasonably good correlation with FISH.

In 1996, Baselga and colleagues published a trial on the use of single-agent trastuzumab in a group of heavily pretreated breast cancer patients and reported a response rate of 11.6%.¹²³ Subsequently, two pivotal trials were undertaken to further investigate the activity of trastuzumab.^{119,124} In the pivotal monotherapy study, 222 women with metastatic breast cancer who had received two prior chemotherapy regimens were treated with trastuzumab as a single agent.¹¹⁹ The response rate was 22%, with a median duration of response of 9.1 months and median survival of 13 months. In the second pivotal trial, trastuzumab was combined with chemotherapy.¹²⁴ Patients were stratified into one of two chemotherapy regimens based on preceding anthracycline adjuvant therapy. Those without anthracycline exposure received doxorubicin and cyclophosphamide given every 3 weeks with or without trastuzumab, and those who had received prior anthracycline therapy received paclitaxel every 3 weeks with or without trastuzumab. A total of 469 patients were randomized. With a median follow-up of 35 months, there was a statistically significant difference in time to progression, response rate, median response duration, and, most importantly, increased overall survival (25 months vs. 20 months; $P < .001$) for patients who received chemotherapy and trastuzumab.

A first-line trastuzumab monotherapy trial was later performed by Vogel and associates.¹²¹ A total of 114 patients were randomized to receive a standard loading dose of 4 mg/kg followed by 2 mg/kg or 8 mg/kg followed by 4 mg/kg weekly. Response rates of 24% for the lower dose and 28% for the double dose were seen, establishing the 4-mg/kg loading dose followed by 2 mg/kg weekly as standard. A recent phase II study evaluated trastuzumab, 8 mg/kg loading dose, with paclitaxel, 175 mg/m², and then trastuzumab, 6 mg/kg every 3 weeks, until disease progression in pretreated metastatic breast cancer patients.¹²⁵ Plasma trastuzumab trough levels and clinical response rates compared favorably with those achieved with the standard weekly trastuzumab regimen.

Trastuzumab is generally well tolerated, with the most significant reported toxicities being hypersensitivity reactions and cardiac toxicity. A retrospective review of trastuzumab monotherapy trials estimated the incidence of cardiac dysfunction to be 0.8% for first-line monotherapy and 7% for second-line monotherapy.¹²⁶ Trastuzumab-related cardiac toxicity has most commonly manifested as asymptomatic decreases in LVEF on multiple-gated acquisition scans. The incidence of cardiac dysfunction is greatest in patients receiving concomitant trastuzumab and anthracycline plus cyclophosphamide (27%). The risk is substantially lower in patients receiving paclitaxel and trastuzumab (13%) or trastuzumab alone (3% to 7%); however, most of these patients had received prior anthracycline therapy. In the pivotal randomized study,¹²⁷ cardiac dysfunction was noted in 8% of patients receiving anthracycline plus cyclophosphamide and 1% receiving paclitaxel alone. Most trastuzumab-treated patients developing cardiac dysfunction were symptomatic (75%), and most improved with standard

treatment for congestive heart failure (79%). Most reported cardiac effects are mild to moderate, nonspecific, and medically manageable. Signs and symptoms are similar to those observed in patients who develop anthracycline-induced cardiomyopathy and include tachycardia, palpitations, and exertional dyspnea, which may progress to congestive heart failure. The pathogenesis and histologic changes responsible for trastuzumab-associated cardiotoxicity are currently under investigation. Unlike anthracycline-induced toxicity, trastuzumab-associated toxicity usually responds to standard treatment or the discontinuation of trastuzumab, and there is no evidence that the toxicity is dose related. Current methods for the early detection of cardiotoxicity in trastuzumab-treated patients are similar to those used in anthracycline-treated patients. Cardiac function is established at baseline and monitored regularly during treatment by physical examination and measurement of LVEF. Most patients improve with proper treatment, and some are able to continue to receive trastuzumab.

Trastuzumab and Anthracyclines

In the pivotal randomized study by Slamon and colleagues comparing chemotherapy to chemotherapy in combination with trastuzumab in patients with *HER-2*-overexpressing tumors, the combination of AC with trastuzumab exhibited significant improvements in response rate (56% vs. 42% with chemotherapy alone), time to progression (7.8 months vs. 6.1 months; $P < .001$), time to treatment failure (7.2 months vs. 5.6 months; $P < .001$), and overall survival (median survival, 26.8 months vs. 21.4 months $P = .16$).¹²⁴ In addition, in a subsequent analysis of this trial, the combination exhibited a significant improvement in quality of life compared with chemotherapy¹²⁸ (Table 32–6).

Liposomal doxorubicin (TLC D-99) plus trastuzumab in metastatic breast cancer resulted in a 57% response rate with no reports of significant cardiotoxicity in patients receiving first- or second-line therapy for advanced breast cancer.¹²⁸

Trastuzumab and Taxanes

Paclitaxel-trastuzumab combinations produce overall response rates of 36% to 70% as first-line therapy for metastatic breast cancer^{124,129,130} (Table 32–7). Median duration of response ranges from 7 to 11.6 months. In the pivotal trial,¹²⁷ the combination of paclitaxel with trastuzumab exhibited a significant improvement compared with paclitaxel alone with regard to time to progression (6.9 months vs. 3.0 months; $P < .0001$), time to treatment failure (5.8 months vs. 2.9 months; $P < .0001$), and duration of response (10.5 months vs. 4.5 months; $P < 0.01$). Median survival was also increased in the paclitaxel plus trastuzumab arm (25.1 months vs. 20.3 months; $P = .046$).

Docetaxel and trastuzumab combinations produced overall response rates of 63% to 70% in clinical trials as first-line therapy for metastatic breast cancer.^{131–134} Significant cardiotoxicity was reported in 3% of the patients, and severe fatigue occurred in more than 10% of patients on weekly docetaxel (Taxotere). Hypersensitivity reactions were reported in up to 62% of patients.

Trastuzumab and Platinum Combinations

Platinum compounds have exhibited synergistic activity with trastuzumab in breast cancer cell lines. Slamon and associates,

Table 32-6 Trials with Anthracycline/Trastuzumab*

Study	N	Treatment Arm	Response Rate (%)	Toxicity

LVEF, left ventricular ejection fraction; MS, median survival; TTP, time to progression.

in a phase II trial of Herceptin combined with docetaxel and carboplatin, showed an overall response of 64%, with fatigue and febrile neutropenia in 11% of the patients.¹³⁵ LVEF decreases were reported in 4% of the patients¹⁴² (Table 32-8).

Robert and colleagues performed a randomized study of trastuzumab and paclitaxel with and without carboplatin and reported a 57% response rate with the triplet and a 38% response rate in the paclitaxel-Herceptin arm.¹²⁹ Time to progression was also higher in the platinum-containing arm (13 months vs. 7 months; $P = .002$), with no difference in overall survival.

Yardley and colleagues studied weekly carboplatin-paclitaxel-trastuzumab as first-line therapy for metastatic breast cancer and showed an overall response rate of 66% with a median survival of 29.3 months in patients who did not progress during trastuzumab induction therapy.¹³⁶

Trastuzumab and Vinorelbine

Vinorelbine has demonstrated the greatest antitumor synergy with trastuzumab in preclinical studies. In addition, studies of trastuzumab in combination with vinorelbine have generated very consistent efficacy and tolerability profiles (Table 32-9).

Burstein and coworkers initially reported an overall response rate of 75% for vinorelbine-trastuzumab therapy as first-line therapy for metastatic breast cancer.¹³⁷ Median time to treatment failure was 5.6 months; 38% of patients were progression free after 1 year. Two patients developed grade 1 cardiac toxicity, and one patient developed congestive heart failure.

Jahanzeb and colleagues reported an overall response rate of 78% with vinorelbine in combination with trastuzumab, with a median time to progression of 17 months.¹³⁸

Bernardo and colleagues¹³⁹ and Bunnell and associates¹⁴⁰ studied this combination as initial therapy for metastatic

Table 32–8 Trials with Platinum/Trastuzumab

Study	N	Treatment Arm	Response Rate (%)	Toxicity
Pienkowski et al. (2001), phase II ¹⁷⁶	61	Trastuzumab plus docetaxel, 75 mg/m ² , with cisplatin, 75 mg/m ²	76	Fatigue, 18% Nausea, 12% Febrile neutropenia, 9% CHF, 2%

Table 32–9 Trials with Vinorelbine/Trastuzumab*

Study	N	Treatment Arm	Response Rate (%)	Toxicity
Burstein et al. (2001), phase II ¹³⁷	40	Trastuzumab and vinorelbine, 25 mg/m ² /wk	75; MS 17.9 mo	Neutropenia, 43% Fatigue, 5% No severe cardiotoxicity
Jahenzeb et al. (2002), phase II ¹³⁸	40	Trastuzumab and vinorelbine, 30 mg/m ² /wk	78; TTP 17 mo	Neutropenia, 20% of cycles Neuropathy, 8% Grade 2 LVEF decreased 3%
Bernardo et al. (2002), phase II ¹³⁹	35	Trastuzumab and vinorelbine, 25 mg/m ² /wk	84; MS not reported	Neutropenia, 8% grade 4 No severe cardiotoxicity
Bunnell et al. (2002), phase II ¹⁴⁰	54	Trastuzumab and vinorelbine, 25 mg/m ² /wk	69; MS not reported	Neutropenia, 54% CHF, 2%

*Herceptin was given as 4-mg/kg loading dose, followed by 2 mg/kg/wk.

CHF, congestive heart failure; LVEF, left ventricular ejection fraction; MS, median survival; TTP, time to progression.

breast cancer patients and reported response rates of 84% and 69%, respectively. No severe cardiotoxicity was reported. The most common grade 3/4 toxicity was neutropenia in both studies.

Trastuzumab and Gemcitabine

A gemcitabine-trastuzumab combination in *HER-2*-overexpressing metastatic breast cancer generated a response rate of 37% as front-line therapy.

In a first-line study conducted by the Hoosier Oncology Group, 27 patients received a triplet regimen consisting of paclitaxel, gemcitabine, and trastuzumab every 21 days.¹⁴¹ A partial response was achieved in 92% of 13 evaluable patients. Treatment was well tolerated except for grade 4 myelosuppression.

O'Shaughnessy and coworkers studied gemcitabine with trastuzumab as third-line therapy in 55 patients with metastatic breast cancer and showed an objective partial response in

32% of patients with a median survival of 10.2 months and median time to progression of 6.7 months.¹⁴² The primary grade 3/4 toxicity was neutropenia, which occurred in 9 patients. The activity of this regimen and the absence of severe toxicity in this pretreated population are encouraging.

Trastuzumab and Capecitabine

A preliminary analysis of an 18-patient trial of capecitabine (1125 mg/m² orally twice daily for 2 weeks) with trastuzumab in extensively pretreated patients reported a 47% overall response rate with a median response duration of 10.4 months and minimal side effects.¹⁴³

Other Biologic Therapy

Tyrosine Kinase Inhibitors. Tyrosine kinase inhibitors are small molecules that bind to the adenosine triphosphate (ATP) binding site in the intracellular domain of receptors

and block tyrosine kinase activity either reversibly or irreversibly. The recently developed agents targeting epidermal growth factor receptor (EGFR), ZD1839 (Iressa) and OSI-774 (Tarceva), are selective EGFR-tyrosine kinase inhibitors that have been studied in metastatic breast cancer patients. Results from a phase II study evaluating the safety and efficacy of ZD1839 in metastatic breast cancer patients with ER-negative and tamoxifen-resistant ER-positive tumors reported only modest activity (two partial responses and 10 patients with stable disease out of 17 evaluable patients) with manageable toxicity.¹⁴⁴ In a multicenter phase II trial, OSI-774 also showed minimal activity in previously treated metastatic breast cancer patients, with an acceptable toxicity profile.¹⁴⁵

Recent data suggest that the HER-family signaling pathway may be involved in hormone resistance. The role of combined treatment with these agents with endocrine agents is currently being evaluated.

Targeting the ras-raf-MAPK Pathway. Farnesylation, performed by the enzyme farnesyl transferase, is a key step in the activation of downstream proteins involved in intracellular signaling pathways, including the *HER-2* pathway and other pathways using the ras family of proteins. Therefore, one of the ways of targeting the ras-raf-MAPK pathway is through the use of farnesyl transferase inhibitors (FTIs). Results of a single-agent phase II study of R115777 in metastatic breast cancer (Zarnestra) revealed a response rate of 25% in previously treated patients, and studies are ongoing in combination with other agents.¹⁴⁶

CCI-779 is an mTOR (mammalian target of rapamycin) inhibitor currently undergoing evaluation in metastatic breast cancer, both as a single agent and in combination with endocrine agents and chemotherapy. The ultimate effect of inhibition of mTOR is an arrest of tumor cells in the G₁ phase of the cell cycle, resulting in inhibition of cell replication and tumor growth.¹⁴⁷⁻¹⁵¹ A phase II trial of CCI-779 was carried out in 109 metastatic breast cancer patients previously treated with taxane- or anthracycline-based chemotherapy in the metastatic or adjuvant setting. Data for the first 85 patients were recently reported.¹⁵² Stable disease for longer than 3 months or partial responses were seen in 17 of the 85 patients. Grade 3 or 4 events occurring in more than 5% of patients included infection, gamma-glutamyltranspeptidase elevation, stomatitis, leukopenia, depression, and somnolence. A final report is pending.

Anti-VEGF Therapy. Most of the angiogenesis inhibitors are in phase I/II trials as single agents or in combination with cytotoxic chemotherapy. Agents targeting the vascular endothelial growth factor (VEGF) and its receptors have been the most extensively studied in metastatic breast cancer. Rosen and colleagues humanized the murine antibody A.4.6.1 by placing its complementary determining region into a human IgG1 constant-region framework and further modifying further amino acid residues to optimize antigen binding.¹⁵³ In the resulting product, bevacizumab (or rhMAB-VEGF), 7% of the amino acids are from the murine antibody. Several phase I trials demonstrated a low-toxicity profile and did not show antibody development to bevacizumab. Severe toxic effects that occurred in the phase I trials were infrequent intratumoral bleeding (including fatal hemoptysis), pulmonary emboli, and peripheral venous thrombosis.^{154,155}

Cobleigh and associates evaluated bevacizumab in a phase I/II dose-escalation study. Seventy-five women with previously treated metastatic breast cancer were treated with bevacizumab at 3 mg/kg (n = 18), 10 mg/kg (n = 41), or 20 mg/kg (n = 16) given intravenously every 2 weeks until progression.¹⁵⁶ The end points of the trial were safety, best objective response rate, and pharmacokinetic profile. The median duration of treatment was 10 weeks. Dose-limiting toxicity was headache associated with nausea and vomiting in patients treated at the 20-mg/kg dose level. Ten percent of patients had an objective response, including one complete response in a supraclavicular node at 10 mg/kg and six partial responses. Median duration of confirmed response was 5.6 months. Twelve of 75 patients had ongoing response or stable disease at the last tumor assessment at 5 months, and three patients were treated for 1 year or longer without disease progression. Median survival was 10.2 months.

A phase III trial of bevacizumab and capecitabine versus capecitabine alone in previously treated metastatic breast cancer patients was recently reported.¹⁵⁷ Patients randomized to the combination arm were eligible to continue bevacizumab therapy after progression either alone or in combination with other therapies. The primary end point of the trial was time to progression. Secondary end points were safety, objective response rate, duration, and survival. Study results showed no improvement in progression-free survival, although there was a statistically significant improvement in response rate with the combination (9.1% vs. 19.8% by independent review). The response rate using capecitabine and bevacizumab was not higher in VEGF-overexpressing subjects. The response rate using capecitabine alone was lower in VEGF-overexpressing subjects, although the sample size was too small for definitive conclusion.

ECOG-2100 is an ongoing phase III trial of paclitaxel with or without bevacizumab in patients with metastatic breast cancer as front-line therapy.¹⁵⁸ Patients are randomized to weekly paclitaxel with bevacizumab or weekly paclitaxel alone. The primary end point of this study is time to progression. A total of 685 patients will be enrolled. This study was activated in late December 2001 and completed accrual in April 2004.

BISPHOSPHONATES

Bisphosphonates are osteoclast inhibitors that have an affinity for bone and are preferentially delivered to sites of increased bone formation or resorption. Once deposited on the surface of bone, bisphosphonates are ingested by osteoclasts that are engaged in bone resorption.¹⁵⁹ Bisphosphonates are potent inhibitors of osteoclastic bone resorption and are effective in treating cancer-induced hypercalcemia, Paget's disease of bone, and postmenopausal osteoporosis. Pamidronate, a second-generation bisphosphonate, and zoledronate, a third-generation bisphosphonate, are approved for metastatic breast cancer.^{160,161} Clodronate is available in oral form and is currently investigational.

When bisphosphonates are administered intravenously, clearance from the plasma is rapid, and most of the drug is taken up by the skeleton, where it remains for a prolonged period of time.^{162,163}

Bony Metastasis

Bony metastases are seen in 30% to 40% of metastatic breast cancer patients. Median survival with bone-only disease is longer than for those patients with visceral metastases. Bony metastases can cause pain, pathologic fractures, hypercalcemia, and spinal cord compression.

Hortobagyi and colleagues randomized 382 women receiving chemotherapy for metastatic breast cancer with bony lesions to receive either pamidronate, 90 mg, or placebo IV over 2 hours on a monthly basis for 12 months.¹⁶⁴ The overall reduction in skeletal related events was 43% versus 56% ($P = .008$), and the median time to a skeletal event was 14 versus 7 months ($P < .001$) for the pamidronate- and placebo-treated groups, respectively. Hortobagyi and coworkers randomized 374 patients receiving hormonal therapy for metastatic breast cancer with bony lesions to receive either pamidronate, 90 mg monthly, or IV placebo over 2 hours for 2 years.¹⁶⁵ Similarly, the overall reduction in skeletal related events was 56% versus 67% ($P = .03$), and the median time until the first skeletal event was 10 versus 7 months ($P = .05$) for the pamidronate and placebo groups, respectively. Overall survival did not change in either of these studies.

Rosen and colleagues in 2001 compared zoledronate at 4 or 8 mg IV to pamidronate at 90 mg IV.¹⁶⁶ There was no statistically significant difference seen in terms of skeletal-related events or time to the first skeletal event. Zoledronate was associated with an elevation in serum creatinine at the 8-mg dose and with a 5-minute bolus infusion. With the recommended dose of 4 mg over a 15-minute bolus, no change was noticed in serum creatinine. The shorter infusion time of zoledronate and equivalent therapeutic efficacy relative to pamidronate makes zoledronate more convenient for many patients.

Ibandronate, a highly potent third-generation bisphosphonate, has been studied in three multicenter randomized trials as intravenous and oral forms.^{167,168} In the intravenous study, patients were randomized to 6 mg ibandronate or placebo infused over 1 to 2 hours every 3 to 4 weeks. In the other two trials, an oral formulation of 50 mg of ibandronate was used. The intravenous form resulted in a 40% reduction in the risk for a skeletal-related event as compared with placebo ($P = .0033$). Oral ibandronate provided a similar reduction in skeleton-related events 38% ($P < .0001$) compared with placebo.

Duration

The optimal duration of bisphosphonate use is unknown because this issue has never been the focus of a clinical trial. In the previously described trials of pamidronate in women with osteolytic disease, pamidronate (or placebo) was given for 2 years or until patient refusal, physician- or patient-defined unacceptable toxicity, or death. In the metastatic setting, this question is not currently being studied, although many clinicians continue bisphosphonate therapy indefinitely as performance status allows.

Safety and Adverse Effects

In a randomized comparison of pamidronate (90 mg as a 2-hour infusion) versus zoledronic acid (4 mg as a 15-minute infusion), 6% to 8% of patients with breast cancer

experienced deterioration of renal function during the first 12 months of bisphosphonate therapy.¹⁶⁹ In that study, deterioration of renal function was defined as a change in baseline serum creatinine of 0.5 mg/dL or two times baseline value in patients with normal baseline serum creatinine (<1.4 mg/dL), or a change from baseline serum creatinine of 1.0 mg/dL or two times baseline value in patients with abnormal baseline serum creatinine (1.4 mg/dL).

There are limited data on the long-term renal safety of bisphosphonates. In an uncontrolled study of 22 patients treated with pamidronate ($n = 18$) or zoledronic acid ($n = 4$) for more than 2 years (median, 3.6 years), the last serum creatinine level was significantly higher than baseline values.¹⁶² Shorter infusion times have been associated with a higher risk for renal toxicity. Intravenous infusions of pamidronate over less than 2 hours, especially those less than 1 hour given on a long-term basis (more than 1 year), have occasionally been associated with renal toxicity, including albuminuria followed by azotemia. More serious renal toxicity has also been reported with long-term use of higher doses or more frequent dosing of pamidronate. The safety and frequency of nonrenal side effects are similar for pamidronate and zoledronate. In randomized controlled trials, the incidence of most adverse effects in women treated with pamidronate was similar to that observed in the placebo group. Transient myalgias, arthralgias, and flulike symptoms with fever tend to occur more often in women treated with pamidronate. Mild infusion-site reactions have also been reported. Uveitis and other ocular adverse effects are rare but well described.^{169,170} Women have rarely discontinued pamidronate therapy because of adverse effects.

Hormonal and Biologic Therapy for Metastatic Breast Cancer

Ruth Oratz

HISTORICAL BACKGROUND

Hormonal therapy for breast cancer dates to the 19th century when Beatson¹ observed that bilateral oophorectomy resulted in tumor regression in premenopausal patients with advanced disease. It was postulated that ovarian function caused tumor growth. In the early 20th century, surgical removal of the ovaries was performed, as well as photon irradiation to the ovaries, hypophysectomy, and surgical adrenalectomy, as means of reducing stimulation of tumor growth. Response rates following these procedures ranged between 30% and 40%, but morbidity and operative mortality were significant.^{2,3} Estrogen preparations were then studied, including diethylstilbestrol (DES), ethinyl estradiol, and conjugated estrogens.¹ These agents produced antitumor responses in the 30% range, but toxicity included nausea, vomiting, uterine bleeding, fluid retention, increased thromboembolic phenomena, and congestive heart failure. In addition, there was the potential risk that estrogen would cause increased tumor growth.

Once the assays for quantifying estrogen receptor (ER) and progesterone receptor (PR) were standardized, clinical responses to hormonal therapy could be correlated with receptor status.^{4,5} For patients with ER- or PR-positive tumors, initial response rates are in excess of 60%, whereas for patients with receptor-negative tumors, response rates to hormonal therapy are less than 10%. In patients whose tumors had mixed hormone receptor status (ER positive and PR negative or vice versa), intermediate responses in the range of 20% to 45% have been reported.^{6–10}

What are the mechanisms of action of endocrine therapies?

As the biochemical mechanisms by which estrogen stimulates cancer cell growth, the role of the ER and coactivators in signaling intracellular pathways, and the physiology of estrogen production have become more clearly elucidated, better hormonal therapies targeted to these mechanisms have been developed. The different classes of hormonal agents act at various points in the estrogen–tumor cell interaction.

Estrogen is the principal growth promoter for breast cancer cells that express its receptor (ER positive). The circulating estrogens are estrone and estradiol. There are two fundamental ways to interfere with estrogen's action as a promoter of cancer cell growth: estrogen antagonism and estrogen deprivation. Estrogen antagonism uses drugs that compete with estrogen for its binding to the ER, thereby interrupting the signal for cell proliferation. Estrogen antagonism treatments include selective ER modulators (SERMs), such as tamoxifen, or antiestrogens, such as fulvestrant. Estrogen deprivation reduces circulating levels of estrogen by interfering with estrogen production by the ovaries, adrenal glands, or peripheral tissues. Estrogen deprivation treatments include luteinizing hormone–releasing hormone (LHRH) or gonadotropin-releasing hormone (GnRH) agonists in premenopausal women and antiaromatase agents in postmenopausal women (Table 32–10).

Are the considerations different in premenopausal and postmenopausal women?

In selecting the appropriate hormonal therapy, it is important to understand the differences between premenopausal and postmenopausal patients. In premenopausal women, there are high levels of circulating estrogen. Estrogen in younger women is produced primarily in the ovaries under control by the hypothalamic–pituitary axis. The hypothalamus produces LHRH, which stimulates the anterior pituitary. In premenopausal women, the anterior pituitary then releases follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH and LH control ovarian estrogen production. The most effective hormonal therapies in premenopausal women are therefore either those that compete with estrogen for its receptor (antiestrogens or SERMs) or those that eliminate the hypothalamic–pituitary signal to the ovary for estrogen production (LHRH antagonists). Oophorectomy is also effective.

In postmenopausal women, circulating estrogen levels are significantly lower. The ovaries are not the primary site of estrogen production. Rather, estrogen is synthesized in the adrenal gland and in peripheral tissues. The enzyme aromatase controls the final step in the metabolic conversion from their precursors to estradiol and estrone. Inhibition of the aromatase enzyme results in significantly decreased amounts of estrogen and therefore is an effective hormonal therapy in postmenopausal women. Antiestrogens or SERMs are also useful in postmenopausal patients. Pure antiestrogens may have a role in treatment for both premenopausal and postmenopausal women, but to date they have been used only in postmenopausal patients.

When is hormonal therapy appropriate in the treatment of metastatic breast cancer?

Overall, hormonal therapy may result in significant clinical responses in 30% to 50% of patients in whom the tumor is ER positive. The more strongly expressed the ER and PR, the more likely a clinical response is to be observed. Hormonal therapy should always be considered for patients with ER- or PR-positive tumors. Strong ER or PR expression by the tumor

Table 32–10 Hormonal Therapy in Metastatic Breast Cancer

Agent	Mechanism	Response Rate (%)	References
Tamoxifen	Antiestrogen	16–62	2, 9–11
Toremifene	Antiestrogen	48–68	43–46
Megestrol acetate	Progestin	25–45	47–51
Mifepristone	Antiprogestin	10–18	52, 53
Aminoglutethimide	Aromatase inhibitor	20–40	54, 55
Anastrozole	Aromatase inhibitor	10–20	123–125
Goserelin	LH-RH agonist	30–45	126–128
Leuprolide	LH-RH agonist	44	61, 129
Danazol	Androgen	20	62

LH-RH, luteinizing hormone–releasing hormone.

Table 32–11 Predictors of Response to Chemotherapy and Hormonal Therapy

Chemotherapy	Hormonal Therapy
Estrogen receptor–negative	Estrogen receptor–positive
Progesterone receptor–negative	Progesterone receptor–positive
Visceral and multiple metastatic sites	Bone or soft tissue metastases
Long disease-free interval	Long disease-free interval
High proliferative rate of tumor	Postmenopausal status
Premenopausal status	Prior response to endocrine therapy
Good performance status	

is more common in postmenopausal than in premenopausal women. However, even premenopausal patients may have ER-positive cancers and should be considered candidates for hormonal therapy. Up to one third of women who have tumors of unknown ER status may respond to first-line hormonal therapy. It is reasonable to consider a trial of hormonal treatment in such patients also.

Responses to endocrine therapy are more often seen in soft tissue and bone metastases than in visceral metastases. However, patients with multiple sites of involvement or visceral disease have also benefited from hormonal treatment. Other factors that may predict response to hormonal manipulation include older age, longer disease-free interval (from time of initial diagnosis to development of metastatic disease), and indolent disease progression¹¹ (Table 32–11).

The risk-to-benefit ratio is often more favorable for hormonal therapy than for chemotherapy, making these agents particularly valuable in patients who would not be able to tolerate chemotherapy because of other medical conditions or poor performance status. Hormonal agents may be useful in achieving remissions (partial or complete), maintaining stable disease, and prolonging response following chemotherapy. Often, if a patient has responded to an initial hormonal maneuver and then her cancer progresses, she may respond again to a second- or even third-line hormonal treatment.

ANTIESTROGENS

Tamoxifen

What types of hormonal therapies are in clinical use?

Tamoxifen is a nonsteroidal antiestrogen that was first described in the early 1970s. Its mechanism of action is competitive binding of the ER. The half-life of the drug is 7 days. Response rates in ER-positive tumors range from 16% to 52%.^{5,12,13} Tamoxifen may also exert non-hormone receptor-mediated actions through growth hormone-mediated pathways, protein kinase C pathways, or calmodulin antagonism. These mechanisms of action may account for activity seen in up to 15% of patients with ER-negative tumors.

Clinical trials with tamoxifen have been conducted in both the advanced disease and adjuvant settings. In advanced metastatic disease, several trials were designed to address the question of dose intensity.¹⁴ In a comparative study of 10 mg and 20 mg daily of tamoxifen, the response rates were 51% and 60%, respectively.¹⁴ In a randomized trial of tamoxifen or tamoxifen plus fluoxymesterone, the tamoxifen dosage was increased sequentially, and the fluoxymesterone dose remained constant.¹⁵ The tamoxifen dose reached as high as 100 mg/m² orally twice a day. Higher response rates were seen as the dose of tamoxifen was increased, but there was no overall or disease-free survival benefit. Toxicity also increased with increasing dosages. It has therefore been recommended that 20 mg daily given orally be the standard therapeutic dosage for tamoxifen.

What are the most common side effects of tamoxifen?

The most commonly reported side effects of tamoxifen are hot flashes and vaginal discharge in about 50% and 25% of patients, respectively¹⁶ (Table 32–12). Other toxicities are thromboembolic phenomena, such as phlebitis and thrombosis. These have been observed in about 1% to 2% of cases overall and are rarely associated with death.^{16–18} Ophthalmologic complications include corneal and retinal

Table 32-12 Effects of Tamoxifen

Favorable Effects	Unfavorable Effects
Antitumor activity	Hot flashes
Decreased incidence of new primary breast cancer	Vaginal discharge
Lower serum cholesterol	Increased incidence of thromboembolic phenomena (venous thrombosis)
Lower serum low-density lipoprotein	Ophthalmologic complications (corneal and retinal changes)
Decreased incidence of myocardial infarction	Decreased bone density in premenopausal women
Increased bone density in postmenopausal women	Endometrial proliferation, endometrial carcinoma

changes; however, these are usually associated with higher doses than are conventionally used.¹⁹⁻³¹ In rats, tamoxifen has been shown to cause liver cancer,^{32,33} but this problem has not emerged as a meaningful toxicity in the very large number of women who have received the drug and have been carefully followed over long periods of time.

Because tamoxifen binds the ER, it has some properties that are estrogen agonist as well as estrogen antagonist. As an estrogen antagonist, it might be predicted that tamoxifen would cause loss of bone mineral, thereby increasing the risk for osteoporosis, whereas its estrogen-agonist effects might predict enhanced protection against bone mineral loss. A number of clinical studies have addressed this issue. In two randomized placebo-controlled studies, tamoxifen was shown in postmenopausal women to be associated with an increase in bone mineral density. This is believed related to the estrogenic effect on cancellous bone.^{18,28} In contrast, in premenopausal women, tamoxifen causes a decrease in bone density.

Tamoxifen causes changes in the serum lipid profile that are similar to those seen with estrogen replacement therapy. There may be reductions in total cholesterol and low-density lipoprotein (LDL) and relative increases in high-density lipoprotein (HDL).^{31,33} This effect may contribute to the observation that tamoxifen treatment reduces the risk for mortality from coronary artery disease. Reduced rates of fatal myocardial infarctions have been recorded in patients receiving tamoxifen compared with control patients in randomized studies of postmenopausal women.³⁴

Another proestrogenic effect of tamoxifen is its influence in causing endometrial proliferation and endometrial carcinoma. A possible link between tamoxifen and endometrial cancer was first reported in 1985.³⁵ Since then, between 100 and 150 cases of tamoxifen-associated endometrial carcinoma have been reported.³⁶ Two important randomized studies yielded data relating to this. Both were trials in which patients were receiving adjuvant therapy and were randomized to either tamoxifen or placebo. In one study, 1846 women were randomly assigned to tamoxifen or placebo. A 6.4-fold increased relative risk for endometrial carcinoma was seen in the 931 tamoxifen-treated patients compared with the 915 control patients. The greatest risk was seen in those women taking tamoxifen for longer than 5 years. The dose was 40 mg daily given orally, twice the standard recommended dose.³⁷ In another adjuvant trial, data linking tamoxifen to endometrial cancer were noted.³⁸ In this trial and its accompanying registry, 15 of 1419 women randomized to treatment with tamoxifen, 20 mg given orally four times a day, developed endometrial cancer. (Of note, one of these patients was randomized to this arm but never received tamoxifen.) An

additional 8 of 1220 tamoxifen-treated patients in the registry also developed endometrial carcinoma. This compares with 2 of 1424 patients randomized to placebo. The absolute risk for endometrial cancer was one or two cases per year per 1000 treated women (0.2% per year). The relative risk in the tamoxifen-treated group was 7.5 in this study.³⁸ In all cases, the risk increased with longer duration of therapy. Cumulatively, in all randomized adjuvant studies, the incidence of endometrial carcinoma has been 0.9% for tamoxifen-treated women versus 0.2% for the control groups. Other endometrial abnormalities associated with tamoxifen use include endometrial hyperplasia, proliferation, and polyps.

Tamoxifen remains an important hormonal treatment for premenopausal and postmenopausal women with ER-positive tumors. All women with breast cancer receiving tamoxifen should be encouraged to have routine annual or semiannual gynecologic examinations. Whether ultrasound or endometrial sampling should be routinely recommended requires further study. Careful evaluation of clinical presentations of abnormal vaginal bleeding should be undertaken.^{39,40}

In premenopausal patients, tamoxifen does not always induce menopause or amenorrhea. To the contrary, most menstruating women treated with tamoxifen maintain menses.⁴¹ Tamoxifen has no definite effect on either FSH or LH in premenopausal patients and may even result in elevations of both serum estradiol and estrone levels. Premenopausal patients taking tamoxifen, therefore, continue to ovulate and may get pregnant. Contraception must be advised because the risk for pregnancy may be increased, and the risk to the fetus of exposure to this antiestrogen may be significant. The elevations in circulating native estrogens may theoretically abrogate the efficacy of tamoxifen in this patient population, although this has not been demonstrated clinically.^{41,42} Nonetheless, responses to tamoxifen have been documented in premenopausal patients.⁴³⁻⁴⁵ Tamoxifen remains a therapeutic option for young patients with metastatic breast cancer.

Other Antiestrogens

Tamoxifen has proved to be a highly useful agent in the treatment of metastatic breast cancer. Ideally, novel antiestrogens could take advantage of the beneficial properties of tamoxifen while improving the toxicity profile and providing clinical options. One approach would be the development of antiestrogens that are not cross-resistant with tamoxifen. Another would be to define new agents that do not have the stimulatory effects on the endometrium and do not cause the unpleasant side effects of hot flashes and menopausal symptoms. Finally, enhancing the activity of these agents with

respect to the effects on lipids and bones would be beneficial. A number of other antiestrogen compounds have been developed in response to these objectives.

Toremifene (Fareston), an analogue of tamoxifen, is a more specific and more potent blocker of the ER. At low concentrations toremifene is an estrogen antagonist, but at higher concentrations it is cytolytic, and the effects cannot be reversed by estrogen.⁴⁶ It is also a partial estrogen agonist, causing some stimulation of the uterus in experimental animal models. It was hoped that toremifene would provide equal if not increased clinical efficacy compared with tamoxifen and have fewer side effects. In early phase II studies, toremifene used in doses greater than 60 mg resulted in response rates of 48% to 68%.^{47,48} Three small randomized studies were performed comparing toremifene and tamoxifen. Similar response rates and time to progression were observed in all arms.^{49–51} Subsequent studies showed activity, but not significant benefit, when compared with tamoxifen.^{48–54}

Other antiestrogens, including droloxifene, idoxifene, and TAT-59, are undergoing preclinical and clinical evaluation. To date, none of these agents has been demonstrated to be superior to tamoxifen, and they are not available for general use.⁵⁵

AROMATASE INHIBITION

What is the role of aromatase in estrogen production?

In all women, cholesterol is metabolized through a series of intermediate steps to androstenedione and testosterone. These hormones are in turn converted to estrone and estradiol, respectively. This final conversion to circulating estrogens is catalyzed by the enzyme aromatase. In postmenopausal women, the ovaries are no longer the primary site of estrogen production. They become devoid of aromatase, the enzyme required for the final step in the metabolic conversion of precursors to estrone and estradiol. Aromatase is present in the

adrenal cortex and in peripheral tissues such as skin, fat, muscle, and breast tissue. Estrogen is synthesized in these peripheral sites in postmenopausal women and is present in sufficient levels to stimulate the growth of ER-positive breast cancer cells. Inhibition of peripheral aromatase results in significantly diminished circulating estrogen levels in postmenopausal women. Treatment with aromatase inhibitors results in nearly undetectable serum levels of circulating estrogen.^{56,57} This decrease in estrogen translates into objective antitumor activity in women with ER-positive metastatic breast cancer (Fig. 32–1).

What is the mechanism of aromatase inhibition, and how do aromatase inhibitors work?

Several drugs have been developed to interfere with peripheral estrogen synthesis (Fig. 32–2). There are nonspecific, nonselective aromatase inhibitors and selective aromatase inhibitors. Aminoglutethimide is a nonspecific enzyme inhibitor and is no longer a preferred treatment, although it may have a role in treating a small percentage of patients. Newer generation specific aromatase inhibitors have been developed. Three of these are now in widespread use and are approved for treatment of metastatic breast cancer: anastrozole, letrozole, and exemestane.⁵⁸ Other agents not in use in the United States and Europe include fadrozole, vorozole, and formestane.⁵⁹

Selective aromatase inhibitors only affect the aromatization of androstenedione to estrone and testosterone to estradiol. They do not affect the other metabolic pathways in the adrenal cortex. Unlike aminoglutethimide, this class of agents does not inhibit production of cortisol or aldosterone. This selective activity is specific in reducing estrogen levels, leaving the other adrenal cortical hormone pathways intact. Selective aromatase inhibitors are better tolerated, are more potent, and have a more favorable safety profile than aminoglutethimide.

There are two classes of selective aromatase inhibitors: competitive and noncompetitive. The competitive aromatase

Figure 32-3 Chemical structures of aromatase inhibitors.

inhibitors are steroidal or nonsteroidal compounds that reversibly bind to the active enzyme-binding site of aromatase. Nonsteroidal competitive inhibitors include fadrozole, anastrozole, letrozole, and vorozole (Fig. 32-3). These agents compete with endogenous substrates (androstenedione and testosterone) for the binding site on the aromatase enzyme. This binding is strong but reversible. Because this binding is reversible, the efficacy of these drugs relates to the concentration of aromatase inhibitor versus the natural ligand. Enzyme activity can be recovered if the inhibitor is removed. Anastrozole and letrozole are available in the United States and Europe. Fadrozole is available only in Japan. Vorozole is not in clinical use at this time.

The noncompetitive aromatase inhibitors are by contrast steroidal compounds that bind covalently and irreversibly to the aromatase enzyme itself. Exemestane (see Fig. 32-3) and formestane are steroidal, noncompetitive inhibitors. This

nonreversible binding is sometimes referred to as “suicide” binding because the bound enzyme is never active again. Aromatase activity is restored only when new enzyme is produced by the body. These agents may have some intrinsic, albeit weak, hormonal androgenic effects. Exemestane is available in the United States and Europe, and formestane is available outside of the United States. These compounds are discussed in more detail subsequently.

Although there are differences in the mode of action, both classes of aromatase inhibitors lead to potent suppression of aromatase activity, and both have significant clinical benefit. The enzyme is rapidly regenerated, and it is therefore not clear that either type of inhibition (reversible or irreversible) is clinically superior or relevant. There are currently no clinical data that directly compare these different agents. However, the different modes of action may allow for the possibility of sequential use in selected patients.^{59,60}

How are aromatase inhibitors used in clinical practice?

Both the competitive and noncompetitive aromatase inhibitors are used in treating postmenopausal patients with ER-positive metastatic breast cancer. All of these agents have significant antitumor activity and are well tolerated. Initially, the aromatase inhibitors were tested as second-line therapies, compared with megestrol acetate in women whose disease progressed on tamoxifen. Subsequent clinical trials have demonstrated significant activity as first-line agents for advanced disease. These agents have replaced megestrol acetate in second-line therapy and are challenging tamoxifen in the first-line setting. Anastrozole, letrozole, and exemestane are all oral agents with once-daily uniform dosing and favorable therapeutic index. Their efficacy and ease of administration have led to high levels of physician and patient satisfaction. Quality of life is an important consideration for women with metastatic disease. These agents offer meaningful clinical benefit with few side effects and little intrusion on the activities of daily living. Few clinic visits and little monitoring and management of toxicity are required. They do not cause the more troubling side effects often seen with chemotherapy, such as severe nausea and vomiting, alopecia, neutropenia, or skin rash. Aromatase inhibitors have gained an important place in the management of advanced breast cancer. They epitomize rational, targeted antitumor therapy.

Aminoglutethimide

Aminoglutethimide is an aromatase inhibitor that has been in clinical use for many years. It acts principally at the adrenal gland to block the conversion of cholesterol to pregnenolone. Pregnenolone is the direct precursor of androstenedione. Androstenedione is then converted by aromatase to estrone. Aminoglutethimide blocks aromatase, but it also blocks the activity of the hydroxylase enzymes that lead to the production of cortisol and desoxycortisol by the adrenal gland. Initially, aminoglutethimide was used as a chemical means of adrenalectomy.⁶¹ When used as an anticancer agent, it results in decreased levels of circulating estrogen, but it also results in decreased levels of aldosterone and cortisol. Therefore, hydrocortisone must be administered with aminoglutethimide in order not to render patients cortisol deficient. In addition, careful attention to fluid and electrolyte balance is required.

The standard dosing recommendations for aminoglutethimide are to initiate treatment at 250 mg/day orally and then to escalate to 250 mg orally four times a day. Cortisone replacement should be initiated simultaneously and may be given as hydrocortisone, 10 mg orally four times a day. When both drugs are given together, the toxicity is more manageable. The major side effects of aminoglutethimide are fatigue (in as many as 35% of patients); rash (22%); and nausea, vomiting, and dizziness (15%). The response rates range between 20% and 40%, with a median duration of response of 11 months.^{46,62}

Anastrozole

Anastrozole (Arimidex), an achiral triazole derivative, is a selective, competitive aromatase inhibitor that is approved for use in the treatment of metastatic breast cancer. The half-life of anastrozole is 50 hours; steady state is reached in 7 to 10

days. The drug is predominantly metabolized in the liver. Once-daily dosing is appropriate, and the recommended dosage is 1 mg daily given orally.⁶³

Two well-defined randomized clinical trials have demonstrated the efficacy of anastrozole in postmenopausal women with metastatic breast cancer who showed progression while taking tamoxifen. Most of these patients had tumors that were ER positive, but a small number had unknown or ER-negative status. The patients who were ER negative were required to demonstrate response to tamoxifen. The overall response rates were about 10%, with an additional 25% of patients maintaining stable disease for more than 6 months. A few complete responses were noted. There was no improvement in response when the dose was escalated to 10 mg/day from 1 mg/day. This treatment is well tolerated, with few side effects reported. About 15% of patients had mild nausea, headache, hot flashes, and weakness. About 10% of patients reported pain.^{64,65} Compared with megestrol acetate, anastrozole resulted in a statistically significant survival advantage and had fewer side effects. A major advantage for anastrozole is a decrease in the incidence of peripheral edema, weight gain, and thromboembolic events. Response rates and disease stabilization rates were not statistically different. Based on these data, anastrozole was approved for use in second-line treatment.^{63,66-68}

In the first-line setting, anastrozole has been compared with tamoxifen in two phase III trials, one conducted in North America and the other internationally. In both trials, the anastrozole dose was 1 mg/day orally, and the tamoxifen dose was 20 mg/day orally. Both studies treated postmenopausal patients with metastatic and locally advanced breast cancer that was either ER positive, PR positive, or of unknown receptor status. In both trials, anastrozole was equivalent to tamoxifen in overall response rates. A statistically significant advantage in time to progression and overall clinical benefit was noted for anastrozole in the North American study. Clinical benefit is defined as complete responses plus partial responses plus stable disease for at least 24 weeks. This advantage for anastrozole was not seen in the international study. One explanation may be that the North American study had a higher rate of known ER-positive, PR-positive patients than the international study, in which a higher percentage of patients had tumors with unknown receptor status. It might be hypothesized that more of these patients had ER-negative tumors and therefore might not have benefited as much from hormonal therapy. Anastrozole caused fewer thromboembolic events and less vaginal bleeding than tamoxifen.^{69,70}

Letrozole

Letrozole (Femara) is a potent selective, nonsteroidal, competitive aromatase inhibitor. It is a benzhydryl triazole derivative with a half-life of about 48 hours. Plasma concentrations reach steady state in about 2 to 6 weeks. Clearance is predominantly renal. In postmenopausal women with metastatic breast cancer, daily doses of letrozole from 0.1 to 5 mg cause significant suppression of plasma estrogen levels (75% to 95% suppression). Other hormones, including glucocorticoids, mineralocorticoids, and thyroid hormones, are not clinically affected.⁷¹⁻⁷⁵ The recommended dose is 2.5 mg/day.

In clinical trials, letrozole has also been shown to be active in the treatment of breast cancer. In the second-line setting, studies comparing letrozole to megestrol acetate

demonstrated statistically significant higher response rates for letrozole, longer duration of responses, and longer time to treatment failure. The overall response rate for 2.5 mg/day of letrozole was 24% and that for 40 mg four times per day of megestrol acetate 40 was 16%. The median duration of response was 33 months versus 18 months.^{76,77} Another large study comparing letrozole to megestrol acetate showed that these two agents were equivalent in clinical activity. The toxicity profile of letrozole was much more favorable than that of megestrol acetate.⁷¹ There was less weight gain and fewer cardiovascular events, including thrombophlebitis, myocardial infarction, cerebrovascular accidents, and pulmonary emboli, in the patients treated with the aromatase inhibitor.

Letrozole has also been tested in the first-line metastatic setting. In a large international trial, women with locally advanced, locoregionally recurrent, or metastatic breast cancer were randomly assigned to treatment with either letrozole (2.5 mg/day) or tamoxifen (20 mg/day). In this study, letrozole treatment resulted in statistically significant higher response rates (30% vs. 20%) and greater overall clinical benefit (49% vs. 38%). Time to progression and time to treatment failure were longer in the letrozole group. The rate of adverse events was similar in both treatment arms, although the pattern of toxicity was somewhat different, consistent with observations in other studies.^{78,79}

Fadrozole

Fadrozole is presently available only in Japan and is not used in the United States or Europe. It has also been studied as second-line therapy in postmenopausal women with advanced breast cancer compared with megestrol acetate. In two randomized, double-blind studies, there were no differences in response rates.⁸⁰ There was no definitive difference in median survival time. It was concluded that fadrozole and megestrol acetate were equivalent. The dose of fadrozole is 1 mg twice daily.

In the first-line metastatic setting, fadrozole (1 mg twice daily) has been compared in a phase III randomized study with tamoxifen (20 mg/day orally).⁸¹ This study was not double-blind. Patients were crossed over when there was disease progression or toxicity. No significant differences in response rates were noted. The tamoxifen-treated patients had longer time to treatment failure (8.5 months) compared with the fadrozole-treated patients (6.1 months). Duration of response and overall survival were similar in both treatment arms.⁸¹

Vorzole

Vorzole is also a selective, nonsteroidal aromatase inhibitor. It has been shown to suppress aromatase enzyme activity in doses of 2.5 and 5 mg once daily.^{82,83} In one study of patients with advanced breast cancer failing on tamoxifen, women were randomly assigned to treatment with either vorzole (2.5 mg once daily) or megestrol acetate (40 mg four times daily). This was not a double-blind study. There were no significant differences between the groups in overall response rate, clinical benefit, time to progression, or survival. Vorzole was determined to be equivalent in efficacy to megestrol acetate.⁸⁴ In two other open-label studies of patients with advanced breast cancer, vorzole was compared with aminoglutethimide.^{85,86} In both studies, vorzole was superior to

aminoglutethimide in overall response rates and overall clinical benefit. However, duration of response, time to treatment failure, time to progression, and overall survival were similar for both agents. Therefore, it was concluded that vorzole offered no significant advantages over megestrol acetate or aminoglutethimide. It is no longer in clinical development or clinical use.

Exemestane

Exemestane (Aromasin) is a potent steroidal aromatase inhibitor that partially lacks cross-resistance with nonsteroidal aromatase inhibitors. Exemestane is a derivative of androstenedione and competes with this natural ligand for the binding site on the aromatase enzyme. Its binding with aromatase is irreversible; therefore, this agent is sometimes called a "suicide" inhibitor. The dose of exemestane is 25 mg/day, and the half-life of the drug is 24 hours.

Exemestane was first studied in the third-line setting in patients whose metastatic breast cancer progressed after two endocrine therapies. In these third-line studies, activity was seen with exemestane. Response rates ranged from 7% to 13%, and overall clinical benefit was seen in 24% to 30% of treated patients.^{87,88} These studies demonstrated that women treated with nonsteroidal aromatase inhibitors may still derive benefit from further hormonal therapy with the steroidal agent exemestane. This observation has implications for sequencing of hormonal therapy.

In the second-line setting, exemestane (25 mg/day) was also compared with megestrol acetate (40 mg four times daily). A phase III randomized trial was conducted in women whose advanced breast cancer progressed while taking tamoxifen. Although not statistically significant, objective response rates were slightly better for exemestane than for megestrol acetate (15% and 12.4%, respectively). Statistically significant advantages in median duration of survival, overall survival, time to tumor progression, and time to treatment failure were noted in favor of exemestane.⁸⁹ Exemestane-related toxicity is similar to that of other aromatase inhibitors. All of these agents are better tolerated than megestrol acetate.

Exemestane has not yet been compared with tamoxifen as first-line therapy in a large randomized phase III trial, but phase III studies are ongoing. In a small randomized phase II trial of exemestane versus tamoxifen, there was a suggestion of superiority of exemestane in response rate, overall clinical benefit, and time to progression.⁹⁰ However, it may be reasonable to extrapolate from the experience with the other aromatase inhibitors that this agent will also be at least equivalent to if not superior to tamoxifen.

Formestane

Formestane, like exemestane, is a steroidal, noncompetitive aromatase inhibitor. Formestane suppresses serum estrogen concentrations significantly but is less effective than anastrozole in this regard.⁹¹ Its antiaromatase activity is less consistent than other aromatase inhibitors.^{91,92} It has been tested in second- and third-line therapy and in first-line therapy of advanced breast cancer. Unlike the other aromatase inhibitors, formestane is not available in oral formulation and is administered as an intramuscular injection, 250 mg every 14 days. In comparison with megestrol acetate, formestane showed no

advantages in either time to treatment failure or overall survival. Formestane was considered equivalent to megestrol acetate in efficacy and safety and offered a suitable alternative to progestin for the treatment of women with metastatic breast cancer.^{93,94} Formestane was also tested against tamoxifen in the first-line setting. It was found to be comparable to tamoxifen in efficacy and tolerability, with no statistically significant differences in response rates, duration of response, or survival. Tamoxifen was superior in time to treatment failure (9.7 months vs. 6.5 months) and time to progression (9.7 months vs. 7.0 months)⁹⁵ (Table 32–13).

Should aromatase inhibitors be first-line therapy?

Data from first-line trials comparing aromatase inhibitors to tamoxifen have established the efficacy of anastrozole and letrozole in this setting. Preliminary studies of exemestane in this setting indicate that this agent will also most likely have a role in first-line therapy. Data from large, randomized trials is pending. Compared with tamoxifen, antiaromatase agents result in fewer hot flashes; less vaginal bleeding, discharge, and endometrial abnormalities; and fewer thromboembolic events. However, a serious concern is the increased rate of bone mineral density loss with antiaromatase agents, associated with a higher rate of fractures and increased musculoskeletal complaints.

In summary, several aromatase inhibitors have been tested in the treatment of advanced breast cancer. Arimidex, letrozole, and exemestane have all demonstrated superiority over megestrol acetate in the second-line treatment of postmenopausal women with advanced breast cancer. All three of these agents are available in the United States and Europe and are approved for this indication. These agents have replaced megestrol acetate in the second-line setting. Fadrozole, vorozole, and formestane are active agents but not superior to megestrol acetate. Fadrozole is available in Japan. The other two agents are not in clinical use at this time. The antiaromatase agents are better tolerated than megestrol acetate. Major toxicities include hot flashes (5% to 13%); headache (<10%); and nausea (5% to 30%). There is significantly less weight gain, edema, thromboembolic events, and cardiovascular events compared with megestrol acetate.

Are there differences between the antiaromatase agents?

Although there are some differences in mechanism of action among these agents and therefore theoretically some potential differences in efficacy, clinical data do not demonstrate significant differences in response rates, duration of responses, or time to treatment failure. In vitro data point out some differences in suppression of aromatase activity, levels of aromatase protein, and levels of circulation serum estrogens. However, the clinical significance of these differences is not yet apparent.^{96,97} These observations are drawn from similar but not identically designed studies comparing the single agents either to megestrol acetate or to tamoxifen. A recently completed randomized phase III head-to-head comparison of letrozole and anastrozole in the second-line setting has been published. This study demonstrated superiority of letrozole over anastrozole in objective response rate (19% vs. 12%, respectively). There were, however, no differences in time to progression, overall clinical benefit, duration of response, or overall survival. Adverse events were comparable for both drugs.⁹⁸ A head-to-head comparison of anastrozole and exemestane is ongoing.

How can these agents be used sequentially?

With several agents now available for endocrine therapy of metastatic breast cancer, the optimal sequence of administration is yet to be determined. Several trials have examined different sequences of antiaromatase agents. In one phase II trial, exemestane was administered to postmenopausal women with metastatic breast cancer that had progressed during treatment with a nonsteroidal aromatase inhibitor (including aminoglutethimide, anastrozole, letrozole, and vorozole). Objective responses were seen in 6% of patients, but overall clinical benefit was observed in 24% of patients. Furthermore, the median duration of response on exemestane was 58.4 weeks, and median duration of overall success was 37 weeks—a very meaningful and impressive observation. One fourth of patients derived a significant benefit from exemestane therapy after failing on a nonsteroidal aromatase inhibitor.⁹⁹

Another smaller study examined two different sequences of therapy: (1) exemestane followed by either anastrozole or

letrozole, and (2) letrozole or anastrozole followed by exemestane.¹⁰⁰ In this trial, the clinical benefit rate for patients treated initially with exemestane was 40%, and it was 25% for the other sequence. These results also suggest lack of cross-resistance between the steroidal and nonsteroidal antiaromatase agents. Activity appears to be independent of the sequence of use.

At the present time, there is no standard recommendation regarding the proper sequencing of antiaromatase agents. They may be used in first-line therapy or second-line following tamoxifen; crossover from one type of aromatase inhibitor to another may result in additional benefit.¹⁰¹

What are the side effects and long-term risks of aromatase inhibitors?

In general, the aromatase inhibitors are well tolerated with few side effects. The most common side effects are hot flashes, vaginal dryness, musculoskeletal pain, and headache. These are mild and not dose limiting. Compared with megestrol acetate and tamoxifen, the aromatase inhibitors have significantly lower incidences of hot flashes, vaginal bleeding, vaginal discharge, and thromboembolic phenomena.

Musculoskeletal Effects

Aromatase inhibitors are associated with a higher incidence of musculoskeletal symptoms and fractures.¹⁰²⁻¹⁰⁶ The long-term implications of these skeletal problems, including osteoporosis and fractures, are not fully defined. Bone mineral density depends on estrogen. Tamoxifen has some estrogen agonist action on bone and helps prevent bone demineralization in postmenopausal women.^{107,108} Aromatase inhibitors accelerate bone demineralization and result in a higher fracture rate. Concomitant use of bisphosphonates may help ameliorate this side effect.¹⁰⁹ Exemestane, because of its mild androgenic effect, may have fewer skeletal complications than the other aromatase inhibitors. In an ovariectomized rat model, exemestane was shown to prevent bone loss.¹¹⁰ This effect was also noted in a short-term study of healthy postmenopausal women, in which markers of bone turnover were measured after estrogen suppression.^{111,112}

Cardiovascular Effects

The long-term cardiovascular effects of the antiaromatase agents are not well defined. The estrogen-lowering properties of aromatase inhibitors may result in an unfavorable effect on blood lipids. One study in postmenopausal women taking letrozole for breast cancer showed increases in total serum cholesterol, apolipoprotein B, and serum-to-lipid risk ratios for cardiovascular disease.¹¹³ In another study comparing anastrozole and tamoxifen in the adjuvant setting, tamoxifen was shown to reduce serum levels of total cholesterol but to increase serum triglycerides. Anastrozole had no detrimental impact on the lipid profile, with stable levels of total cholesterol and LDL before and after treatment. Furthermore, anastrozole treatment resulted in beneficial changes in serum triglycerides and HDL.¹¹⁴

Endometrial Effects

The aromatase inhibitors, unlike tamoxifen, do not have a proliferative effect on the endometrium and are not associated with an increased risk for uterine carcinoma.¹¹⁵

What is the role of estrogen-receptor regulators in clinical practice?

Fulvestrant (Faslodex) is the first agent in a new class of ER down-regulators to be available for clinical use. ER down-regulators bind the estrogen receptor in such a manner as to inhibit the activation functions of the receptor and also to disrupt the dimerization and nuclear localization of the ER. This is in contrast to SERMs (such as tamoxifen), which only inhibit but do not completely inactivate the activation functions of the ER. Therefore, fulvestrant theoretically results in more effective blockade of the ER. In animal models, fulvestrant demonstrated longer suppression of breast cancer tumor growth than tamoxifen.¹¹⁶⁻¹¹⁸

In phase II clinical trials in patients with advanced hormone-sensitive breast cancer, fulvestrant showed a significant clinical benefit in 69% of patients. This included complete responses, partial responses, and stable disease.¹¹⁹ When compared with megestrol acetate in a historical, retrospective analysis, fulvestrant treatment was associated with longer median survival (54 months vs. 30 months).¹²⁰ Two randomized phase II trials were conducted to evaluate fulvestrant as second-line therapy. Randomization was between fulvestrant and anastrozole following tamoxifen failure. Preliminary results showed no significant differences between the treatments in time to progression (about 5 months) objective response rates (about 17%), or median duration of clinical benefit (about 11 months). Fulvestrant is a safe and effective agent that is at least as effective as aromatase inhibition in second-line therapy of postmenopausal women with advanced breast cancer. There are no efficacy data for fulvestrant in premenopausal women. It has been approved for use in the United States and Europe.

Fulvestrant is an injectable agent. The recommended dose is 250 mg/month injected intramuscularly. The pharmacokinetics reveal a serum half-life of about 40 days, with plasma levels approaching steady state after three to six doses. Fulvestrant is rapidly cleared by the liver and is metabolized through a number of different possible biotransformation pathways analogous to those of endogenous steroids.¹²¹

How are progestins used in treating metastatic breast cancer?

Progestins, as well as estrogens, have been shown to induce responses in breast cancer. They may interact directly with the PR or may indirectly affect the ER. Progestational agents have been used as second-line hormonal treatment after tamoxifen.¹²²

The most commonly used progestin is megestrol acetate. The standard dose is 40 mg given orally four times a day. Doses of up to 1000 mg/day have been studied, but there is no clearcut benefit in either response rate or overall survival to higher doses, and toxicity increases as the dose increases.^{123,124}

Response rates in patients who have previously responded to tamoxifen range from 25% to 45%.^{125,126} The median duration of response is 7 months.

Toxicities related to megestrol acetate include weight gain, fluid retention, glucose intolerance, increased blood pressure, thromboembolic effects, and mild nausea. Weight gain is a particularly unpleasant side effect. Many women may gain more than 10% of body weight; in some studies, this was a median weight gain of 2 to 5 kg.^{122,125,126} Vaginal bleeding may also be seen, most often when the drug is discontinued, as a result of progestin withdrawal after exposure of the endometrium.

Recently, synthetic antiprogestins that act by binding to the PR have been produced. Mifepristone was originally developed as an abortifacient and was approved for this use in France. The compound has a direct antiproliferative effect on PR-positive breast cancer cells and has been shown to have activity in a number of clinical trials. The doses range from 200 to 400 mg/day in a divided administration schedule. Response rates are about 10% to 18%.^{127,128} The drug is generally well tolerated with mild toxicity. The most common side effects are hot flashes, nausea, and dizziness in up to 18% of patients.

What is the role of LHRH agonists in the treatment of advanced disease?

Another category of agents with efficacy in the hormonal treatment of metastatic breast cancer are the LHRH agonists. These drugs act to suppress ovarian production of estradiol by blocking release of both FSH and LH by the pituitary. Complete endocrine blockade results, and patients become amenorrheic. These agents are most effective in premenopausal patients and have little efficacy in postmenopausal women.^{5,129}

Goserelin (Zoladex) is a commonly used LHRH agonist. It is administered by monthly deep subcutaneous injection. The response rate is about 30% to 45%. Toxicity is notable for hot flashes in 80% of patients and medical menopause in all patients. In postmenopausal ER-positive patients, goserelin did demonstrate a modest degree of activity, suggesting the possibility of other mechanisms of action.^{130,131}

Leuprolide (Lupron) is another LHRH agonist that has been clinically useful. This drug demonstrated a 44% response rate in one study of premenopausal patients.¹³²

Are androgens effective hormonal agents?

Androgens have also been used for the hormonal manipulation of breast cancer. These agents may be considered for therapy after antiestrogens, aromatase inhibitors, progestins, and LHRH agonists. The proposed mechanism of action of the androgens is as antiprogestational agents. Although response rates may approach 20%, the toxicity of the androgens renders them less useful than other hormonal modalities in women with metastatic breast cancer. These agents are virilizing and cause hirsutism, deepening of the voice, hair loss, acne, and increased libido in 60% to 70% of patients. The most commonly used agents in this category are danazol, testosterone, and fluoxymesterone.^{133,134}

SURGERY

What is the role of surgical hormonal manipulation?

There are three surgical interventions that may offer effective hormonal treatment of metastatic breast cancer: (1) oophorectomy, (2) adrenalectomy, and (3) hypophysectomy. Oophorectomy has been used for more than 100 years as a means of inducing responses in premenopausal patients with advanced breast cancer.¹³⁵ Complete ablation of ovarian function may be achieved by surgical removal of the ovaries or by radiation therapy. Surgical oophorectomy has produced response rates of 27% to 37% in premenopausal patients.^{135,136} Adrenalectomy may be useful as an alternative means of hormone ablation. After menopause and cessation of ovarian function, the adrenal gland is the primary source of endogenous estrogen production. Surgical adrenalectomy produces antitumor responses in about 20% to 30% of treated patients. In addition to the risks of surgery and general anesthesia, patients are subjected to the need for permanent steroid replacement therapy.¹³⁷ Hypophysectomy may also result in some antitumor responses. However, this intervention is rarely indicated given the broad range of other hormonal manipulations available.

THERAPEUTIC CONSIDERATIONS

What is the appropriate sequencing of hormonal therapies?

In choosing hormonal therapy, the treating physician should consider efficacy, potential toxicity, ease of administration, and patient compliance. Tamoxifen remains an important first-line hormonal treatment for metastatic disease. It is well tolerated and has excellent response rates and an acceptable toxicity profile. It should be noted that “tamoxifen withdrawal” may in and of itself result in benefit for patients who have responded to tamoxifen and then experience disease progression. The theoretical explanation is that prolonged exposure of the ER to tamoxifen results in an adaptation of the ER to respond to the mild agonist properties of tamoxifen (a SERM) as a growth factor rather than as a growth inhibitor. Therefore, removing this stimulation may result in some tumor regression. The frequency and duration of response to this manipulation are difficult to quantify, but they should be considered in clinical practice.

Aromatase inhibitors have become important in first-line treatment of metastatic hormone-sensitive breast cancer because an increasing number of patients will have received tamoxifen as part of adjuvant therapy. Anastrozole, letrozole, and exemestane have all shown activity, are superior to megestrol acetate, and are well tolerated. There is the theoretical option of sequencing the competitive (anastrozole and letrozole) and noncompetitive (exemestane) antiaromatase agents, with responses seen in either direction of sequence. Fulvestrant is an option for either second- or third-line hormonal therapy.

Additional hormonal manipulations may continue to produce meaningful clinical responses in patients with hormone-sensitive disease that is following a relatively indolent course. The other agents discussed earlier (megestrol acetate, aminoglutethimide, LHRH agonists, androgens, surgery) may be considered for these therapeutic endocrinologic options.

After disease progresses and becomes refractory to all hormonal treatments, chemotherapy should be considered. Hypothetically, hormone refractoriness develops because sensitive tumor cell populations are selectively killed, leaving behind resistant ER- and PR-negative cells. Cytotoxic chemotherapy may produce responses in this setting.

What is tumor flare in response to hormonal treatment?

The syndrome of hormone-induced tumor flare is not uncommonly reported and may be seen in up to 3% of patients started on tamoxifen, estrogens, or other endocrine therapy.^{138,139} Bone pain is the most common complaint and may be associated with diffuse increased uptake on bone scan. Erythema of cutaneous nodules may also develop. Hypercalcemia may occur, especially in patients with multiple osseous metastases. The mechanism of tumor flare is probably a reactive process to hormonal therapy and may represent increased osteoblastic activity in the case of bone metastases.¹⁴⁰ Patients should be forewarned that pain may increase initially during the early weeks of hormonal treatment. Usually, the flare syndrome subsides spontaneously and requires no special intervention. Analgesics should be prescribed for comfort. The serum calcium level should be monitored if there is clinical suspicion of hypercalcemia and then treated appropriately if detected. Tumor flare may actually predict a better outcome to endocrine therapy.¹⁴¹

Is there a role for combining hormonal therapies?

Combination regimens of multiple chemotherapeutic agents have definitely resulted in higher response rates and prolonged survival than have single-agent regimens. It was therefore reasonable to question whether combinations of hormonal agents would also produce better clinical results than single-agent endocrine treatments. Several clinical trials have addressed this question.

Two randomized trials, conducted by the National Cancer Institute (NCI) and the North Central Cancer Treatment Group (NCCTG), compared tamoxifen alone with the combination of tamoxifen plus fluoxymesterone. In both studies, there was a slightly higher response rate for the combination arm, but this was not significantly different, and there was no survival difference. Toxicity was greater for patients receiving the combination and included alopecia, skin changes, and voice changes, which were not noted in the tamoxifen-only group.^{142,143} In trials comparing tamoxifen alone with tamoxifen plus medroxyprogesterone acetate¹⁴³ and tamoxifen alone with tamoxifen plus aminoglutethimide,¹⁴⁴⁻¹⁴⁶ no advantage was seen for the combination in response rate, duration of response, or overall survival. Based on these data, current recommendations are for sequencing single-agent

hormonal treatments rather than combining multiple agents simultaneously.

Is there a role for combining chemotherapy and hormonal therapy?

Theoretically, there may be a rationale for combining chemotherapy and hormonal therapy. Tumors are made up of heterogeneous populations of cells that are hormone dependent and hormone independent. It may be postulated that combinations of both cytotoxic agents and endocrine treatments would result in greater cell kill and increased clinical responses. A series of clinical trials were conducted to study this hypothesis. In summary, although some increases in response rates were noted, no survival benefit was observed, and toxicity was greater. Two randomized studies^{147,148} compared the CMF (cyclophosphamide, methotrexate, and 5-fluorouracil) regimen with the combination of CMF plus tamoxifen. The response rates were 74% and 75% for the combination arms and 51% and 49% for the CMF-alone arms. This increase in response rate, however, did not translate into survival or progression-free survival benefits.^{147,148} Another trial compared treatment with CAF (cyclophosphamide, doxorubicin [Adriamycin], and 5-fluorouracil) with CAF plus tamoxifen. No advantage was seen for the combination over chemotherapy alone.¹⁴⁹ AC (doxorubicin, cyclophosphamide) chemotherapy was compared with AC plus tamoxifen in another study.¹⁵⁰ Again, no survival advantage or difference in response rate was detected. At the present time, there are no data to support combining chemotherapy and hormonal therapy simultaneously in the treatment of metastatic breast cancer.

Hypercalcemia from Metastatic Breast Cancer

Ruth Oratz

How is hypercalcemia defined, and what is its presentation in metastatic breast cancer?

Hypercalcemia is a common metabolic complication of malignancy. It is seen in breast cancer, lung cancer, and gastrointestinal and gynecologic malignancies. Up to one third of breast cancer patients may develop hypercalcemia at some point during the course of the illness. The mean survival following the development of hypercalcemia is 3 months.¹⁻³ Hypercalcemia is defined as elevation of the corrected serum calcium to greater than 10.5 mg/dL. Patients usually become symptomatic at levels greater than 14 mg/dL. The clinical presentation includes symptoms of fatigue, anorexia, constipation, and nausea. At first, these may be subtle and difficult to distinguish from the symptoms of advanced metastatic disease or the treatments used to palliate metastatic disease (chemotherapy and radiation therapy). As the hypercalcemia progresses, patients may become dehydrated, confused, lethargic, or stuporous. Seizures may occur. Slowed cardiac conduction may become evident on the electrocardiogram, and ultimately bradyarrhythmias and complete heart block may ensue. If left untreated, hypercalcemia is potentially fatal.⁴

The differential diagnosis of the clinical presentation of hypercalcemia includes central nervous system (CNS) metastases (particularly carcinomatous meningitis), other metabolic disorders (hyponatremia, hypernatremia, hypoglycemia, hyperglycemia), infection, subdural hematoma, subarachnoid hemorrhage, and oversedation from narcotic analgesics. The differential diagnosis of the finding of elevated serum calcium is primary hyperparathyroidism.

What is the cause of hypercalcemia in patients with metastatic breast cancer?

There are two physiologic explanations for the development of serum hypercalcemia in patients with metastatic breast cancer: (1) increased release of calcium into the serum by osteolytic bone destruction from metastatic lesions and (2) humorally mediated hypercalcemia by parathyroid hormone (PTH)-like factors. In metastatic breast cancer, bone destruction by osteolytic metastases is the more common cause of hypercalcemia. Bone destruction by tumor cells leads to activation of osteoclasts, and this may lead to hypercalcemia.³ In

the absence of significant bone metastases, PTH-like factors secreted by the tumor mediate bone resorption and release of calcium.⁵⁻⁷

How is hypercalcemia treated?

Treatment of hypercalcemia is most effectively managed by reducing the underlying tumor burden. Other therapeutic measures include restoring adequate hydration and instituting antihypercalcemic agents. Vigorous hydration with normal saline helps to lower the serum calcium concentration, correct intravascular volume depletion, and enhance urinary calcium excretion. Hydration alone will not result in long-term remission of hypercalcemia, however.

The bisphosphonates are stable analogues of pyrophosphate and act by inhibiting osteoclast activity. A number of these agents are useful in the clinical setting.⁸⁻¹² Etidronate, pamidronate, and zoledronate are the most commonly used of these drugs and require intravenous infusion. Infusion time varies from 90 minutes to 24 hours depending on the agent. They are extremely effective in lowering serum calcium and are active in more than two thirds of patients. The bisphosphonates are generally well tolerated with few side effects, including fever, mild renal insufficiency, and hypophosphatemia or hyperphosphatemia. Dosing is adjusted for both the serum calcium concentration and serum creatinine. Electrolytes should be carefully monitored during administration. These agents should be considered as first-line therapy for hypercalcemia, particularly when multiple osseous metastases are present.

There are additional data that bisphosphonates may also contribute to bone healing in skeletal metastases and may help alleviate bone pain, reduce the incidence of pathologic fractures, and lower analgesic requirements.^{7,11} The bisphosphonates are therefore indicated in the presence of bone disease as evidenced by radiographic imaging and as prophylactic therapy in women with extraskeletal metastases without evidence of bone metastases.

Gallium nitrate is another useful antihypercalcemic agent. Its mechanism of action is the inhibition of calcium resorption from bone. Randomized double-blind studies have shown that gallium nitrate is more effective in inducing normocalcemia and maintaining duration of response than calcitonin. The median duration of normocalcemia following treatment with gallium nitrate is 7.5 days, whereas it is 1 day after calcitonin treatment. Gallium nitrate is also given by continuous intravenous infusion and is administered over 5 days. It may be nephrotoxic and should not be administered with other nephrotoxic agents such as aminoglycosides.¹³

Calcitonin is normally secreted by the parafollicular cells of the thyroid gland and modulates serum calcium by inhibiting osteoclastic bone resorption and enhancing renal excretion of calcium in the distal tubule.¹⁴ It is therefore useful as a treatment for malignant hypercalcemia. Although calcitonin will induce a hypocalcemic response in up to 80% of treated patients, the duration of response is short, and tachyphylaxis limits its usefulness. Salmon calcitonin is the most potent form of the hormone and is given by subcutaneous injection every 12 hours. Side effects include nausea, vomiting, and allergic reactions.¹⁴

Mithramycin has also been used to treat malignant hypercalcemia in patients with metastatic breast cancer. This anti-neoplastic agent was shown to cause hypocalcemia—possibly by its toxic effects on osteoclasts. It is administered by intravenous bolus and results in lowering of the serum calcium within 3 to 4 days after administration. Its duration of response is unpredictable, and the main side effects are nausea, myelosuppression, and nephrotoxicity. It is not recommended for first-line therapy.¹⁵ Other agents, including glucocorticoids and loop diuretics, have been used in managing malignant hypercalcemia, but their effects are neither significant nor long lasting, and they should be reserved for use as adjunctive agents.¹⁶

V

Brain Metastases from Breast Cancer

*Erik C. Parker and
Patrick J. Kelly*

What is the scope of the problem?

Even though metastases to organs other than the brain are more common, brain metastases are more debilitating and more rapidly fatal if untreated than metastases to other organ systems. Twenty-five percent (or 131,000) of the 527,000 cancer patients expected to die each year in the United States ultimately develop intracranial metastases.¹ Brain metastases from solid tumors are solitary in about 50% to 65% of the cases when the diagnosis is made during life.² In 9% of the patients, the brain metastasis may be the only apparent site of the cancer.³ Statistics indicate that patients treated by operation and irradiation^{4,5} survive longer with a higher quality of life than those who undergo radiation therapy alone.^{4,6–8} Surprisingly, only a small percentage of these patients are ever offered a surgical procedure.

Other than lung cancer, breast cancer is the most common source of metastases to the central nervous system (CNS). In contrast to most other cancers, breast cancer more commonly tends to involve all intracranial and intraspinal compartments—bone, meninges, parenchyma—and can involve two or more compartments simultaneously. Breast cancer metastases are frequently more slowly growing and more sensitive to radiation and chemotherapy than metastatic cancers from other organ systems. The goal of surgical intervention is to decompress brain and spinal cord to preserve neurologic function and provide the time necessary for chemotherapy and radiation therapy to exert their efficacy.

The following paragraphs describe the patterns of breast cancer metastases to the CNS and the symptoms and signs associated with these lesions. The various elements of the diagnostic workup are outlined, and the therapeutic options for CNS metastases from breast cancer are discussed.

CLINICAL PRESENTATIONS

What are the anatomic patterns of central nervous system involvement?

Metastatic tumors in general, and tumors from the breast in particular, reach the CNS primarily by the intravascular route. Tumor cells from the primary site or from a non-CNS metastatic deposit, notably the lung, enter the bloodstream

and are carried to capillary networks in the CNS. These blood-borne metastatic tumor cells are deposited there and continue to grow in this new location. In addition, tumor cells can enter the veins and be carried to other venous plexuses located within the vertebral bodies of the spine or within the spinal canal, where the deposited tumor cells can then grow as an enlarging solid mass.

Blood-borne metastatic tumors can reach and grow in any tissue supplied by blood vessels: bone, meninges (coverings of the brain), and within the substance of the brain itself or within the spinal cord. Breast metastases seem to exploit these opportunities more than most metastatic tumors. In general, breast cancer metastatic to the CNS is classified into three broad categories: (1) intra-axial (within the substance of the brain), (2) extra-axial (outside the substance of the brain), and (3) diffuse cerebrospinal fluid (CSF) dissemination.

What is the presentation of intra-axial lesions?

The most common site of metastatic tumor deposits is at the junction of the gray and white matter of the cerebral hemispheres. Thus, most of these lesions are just beneath the cortical layer on the “surface” of the brain. However, the cortical surface is made up of the hills and valleys of the gyri and convolutions and the sulci and fissures, respectively. A metastatic tumor located at the gray–white junction in the crown of a gyrus can seem very superficial and just beneath the skull on contrast-enhanced CT. In contrast, a metastatic tumor at the gray–white junction at the depths of a deep sulcus or fissure may appear to be 4 to 5 cm below the surface of the brain (Fig. 32–4).

Occasional breast metastatic tumors, however, can be found deep within the substance of the cerebral hemispheres in deep gray matter masses such as the basal ganglia or the thalamus. Metastases can also occur to the choroid plexus, which is located in the lateral, third, and fourth ventricles. Additionally, 15% of metastatic tumors can be found in the cerebellum.

Probably because the brain stem receives 10% of the blood supply to the CNS, about 10% of all metastatic tumors can be found in the brain stem.

What is the presentation of extra-axial metastases?

A small percentage of metastatic breast tumors target the dural covering of the brain or diploic layer of the skull. These usually grow intracranially and compress the surface of the brain (Fig. 32–5). Metastases to the dura or bone at the base of the skull compress the base of the brain or the cranial nerves located there. On occasion, skull metastases can grow outward as well as internally, causing a protrusion or deformity of the skull in this region. In these cases, patients will complain of a firm, enlarging “bump” on the head.

Dural metastases can grow along the surface of the brain and present as an extensive sheet of tumor covering a large portion of the cerebral cortex. More usually, however, the dural-based lesion grows as a defined mass and locally compresses the cerebral cortex. This pattern is similar to the growth pattern of meningiomas, benign primary tumors of the dura, which are not metastatic. Nevertheless, metastatic breast tumors growing in this fashion can occasionally be confused with meningiomas and will not infrequently invade the arachnoid sac and pial covering of the brain to invade and derive blood supply from the brain itself.

Metastatic tumors can grow into the spinal canal directly from a metastatic deposit to some element of the vertebra (usually the vertebral body), narrow the spinal canal, and compress the spinal cord. In addition, metastatic tumor cells carried to the spinal canal through the vertebral venous (Batson’s) plexus and deposited in the epidural fat surrounding the spinal cord can grow, restrict the diameter of the spinal canal, and compress the spinal cord in the absence of any obvious bone involvement.

Figure 32–4 Preoperative (*left*) and postoperative (*right*) contrast-enhanced CT scans showing an intra-axial metastatic tumor from breast in a 48-year-old woman. Note the subcortical location, which appears deep below the surface of the brain but which is, in fact, just beneath the interhemispheric fissure. Note also the significant degree of white matter edema. The postoperative contrast-enhanced CT scan confirms complete excision of the tumor. The white matter edema may require weeks to resolve.

Figure 32-5 A, A preoperative gadolinium-enhanced MRI scan showing a breast carcinoma metastasis to the skull. This has eroded through the dura in the right frontal region and invaded the frontal lobe. Note the edema and mass effect in the brain as evidenced by the compression of the ventricular system. B, Postoperative contrast-enhanced CT scan after resection of the tumor and cranioplasty. Note the absence of mass effect and that the ventricular system has now resumed a normal configuration.

How does metastatic breast cancer disseminate through the cerebrospinal fluid?

Metastatic breast tumor cells can enter the CSF in three major ways. First, tumor cells transmitted to blood vessels that traverse the subarachnoid space or are located in the thin pial surface can rupture through the wall of the vessel and seed the CSF. Second, and more frequently, large or small tumor metastatic deposits can grow through the cortex and pial surface and thus be in contact with the CSF, which bathes the surface of the brain. These cells then break off the main tumor mass and are carried by the CSF to distant locations. Finally, tumor cells can be deposited and grow in tufts of choroid plexus, a structure composed of fine blood vessels that manufactures most of the CSF. Choroid plexus is located within each of the components of the ventricular system (cavities of the brain). Tumor cells can break off the metastatic tumor mass growing from the choroid plexus and seed the CSF.

CSF is produced in the ventricles and exits at the base of the brain. In its flow pattern, CSF then bathes the entire surface of the brain, spinal cord, cranial nerves, and spinal nerves; passes along the base of the brain; and then passes over the surface of the brain to absorption sites, most of which are located along the large dural sinuses (veins). Tumor cells that enter the CSF can survive and be transported to and

deposited on any structure bathed by CSF. Tumor cells transported in this way frequently grow as a sheet of cells within the arachnoid space and cover the brain surface, surrounding and not infrequently invading cranial and spinal nerves.

What is the clinical presentation of carcinomatous meningitis?

Interference with the flow of CSF causing hydrocephalus is the most frequent result of CSF dissemination by most metastatic tumors. Occasionally, metastatic tumor cells disseminated through the CSF and subarachnoid space can induce an inflammatory reaction and produce symptoms similar to bacterial or viral meningitis; this is more commonly associated with metastatic breast cancer than with other solid metastatic tumors.

How do metastatic brain tumors cause symptoms?

In general, metastatic tumors produce symptoms in three ways: (1) by impairing the function of, or destroying, brain or cranial nerve tissue; (2) by producing seizures; and (3) by causing increased intracranial pressure (Table 32-14).

Table 32-14 Signs and Symptoms of Brain Metastases

Seizure
Visual field deficit

Impaired Function or Destruction of Brain or Cranial Nerve Tissue

Breast tumors metastatic to the substance of the brain are growing masses that compress adjacent normal tissue. In addition, many of these tumors parasitize the blood supply to the brain and thus reduce the supply of oxygen and nutrients to brain tissue. Finally, some tumors cause chemical abnormalities around them that poison the surrounding normal cells and cause dysfunction of the neurons and swelling. These factors, alone or in combination, impair or inhibit the function of that part of the brain.

The symptoms that result depend on what part of the brain is involved. A metastatic tumor in the motor strip will cause weakness of the lower part of the face, arm, or leg, singly or severally, on the opposite side of the body. A tumor in the occipital lobe may cause loss of some or all of the visual field on the side opposite the tumor. Destruction of large parts of the dominant frontal lobe (the left frontal lobe in most persons) or of the connections between the frontal lobes may cause personality changes.

However, there are parts of the brain that can be destroyed with no noticeable change in the patient's neurologic function or behavior. Large regions of the right frontal lobe and some of the right temporal lobe can be destroyed without noticeable effects. Metastatic tumors in these "silent" regions produce symptoms by the mechanisms listed below.

At the base of the skull, metastatic tumors can compress cranial nerves such as the optic nerves and chiasm, the fifth cranial nerve (which transmits sensation from the face), or the lower cranial nerves (which control important functions such as swallowing).

Seizures

Tumors in functional brain regions can cause electrical dysfunction (irritation). This is due to chemical abnormalities produced by the tumor in the local environment of the neuronal elements. In addition, loss of oxygen and nutrients owing to the tumor's parasitizing the blood supply of the neurons can cause cortical irritation. Finally, destruction of inhibitory neurons by the tumor can "disinhibit" other neurons, allowing them to discharge with a higher frequency than usual. Any or all of these factors can result in abnormal brain electrical phenomena that clinically manifest as seizures (also called "fits," convulsions, or epilepsy). The actual clinical presentation of the seizures frequently depends on the region of the brain involved. Seizures can be focal or generalized.

Focal Seizures. Focal seizures are not associated with a loss of consciousness and can be sensory or motor. For example, metastatic tumors in or near the motor strip can produce focal motor seizures, which present as twitching of the face, arm, or leg, or all three. Tumors in the sensory areas of the

brain can cause sensory seizures: episodic paresthesia (pins-and-needles sensations) on the opposite side of the body. Lesions located in the occipital regions in or near the visual areas can cause abnormal visual phenomena—formed or nonformed hallucinations such as flashing lights in the opposite (contralateral) visual field.

Generalized Seizures

Partial Complex Seizures. These are usually associated with lesions of the deep temporal area (mesial or hippocampal regions) or base (orbital surface) of the frontal lobe. Brief episodes in which the patient loses consciousness and will not respond to those around him or her (absence attacks) and episodes in which the patient in this brief unresponsive period exhibits a programmed and stereotypic movement (automatism) are referred to as *partial complex seizures*. In addition, an olfactory hallucination in which the patient experiences an unpleasant odor (frequently the smell of burning rubber) is called an *uncinate fit* and is characteristic of mesial temporal or basal frontal lesions.

Grand Mal Seizures. Grand mal seizures can occur with any intracranial tumor in any location. These generalized seizures are familiar to most medical practitioners and nonmedical people alike. In these spells, the patient loses consciousness, extends head, arms, and legs (tonic phase), and then "shakes" (clonic phase). The jaw muscles clamp shut, the tongue or the inside of the mouth is frequently bitten, and the patient's airway can become compromised. Patients may also lose bladder control. Occasionally, the seizure may be preceded by focal components, such as twitching of the face or arm or a loss of the ability to speak, before the electrical disturbance spreads to both sides of the brain to produce the grand mal seizure.

Increased Intracranial Pressure

The inside of the skull can be considered a nonexpandable closed box. There is room within for only the brain, its blood supply, and spinal fluid. The mass of a metastatic tumor within the cranial cavity takes up space. In addition, swelling of brain tissue around the tumor adds to the mass effect. As the mass grows, blood vessels and spinal fluid spaces can be compressed, which accommodates the growing mass for a time. The brain can re-form around the growing mass as water between the cells of the brain and within the cells is redistributed. Finally, no further shifts of blood or water are possible, and pressure inside the skull begins to increase.

There is another mechanism for increased intracranial pressure: hydrocephalus. As explained earlier, most of the CSF is produced by the choroid plexus located within each of the ventricles of the brain. It flows to the base of the brain and then around the surface of the brain, where it is finally absorbed. All elements of the ventricular system are normally in communication. Fluid produced in the two lateral ventricles passes to the midline third ventricle by means of the foramina of Monro. This fluid, as well as fluid produced by the choroid plexus of the third ventricle, passes through the narrow aqueduct of Sylvius to the fourth ventricle, located between the brain stem and the cerebellum, and from there to the basilar cisterns around the brain stem (cisterna magna and cerebellopontine angle cisterns).

A tumor mass that compresses any component of this fluid pathway can cause the buildup of fluid upstream from that

obstruction. The ventricles of the brain enlarge, and this is called *obstructive hydrocephalus*. Obstructive hydrocephalus is most frequently noted in patients with metastatic lesions in the posterior fossa, brain stem, or cerebellum. Here the tumor mass and associated swelling (edema) deform and ultimately obliterate the fourth ventricle, the aqueduct of Sylvius, or both.

Hydrocephalus can also result from subarachnoid metastases that obstruct the flow of spinal fluid along the base or surface of the brain (communicating hydrocephalus). Obstructive and communicating hydrocephalus results in retention of an increased amount of CSF inside the “closed box” of the intracranial cavity. This results in increased intracranial pressure.

As increased intracranial pressure becomes symptomatic, patients initially complain of a dull headache. Characteristically, the headache occurs in the morning but persists throughout the day and night. It can awaken the patient from sleep; not infrequently it is associated with nausea and, in some instances, vomiting. As pressure increases, blood delivery to the brain decreases, and this results in nonspecific symptoms such as mental sluggishness and recent memory dysfunction.

The intracranial cavity is divided into three separate compartments by membranes formed by the dura mater. These include the supratentorial and infratentorial compartments separated from each other by the tentorium, and the right and left supratentorial compartments separated by the falx cerebri. The cerebral hemispheres occupy the right and left supratentorial compartments; the brain stem and cerebellum occupy the infratentorial compartment (posterior fossa). As intracranial pressure continues to increase, part of the brain itself is shifted into another compartment of the intracranial cavity. This is called *herniation*, which causes its own set of symptoms and signs.

What are the signs and symptoms of herniation?

In transfalcine herniation, a large mass in one hemisphere pushes the medial aspect of that hemisphere across the falx into the other supratentorial compartment. When this happens, patients can become confused, are occasionally disoriented, and lose control of bowel and bladder function.

Herniation of the medial temporal lobe across the tentorium into the infratentorial space results in compression of the midbrain—a component of the brain stem that controls consciousness and eye movements and transmits motor control from the cerebral hemispheres to the lower brain stem, spinal cord, and eventually the spinal nerves that activate the muscles of the face, arms, and legs. Compression of the midbrain results in papillary abnormalities, then paralysis and abnormal motor reflexes (decerebrate and decorticate posturing), and finally coma. The prognosis is very poor once this scenario has occurred, and the probability of useful survival is low, despite aggressive therapy delivered at this late stage.

The goal of our efforts in the management of CNS metastases from breast cancer is early diagnosis and treatment to prevent neurologic progression due to tumor mass effect and increased intracranial pressure. Treatment must be instituted long before herniation becomes a possibility.

How do calvarial metastases present?

These lesions frequently deform the skull as the inner and outer tables of the calvarium are pushed apart by the expanding mass in the diploë. The protruding outer table can result in a cosmetic deformity if located in front of the hairline or in a painful hard or firm protrusion of the skull beneath the scalp when located behind the hairline. Breast metastatic tumors that break through the inner table of the skull and grow intracranially frequently invade the dura and cross the arachnoid space to compress and usually invade the underlying brain tissue. In this case, and depending on the anatomic location of the lesion, patients can experience seizures or neurologic deficit similar to the situation noted with intra-axial tumor masses. A large mass growing from the skull intracranially will eventually raise intracranial pressure.

How does breast cancer affect the spinal cord?

Patients with metastatic lesions that compress the spinal cord usually present with localized pain that corresponds to the level of cord compression. Percussion over this area will evoke or worsen the pain. Patients with bone involvement may complain of pain for many weeks before the onset of neurologic deficit as a result of spinal cord compression.

As the spinal cord compression continues, neurologic deficit progresses over the next few hours or days. The patient complains of numbness of the body and legs below the region of cord compression and difficulty walking, due at first to a proprioceptive gait disturbance and then to weakness. Eventually, the weakness in the legs (for thoracic lesions) and arms and legs (for upper and mid-cervical regions) becomes noticeable and progresses to complete flaccid paralysis in hours or days if not treated. Not infrequently, when the expanding mass is located lateral to the spinal cord, the sensory loss to pain and temperature is noted on one side of the body, and the muscle weakness is noted on the opposite side. If untreated, the sensory and motor deficit will progress to bilateral involvement. Bowel and bladder control is lost as the neurologic deficit progresses.

Cauda equina (lumbar and sacral) metastases produce back pain and occasionally radicular pain in the legs. The neurologic deficit may involve only one nerve root initially but then progresses over the next several days to involve several nerve roots and then the entire cauda equina. Neurologic examination will reveal percussion tenderness, flaccid paraplegia, areflexia, and sensory loss below the level of the lesion involving the sacral dermatomes.

How does breast cancer affect the pituitary gland?

Metastases to the pituitary gland are not common in most cancers. However, in series of breast cancer patients, pituitary metastases can account for as much as 20% of all intracranial metastases.⁸ A growing mass lesion in the pituitary fossa can cause endocrine dysfunction, headaches, and ultimately visual field impairment as the lesion enlarges.

What is carcinomatous meningitis?

The symptoms of carcinomatous meningitis are similar to those of any meningitis: headache, photophobia, stiff neck, and low-grade fever. Elevation of the supine patient's legs off the bed will frequently result in pain in the back and in a sciotic distribution. Sometimes, the pain is referred also to the occipital region. These patients are frequently lethargic and occasionally confused. Elevation of intracranial pressure can also be noted if the meningeal process impedes the flow of CSF.

How is central nervous system metastasis diagnosed?

A history of breast cancer months or even several years in the past should raise suspicion of a CNS metastasis in a patient presenting with headaches, diplopia, sensory abnormalities, focal weakness, neck or back pain, or seizures. In fact, the existence of any of these symptoms should prompt a CT or magnetic resonance imaging (MRI) examination of the head or spine, depending on the symptoms. The clinician should record the histologic subtype of the breast tumor and question the patient on how it was found as well as how and how soon it was treated. Was the tumor treated by biopsy and radiation, chemotherapy, or both; by lumpectomy; or by radical mastectomy? Were any lymph nodes positive for tumor? The patient should be questioned about symptoms that could reflect pulmonary, liver, or bone metastases. A nonaggressively treated primary tumor or the presence of positive nodes or distant metastases increases the likelihood of future CNS metastases. The clinician should carefully record the duration of the neurologic symptoms and their mode of onset. The clinical manifestations of seizures, especially focality of onset, can provide important information regarding the anatomic localization of the CNS lesion.

A general physical examination is important to investigating the presence of non-CNS disease, which may increase suspicion of the existence of CNS metastases, and assessing the risk-to-benefit ratio of any therapeutic interventions for CNS metastases, if found. Each breast should be examined for recurrent disease or metastases to the other breast. Auscultation of the lungs may reveal evidence of pulmonary metastases.

DIAGNOSTIC MODALITIES

What are the roles of computed tomography and magnetic resonance imaging?

The introduction of CT in the early 1970s revolutionized the evaluation of cancer patients for the existence of CNS metastatic disease. With CT, clinicians could actually see metastatic tumors directly instead of having to infer their presence and location indirectly from intracranial shifts of blood vessels and parts of the ventricular system from their normal positions on cerebral angiography and ventriculography. Additionally, CT scanning allowed the discovery of

tumors before they became symptomatic. Because of these advantages, CT rapidly became the standard diagnostic procedure for the detection and localization of metastases.

Metastatic tumors produce swelling (edema) of the surrounding brain tissue. This is easily detected on CT because it is hypodense in comparison with normal brain tissue. More importantly, metastatic tumor masses in general, and breast cancer metastatic lesions in particular, accept contrast on the contrast-enhanced CT series and appear as a white circumscribed mass with hypodense (edematous) brain tissue surrounding the lesion. In addition, multiple metastatic lesions can be noted. This is important information if surgery is a consideration.

CT scanning also provides information on the degree of the mass effect produced by the lesion and surrounding edema. The midline of the brain, some of the more prominent sulci and fissures, and the ventricular system are usually seen very well on CT scanning. Enlargement of the ventricular system owing to hydrocephalus is easily detected.

MRI provides many of the same benefits of CT scanning while offering several advantages. MRI provides exquisite anatomic detail of the normal structures of the brain and spinal cord. It is also much more sensitive than CT and has become the imaging modality of choice in the detection of small intracranial metastases. These lesions are characterized by edema (prolonged signal on T2-weighted images) and by contrast enhancement, which shows the metastatic tumor deposit. The contrast agent used with MRI, gadolinium, has a much lower potential for toxicity than traditional contrast agents used during CT scanning. Recent studies have established the utility of triple-dose gadolinium administration in demonstrating smaller metastatic lesions, especially in patients with a single known metastasis or equivocal findings on previous MRI examination.^{9,10} MRI also provides a safe, effective, and noninvasive method of evaluating the spinal cord when spinal metastases are suspected.

MRI can be used to provide additional diagnostic information about the characteristics of a lesion. Radiation-induced necrosis, an infrequent complication of brain irradiation, can be indistinguishable from tumor progression using conventional CT and MRI techniques. When the clinical situation warrants further investigation, magnetic resonance spectroscopy may be useful. This technique, which provides information on the relative concentration of various compounds in a given volume of tissue, can be used to differentiate between tumor progression and radiation necrosis as well as other lesions of similar appearance such as cerebral abscess and demyelinating disease.^{11,12}

An area in which CT scanning remains the most useful modality is imaging of bony structures because it provides exquisite bone detail. This is an important consideration in the evaluation of metastatic breast cancer, which can metastasize to the skull. The clinician should request bone windows, which allow improved visualization of the bony structures including the skull base and calvarium. In addition, CT is also useful in the evaluation of spinal metastases, especially when the vertebrae are involved.

With MRI's ever-increasing availability and its inherent advantages, it has become the screening tool of choice for evaluating the CNS in patients with metastatic cancer (Fig. 32-6). CT scanning remains useful, however, because it is better tolerated by many patients, provides superior imaging of

Figure 32-6. A, A preoperative gadolinium-enhanced MRI scan reveals multiple ring-enhancing lesions. The largest of these lesions is located in the left parietal lobe and is exerting mass effect on the ventricular system and surrounding brain parenchyma. Multiple smaller metastases are present and involve both hemispheres. The location of these lesions at the gray-white junction is typical of metastatic lesions. B, A postoperative MRI reveals complete excision of the left parietal lesion with resolution of mass effect. The remaining lesions will be treated with radiation therapy.

bony structures, and is quick and inexpensive. Additionally, it may be used with patients for whom MRI is contraindicated because of the presence of a pacemaker or some other implanted medical device.

When is lumbar puncture useful in diagnosing central nervous system metastases?

Examination of spinal fluid obtained by lumbar puncture, C1-2 puncture, or cisterna magna puncture is necessary to establish the presence of carcinomatous meningitis and in situations in which there is suspicion of tumor cell seeding of the CSF. Lumbar puncture should not be performed without CT or MRI to exclude an intracranial mass lesion. Lumbar puncture should not be done if there is evidence of increased intracranial pressure, a midline shift on CT or MRI, or evidence of other significant mass effect.

THERAPEUTIC OPTIONS

When is surgery indicated?

The decision to remove an intracranial metastasis depends on a careful analysis of the risks and benefits of the surgery.

Obviously, no surgeon is ever going to cure cancer by removing a distant metastasis. However, as a baseline, it is good to consider that the mean survival of a patient with metastatic disease to the CNS treated without surgery is about 3 months. Removing metastatic tumor masses from the brain prolongs survival. The degree of prolongation will depend on many factors, including the biology of the original tumor, the presence of extra-CNS metastases, and the age and general medical condition of the patient.

There is a great deal of benefit in resecting a solitary brain metastasis in a patient with a past history of breast cancer, no other evidence of disease, and a long tumor-free interval between the initial primary and the discovery of the CNS metastasis. In contrast, there is only modest benefit in resecting a metastasis in a patient recently diagnosed with breast cancer with multiple metastases in other organ systems.

Surgical risk relates to the anatomic location of the metastatic tumor and its depth below the surface of the brain. A metastasis can be removed from the nondominant frontal lobe with very low risk. The risk of removing a lesion in the brain stem is high and usually unacceptable. In the past, clinicians were pessimistic about the benefit derived from the surgical resection of a solitary metastatic brain tumor because the benefit of resection did not outweigh the risk of classic procedures to resect them. However, improvements in surgical techniques and perioperative management have resulted in significant reductions in surgical mortality and morbidity.^{1,5,6,13,14} It has for some time been generally agreed

that surgical excision is indicated in a medically stable patient harboring a “surgically accessible” solitary intracranial metastasis.^{14,15} Randomized prospective trials have demonstrated significantly improved length of survival for patients undergoing resection of single metastases followed by whole-brain irradiation as compared with those receiving radiation alone. One such study demonstrated an increase in length of survival from 15 to 40 weeks and duration of functional independence from 8 to 38 weeks.¹⁶ Another trial had similar findings, with survival increased from 24 to 40 weeks and independence from 14 to 30 weeks.¹⁷

Aggressive surgical treatment is becoming more accepted in the setting of multiple or recurrent metastatic brain tumors. A retrospective study compared the outcomes of matched patients with either single or multiple brain metastases. Patients with multiple lesions undergoing resection of all lesions displayed results similar to those undergoing resection of a solitary metastasis. Those with multiple tumors who underwent surgery in which all known lesions were not resected, however, had a significantly shorter median postoperative survival and lower rates of symptomatic improvement. Operative morbidity and mortality were not significantly different among the three groups. These findings led the authors of this study to conclude that patients with limited systemic disease and more than one accessible metastatic brain tumor should be considered for surgical resection of all such lesions.¹⁸ Similarly, reoperation for recurrent intracranial metastases is becoming more frequently advocated. It has been demonstrated that in younger patients with controlled systemic disease and a high functional status, repeat resection of these lesions can improve outcome. When properly selected, patients undergoing second and even third operations may enjoy prolonged survival and improved quality of life.¹⁹

Many metastatic lesions lie close to the cortical surface, are macroscopically circumscribed, and can be resected by conventional craniotomy with acceptable levels of mortality and morbidity. Some neurosurgeons recommend not operating on more deeply seated tumors, however, especially in the dominant hemisphere, where the risk is higher and the benefit is not as clear.⁵ The use of stereotaxis is often of benefit in cases involving surgically complex tumor locations.

What is nonstereotactic craniotomy?

Traditional approaches to the removal of any brain lesion (including metastatic tumors) involve opening the scalp, skull, and dural coverings of the brain. These techniques have evolved over the past 100 years. With the exception of stereotactic guidance and the operating microscope, they have changed little in the past 50 years. Classic craniotomy still has a place in the resection of skull- and dural-based lesions and skull-based metastases. There is rarely a problem in finding these superficial lesions and their borders. In addition, these lesions must be dissected away from invaded brain tissue in many cases, and adequate exposure is necessary.

Classic craniotomy for intra-axial metastatic tumors employed large scalp flaps and craniotomy openings that exposed much normal brain tissue to unnecessary injury. Localization methods for metastatic tumors were qualitative and imprecise, and in some cases surgeons could actually miss

the metastatic tumor—especially when the lesions were small or deep below the surface of the brain. The incorporation of surgical ultrasonographic imaging increased the number of cases in which a surgeon could locate and completely resect the lesion.

What is stereotactic resection?

With the advent of CT and MRI, surgeons began rethinking their surgical approaches to common intracranial tumors. These computer-based imaging modalities provide precise information on the anatomic localization and extent of intracranial tumors. In addition, CT and MRI provide a three-dimensionally-precise database that can be transported to a stereotactically defined surgical field. Imaging-based stereotaxis improves the accuracy with which CT and MRI information can be used in surgical planning for the removal of metastatic tumors and also makes minimally invasive resection techniques for metastatic tumors possible.^{15,20}

During the past 2 decades, we have developed and refined the technology of computer-assisted volumetric stereotactic removal of a wide variety of intra-axial lesions, including metastatic tumors.^{15,20–22} The technique has proved especially useful in the safe resection of metastatic tumors from important subcortical areas. The technique provides a safe, minimally invasive method of removing solitary metastatic tumors. We are now evaluating the benefit of removing two or more lesions in selected cases.

When using frame-based stereotaxis, computer simulation of the operation is carried out from a preoperative database comprising stereotactic CT, MRI, and digital angiography (DA). This information is acquired with the patient's head held in a CT- or MRI-compatible stereotactic head frame, placed under local anesthesia. The tumor volume is reconstructed from the imaging studies.^{15,23} The surgeon chooses a surgical approach, and the surgical procedure is simulated on a computer display terminal.

The actual procedure is done under general anesthesia. The stereotactic head frame is reapplied, and the surgery is done through a 2- to 3-inch incision and a circular bone opening. A computer display shows the relationship of the CT- and MRI-defined tumor volume to the three-dimensionally-defined surgical field. These computer-generated images allow the surgeon to find not only the tumor but also the interface between tumor and surrounding brain tissue (Fig. 32–7). Thus, the surgical approach is preplanned, is direct, and exposes no more brain tissue than absolutely necessary to remove the tumor.

A more recently developed technology, which has become very widespread over the past few years, is frameless stereotaxis. This system, although less precise and therefore less well suited to deeply located tumors, does not require the placement of a head frame during the data acquisition phase. Instead, fiducials, markers that are visible on CT and MRI scans, are placed on the patient's head before obtaining preoperative imaging studies. These fiducials remain in place until the time of the operation. When the patient is under general anesthesia and the head has been secured in place, the fiducials are used to register the patient's current position in space relative to some fixed reference point. A computer that has been loaded with the CT or MRI information then

Figure 32-7. Frame-based, computer-assisted stereotactic craniotomy with volumetric excision of a metastatic tumor. The reformatted CT- and MRI-defined limits of the tumor are presented to the surgeon on a computer display screen as well as into a heads-up display unit on the operating microscope (A). The surgeon exposes the tumor by a stereotactically placed circular bone opening. The computer display helps the surgeon know where the tumor stops and normal brain tissue begins. (From Kelly PJ, Kall BA, Goerss SJ, et al. Results of computer-assisted stereotactic laser resection of deep-seated intracranial lesions. *Mayo Clin Proc* 1986;61: 20–27.)

Figure 32-8. An example of use of a frameless stereotactic system. In this case, the Cygnus system (Compass International Inc., Rochester, MN) is being used in planning the resection of a metastatic tumor. Following registration of the system, the location of a pointer placed into the operative field is displayed in real time on the computer screen. This location is indicated by cross-hairs, which are superimposed over sagittal, coronal, and axial images as well as a three-dimensional reconstruction of the MRI data. Although not as precise as frame-based stereotaxis, this allows very accurate placement of scalp and bone flaps and can be used during the operation to aid in tumor resection and maintain spatial orientation.

correlates the three-dimensional imaging data to the location and orientation of the patient's head. The system can then be used intraoperatively to view the location of a pointer or some other specialized surgical instrument on a three-dimensional representation of the imaging data. Although this type of stereotaxis is less well suited to cases in which a high degree of precision is required, it can be very useful for placing a skin incision and underlying bone flap for routine tumor resections (Fig. 32-8). This type of approach also has some advantages over frame-based stereotaxis. It avoids the need for a second procedure (placement of the head frame before obtaining the imaging studies), is better tolerated by most

patients, and is cost-effective because the fiducials can be placed and studies can be obtained before the patient is admitted, allowing admission on the morning of surgery. Each case must be evaluated independently in order to select the most appropriate form of stereotaxis (if any) for the given resection.

What is stereotactic radiosurgery?

Stereotactic radiosurgery is based on many beams of radiation intersecting at a precise point. At this point, the radiation dose

is additive so that the radiation delivered to the location is very high. The patient's head, held in a stereotactic frame, is positioned so that a target, often a metastatic tumor, is in the center of all of these intersecting beams of radiation; the tumor receives a lethal dose of radiation, while the surrounding brain tissue receives a much smaller dose of radiation. Typically, stereotactic radiosurgery is done in a single treatment session. If the therapy is effective, the tumor stops growing, and its cells die within several weeks or months. The dead tissue is eventually cleared from the brain tissue after an inflammatory reaction.

There are two general methods of delivering stereotactic radiosurgery: the Leksell gamma knife and a stereotactic linear accelerator. With the gamma knife, radiation from cobalt 201 sources arranged in a spherical pattern is collimated into narrow beams directed toward the center of the sphere²⁴ (Fig. 32–9). In stereotactic linear accelerator radiosurgery, a radiation generator tube is rotated around the patient's head, directing the constant beam toward a present center (isocenter) point.²⁵ Both of these modalities use gamma radiation. The gamma knife beams project toward the center of a sphere; the linear accelerator directs the beam toward a central target as the linear accelerator tube rotates.

There is an important appeal in using stereotactic radiosurgery: it is totally noninvasive. There is no skin incision or bone opening and no brain manipulation, and the procedure can be accomplished during a 1-day hospitalization. Indeed, many centers offer this form of treatment on an outpatient basis. These factors make radiosurgery a cost-effective alternative for the treatment of brain metastases.²⁶

Radiosurgery is appropriate for small (<3 cm in diameter) tumors. Larger tumors and those associated with significant swelling around the tumor are not good candidates for stereotactic radiosurgery because more swelling of the surrounding brain parenchyma will occur after radiosurgery in the weeks

Figure 32–9. In this photograph, a patient is preparing to undergo gamma knife radiosurgery. The patient has been placed in a head frame that has then been attached to the collimator. This collimator directs 201 separate beams of radiation toward the target. This target has been defined during the planning stage of the procedure based on imaging data (usually MRI) obtained with the head frame in place. (Photo courtesy of Elekta, Stockholm, Sweden.)

and months following treatment. This could result in increased intracranial pressure and mass effect, neurologic deficit, and risk for herniation.

Stereotactic radiosurgery may be useful when other forms of therapy are not appropriate or are of little benefit. An example is a metastatic tumor located in the brain stem. Such tumors are usually associated with a very poor prognosis. In these cases, surgical resection may be contraindicated because of excessive risk for neurologic deficit, and whole-brain radiation therapy is of questionable benefit. Radiosurgery has been shown to be an effective palliative treatment option for this group, with survival times approaching those of patients with metastatic tumors in other parts of the brain.²⁷ Radiosurgery may also be used to treat patients harboring multiple tumors with good results.²⁸

When is radiation therapy indicated?

Even though an apparent gross total excision of metastatic tumor may have been achieved, local postoperative external-beam radiation therapy is usually recommended. This is because microscopic residual tumor may remain following surgical resection and will continue to grow if not treated. Whole-brain irradiation is more controversial. This practice is based on the assumption that other microscopic metastatic tumors, not yet visualized on CT or MRI, may exist throughout the brain. In cases in which surgery or radiosurgery is not an option and whole-brain radiation therapy is used as the primary treatment modality, its efficacy is well documented; median survival time is increased to 4 months, as compared with 1 month for patients treated with steroids alone.²⁹

The utility of whole-brain radiation following successful removal of a single brain metastasis is less certain. A prospective trial examined patients who had undergone complete surgical resection of a solitary brain metastasis. Patients were randomized into groups receiving postoperative whole-brain radiotherapy and those receiving no further treatment. Not surprisingly, the patients treated with radiation had lower rates of tumor recurrence or appearance of new metastases. Likewise, they were less likely to die of neurologic causes than those who were not irradiated. However, when survival and length of functional independence were compared, there was no significant difference between the two groups.³⁰ Similarly, adjuvant whole-brain radiation conferred no improvement in length of survival in patients treated with stereotactic radiosurgery.²⁸

Whole-brain radiation is not without complications; most notably, it has been found to be associated with a significant risk for the development of a progressive dementia.³¹ Because of concerns about cognitive decline, there is a growing trend toward avoiding postoperative radiation in patients with completely resected tumors, particularly the elderly. With the widespread availability of high-resolution MRI, which is very sensitive for metastatic disease, the use of routine postoperative radiation is now being called into question, and there is ongoing investigation into its role in the treatment of CNS metastatic cancer.

When is intrathecal chemotherapy indicated?

Intrathecal chemotherapy is considered when there has been documented CSF seeding and in the treatment of

carcinomatous meningitis. The chemotherapeutic agents can be administered by repeated lumbar punctures. A more tolerable alternative to many lumbar punctures, however, is the insertion of an Ommaya reservoir. The Ommaya reservoir consists of a medical-grade plastic bubble, which sits permanently under the scalp, connected to a catheter directed through a small hole in the skull into the lateral ventricle of the brain. The bubble (reservoir) may be tapped through the scalp with a thin needle. The chemotherapeutic agent is then instilled into the reservoir and on into the ventricular fluid, which then bathes the entire brain and spinal cord surface with the chemotherapeutic agent as the CSF circulates.

What are the expected results of treatment?

Average survival following resection of a solitary brain metastasis followed by radiation therapy is about 1 year when all types of cancer are considered as a group and for breast cancer in general. Postoperative mean survival in CNS metastatic breast cancer is 11.5 months, 2-year survival is 18%, and 3-year survival is 16%. However, there is wide variation in postoperative survival in breast cancer patients undergoing resection procedures for CNS metastases. This is usually related to the basic malignancy, its degree of local control at the primary site, and metastatic disease in other organ systems. A long tumor-free interval between initial diagnosis and CNS metastasis indicates prolonged survival following removal of the brain metastasis; shorter duration of survival is expected for older patients and those with a poorer preoperative functional status.

Comparison of results between definitive modalities of treatment of brain metastases can be difficult. In the absence of prospective randomized studies, selection bias and other factors can obscure differences in outcome. Although it is clear that most patients treated with either radiosurgery or surgical resection will live longer than those treated with radiation alone, there is a less dramatic difference between these two modes of therapy. Some studies have found that patients treated with surgery have better local control and longer survival than those treated with stereotactic radiosurgery.³² Others, however, have suggested that there is no benefit to surgery over radiosurgery in selected patients.³³

Surgical morbidity is directly related to the anatomic location of the lesion and the surgical approach employed. Stortenbecker,^{2,34} in 1954, reported a 30-day operative mortality of 24%. Ransohoff,⁵ in 1975, reported a 10% mortality (morbidity not available). Haar and Patterson,¹³ in their 1972 series, found an 11% mortality and 24% morbidity. Kelly and colleagues,¹⁴ in 1988, reporting on a series of stereotactically resected, centrally located, and deep-seated tumors, found no mortality and 9% morbidity. Postoperative results have improved: postoperative morbidity following stereotactic resection is now less than 6% (unpublished data).

What are the future directions for diagnosis and treatment of central nervous system metastases?

In the future, patient empowerment by information technology and cost consciousness will emphasize quality-of-life issues, reduction of length of hospital stays, and the avoidance

of costly rehabilitation and nursing care made necessary by neurologic deficits. Physicians will therefore stress early detection of CNS metastases and low-morbidity, minimally invasive, cost-effective procedures to treat them.

In the past, brain surgery in patients with metastatic disease was considered risky and futile. Spatial errors in locating metastatic tumors by subcortical incision into important brain tissue and large craniotomies to resect large and symptomatic metastatic tumors could result in the disruption of more brain parenchyma than intended, causing postoperative neurologic deficit and an unacceptable quality of life.

Stereotactic techniques have greatly reduced the risk of metastatic tumor resection procedures. Oncologists, who once submitted their patients for brain surgery only as a last resort after radiation therapy had failed to control the CNS metastasis, are now considering surgical resection of the lesion as a first option. This course of action is now considered preferable to external-beam radiation therapy alone, in which a significant risk for dementia exists if survival is prolonged.

Modern, minimally invasive, low-risk surgical options that provide prolonged life expectancy and maintain quality of life from a neurologic standpoint now exist. A recently developed and much promoted method of tumor resection, the use of intraoperative MRI, may prove to be useful. As yet, however, the technology is cumbersome and expensive and has not been shown to provide improved outcomes or reduced morbidity in the treatment of metastatic brain tumors. Development of endoscopic or robotic techniques using frameless stereotactic control may reduce the risk and the cost of removing small CNS metastases.

The detection of CNS metastatic disease is now very straightforward with modern imaging methods such as high-resolution CT and MRI. Intracranial and intraspinal metastatic lesions are detected earlier than in the past and before the patient has developed neurologic deficit. Magnetic resonance perfusion scans and spectroscopy will further increase the sensitivity for the detection of intracranial brain metastases. It is clear that breast cancer patients with good local control of their primary disease can derive significant benefit from surgical resection of metastatic lesions. In the future, surgery will stress minimally invasive techniques that provide maximum tumor removal with much less risk than that associated with neurosurgery in the past. With early detection methods, we will be resecting smaller and smaller lesions from neurologically normal patients.

As the risk of resecting these lesions declines, the employment of surgical and radiosurgical procedures for the treatment of patients with multiple metastases is becoming more commonplace. In addition, as new metastatic lesions to the CNS are discovered, repeat minimally invasive and radiosurgical procedures may prolong quality of life. Future research should be directed toward defining strategies that direct the use of currently available treatment modalities to maximize survival while optimizing quality of life.

Spinal Column Metastases from Breast Cancer

Andrea F. Douglas and Paul R. Cooper

Carcinoma of the breast that metastasizes to the spine can adversely affect the patient's quality of life by producing intractable pain and motor, sensory, and sphincter deficits that prevent normal functioning. Prevention of paraplegia and sphincter deficit results in an improved quality of life. Restorative surgery may result in longer survival as well, but available data have failed to make this clear.^{1–3}

Advances in imaging of the spine with MRI and high-resolution CT provide heretofore unobtainable information regarding the anatomy of bone involvement and neural compression. These improvements in imaging, along with technical and conceptual advances in surgical management, have resulted in improvement in neurologic outcome and quality of life for patients with metastatic breast tumors to the spine.

Nonetheless, there still exists a certain reluctance on the part of medical and radiation oncologists to integrate surgery into an overall management strategy. Frequently, when surgical therapy is considered, patients have a severe neurologic deficit that is unlikely to respond to treatment. It is worthwhile, then, to review the evolution in management of this entity that has occurred during the past 15 to 20 years.

What are the clinical presentations of breast cancer metastases to the spine?

Eighty-five to 90% of patients with breast cancer who present with spinal metastases already have a known primary lesion, and most already have documented metastatic disease in other locations.

Pain

Pain is the most common first symptom of spinal metastases; even in patients who present with neurologic deficit, careful questioning will reveal that pain preceded the onset of neurologic symptoms by days or weeks. The pain may be constant or exacerbated by changes in position. It may be localized to the site of the spinal metastasis, or it may be radicular and follow a dermatomal pattern from compression of a nerve root within the spinal canal or as it exits the spinal canal in one of the bony neural foramina.

In the cervical spine, pain will characteristically radiate from the neck to the shoulder, arm, or hand. Thoracic pain may be localized to the spine or follow a dermatomal pattern, unilaterally or bilaterally. In the lumbar region, metastases commonly produce lower back pain; when radicular pain is present, it involves the buttock, leg, and foot, and the patient's symptoms may be mistakenly ascribed to a lumbar disc herniation. This is particularly true when spinal involvement is the first presentation of metastatic disease.

Sensory Deficit

Loss or diminution of pinprick or light-touch perception in the trunk may provide a general idea of the level of spinal cord compression in the thoracic spine. Cervical spinal cord compression frequently does not produce upper extremity sensory loss and results in an upper thoracic sensory level. However, the presence of sensory loss or pain in a dermatomal distribution involving an upper extremity may provide reliable localization of the site of the lesion.

Motor Deficit

Motor deficit may result from compression of the spinal cord, nerve roots exiting from the spinal canal, or the nerves of the cauda equina within the spinal canal. When the spinal cord is compressed, the motor deficit will usually be bilateral, although it may be more pronounced on one side or the other. Weakness of the upper extremities is evidence of compression of the cervical spinal cord. Laterally placed cervical lesions may compress a single root and produce unilateral motor deficit confined to one or two muscle groups. Sphincteric dysfunction with urinary retention and loss of voluntary control of the rectal sphincter resulting from cervical or thoracic spinal cord compression is a late sign and is usually present only when motor deficit is profound. However, with compression of the conus medullaris at the T11 through L1 levels, bladder and bowel dysfunction tend to be among the first symptoms.

With metastases at the L1 level and below, motor deficit will result from compression of the peripheral nerves of the cauda equina, and weakness is more likely to be unilateral or more marked on one side than is the case when deficit results from spinal cord compression. When compression at these levels is severe or located centrally within the spinal canal, involvement of the sacral nerve roots will produce sphincter dysfunction. With compression at lower lumbar levels, sphincteric dysfunction may be severe, with simultaneous preservation of proximal motor function in the legs.

Reflex Changes

Compression of the upper motor neurons contained within the spinal cord may produce increased deep tendon reflexes. Lower motor neuron dysfunction caused by cauda equina

involvement or compression of a single nerve root within a neural foramen will result in decreased deep tendon reflexes. For the most part, assessment of the deep tendon reflexes is not helpful in localizing a lesion unless the reflexes are clearly asymmetrical. However, the presence of a Babinski reflex is a generally reliable sign of spinal cord (or brain) dysfunction.

What are the components of an appropriate imaging evaluation of known or suspected spinal metastases?

The goal of the imaging evaluation of a patient with known or suspected metastatic disease of the spine is localization of the lesion, documentation of the presence of neural compression, evaluation of the three-dimensional anatomy of bony destruction, and determination of spinal alignment and stability. No single imaging modality is capable of achieving all of these goals. In patients with suspected metastatic spinal involvement, we routinely use a combination of plain films, MRI, and CT.

Plain Films

Plain films are an essential first study in all patients with known or suspected metastatic disease of the spine. The level to be examined is determined by the patient's signs and symptoms. Lateral plain films will show vertebral body destruction and are the best study for the assessment of spinal alignment. Films done in the frontal projection are useful for demonstration of destruction of the pedicles and delineation of paraspinal soft tissue masses (Fig. 32–10). Dynamic lateral views of the spine in flexion and extension are also useful in determining spinal instability that may result from bony destruction.⁴

Magnetic Resonance Imaging

MRI is the imaging modality of choice for the assessment of neural compression by bone or soft tissue. Sagittal and axial images will show the level and exact configuration of neoplastic involvement and compression. Sagittal images will also provide a useful assessment of alignment, in addition to showing displacement of the spinal cord by bone or metastases (Fig. 32–11). An altered signal within bone will define the presence and extent of metastases, although CT images provide superior definition of bony anatomy. Contrast enhancement of metastases using intravenous gadolinium is unnecessary because the contrast may alter the abnormal marrow signal typically observed with bony metastatic disease, causing the lesion to appear normal in comparison to other vertebral levels.

Because the presence of central nervous system metastases has such a profound effect on prognosis and therapeutic decision making, it is essential that the brain be studied with MRI with and without gadolinium enhancement at the same time that evaluation of the spine is being carried out.

Computed Tomography

Ideally, axial CT is performed after the metastatic lesion is localized by plain films or MRI. CT provides superior definition of bony anatomy and is a particularly valuable aid to the surgeon in determining spinal stability, the need for internal fixation, and the type of operative approach based on the

Figure 32-10 *A*, This anteroposterior projection plain film of the thoracolumbar junction shows loss of definition of the right pedicle of L1 (*arrow* points to destroyed pedicle). *B*, In the lateral projection of the same patient, loss in height of the involved spinal level secondary to a pathologic compression fracture is notable. The relative preservation of the disc spaces adjacent to the metastatic lesion is an important finding distinguishing this entity from osteomyelitis of the spine.

exact extent and location of bone destruction. Axial images taken at 1-mm intervals can be reformatted in the sagittal and coronal planes to provide accurate delineation of the three-dimensional bony anatomy of the lesion and to assess spinal alignment (see Fig. 32-11C). This technique is particularly valuable at the cervicothoracic junction or other regions that are difficult to image on plain films.

In distinction to MRI, the intravenous administration of iodinated contrast agents in CT will result in enhancement of tumor and provide clearer definition of neural compression within the spinal canal. Contrast administration may be helpful in defining the location of tumor when MRI is unavailable or cannot be performed because of patient refusal or the presence of implanted cardiac pacemakers, or when metallic internal fixation devices from prior spinal surgery are likely to preclude useful MRI examination.

Computed Tomographic Myelography

Myelography using iodinated contrast material placed in the subarachnoid space followed by CT scanning has been used infrequently since the advent of high-resolution MRI. Even when MRI is unavailable or cannot be used, plain CT after intravenous contrast administration is usually sufficient to define the presence and extent of metastases. Myelography is

probably most useful in patients with internal fixation devices who are suspected of having recurrent tumor. Because the metallic implants will produce extensive artifact on MRI, CT myelography may be the only imaging modality that can define the extent of neural compression.

Spinal Angiography and Embolization

In the past, spinal angiography was performed preoperatively in all patients before transthoracic or lumbar retroperitoneal resection of spinal tumors. Because these approaches necessitate ligation of radicular vessels supplying the vasculature to the spinal cord, it was formerly believed that definition of the arterial supply of the anterior spinal artery was essential to avoid spinal cord ischemia and infarction. In practice, unilateral ligation of three or even four adjacent radicular vessels is safe, and spinal angiography is unnecessary except in reoperations in which an approach is contemplated that is contralateral to previously ligated radicular vessels. Additional ligation of radicular vessels in this situation can result in spinal cord ischemia and exacerbation of neurologic deficit.

Embolization of tumor vessels may be carried out at the time of spinal arteriography. This technique may be helpful for tumors that are known to be highly vascular such as metastatic hypernephroma, melanoma, or thyroid tumors.

A

B

C

Figure 32-11 A, Sagittal T1-weighted MRI of a metastatic lesion confined to a single level at the thoracolumbar junction. There is obvious compression of the subarachnoid space by the epidural extension of the metastatic tumor, which occupies about half of the spinal canal at that level. B, Axial T2-weighted MRI of the same patient shows the involvement of the entire vertebral body by the tumor with right-sided extension into the spinal canal. C, The sagittally reconstructed CT image confirms the compression fracture caused by the metastatic tumor but also confirms that the spinal canal encroachment is caused by tumor and not destroyed bone.

Metastatic breast neoplasms are infrequently highly vascular and embolization is rarely necessary.

What considerations are most important in therapeutic decision making for spinal metastases?

Surgical resection of spinal metastases of carcinoma of the breast is an important treatment option for palliation of pain

and prevention of irreversible neurologic deficit. Surgeons have become increasingly aggressive in selecting patients for operative resection and more radical in their choice of operative approaches.⁵⁻¹² However, there has been a reluctance on the part of some medical oncologists to refer their patients for resection of spinal metastases because operative resection is rarely curative, patients are frequently debilitated from their systemic disease and prior treatments, and historically the neurologic outcome after laminectomy was little or no better than radiation and chemotherapy.^{6,13-18} It is now clear that

Table 32-15 Clinical Criteria Favoring Radiation Therapy as Primary Treatment Modality

Radiation-responsive tumor
Moderately radiation-responsive tumor in a patient with little or no neurologic deficit
Neural compression from soft tissue only
Expected survival less than 3–4 mo
Patient unlikely to tolerate surgical intervention
Complete neurologic deficit below the level of compression
Multiple vertebral body lesions at multiple spinal levels

properly timed resection of spinal metastases in selected patients has an important role to play in their overall management.^{19–25}

Indications for Nonoperative Management

The indications for radiation therapy and other forms of nonoperative management are listed in Table 32-15 and discussed in detail in this section.

Patients who are found to have small metastatic lesions of the vertebral bodies without extension into the spinal canal in the course of a routine evaluation for clinical staging are appropriate candidates for radiation therapy. Similarly, patients who present with spinal pain and are neurologically intact without imaging or clinical evidence of spinal cord or cauda equina compression by tumor or spinal instability and deformity may be managed initially with radiation therapy. Patients with an expected survival of less than 3 to 4 months are usually not candidates for spinal surgery, nor are those who are so debilitated that they are unlikely to tolerate surgical intervention. If any of these patients has any evidence of kyphotic deformity, then thoracolumbosacral orthotic bracing or rigid cervical collars should be used, and bedrest should be encouraged.

Patients with a complete neurologic deficit will not regain useful motor function even if decompressed; thus, operative decompression makes little sense. Even in patients with preservation of sensation but absent motor function, return of sufficient motor function to permit ambulation is exceptional, and operative decompression must be approached with a good deal of skepticism.

The patient with mild deficit (e.g., ambulatory but with less than normal strength) may be a candidate for radiation therapy provided that the total amount of tumor mass (and particularly that within the spinal canal) is small. Such patients must be examined at least twice daily, and surgical consultation must be obtained at the moment that there is progression of neurologic dysfunction. Patients with mild deficit should be placed on corticosteroids, which are useful for pain palliation and may ameliorate neurologic deficits while radiation therapy is being carried out.

Indications for Operative Management

The indications for operative management as the primary treatment modality are listed in Table 32-16 and are discussed in detail subsequently.

Patients who present with rapidly progressive neurologic deterioration are unlikely to have amelioration of their deficit with radiation or chemotherapy. Although administration of high-dose corticosteroids (methylprednisolone, 250 mg every 6 hours) may result in temporary improvement of neurologic

Table 32-16 Clinical Criteria Favoring Surgical Intervention as Primary Treatment Modality

Neural compression secondary to retropulsed bone
Neural compression from spinal deformity
Spinal instability resulting from ligamentous and bony destruction by tumor
Rapid progression of neurologic deficit
Failure of radiation therapy (after prior therapy or progression of deficit during treatment)
Occult primary tumor

function, recurrent deterioration is the rule, and such patients are best referred for early surgical consultation. Although patients who present with slowly progressive but severe deficit (nonambulatory but with movement of the lower extremities) may sometimes respond to radiation therapy, reversal of deficit is more rapid, more complete, and more certain with operative decompression. Moreover, operative intervention removes the risk for deterioration during or after radiation therapy.

In patients with neural compression, it is important to use imaging studies to determine whether compression is caused by a soft tissue tumor or partially destroyed vertebral body that has retropulsed into the spinal canal. This distinction is of great importance and frequently difficult to make on MRI alone. Axial or sagittal CT scans will readily distinguish bone from soft tissue tumor (see Fig. 32-11C). If there is bone in the spinal canal, surgical decompression is indicated; radiation therapy as the primary treatment in this situation is futile and will not prevent further neurologic deterioration. Similarly, surgical therapy is also indicated when compression is caused by spinal instability, subluxation, or kyphotic deformity resulting from bony destruction.

Neurologic deterioration in patients who have been managed with radiation therapy or chemotherapy as the primary treatment is an indication for surgery. It is inexcusable for patients who present intact or who have mildly impaired motor function to be observed, because they deteriorate while receiving radiation therapy. Although systemic chemotherapy may decrease the size or slow the growth of metastatic lesions, it has been our experience that chemotherapy is rarely effective in reversing neurologic deficit caused by spinal cord or cauda equina compression from metastatic carcinoma of the breast.

Patients with metastatic disease with a solitary spinal metastasis and pain alone or pain with neurologic deficit have received attention recently as a unique group with respect to the indications for surgery. This group of patients is thought to be among those who would reap the greatest benefit from en bloc surgical resection of their tumor; en bloc resection may be oncologically superior in reducing local tumor recurrence compared with traditional piecemeal resection.^{7,11,12,24} Adjunctive postoperative radiation therapy is recommended in this group, but recent studies have suggested that preoperative radiation leads to higher surgical complication rates because of scarring and an increased incidence of wound breakdown and infection.^{8,26,27,28} It must be emphasized, however, that a single metastasis to the spine without other systemic disease is an exceedingly unusual phenomenon. Even in patients without initial evidence of systemic metastases, diffuse disease is usually present and will become manifest with the passage of time.

What are the surgical approaches to spinal metastases?

More than 25 years ago, the reported results of surgical treatment of metastatic disease of the spine followed by radiation therapy were no better than radiation alone. In 1978, Gilbert and colleagues,¹⁶ in a widely cited study, could find no difference in outcome when patients with metastatic spinal tumors who had been treated with radiation therapy or surgery were compared. Other authors who performed meta-analyses of results reported in the literature reached similar conclusions.^{6,13,14} The failure of surgery to improve on the results of radiation therapy led Black²⁹ in 1979 to state that “radiotherapy alone should, in general, be the primary form of treatment for spinal metastasis. Radiotherapy seems to be superior to surgical decompression alone, and it is equally as effective as a combination of operation and radiotherapy.”

In retrospect, the reasons for the unsatisfactory results of surgery are now clear. Surgical treatment at the time that Black and others did their reviews consisted almost exclusively of laminectomy, regardless of the location of the tumor, extent of bony destruction, or presence of spinal deformity.^{6,30–35} Because most epidural metastatic lesions originate from the vertebral body, compression usually originates anterior to the spinal cord or cauda equina. Laminectomy with posterior decompression does little to relieve the ventral pressure on the spinal cord. Attempts to remove anterior tumor through a posterior approach usually result in manipulation of the spinal cord and failure to remove the large bulk of ventral tumor. In addition, the resected laminae are frequently the only bony elements providing stability, and their removal may lead to kyphosis with subsequent compression of the spinal cord as the spine deforms further following the operation.

The development of anterior approaches to the spine by a number of groups^{23,36–40} revolutionized the ability of surgeons to prevent or reverse neurologic deficit. An understanding of spinal biomechanics and the application of internal fixation techniques have enabled spinal surgeons to perform radical resection of spinal tumors and vertebral elements while retaining stability, preventing spinal deformity, and minimizing local recurrence. Although quality of survival is clearly improved, it is not yet clear whether the length of survival is affected.^{1,27,41,42}

A detailed description of the operative techniques currently used is beyond the scope of this discussion; however, the indications for various procedures and the general nature of the approaches and the techniques available are informative and aid the medical oncologist in understanding why particular operative treatments are chosen by the spinal surgeon.

Thoracic Spine

The thoracic region is the most common location for spinal metastases. Because the thoracic spine is stabilized by the rib cage, even extensive bony destruction by vertebral metastases may not compromise spinal stability or alignment. However, the thoracic spinal canal is small in relation to the size of the spinal cord, and relatively small volumes of intraspinal tumor may result in profound neurologic deficit.

Because most thoracic metastases originate in the vertebral body, decompression is most safely and effectively carried out

through anterior or anterolateral approaches. We prefer to use a thoracotomy approach to the thoracic vertebral bodies.⁴³ The vertebral body is resected along with epidural tumor. The vertebral body is replaced with methylmethacrylate, which is molded to the contours of the bony defect.⁴⁴ The strength of the methylmethacrylate fixation may be enhanced by Steinmann pins or a stent of Silastic tubing filled with methylmethacrylate placed within the liquid cement before it hardens, or with the use of plates or rods secured to the adjacent vertebral bodies by intravertebral screws (Fig. 32–12). We usually avoid the use of bone grafts because of the limited life expectancy of most patients and the high incidence of failed fusion in patients who have been or will be treated with radiation therapy.

Above the T11 level, resection of a single vertebral body with acrylic vertebral body replacement will generally not result in spinal instability, and no further treatment is indicated provided that the posterior vertebral elements (laminae and facets) remain intact. If two or more contiguous vertebral bodies must be resected or if there is involvement of the posterior vertebral elements, a second posterior incision is made, and supplemental posterior fixation is used, usually during the same anesthetic period. At T11 and T12, the point of transition from the relatively stable thoracic spine to the more mobile lumbar spine junction, anterior instrumentation must be used or consideration given to the use of additional posterior fixation devices (Fig. 32–13).

The lateral parascapular approach has been described and may be used to achieve both anterior and posterior decompression of the spinal cord with one incision through an extrapleural approach.⁴⁵ It has the disadvantage of providing less direct access to the anterior aspect of the spinal cord; in addition, it is difficult to place anterior fixation devices using this technique. Other posterolateral approaches with resection of the pedicle have been described, but these have disadvantages similar to those of the lateral parascapular approach.

Although laminectomy is contraindicated in patients who have ventral compression of the spinal cord, its use is still appropriate and effective in certain circumstances.⁴² In 15% to 20% of patients with spinal metastases, compression is located only dorsally and may be effectively relieved with laminectomy. If the vertebral body is not involved by tumor, no additional surgical treatment is required. If the vertebral body is involved but there is no anterior spinal cord compression, posterior fixation would be indicated.

If there is circumferential compression of the spinal cord, both anterior and posterior decompressive procedures may be used.^{5,6,9,11,12,24,26} The anterior compressive lesion would usually be treated first. Combined anterior and posterior decompressive procedures (vertebral body resection and laminectomy) will usually require the use of posterior fixation.

Lumbar Spine

The lumbar region is the second most common site of spinal metastases. The spinal cord ends at about L1, and metastatic spinal lesions below this level will affect the lumbar and sacral nerve roots of the cauda equina. Anterior compression of neural elements in the lumbar spine may be treated with vertebral body resection through a retroperitoneal approach. Because of the greater mobility of the lumbar spine, anterior instrumentation is usually indicated after vertebral body resection

B

Figure 32–13 *A*, Postoperative lateral radiograph of a patient with a metastasis at the thoracolumbar junction. After resection of the T11-L1 vertebral bodies through an anterior thoracolumbar approach, the vertebral bodies were replaced with methylmethacrylate, and an anterior fixation device was placed. A second incision was then made to place a rod-and-hook construct posteriorly to provide additional stabilization. *B*, A postoperative anteroposterior radiograph of the same patient.

Figure 32-14 A, Preoperative sagittally reconstructed CT view of the cervical spine showing the destruction of the vertebral body of C3 by tumor with a notable kyphotic deformity. B, Postoperative lateral cervical radiograph showing radiopaque acrylic vertebral body replacement of C5 reinforced by an anterior cervical plate and supplemented by posterior cervical lateral mass plates spanning the level of the anterior fusion.

and replacement with methylmethacrylate. If there is involvement of the posterior vertebral elements or laminectomy is indicated, supplemental posterior fixation will be necessary.

As is the case for the thoracic spine, laminectomy is indicated when there is posterior compression of the dural tube. Because the nerve roots of the cauda equina are much more tolerant of manipulation than the spinal cord, laminectomy may sometimes be appropriate and effective below the L1 level to resect a tumor or tumor-involved vertebral body anterior to the spinal cord. If the vertebral body is involved, placement of posterior instrumentation will be necessary.

Cervical Spine

The cervical vertebrae are the least commonly affected region of the spine with metastatic disease. Compression almost always results from tumor extending out of an involved vertebral body or from the bone of a partially destroyed vertebral body retropulsed into the spinal canal. Because the cervical region is the most mobile segment of the spinal axis, vertebral body involvement commonly results in kyphotic deformity.

Anterior compression is managed from the same anterior approach used for spinal cord compression caused by cervical disc herniations or degenerative disease. The vertebral body is resected down to the dura, although extensive lateral resection of tumor is limited by the vertebral arteries. If kyphotic deformity is present, it may be corrected at the time of resection. Steinmann pins may be placed in the vertebral bodies above

and below the one resected to secure the methylmethacrylate. Alternatively, anterior cervical plates may be screwed to the vertebral bodies adjacent to the one resected, stabilizing the spine and preventing the acrylic from displacing. If there is a kyphotic deformity or if laminectomy is also necessary for decompression of posterior tumor, supplemental posterior instrumentation may be appropriate (Fig. 32-14).

What are the outcomes of spinal surgery for breast cancer metastases?

There have been no large series in which the results of spinal surgery for the treatment of breast metastases have been specifically examined; however, 94% of our own patients with a variety of metastatic tumors had improvement or stabilization of their motor deficits after operation, and more than 90% were ambulatory.¹⁹ Other authors have reported similar satisfactory neurologic results.^{3,11,22,25,28,46} Although the procedures necessary to relieve neural compression are often extensive, we had no mortality within 30 days of surgery in our series.¹⁹

With increased length of survival as a result of aggressive chemotherapy of systemic disease, a major problem has been recurrence of local spinal disease in patients whose systemic disease is otherwise well controlled. Although surgical resection of spinal metastases is not curative, it is now clear that

aggressive reduction of tumor bulk will minimize the incidence of local recurrence in patients with extended survival. Our goal in patients with a single metastasis or well-controlled systemic disease is removal of all grossly visible tumor and all bone that is involved with tumor on imaging studies. This may frequently entail total resection of all vertebral elements (spondylectomy) using combined anterior and posterior surgery.^{7,9-11} This has been generally well tolerated and appears to have minimized local recurrence.

Because neurologic outcome after surgery is closely related to the patient's preoperative deficit, it is essential that patients be decompressed early before severe neurologic dysfunction is present. It is therefore important that spinal surgeons share, along with medical and radiation oncologists, in the formulation of management strategies at the time of presentation.

Ocular Metastases from Breast Cancer

Carol L. Shields,
Hakan Demirci, and
Jerry A. Shields

How common are ocular metastases?

Historically, metastatic tumors to the eye were believed to be rare. A classic ophthalmic textbook in 1966 stated that few surgeons had observed more than one case of ocular metastasis.¹ It was later realized that ocular metastases were more common, and over the past 43 years there have been several reports on the incidence and prognosis of patients with metastatic tumors to the eye.^{2–11} Albert and associates found that 2% of 213 patients with known systemic cancer and metastases had choroidal metastases.³ Bloch and Gartner reported that 8% of eyes in 230 patients with autopsy-proven carcinomas had histologically confirmed uveal metastatic foci.⁵ Nelson and coworkers found in an autopsy study that 4% of patients dying of carcinoma had ocular metastases.⁸ They estimated that in the year 1983, 22,000 patients who died of cancer had ocular metastatic disease.⁸ As the life expectancy of patients with cancer improves, it is expected that the number of patients with ocular metastases will rise accordingly.

Most reports on ocular metastases come from pathology laboratories or from general cancer centers where patients have had known primary cancers or metastatic disease and the eyes were subsequently examined. These studies have focused on the source of the primary tumor as well as on general clinical and histopathologic features of the tumor (derived from autopsy or pathology reports in some instances).^{2–6,8} Ocular metastases on file at the Armed Forces Institute of Pathology were reviewed by Hart in 1962² and Ferry and Font in 1974.⁶

There are only a few comprehensive reports on the clinical features of ocular metastases from an ophthalmologic point of view. In 1979, Stephens and Shields reviewed 70 cases of uveal metastases and provided general details on the clinical findings of these tumors.⁷ In 1997, Shields and coworkers reported extensive detail on the clinical features and management of uveal metastases in a large group of 420 consecutive patients.¹¹ Others have focused on the features of uveal metastases from specific primary sites such as breast,^{12–16} prostate,¹⁷ and skin^{18–20} and carcinoid tumors.²¹ In 1987, Freedman and Folk reported on the clinical aspects of metastatic tumors to the choroid in 61 patients, and they addressed specifically the factors affecting the median survival time after ocular diagnosis.⁹ Later, Shields and Shields summarized their experience with clinical features, diagnostic techniques, and management of

uveal metastases in a textbook and three atlases on ocular tumors.^{22–26}

What are the most common sites of ocular metastasis?

Metastatic tumors generally spread to the ocular region through hematogenous dissemination. Metastases can occur in the intraocular structures such as the uvea, retina, optic disc, or vitreous cavity, and they can manifest in the adnexal structures like the eyelid, conjunctiva, or orbit.^{11,27–33} Most ocular metastases are detected in the uvea. The uvea is a vascular bed located between the retina and sclera. It is composed of melanocytes, sensory nerves, and a high-flow network of blood vessels that provide nutrition to the outer layers of the retina. The uvea is divided into the iris, ciliary body, and choroid. In an analysis of 950 individual uveal metastases, metastatic tumors occurred most often in the choroid (88%) and less frequently in the iris (9%) or ciliary body (2%)¹¹ (Fig. 32–15). Occasionally, metastases are located in the orbit.^{27–29} Rarely, ocular metastases are found in the eyelid, conjunctiva, optic disc, or other structures.^{30–33}

Uveal metastases most commonly originate from primary cancers in the breast (47%), lung (21%), gastrointestinal tract (4%), kidney (2%), skin (melanoma) (2%), prostate gland (2%), and other sites (4%)¹¹ (Table 32–17; Fig. 32–16). In about 17% of all patients, the primary tumor site remains unknown. Orbital metastases most frequently originate from primary cancers in the breast (53%), prostate gland (12%), lung (8%), skin (melanoma) (6%), kidney (5%), gastrointestinal tract (5%), and others (4%).^{27,28} In 7% of patients, the primary site remains unknown.

At the time of presentation with a uveal metastasis, about 30% of patients had no known history of primary cancer.¹¹ Subsequent evaluation of these patients revealed a primary tumor most commonly in the lung (35%) and less frequently in the breast (7%) and other sites (6%) (Figs. 32–17 and 32–18). Despite repeated evaluation, the primary site in these select patients who present without a history of cancer remains unknown in 51% of patients. Nearly half of such patients with no detectable primary site died of diffuse metastatic disease shortly after the ocular diagnosis.¹¹

PATIENT FEATURES

Breast cancer is the most common malignancy to metastasize to the uvea, accounting for 39% to 49% of all uveal

metastasis.³⁻¹¹ In a review of 3802 breast cancer patients, Kamby and coworkers reported that the five most common sites of metastasis from breast cancer were the lung (71%), bone (71%), lymph nodes (67%), liver (62%), and pleura (50%).³⁴ Ocular metastasis from breast cancer occurs in 9% to 37% of patients, depending on the source of the study.^{5,8,14} Uveal metastases represent the smallest detectable lesions of systemic dissemination of breast cancer and occur at a median of 3 years following diagnosis of the primary tumor.¹⁴

Uveal metastases are more commonly found in women, primarily owing to the high frequency of breast cancer metastatic to the eye. In an analysis of 450 patients with uveal metastases from all primary cancer sites, the tumor was found in men in 33% and women in 67%.¹¹ Uveal metastases in men originated from cancer of the lung (40%), gastrointestinal tract (9%), kidney (6%), skin (melanoma) (4%), prostate gland (6%), breast (1%), others (4%), and unknown primary site (29%). Single cases of breast cancer metastatic to the eye in men have been published.³⁵ Uveal metastases in women

Figure 32–16 Location of primary cancer in 420 patients with uveal metastases.

Figure 32–17 Eventual primary cancer site in 142 patients who presented with a uveal metastasis and no prior history of cancer.

were from cancer of the breast (68%), lung (12%), gastrointestinal tract (2%), kidney (<1%), skin (melanoma) (1%), prostate gland (0%), others (4%), and unknown (12%). In an analysis of 264 patients with uveal metastases from breast cancer, the primary tumor was found in women in 99% and men in 1%.¹⁵

What patient characteristics increase the risk for ocular metastases?

Ocular metastases from any primary site typically occur in the sixth to seventh decades of life at a mean age at 58 years (median, 58 years; range, 10 to 85 years).¹¹ For breast cancer metastasis, the mean age at diagnosis of the ocular metastasis was 56 years (median, 57 years; range, 23 to 84 years).¹⁵

Most patients with ocular metastases from breast cancer have a known history of breast cancer and previous nonocular metastases. Of 264 patients with uveal metastasis from breast cancer, the eye finding was the first manifestation of

breast cancer in 3%.¹⁵ In 14% of patients, the ocular metastasis was the first metastatic site. The locations of systemic nonocular metastases before and after the detection of ocular metastasis are listed in Table 32–17.

Of those patients who develop ocular metastases, the mean age at diagnosis of the primary breast cancer was 56 years (median, 57 years; range, 23 to 84 years).¹⁵ The initial treatment of breast cancer was radical or modified mastectomy (83%), systemic chemotherapy (42%), external-beam radiotherapy (27%), lumpectomy with or without lymph node dissection (14%), and hormone therapy (4%). The axillary lymph nodes were involved in 46% of patients who developed eventual uveal metastases. At the time of diagnosis of the ocular metastases, 52% of patients were on systemic therapy, including chemotherapeutic agents (36%), hormone therapy (20%), and immunotherapeutic agents (2%). Uveal metastases developed a mean of 65 months after the diagnosis of the primary breast cancer (median, 48 months; range, 0 to 300 months).¹⁵

Intraocular metastases show a strong tendency to involve the posterior uvea (choroid). Less commonly, the tumor

Figure 32-18 Choroidal metastasis from lung cancer. The amelanotic choroidal mass was discovered in a patient with no known cancer. Subsequent systemic evaluation revealed a primary lung cancer.

Figure 32-19 Choroidal metastasis from breast cancer. The well-circumscribed choroidal metastasis in the posterior pole of the eye was discovered in a patient with breast cancer.

affects the iris or ciliary body. Rarely do metastases involve the optic disc or retina. Of 361 eyes with uveal metastases, the tumor was located in the choroid in 349 eyes, iris in 23 eyes, and ciliary body in 2 eyes.¹⁵ Some patients had metastatic tumors in more than one intraocular location.

In general, intraocular metastases commonly show multifocality, bilaterality, or both. In an analysis of 520 eyes with uveal metastases from all primary sites, the median number of metastatic tumors per eye was 1, and the mean was 1.6.¹¹ Furthermore, 370 eyes (71%) had 1 focus, 63 (12%) had 2 foci, and 87 (17%) had 3 or more foci, up to a maximum number of 13 metastatic foci in one eye.¹¹ The tumor was unilateral in 76% and bilateral in 24% of patients. With regard to ocular metastases from breast cancer, the tumor was unilateral in 62% and bilateral in 38%.¹⁵ Of 99 patients (38%) with bilateral uveal metastases from breast cancer, 85 (32%) had bilateral involvement at the time of diagnosis, and 14 (5%) developed the second eye involvement after a mean follow-up of 10 months (median, 7 months; range, 2 to 33 months). The mean number of the uveal metastatic tumors (from breast cancer) per eye was 2 (median, 1; range, 1 to 19), and more than one metastatic focus was detected in 48%.¹⁵

What are the clinical features of ocular metastases?

The clinical features of metastatic tumors to the eye vary with the location of the ocular tumor.²³⁻²⁶

Choroidal Metastases

The patient with a metastatic tumor to the choroid may be asymptomatic or may experience painless blurred vision. In rare instances, pain caused by secondary glaucoma can be

the initial manifestation. Ophthalmoscopic examination of a choroidal metastasis characteristically reveals a homogeneous, creamy yellow placoid lesion in the posterior choroid (Fig. 32-19; see also Fig. 32-18). Tumors that are slightly more elevated can produce a serous detachment of the retina and alterations in the retinal pigment epithelium (RPE). The RPE changes can be marked, appearing as well-delineated clumps of golden-brown pigment on the surface of the tumor. In some instances, the tumor may appear multinodular.

In some cases, a choroidal metastasis can be highly elevated and have a dome shape, similar to a primary amelanotic melanoma.³⁶ The finding of multiple choroidal tumors in such a case, however, is strong evidence for a metastatic tumor rather than a primary melanoma, which is usually solitary.

Serous detachment of the sensory retina is associated with choroidal metastases from breast cancer in 64% of cases.¹⁵ In some instances the detachment involves only the fovea adjacent to the tumor, whereas in other cases it may be bullous. When the detachment is extensive, dramatic shifting of the subretinal fluid can be demonstrated with movements of the patient's head.

Several conditions can clinically simulate a metastatic cancer to the choroid and should be considered in the differential diagnosis.³⁷ These include amelanotic nevus, amelanotic melanoma, hemangioma, osteoma, posterior scleritis, retinitis and choroiditis, rhegmatogenous retinal detachment, Harada's disease, uveal effusion syndrome, and central serous chorioretinopathy.^{23-26,37-39} A detailed history is often helpful in making the differentiation, but the ophthalmoscopic differences are also very important. The specific clinical features of the various tumors and pseudotumors are illustrated in textbooks.²²⁻²⁶ With some experience, the clinician can differentiate simulating lesions from metastatic tumors by their typical ophthalmoscopic features and by using ancillary diagnostic procedures, to be discussed subsequently.

A choroidal melanoma is the most important lesion to differentiate from a metastatic tumor.³⁶ The melanoma is characteristically pigmented but can be completely amelanotic and closely resemble the color of a metastasis. The melanoma is typically unilateral, solitary, and more elevated. An amelanotic melanoma frequently has large visible intrinsic blood vessels and often assumes a mushroom shape from herniation through Bruch's membrane; these findings rarely occur with a metastatic tumor.

A choroidal hemangioma can also resemble a metastatic tumor in size, shape, and location.³⁸ The distinct red-orange color of most hemangiomas differentiates them from the yellow color of a metastatic tumor. A choroidal hemangioma is classically unilateral and unifocal.

A choroidal osteoma characteristically appears as an amelanotic choroidal mass.³⁹ Like a metastatic tumor, it is more common in women. In contrast to a metastatic tumor, it has an irregular but well-defined border and can show subretinal neovascularization on the surface. We have seen one patient who underwent three breast biopsies elsewhere because a choroidal osteoma was suspected to be a metastatic cancer, before the correct diagnosis was eventually established. Ultrasonography and CT of a choroidal osteoma reveal echoes characteristic of a calcified plaque.

A number of inflammatory processes of the fundus can simulate a choroidal metastasis. Certain viral and mycotic infections are more commonly seen in patients with systemic cancer, thus making the differentiation even more difficult. Patients with cytomegalovirus (CMV) retinitis often have a history of cancer and are on chemotherapy. The yellow-white areas of retinal necrosis may be bilateral and multiple. In contrast to metastatic tumors, they involve the retina rather than the choroid, have an irregular border, and frequently show surrounding and overlying retinal hemorrhages. Mycotic retinitis or choroiditis also can resemble a choroidal metastasis but is more likely to be associated with inflammatory signs.

Ciliary Body Metastases

Ciliary body metastases are often difficult to detect clinically. They can masquerade as a chronic uveitis or secondary glaucoma, and the affected patient may be treated with topical or systemic corticosteroids or glaucoma medications, while the tumor remains undetected. Like primary ciliary body melanoma, a ciliary body metastasis can produce a shallow anterior chamber, subluxated lens, or cataract. Prominent episcleral blood vessels can occur in the quadrant of the lesion. In some cases, the ciliary body may be involved because of anterior extension of a diffuse tumor from the choroid. With time, some ciliary body metastases can extend through the iris root into the anterior chamber. The differential diagnosis of a ciliary body metastasis includes many of the same conditions that fall under the differential diagnosis of choroidal metastasis, except for those that affect only the posterior pole, such as central serous chorioretinopathy, choroidal hemangioma, and osteoma.

Iris Metastases

The clinical presentation of iris metastases can vary greatly.^{11,33} Some patients with iris metastases are visually asymptomatic or have only mild symptoms. In some instances, however, pain caused by inflammation or secondary glaucoma can be the presenting manifestation. Occasionally, iris metastases are

Figure 32-20 Iris metastasis. The amelanotic papillary margin metastasis on the iris originated from breast cancer and has shed cells into the anterior chamber angle, causing tumor-related hypopyon.

multiple and bilateral. Slit-lamp biomicroscopy reveals an iris mass that is usually pink or white, depending on the intrinsic vascularity. In some cases, iris metastases are friable, and loosely cohesive cells settle in the inferior portion of the anterior chamber angle, producing a pseudohypopyon, simulating endophthalmitis (Fig. 32-20). The differential diagnosis of metastatic tumors to the iris includes amelanotic melanoma, leiomyoma, granulomatous iritis, and endophthalmitis.

Retinal Metastases

Metastatic tumors to the retina are extremely rare. Retinal metastases are less cohesive than choroidal metastases and may seed tumor cells into the vitreous. They sometimes resemble a retinitis and can have associated exudation or hemorrhage.

Optic Disc Metastases

Metastatic tumors can develop in the optic disc, and both optic nerves can be involved simultaneously.³² Optic disc metastases can clinically resemble papilledema, papillitis, or various types of pseudopapilledema.

Vitreous Metastases

Metastatic tumors to the vitreous are extremely rare and generally occur in patients who have retinal or ciliary body metastasis. Affected patients develop floaters, and vitreous examination reveals clumps of tumor cells. The differential diagnosis includes inflammatory vitritis, senile vitritis, endophthalmitis, vitreous hemorrhage, sychysis scintillans, asteroid hyalosis, and large cell lymphoma.

Conjunctival Metastases

Conjunctival metastases appear as a circumscribed or diffuse pink mass with prominent feeder vessels.^{25,30,31} Most often, they are found on the bulbar conjunctiva near the limbus and can be multifocal. The differential diagnosis includes pinguecula, pterygium, conjunctivitis, squamous cell carcinoma, and amelanotic melanoma.

Eyelid Metastases

Isolated eyelid metastasis from systemic cancer is rare. In most instances, an eyelid metastasis is an anterior extension

of an orbital metastasis. It appears as a noninflammatory mass and can resemble a chalazion, hordeolum, or basal cell carcinoma.

Orbital Metastases

Orbital metastasis from breast cancer usually presents with painless proptosis, ocular motility problems, or a palpable mass.^{24,27-29} Enophthalmos, an uncommon finding, strongly suggests metastases from scirrhous breast carcinoma; however, orbital varix, congenital orbital asymmetry, and post-traumatic orbital fat atrophy can produce a similar picture.⁴⁰ Orbital metastases are best visualized by CT or MRI and appear most often as a diffuse, poorly circumscribed mass within the orbital soft tissues. It is rare to find bilateral simultaneous metastases. The differential diagnosis includes orbital inflammatory pseudotumor, cavernous hemangioma, neurilemoma, and lymphoma.

What are the clinical features of ocular paraneoplastic syndromes?

A paraneoplastic syndrome is defined as the malfunction of an organ system from cancer in a remote site of the body without the presence of metastases in that end organ. Neurologic paraneoplastic syndromes include peripheral neuropathy, cerebellar degeneration, myasthenia gravis, and motor neuron degeneration. Ocular paraneoplastic syndromes include optic neuritis, external ophthalmoplegia, and retinal disease.⁴¹ Retinal paraneoplastic syndromes consist of carcinoma-associated retinopathy (CAR), melanoma-associated retinopathy (MAR), acquired cone dysfunction, bilateral diffuse uveal melanocytic proliferation (BDUMP), and Vogt-Koyanagi-Harada (VKH)-like syndrome. Breast cancer can produce CAR and BDUMP. In CAR, the patient notes night blindness, photopsia, transient obscuration of vision, ring scotoma, and photophobia. In BDUMP, multiple pigmented and nonpigmented uveal tumors develop along with dilated episcleral vessels, rapid-onset cataract, anterior uveitis, and serous retinal detachment.

Once an ocular metastasis is suspected, how is the diagnosis confirmed?

A number of ancillary ophthalmic procedures may aid in the diagnosis of metastatic tumors. These include a systemic evaluation, intravenous fluorescein angiography (IVFA), indocyanine green (ICG) angiography, ultrasonography, optical coherence tomography (OCT), CT, MRI, fine-needle aspiration biopsy (FNAB), and surgical biopsy.

Systemic Evaluation

Once a metastatic tumor to the intraocular structures is suspected on the basis of ophthalmic examination, a detailed systemic evaluation is mandatory. The patient's history may reveal a previous malignancy, which can be helpful in the diagnosis. As mentioned earlier, however, many patients seen by the ophthalmologist have no history of cancer. Initially, if a female patient has a suspected metastatic tumor, breast and lung examination with appropriate ancillary studies is

indicated. In men, the evaluation should be directed initially toward a primary tumor in the lung; later, if the lung is normal, gastrointestinal tract, kidney, thyroid, pancreas, and other organs are evaluated.

Fluorescein Angiography

IVFA is a method of imaging the vascularity within a choroidal tumor and is sometimes helpful in the diagnosis of a choroidal metastasis.^{11,22-26} In contrast to choroidal hemangioma and melanoma, most metastatic carcinomas are hypofluorescent in the arterial and early venous phases and show progressive hyperfluorescence in the subsequent phases. Pinpoint foci of hyperfluorescence appear over the tumor in the venous phase and persist into the late angiograms. There may be moderate late hyperfluorescence of serous subretinal fluid related to the metastatic tumor.

Indocyanine Green Angiography

ICG angiography provides detail of the choroidal vascular pattern. Imaging of choroidal metastases with this technique generally reveals mild hypofluorescence throughout the angiogram, whereas choroidal melanoma shows gradual hyperfluorescence over 5 to 10 minutes, and choroidal hemangioma shows bright hyperfluorescence within 1 minute.⁴²

Ultrasonography

Ocular ultrasonography provides resolution within 1 mm and is useful in the diagnosis of intraocular metastasis. A-scan ultrasonography demonstrates a sharp initial spike and moderate internal reflectivity. This is in contrast to malignant melanoma, which usually shows relatively low internal reflectivity. B-scan ultrasonography typically shows a choroidal mass pattern with moderate to high acoustic solidity, overlying subretinal fluid, and no choroidal excavation. In contrast, melanoma shows relative acoustic hollowness.

Optical Coherence Tomography

OCT is a method of imaging the retina with high resolution of 8 μ m. This technique allows for subclinical analysis of minor subretinal fluid, retinal edema, and retinal pigment epithelial changes associated with choroidal metastases. This can assist in deciphering the exact cause of visual loss.

Computed Tomography

CT is used most frequently in the evaluation of metastatic orbital tumors and less often for intraocular tumors. This technique can demonstrate the anatomic location and configuration of orbital metastases as well as surrounding periorbital changes. It is important to evaluate the brain in all patients with ocular metastasis from breast cancer because brain involvement occurs in nearly 30% of patients (Table 32-18).

Magnetic Resonance Imaging

MRI is useful in delineating the anatomic location, configuration, and internal tissue qualities of choroidal and orbital metastases. It is superior to CT for soft tissue resolution, especially when using fat-suppression technique, orbital surface coil, and gadolinium enhancement. In general, uveal metastases are slightly hyperintense compared to vitreous on T1-weighted images and hypointense compared to vitreous on

Table 32-18 Locations of Systemic Nonocular Metastases Before and After the Uveal Metastasis Was Established in 264 Consecutive Patients with Uveal Metastasis from Breast Cancer*

Location of Systemic Metastases	No. of Patients (%)
Diagnosed Before the Ocular Metastasis Was Established	
Lung	71 (27)
Long bone	68 (26)
Chest wall	19 (7)
Spine	17 (6)
Liver	14 (5)
Other breast	16 (6)
Brain	15 (6)
Skin	10 (4)
Skull	8 (3)
Others	6 (2)
None	116 (44)
Diagnosed After the Ocular Metastasis Was Established	
Brain	73 (28)
Lung	64 (24)
Long bone	64 (24)
Liver	37 (14)
Spine	22 (8)
Chest wall	18 (6)
Skull	10 (4)
Skin	5 (2)
Others	14 (5)

*Some patients had more than one treatment modality; some patients had systemic metastases in more than one location.

Data from Demirci H, Shields CL, Chao A, Shields JA. Uveal metastasis from breast cancer in 264 patients. *Am J Ophthalmology* 2003;136:264-271.

T2-weighted images.⁴³ The associated retinal detachment is hyperintense compared to vitreous on T1-weighted images and isointense compared to vitreous on T2-weighted images. Metastatic carcinomas show mild enhancement with gadolinium. Orbital metastases show a hyperintense signal compared to the suppressed orbital fat on T1- and T2-weighted images and moderate gadolinium enhancement.

Fine-Needle Aspiration Biopsy

When the diagnosis of an ocular lesion is particularly difficult to establish, FNAB is appropriate.^{23,44} This technique requires exceptional skill for lesions within the eye, using indirect ophthalmoscopy to guide the needle through the pars plana of the ciliary body into the solid mass. For orbital lesions, ultrasound or CT is employed for localization of deep lesions. An adequate cytologic sample is obtained in nearly 90% of cases.⁴⁴ This is especially useful for patients who present with no previous cancer and in whom systemic evaluation is nonrevealing.

Surgical Biopsy

Open surgical biopsy is commonly employed to diagnose orbital, conjunctival, and eyelid metastases and less commonly for intraocular metastases. In such instances, complete resection is performed if the tumor is circumscribed. For ill-defined lesions, incisional biopsy is performed. For intraocular metastases, the biopsy is performed microscopically through a scleral flap. Surgical biopsy obtains more tissue for the pathologist, but radiotherapy or chemotherapy

is generally indicated to eliminate tumor seeding at the biopsy site.

What are the pathologic characteristics of ocular metastases?

Because the intraocular structures and orbit have no lymphatic channels, metastatic tumors reach these sites by hematogenous routes. Probably because of its marked vascularity, the uvea is the location of most ocular metastases, especially the posterior portion of the choroids.

Gross examination of an eye with metastatic carcinoma usually reveals one or more diffuse or nodular amelanotic tumors in the uvea. In rare instances, the mass is highly elevated with a dome shape, similar to that of choroidal melanoma, but melanoma is generally pigmented.

Low-power magnification of a metastatic carcinoma reveals a placoid or diffuse mass, often with an overlying serous detachment of the sensory retina. Well-differentiated tumors may retain certain histologic or histochemical features of the primary tumor. Breast metastases typically appear histologically as solid epithelial nests or glandular structures. It is important to differentiate a primary adenocarcinoma of the retinal pigment epithelium, ciliary body epithelium, or iris pigment epithelium from a metastatic adenocarcinoma.

What are the treatment options for ocular metastases?

The preferred treatment for an ocular metastasis from breast cancer depends on the location, extent, activity, and symptoms related to the ocular tumor as well as the patient's systemic status.^{22-26,45} Management may involve observation alone, chemotherapy, hormone therapy, laser treatment, irradiation, or surgical resection.

Observation

Some metastatic tumors to the eye are inactive and require no treatment. They may have regressed spontaneously, or they may have regressed following systemic treatment of the primary breast cancer months or years previously. With some experience, the ocular oncologist can recognize such inactive metastasis. When located in the choroid, they are generally flat tumors with pigment epithelial clumping on the tumor surface and without retinal detachment.

Chemotherapy and Hormone Therapy

Active tumors, characterized by a homogeneous mass with a secondary retinal detachment, usually require treatment. In general, if the patient is asymptomatic and the eye tumor appears to be controlled with the chemotherapy or hormone therapy that is being used to treat the systemic disease, then no specific ocular treatment is indicated. The patient should be followed at 2- to 4-month intervals for documentation of tumor and visual status.

Laser Photocoagulation and Thermotherapy

Rarely, choroidal metastases are treated with laser photocoagulation or thermotherapy. This is employed only for

small tumors located outside the macular region. Methods of laser treatment using diode red, diode green, or argon laser can be applied to small choroidal metastases measuring less than 5 or 6 mm in base dimension.⁴⁶ Thermotherapy, using a large spot diode laser to heat the tumor to a subphotocoagulation level, is gaining some interest. These methods, however, are damaging to the normal retina and induce a dense scotoma. For this reason, most clinicians prefer focal treatment with radiotherapy rather than methods of laser or thermotherapy.

Radiotherapy

If the patient has an active choroidal metastasis, external-beam irradiation is generally effective in controlling the tumor.^{47,48} The entire uvea or orbit is irradiated, with about 3000 cGy delivered in divided doses over 3 weeks.^{47,48} Plaque brachytherapy is a method of focal radiotherapy using an implant with radioactive sources. The implant is surgically applied to the eye to deliver a radiation dose to a select region. This minimizes radiotherapy to surrounding normal structures. Plaque brachytherapy is employed for circumscribed tumors measuring less than 18 mm at the base and less than 10 mm in thickness.⁴⁹ The benefit of plaque brachytherapy is the speed of treatment—it takes only 2 to 4 days to deliver the dose. This is important for patients whose life expectancy is limited because it occupies less time of their remaining days than other methods of radiotherapy.⁴⁹

After radiotherapy, choroidal metastases decrease in tumor thickness on ultrasonography, and secondary retinal detachment resolves, often with improved visual acuity. Rudoler and associates found that external-beam radiotherapy provides globe preservation in 98% of patients, with visual improvement or vision better than 20/200 in 57% of patients.^{47,48} Ocular radiation complications were found in 12% of patients.^{47,48}

Surgical Excision and Enucleation

In some instances, enucleation or local surgical excision of an intraocular metastasis may be justified. Uncontrollable large tumors occasionally require enucleation for intractable pain caused by secondary glaucoma. However, chemotherapy or radiotherapy, rather than enucleation, should generally be considered first. Local excision of a tumor that has metastasized to the eyelid, conjunctiva, orbit, and occasionally the intraocular structures is justified in certain instances. This technique is useful for both diagnostic and therapeutic reasons.

What is the prognosis of the patient with ocular metastases?

In general, the life prognosis is poor for patients with metastatic tumors to the ocular structures.^{9,15} Patients with breast carcinoma metastatic to the uvea have a mean survival of 18 months, which is better survival than for patients with metastases from lung cancer (mean, 6 months) or cutaneous melanoma (mean, 1 month).⁹ Data collected from our department showed Kaplan-Meier survival estimates for patients with uveal metastasis from breast cancer to be 65% at 1 year, 34% at 3 years, and 24% at 5 years.¹⁵

SUMMARY

Breast cancer metastatic to the eye most commonly is detected in the choroid and much less often in the orbit, conjunctiva, eyelid, ciliary body, iris, retina, and optic nerve. In 16% of patients, the ocular metastasis is the first metastatic site, and in 3% of patients, it is the initial manifestation of breast cancer. Survival is poor, at 24% by 5 years.

VIII

Thoracic Metastases from Breast Cancer

*Jason P. Shaw and
Lawrence R. Glassman*

What is the role of surgery in the treatment of breast carcinoma metastatic to the lung?

The treatment algorithm for patients with breast cancer who are found to have pulmonary metastases remains controversial. Although most patients who develop breast cancer metastases die from complications of their disease,¹ new treatment options have increased median survival times in selected patients.² Furthermore, recent retrospective studies based on tumor registries,³ as well as observational studies,^{4,5} have described favorable outcomes for selected breast cancer patients with isolated pulmonary metastases who undergo surgical resection, compared with historical controls. These findings have made a valid case for surgical resection of isolated pulmonary metastases in selected breast cancer patients.

How is the diagnosis of lung metastasis made?

In the absence of endobronchial lesions or large malignant effusions, most patients with lung metastases are asymptomatic at the time of diagnosis. Pulmonary metastases tend to be peripherally located, often identified during pretreatment staging workup or post-treatment surveillance. Some patients may develop symptoms such as cough, shortness of breath, or hemoptysis, all of which merit further evaluation. Chest radiographs, frequently obtained as part of preoperative evaluation, should be part of the routine surveillance of patients with newly diagnosed breast cancer. If a patient develops symptoms or if a pulmonary nodule is discovered incidentally, further imaging studies, particularly a CT scan of the chest, ought to be pursued. Isolated involvement of the lung and pleural space occurs in 15% to 25% of women with metastatic breast cancer.⁶ Before pursuing thoracic surgical intervention, evaluation should include CT scanning of the chest and abdomen and a bone scan to exclude widely disseminated disease.

Tissue biopsy may be obtained by transthoracic or transbronchial needle biopsy or surgical biopsy. Distinguishing breast carcinoma from primary lung carcinoma may be difficult without immunohistologic stains. Several antibodies indicative of breast cancer origin have been described, including estrogen and progesterone receptors, GCDFP-15, and S-100, whereas expression of thyroid transcription factor-1 (TTF-1) identifies lung adenocarcinomas.⁷ If transbronchial

or transthoracic needle biopsy is nondiagnostic, surgery is indicated to make a diagnosis.

What are the goals of metastasectomy?

Resection of a new pulmonary nodule in a patient with a history of breast cancer may be indicated to aid diagnosis and guide further therapy, and in selected cases to achieve possible curative resection. About 3% of all women with breast cancer develop a solitary pulmonary nodule detectable on chest radiograph^{8,9}; however, only 30% to 40% of those nodules prove to be metastases; of nonmetastatic nodules, most represent primary lung tumors. All solitary lung nodules should be biopsied or resected because nearly half are a new primary lung cancer, especially among smokers.¹⁰ The challenge for the clinician remains in selecting which patients would benefit most from surgical resection of lung metastasis and having clear treatment goals to justify the morbidity of surgery.

What palliative treatments may be beneficial?

Less commonly, resection of a metastatic lesion in a breast cancer patient may be considered for palliation. Patients may develop obstructive symptoms or hemoptysis secondary to tumor invasion of mainstem bronchi. Treatment of the endobronchial lesion may include external-beam radiation, endobronchial radiation (brachytherapy), laser therapy, or endobronchial resection and stenting of the obstructed airway to improve bronchial patency.

What factors must be considered in selecting operative candidates?

The same criteria that apply to patients undergoing pulmonary metastasectomy for other primary tumors apply to those with breast cancer:

- Controlled or controllable primary tumor
- Tumor completely resectable
- No extrapulmonary spread detectable
- No local recurrence
- Adequate cardiopulmonary reserve to tolerate the proposed lung resection

In addition, several other patient- and tumor-specific factors ought to be considered because of their prognostic significance. Positive postsurgical outcomes have been associated with a long disease-free interval (DFI),^{3,11,12} complete resection of the tumor,^{3,9,13} and positive ER status.¹³ Although ER status and DFI may be easily obtainable, preoperative determination of whether pulmonary metastases are amenable to complete resection occasionally poses a formidable challenge to the surgeon. Complete surgical resection is predictive of a favorable outcome, whereas the number of metastases alone is not. Causes of incomplete resections include tumor involvement of lymph nodes, chest wall, or diaphragm and inadequate or short margins of resection.³ For these reasons, preoperative imaging studies are crucial in patient selection and for planning operative strategy.

What is the best surgical approach?

Surgery may proceed after appropriate preoperative evaluation has been completed and the patient deemed a suitable surgical candidate. The surgical approach and extent of pulmonary resection must be individualized. For solitary or unilateral disease, the standard approach has been a small lateral thoracotomy that permits complete palpation of the lung to assess for metastases not seen on CT scan. Options for resection of bilateral disease include median sternotomy, staged or sequential lateral thoracotomies, or bilateral transsternal thoracotomy, also known as a “clamshell” approach.

More recently, video-assisted thoracic surgery (VATS) has become an important technique and may be used in certain circumstances, primarily to aid in diagnosis. The use of VATS for routine resection of pulmonary metastases remains controversial. The same principles that apply to an “open” case ought to apply to VATS in terms of obtaining complete resection. In a prospective trial evaluating the efficacy of VATS for metastasectomy, McCormack and colleagues found that 10 of 18 patients had additional malignant lesions found at thoracotomy after “complete resection” by VATS.¹⁴ The study was set to accrue 50 patients but was closed early with a 56% incomplete resection rate of VATS. It should be noted, however, that this study pre-dates the use of spiral CT scans, which have been shown to be more sensitive in detecting additional pulmonary lesions that might otherwise be missed by traditional CT scans.¹⁵

An ideal case for the VATS technique would be the patient whose lesion has been followed for longer than 3 months in whom no additional lesions have developed; technically, the lesion should be solitary, peripheral, and easily resectable with a superficial wedge. Lesions deeper in the parenchyma or close to the hilum are less well suited to resection by VATS. As a rule, metastasectomy should include an adequate margin of normal surrounding tissue, whereas resection for a primary lung carcinoma requires a formal lobectomy. Conservative nonanatomic resections are ideal for metastasectomy because they preserve lung function and allow for complete resection with a minimal risk for local recurrence. Because many metastases are small and may not be detected by preoperative imaging studies, direct intraoperative palpation of the atelectatic lung may enable the detection of occult nodules. At this time, we generally favor an open approach, using VATS on a case-by-case basis.

What is the long-term survival after metastasectomy?

Long-term results of resection of pulmonary metastases vary and are largely based on retrospective and observational data from heterogeneous patient populations. Nonetheless, the data are encouraging. Retrospective data from a tumor registry of 467 patients undergoing metastasectomy for breast cancer revealed a 5-year survival rate that ranged from 13% to 50%, with cumulative 5- and 10-year survival rates of 35% and 20%, respectively.³ A recent retrospective single-institution study¹⁶ showed a 5-year survival rate of 45% with surgery. These results compare favorably with historical controls; however, there are no randomized trials published to

date comparing surgery and adjuvant therapy to adjuvant therapy alone.

How often do pleural effusions develop in breast cancer patients? What causes them?

Breast carcinoma is the most common cause of malignant pleural effusions in women and the second most common cause in general. Over the course of their disease, 7% to 11% of breast carcinoma patients develop malignant pleural effusions.^{17–19} Although autopsy studies show pleural disease in about half of all breast cancer cases,²⁰ many patients are asymptomatic. Pleural effusions may be caused by obstruction of lymphatic drainage by tumor.²¹ Pleural implants, lymphangitic spread to mediastinal or internal mammary nodes, or tumor cell suspension in the pleural space may all result in increased pleural osmotic pressure. Additionally, the inflammatory response to any of the above may result in increased capillary permeability, resulting in an accumulation of pleural fluid. Malignant effusions need to be differentiated from other common causes of effusions, including infection, congestive heart failure, and hypoalbuminemia.

How are malignant effusions diagnosed?

A new pleural effusion in a patient with a history of breast carcinoma should be viewed as secondary to malignancy until proven otherwise. A malignant pleural effusion is defined by the presence of malignant cells within the pleura or pleural fluid. In most cases, a diagnosis can be established by pleural fluid cytology or percutaneous pleural biopsy. Fluid cytology has a diagnostic yield of 60% to 70%, is easily performed, and is often therapeutic as well as diagnostic.^{19,21,22} Large-volume and repeat taps may increase the diagnostic yield. Percutaneous pleural biopsy has a diagnostic yield of about 45%, is more difficult to perform, and is less clinically applicable. Malignant pleural effusions are usually exudative, often bloody, with low glucose concentration. Specific markers, such as carcinoembryonic antigen levels, although not specific for breast carcinoma, may be elevated. If fluid cytology is nondiagnostic, thoracoscopic pleural biopsy should be considered because it has a sensitivity approaching 95%.¹⁹ Once a diagnosis is made, further treatment is initiated.

How should malignant effusions be managed?

The algorithm for the evaluation and treatment of a breast cancer patient with a pleural effusion is similar to that for any patient with a suspected malignant effusion, keeping in mind a few important differences. In general, patients with malignant effusions secondary to breast cancer have a better prognosis than those with effusions secondary to lung, gastric, or ovarian cancer.²¹ Some patients may have a good response to chemotherapy,^{22,23} with documented cases of resolution after initiation of chemotherapy.^{24,25} However, treatment remains palliative, with more aggressive or surgical approaches reserved for cases of recurrent effusions in symptomatic patients who have failed medical therapy or with trapped lungs.

The approach to managing malignant effusions should be individualized to each patient, taking into account the degree of symptoms, the patient's general condition and expected survival, and the response of the primary tumor to systemic therapy. If the patient is asymptomatic, observation is a valid option. For the symptomatic patient with limited survival and very poor performance status, repeat pleurocentesis is a satisfactory option. Insertion of an indwelling tunneled soft catheter such as the PleurX system (Denver Biomaterial, Denver) allows for chronic home drainage of the effusion and avoids unnecessary hospitalization. Freedom from recurrent effusion may be as good with such an approach as with sclerosants²²; however, randomized trials are underway at the present time. Most malignant effusions recur after thoracentesis or tube thoracostomy alone. Standard practice combines drainage with pleurodesis unless the patient is too debilitated to tolerate the procedure. It is crucial to confirm good lung re-expansion following the initial drainage of pleural fluid before attempting pleurodesis. Pleurodesis with sclerosis using bleomycin²⁶ or sterile talc as a slurry is the current procedure of choice, with both treatments having efficacy rates in the range of 75%.²⁷

What is the management of patients who have failed pleurodesis or have a trapped lung?

For patients with a trapped lung or in whom attempts at pleurodesis have failed, several options are available for palliation. Options include intermittent drainage using an indwelling pleural catheter or VATS to facilitate lung re-expansion by removal of the "visceral peel," with or without partial pleurectomy.²⁸

Indwelling pleural drainage tubes can be inserted under local anesthesia and may be drained intermittently by the patient or caregiver at home when the patient is symptomatic. They have been shown to be safe and effective and are a good treatment option for patients with poor performance status.^{28,29}

Pleuroperitoneal shunting is also an option. Pleuroperitoneal shunts are unidirectional catheters with a valved pumping chamber that facilitate passage of pleural fluid to the peritoneal cavity (Denver shunt, Codmen and Shurtleff, Randolph, MA). The shunts can be inserted using a modified Seldinger technique or through thoracoscopy or minithoracotomy. Although the catheters can be inserted with a low mortality and morbidity, they are easily obstructed by fibrinous debris.³⁰ Additionally, they require that a patient or caregiver actively compress the pump chamber at regular intervals. For these reasons, pleuroperitoneal shunts are a less attractive option.

VATS with or without partial decortication or pleurectomy is a highly effective method of achieving successful pleurodesis³¹ as well as biopsy of the tumor. It also has the advantage of allowing concurrent drainage and pleurodesis. VATS pleurodesis also has the added benefit of ensuring that insufflated talc is uniformly delivered to the pleural surface and that chest tubes are optimally positioned under direct vision. It does require that the patient be able to tolerate general anesthesia and single-lung ventilation, and it may be associated with higher costs than pleurodesis through tube thoracostomy.³²

Pleuroctomy is the most effective form of ensuring successful pleurodesis and prevention of recurrence of a malignant effusion; however, it is associated with high morbidity and mortality rates and is not generally recommended.^{11,33} Its use should be reserved for patients with trapped lung who have a long expected survival and who are in good general condition.

What is the best method for pleurodesis (timing, size of tube, sclerosing agent, patient rotation)?

Successful pleurodesis may be achieved through small-bore chest tubes.³⁴ Smaller chest tubes usually cause less discomfort and are better tolerated by the patient; however, they may become more easily occluded, requiring repeat chest tube insertion. For that reason, we prefer to use a medium-sized chest tube in the range of 20 to 28 French. In addition, the amount of daily pleural fluid drainage should be relatively low, in the range of 100 to 200 mL/day, before initiation of sclerosing therapy. Talc is the most effective agent for use under general anesthesia; other agents, including bleomycin, may be equally effective.³⁵ Talc has been shown to be superior to other agents, including tetracycline or bleomycin in several trials, including one that examined malignant effusions secondary to breast cancer.³⁶ Once the sclerosant is administered, the chest tube should be clamped or placed to water seal for 1 to 3 hours. Patient rotation has been proposed to facilitate distribution of medication throughout the pleural cavity. This practice has not been validated in clinical trials; nuclear tracers injected into the pleural cavity are distributed widely after a short interval. A prospective randomized trial suggested that patient rotation did not contribute to success of talc pleurodesis and was associated with increased patient discomfort.³⁷ There appears to be a similar success rate of pleurodesis using talc slurry through a chest tube, as through talc insufflation (“poudrage”) with VATS. The decision for sclerosis under general anesthesia should be tailored to the needs of the patient.³²

In which patients with breast cancer is chest wall reconstruction indicated?

Breast cancer patients may require chest wall resection and reconstruction for palliation of pain or for removal of an ulcerated mass that produces significant discomfort. This is best accomplished with a multidisciplinary approach, including thoracic and plastic surgeons, as well as medical or radiation oncologists to help provide the best chance of local control. There are primarily three scenarios in which breast cancer patients might require chest wall resection:

1. *Locally advanced disease.* Although most breast cancers are detected earlier with modern screening strategies, occasional patients may present with advanced local disease and direct chest wall invasion. Invasion of the ribs or intercostal musculature requires en bloc full-thickness chest wall resection. Recurrence with solitary disease in the internal mammary lymph node region may also be treated with chest wall resection and reconstruction.
2. *Radiation necrosis,* often seen 15 to 20 years after completion of therapy, results from ischemia and damage to soft

tissues surrounding the irradiated field. The affected area of chest wall may frequently be infected or less often may harbor residual tumor, both of which situations pose particular challenges for the surgeon.

3. *Local recurrence* may involve tumor invasion of the musculoskeletal elements underlying the breast. Often, this occurs in the setting of prior irradiation or infection. Local recurrence may follow several patterns, including primary involvement of internal mammary chain nodes or direct invasion of ribs or chest wall musculature. Local recurrence may cause pain and produce a cosmetically displeasing ulcerated mass, both of which are indications for palliative resection. Some authors have advocated a disease-free interval of longer than 2 years as the criterion for selecting candidates for resection of the chest wall recurrence for local failure.²⁵

What should the preoperative evaluation include?

A thorough history and examination may give clues as to the aggressiveness of the tumor and overall prognosis. A chest wall recurrence carries a worse prognosis in a patient who has undergone prior modified radical mastectomy than in a patient who has undergone prior breast-conserving therapy (i.e., lumpectomy and radiation). Physical examination may give clues to the extent of the disease. Short disease-free interval, rapid growth, overlying skin fixation, and pain may portend a worse prognosis. Preoperative radiologic evaluation should include a chest radiograph and either a CT scan or MRI of the chest to assess the extent of disease. Incisional or needle biopsies of the lesion may help confirm a diagnosis of suspected chest wall recurrence. Preoperative lung function testing should be obtained if a patient has known intrinsic lung disease or poor respiratory reserve, especially if there is a chance that the patient may require concomitant lung resection.

What are adequate margins of resection?

We advocate en bloc resection of all involved ribs and one additional rib cephalic and caudal to the lesion. A minithoracotomy enables manual inspection and palpation of the inner surface of the chest wall and assessment of underlying viscera. Involvement of the great vessels precludes resection. If feasible, a 5-cm margin of clinically normal-appearing tissue in all planes is advocated in the hope of obtaining 1- to 2-cm histologic margins. Although frozen sections of soft tissues may aid in confirming tumor-free margins, some tissues, such as bone, are not amenable to frozen section, and thus sound clinical judgment is paramount. Adequate resection of the diseased tissues is important to provide healthy, viable margins on which subsequent chest wall reconstruction relies.

What are the goals for reconstructing the chest wall?

Chest wall reconstruction must adequately remove all devitalized or tumor-involved tissue, restore rigidity to prevent a

flail chest, and provide adequate soft tissue coverage to close the pleural space and protect the underlying viscera. Reconstruction should provide a tension-free closure with healthy tissue coverage. Careful preoperative planning with plastic surgery consultation should allow for a satisfactory result in all cases.

What are the surgical options for reconstruction?

Reconstruction of the chest wall must be individualized, taking into account the size and location of the defect, the presence or absence of associated infection, and the general condition of the patient. Options for reconstruction include autologous materials (e.g., muscle flaps) or prosthetic grafts including polytetrafluoroethylene (PTFE) or Prolene mesh with or without the use of methylmethacrylate to add structural rigidity. A retrospective study demonstrated no difference in outcomes between Prolene and PTFE for reconstruction, and both were shown to be safe.³⁸ Frequently used regional flaps include latissimus dorsi, pectoralis major, and rectus abdominis flaps. Occasionally, an omental flap can be used if regional myocutaneous flaps are not an option.³⁹ In the presence of significant potential infection, the need to avoid foreign materials should prompt consideration of reconstruction using completely autologous material. This may lack the structural support of the prosthetic materials but is less likely to be complicated by ongoing sepsis.

The choice of flap is based on the size of the defect as well as the region of chest wall affected. Each pedicled flap is tethered by its blood supply, although more complicated free myocutaneous flaps may overcome this obstacle and help in closing larger defects. Split-thickness skin grafts may be required for coverage of donor sites. Chest wall stabilization is required for most full-thickness breast resection defects, particularly if they are large, laterally located involving the curve of the ribs, or involving a significant part of the sternum, or if the patient has poor pulmonary function.

IX

Bone Metastases from Breast Cancer

*James C. Wittig and
Justin G. Lamont*

Breast cancer is the most common cause of skeletal metastases.^{1,2} Bone is the second most common site to be involved by metastatic breast cancer, and it is the first site of metastatic disease in 26% of breast cancer patients.³ It is also the most common site that clinically manifests. On autopsy studies, up to 90% of patients who die from breast cancer have bone metastases.⁴ Patients who develop bone metastases survive an average of 2 years from the time of the first bone metastasis. Although most patients have organ involvement in addition to their bone metastases, there is a subgroup of women who solely develop skeletal metastases. Women who develop bone-only metastases have a more favorable prognosis than those with isolated organ metastases or combined skeletal and organ metastases.^{5,6} In fact, in patients with a single bony metastasis and no organ involvement, proper treatment can in rare cases provide prolonged disease-free survival or even cure.

Skeletal metastases can result in significant complications that have a negative impact on the quality of life. Pain, pathologic fracture, neurologic complications, and hypercalcemia are all potential complications. Pain and pathologic fracture lead to forced immobilization and progressive deterioration. Hypercalcemia is the most common paraneoplastic syndrome and is discussed in Part IV of this chapter.⁷ Neurologic complications, including paralysis from spine lesions, can occur. The axial skeleton and proximal ends of the long bones of the lower extremities are the most common sites of bone metastases. The pattern of skeletal metastatic sites follows the distribution of Batson's plexus or the vertebral vein system.⁸ Batson's plexus is a low-pressure, high-volume, valveless venous system that bypasses caval, portal, and pulmonary

systems and allows direct access of cells to the bone from distant anatomic sites.

Bone metastases stimulate bone resorption and osteolysis primarily through direct or indirect stimulation of osteoclasts. Cancer cells secrete cytokines that stimulate osteoclasts to resorb bone. Passive hyperemia that occurs secondary to the presence of neoplasm also results in stimulation of local osteoclasts. Less prominent mechanisms may include direct resorption of bone by the tumor cells through production and secretion of proteinases that degrade bony matrix.^{9,10} In most instances of breast cancer metastases, the osteoblasts respond to the enhanced osteoclast activity by laying down new bone. This osteoblastic response appears as sclerosis on a plain radiograph.

TREATMENT GUIDELINES

What is the best diagnostic radiographic screening technique for bone metastases?

Early detection of skeletal metastases permits prompt intervention that may have a significant impact on the quality of life. Pain may be absent in up to 50% of patients with skeletal metastases.¹¹ Thus, early detection through periodic surveillance with bone scintigraphy may be justified.¹² ^{99m}Tc-scintigraphy is the best screening method for bony metastases. In the skeletal phase of the scan, lesions usually appear as localized areas of uptake owing to the osteoblastic response induced by the metastatic deposit. Lesions as small as 2 mm can be detected.¹³ Bone scans demonstrate skeletal involvement much earlier than plain radiographs. In order for a lesion to be visualized on a plain radiograph, 30% to 50% of the bone must be destroyed. False-negative bone scans typically occur with tumors that do not evoke a significant osteoblastic response, such as myeloma. False-negative bone scans are unusual in breast cancer patients, however, because breast cancer metastases invariably evoke a mixed osteolytic and osteoblastic response.¹⁴ Bone scintigraphy is an excellent tool for screening for occult metastases, determining multiple sites of disease throughout the body or in the same bone, and monitoring response to treatment. However, bone scan does not provide any information about the structural integrity of bone. Plain radiographs or CT or MRI scans must be correlated with the bone scan.

Plain radiography is often the first radiographic study performed on breast cancer patients who present with pain referable to a specific bone or joint. Plain radiography is also performed as a correlate to a positive bone scan during routine surveillance in an asymptomatic patient. Most metastatic lesions start in the medullary bone, although tumors can metastasize to the cortex and periosteum. Thirty to 50% of the medullary bone must be destroyed before a lesion becomes evident on a plain radiograph.¹² Subtle cortical destruction by a lesion or a cortical metastasis may be radiographically detectable at an earlier stage. Most breast cancer metastases radiographically demonstrate mixed areas of lysis and sclerosis; however, purely lytic and sclerotic lesions do occur. Lesions can be classified as permeative, moth-eaten, or geographic. Permeative and moth-eaten lesions are more

common, consistent with their aggressive, often rapidly growing, malignant nature. These lesions permeate the bone, which is unable to respond rapidly enough against the tumor to encapsulate it. Geographic lesions in which there is a sharp zone of transition between the tumor and adjacent normal bone are less common. This type of radiographic presentation denotes a slower growing, less aggressive neoplasm.

CT and MRI are useful for detecting and characterizing suspected bone metastases that are not visible on plain radiographs. About 50% of patients with bone scan–positive skeletal metastases and negative radiographs have lesions detectable on a CT scan.^{15,16} MRI and CT are useful for determining cortical involvement, extramedullary growth, and intramedullary extent of tumor, all of which are important for determining the indications for surgery as well as for planning a procedure. MRI and CT are also useful for detecting occult fractures through neoplasms and for identifying other causes

of pain, such as arthritic processes and tendinopathies. MRI is better than CT for evaluating the presence and size of any soft tissue component of the neoplasm as well as for determining the intramedullary extent of the lesion. In the evaluation of spine lesions, MRI is important for detecting epidural extension, spinal cord compression, and extent of disease within individual vertebral bodies and throughout the entire spine. In patients who cannot undergo an MRI, CT myelography can be used to evaluate spinal cord compression. CT is especially efficacious for evaluating the presence and depth of subtle endosteal erosion or cortical involvement that may not be evident on plain radiographs. This information is often used when deciding whether a patient's bone should be prophylactically fixed for an impending pathologic fracture (Fig. 32–21).

It can be difficult to differentiate a new sclerotic lesion from a healing lesion on radiographs. In response to treatment,

Figure 32–21 A, Plain radiograph demonstrating a pathologic fracture of the left femoral neck through a permeative mixed sclerotic breast cancer metastasis. Most breast cancer metastases to bone result in a mixed sclerotic and lytic lesion on plain radiographs. B, MRI of same patient demonstrates tumor involvement of the entire femoral shaft that was not accurately depicted on the plain radiograph. This information is important for surgical planning and for monitoring response to treatment. C, Plain radiograph demonstrating a mixed sclerotic and lytic lesion and pathologic fracture of the right proximal humerus. D, Example of a mixed sclerotic and lytic lesion of the right ilium secondary to breast cancer metastases. E, MRI accurately demonstrates the intramedullary extent of the lesion. The lesion is noted to encroach on the acetabulum. Close follow-up or treatment may be warranted to detect early involvement of the hip joint and prevent a potential complication.

most healing lesions become more sclerotic and calcified on plain radiographs. On bone scan, a flare phenomenon, in which the lesion demonstrates more intense uptake, may occur during the early stages of healing. This often signifies a more intense osteoblastic response during the healing phase. The activity on bone scan should become less intense once the lesion is completely healed. This may take several months.

Progression of disease appears as enlargement, increasing lysis, and loss of the osteoblastic response on plain radiographs. Bone scintigraphy is nonspecific in measuring disease progression from response to treatment of isolated metastases and must be correlated with plain radiographs. On bone scan, existing lesions may show increased uptake with disease progression, although rapidly growing lesions with little osteoblastic response and bone formation may show decreased uptake. In addition, the flare phenomenon may occur during the initial stages of healing. The role of MRI in assessing response to treatment is not well defined.

When is magnetic resonance imaging indicated in the assessment of possible bone metastases?

MRI is useful for determining the presence of a metastatic lesion that has not produced sufficient bone destruction to be evident on plain radiographs as well as the presence of lesions that do not demonstrate uptake on the bone scan (false-negative bone scan). The entire bone can be visualized in a single plane, thus enabling detection of additional occult lesions within the same bone. Coexisting lesions should be considered for fixation during the same surgical procedure. Skeletal metastases typically involve the metaphyseal regions of the long bones and therefore may exist in conjunction with arthritis at adjacent joints. Arthritic processes induce sclerosis and cyst formation that may obscure bone scan and plain radiographic results. MRI is especially useful in discerning the presence of a metastatic deposit in the presence of arthritis. Gadolinium contrast enhancement may be useful. MRI often identifies other mechanical abnormalities at adjacent joints that may contribute to or be the sole cause of pain. It is also useful for evaluating complications associated with chemotherapy and radiation such as avascular necrosis, radiation-induced necrosis, stress fractures, and radiation-induced neoplasms.

MRI is crucial for evaluating spine metastases. It is the test of choice for detecting spinal cord compression and can help differentiate among benign osteoporotic compression fractures, infections, and malignant vertebral lesions or fractures.

MRI is problematic in claustrophobic patients who cannot tolerate the study. It is also contraindicated in patients with devices such as cardiac pacemakers, intracranial aneurysm clips, and ferromagnetic fragments in or around the eye. In these instances, CT of the bone with reformatted coronal and sagittal reconstructions may be invaluable.

How do bone metastases affect prognosis?

There is no recognized method of assessing the prognosis of patients with breast cancer who have metastatic lesions restricted to bone. Patients who have only skeletal metastases

at the time of initial diagnosis or who develop skeletal metastases without visceral metastases at a later date have better survival rates than patients who develop visceral metastases only or combined visceral and bony metastases.^{5,6,17} The distribution of skeletal metastases on bone scans and the radiographic appearance of osteosclerosis can be of prognostic value for patients with breast cancer who have metastases confined to bone.¹⁸ Patients whose bone metastases are all cranial to the lumbosacral junction have a significantly longer survival than those who have bone metastases caudal to the junction (36% vs. 16% 5-year survival). The presence of osteosclerosis is indicative of a more slowly growing neoplasm and hence provides a measure of the biologic aggressiveness. The presence of radiographic osteosclerosis in metastatic bone lesions at the time of initial presentation is associated with a more favorable prognosis (42% 5-year survival rate in patients with lesions that demonstrate osteosclerosis vs. 23% 5-year survival rate in patients whose lesions do not demonstrate sclerosis). Sherry and associates¹⁹ found that survival did not correlate with the number of metastatic deposits in patients with metastases restricted to bone.

Patients who can be stratified into a more favorable prognostic category may benefit from more aggressive surgical treatment. Yamashita and coworkers found several variables associated with a more favorable prognosis in patients with breast cancer metastases confined to bone.⁶ These included an absence of extraosseous metastases; cranial bone metastases; a solitary bone metastasis; presence of osteosclerosis on a plain radiograph; and absence evidence of hypercalcemia. In the study by Yamashita and coworkers, the median survival time after first diagnosis of a bone metastasis was 35 months. The median survival after visceral metastases was only 5 months. Perez and colleagues also reported a better prognosis for patients who develop skeletal metastases solely versus visceral metastases.⁵ In their study, the median survival of patients with skeletal metastases was 28 months, and 25% of patients survived at least 5 years. Patients who developed visceral metastases had a median survival of 13 months, and less than 10% survived 5 years.

Pathologic fracture and spinal cord compression are common orthopedic complications that seriously compromise the quality of life of a patient. Yamashita and coworkers reported a 13% rate of pathologic fracture and 32% rate of spinal cord compression.⁶ These rates are similar to those reported by Perez and colleagues.⁵ The median survival after a long bone pathologic fracture was 14 months (range, 1 to 80 months), indicating that about 50% of patients survive longer than 1 year after developing a long bone pathologic fracture. The median survival after spinal cord compression was 8 months (range, 2 to 74 months), and 42% of patients survived longer than 2 years.

What are the indications for biopsy?

The indications for biopsy of metastatic bone lesions are as follows:

1. A known primary breast cancer with a bony lesion suspected to be a metastasis. This is important for staging, prognostic purposes, and planning treatment. The biopsy must confirm the presence of metastatic breast cancer in

bone and exclude primary bone tumors, infections, and metastatic lesions from primary sources other than breast before initiating treatment.

2. Suspected progression of disease or failure of treatment denoted by formation of new bony lesions.
3. Presence of one or more skeletal lesions with no known primary source. Biopsy is performed to establish a diagnosis and direct staging studies. One must not assume that a lesion is metastatic. It must be approached as if it were a primary sarcoma despite the metastatic appearance.
4. Assessment of the efficacy of treatment by the histologic response of a lesion.
5. Presence of localized bone pain with a lesion on bone scan and negative radiographs.²⁰

What is the role of a closed biopsy?

A closed biopsy is performed percutaneously or through a small stab incision in the skin. A specific type of needle is subsequently inserted and directed under radiologic supervision (fluoroscopy or CT scan) down to the neoplasm. Two types of needles can be used, depending on the clinical-radiographic presentation: a fine needle (16 to 22 gauge) for fine-needle aspiration (FNA) or a core needle (trephine-type or Craig needle). This is in contrast to an open biopsy, in which a longer incision is carried directly down to the lesion and biopsy material is obtained under direct visualization.

During closed biopsy procedures, CT guidance is especially important for sampling lesions that are adjacent to critical structures. FNA is usually performed for cytogenetic analysis, most often to confirm the initial presentation of a bone metastasis in the setting of known metastatic breast cancer. Core needle samples are amenable to paraffin block processing and are useful when analysis of the architecture of the tissues and cells is pertinent. Core needle biopsy is indicated in a patient with a history of nonmetastatic breast cancer who develops one or more bony lesions. Adequate sampling with a core needle may be necessary to exclude the presence of a primary bone tumor, infection, or metastatic disease from a second primary neoplasm. Core needles are also used for sampling blastic metastases. It is often impossible to penetrate the sclerotic bone with a fine needle. Fine needles are more effective at sampling purely lytic lesions or lesions with a soft tissue component.

A closed needle biopsy offers several advantages over a formal open biopsy. These advantages include local anesthesia, less blood loss, quicker healing, fewer wound complications, and hence more rapid initiation of chemotherapy and radiation; less surrounding soft tissue contamination with reduced risk for local soft tissue recurrence; and fewer biopsy-related pathologic fractures. Disadvantages, which may include inadequacy of specimen size and sampling error, can be minimized by having the biopsy performed by an experienced radiologist or orthopedic oncologist and the specimen analyzed by experienced pathologists. Several aspirations or cores should be obtained. At experienced centers, the diagnostic accuracy rate of a closed biopsy is similar to that of an open biopsy, and there are far fewer complications than with an open biopsy.²¹

Contraindications to a biopsy may include skin conditions such as infection, bleeding diatheses coexisting with a

hypervascular tumor, and any need for open surgery. In the case of a hypervascular tumor or a patient with a bleeding diathesis, needle biopsy offers obvious advantages over an open biopsy. On the other hand, when a patient develops a pathologic fracture in the presence of known metastatic breast cancer, intraoperative biopsy with frozen section pathologic analysis of the neoplasm is indicated to confirm the presence of metastatic carcinoma. Once the diagnosis is confirmed, fixation commences. In these instances, there is usually no need to perform a biopsy preoperatively.

What are the indications for alternative and adjunctive nonoperative treatments?

Alternative and adjunctive nonoperative treatments of bone metastases include radiation therapy, chemotherapy, hormonal therapy, and bisphosphonates. The indications for radiation therapy include pain relief and suppression of local tumor growth. Suppression of local tumor growth is important in the treatment of impending fractures, after surgical fracture fixation of metastatic lesions, and in the treatment of neural compression. Complications associated with radiation treatment of bone lesions include marrow fibrosis, which may preclude chemotherapy. Marrow fibrosis destroys the hematopoietic ability of bone marrow and therefore interferes with the body's ability to restore blood counts after chemotherapy.

In the management of an impending fracture—a potential fracture in a bone with weakened structural integrity owing to a metastatic lesion—occasionally a lesion will heal with radiation, especially if it is mechanically protected.²² More than 80% of patients with a limited number of well-localized bone metastases can be treated effectively with external-beam radiation.^{23–25} Radiation may render the patient asymptomatic and control the disease for an extended period. Patients with numerous areas of skeletal involvement may benefit more from a systemic approach consisting of chemotherapy with or without endocrine therapy, and with or without systemic radionuclide therapy. Supplemental external-beam radiation may be used to target the most symptomatic areas.

Irradiation of a weight-bearing bone should be undertaken only after careful evaluation of the potential fracture risk produced by the underlying lesion. There is an increased risk for pathologic fracture in the peri-irradiation period owing to an induced hyperemic response at the periphery of the tumor. This weakens the bone and increases the risk for spontaneous fracture. Mechanical protection is important until the bone's structural integrity has been restored.

Radiation achieves at least partial pain relief in 80% to 90% of patients.²⁶ Most metastases begin to respond over the course of 10 to 14 days. Seventy percent of patients experience pain relief within 2 weeks of starting therapy. Within 3 months, 90% of patients achieve pain relief.²⁷ Fifty to 70% of patients achieve sustained pain relief for 1 year or more.²⁸ Patients with breast and prostate metastases who have a significant osteoblastic response derive better pain relief from radiation therapy than patients with long bone lesions from other primary tumors, such as kidney and lung, which are usually more lytic and compromise the mechanical integrity of the bone to a greater degree.²⁹ High doses of postoperative radiation (>3000 cGy) have been associated with poor healing of pathologic fractures. The optimal dose and fractionation

regimen are debated. Generally, 2500 to 3000 cGy is administered over 10 to 15 fractions.

Bisphosphonates are stable analogues of inorganic pyrophosphate. They inhibit bone resorption through inhibition of osteoclast function and have been shown to decrease the rate of pathologic fractures and skeletal complications in patients with breast cancer and metastatic bone lesions. There are different generations of bisphosphonates with different potencies and effects. The bisphosphonates are generally safe compounds with few side effects. Several large randomized studies have been performed to analyze the efficacy of pamidronate in the management of metastatic bone lesions.³⁰

The goals of chemotherapy and hormonal treatment in patients with metastatic disease involving bone are pain control, disease stabilization, and reduction in the risk for morbid skeletal events. Additionally, the use of chemotherapy and hormonal treatment in metastatic breast cancer has been shown to prolong survival.³¹ In one study, there was an 18% complete response rate and a 65% partial response rate in patients with metastatic bone lesions treated with a multi-agent chemotherapy regimen.³¹

Systemic radionuclides can be very effective in treating symptomatic bone metastases. These agents treat all sites rapidly and selectively, thereby reducing toxicity and enhancing the therapeutic ratio.²⁶ Strontium 89 is the most commonly used radioisotope in bony metastatic disease.^{32,33} It localizes in the mineral of bone by combining with the calcium component of hydroxyapatite. Actively calcifying areas concentrate most of the isotope, and therefore it has particular efficacy in treating breast cancer metastases. Degradation of the isotope in host bone administers local short-acting radiation to the adjacent tumor cells. Strontium 89 has very good response rates, ranging from 51% to 91%.³³ The only significant toxic effect of strontium 89 is myelotoxicity, which is usually temporary. Strontium 89 can be safely used in conjunction with external-beam radiation.

When and how should orthopedic surgical management be instituted?

The management of patients with skeletal metastases from breast cancer must be individualized. Important considerations include age, comorbidities, prognosis, pain, presence of an isolated skeletal metastasis or bone-only metastases, location of metastatic disease, presence of an impending or actual pathologic fracture, and the patient's overall activity level. Patients may present with asymptomatic bone metastases, painful metastatic disease, and pathologic fractures. Treatment of patients with asymptomatic skeletal disease is aimed at diagnosis through biopsy, systemic control of disease through chemotherapy, and hormonal treatment and observation of all bones involved with the disease. Referral should be made to an orthopedic surgeon for evaluation, biopsy, recommendations, and periodic observation of lesions. In general, asymptomatic lesions are at low risk for fracture. Serial observation for disease progression and further bony destruction is warranted so that any bone at risk for fracture can be identified and treated before actually fracturing. MRI is important in evaluating spine metastases. A baseline MRI is important to identify any epidural extension of tumor that can cause neurologic compromise. Systemic therapy,

radiation, braces, casts, and analgesics are effective methods for treating selected lesions. Surgery by means of internal fixation or prosthetic replacement offers the most effective and expedient means of pain control and restoration of function for patients with actual pathologic fractures.

Most pathologic fractures do not heal. In a study of 129 pathologic fractures, only 37% of pathologic fractures due to breast cancer healed.²² High doses of postoperative radiation (>3000 cGy) are associated with poor healing. Rigid internal fixation supplemented with bone cement increases the probability of bony union. The surgeon must choose a form of fixation that does not ultimately rely on bony union.

Patients with skeletal metastases often are in poor medical condition and have a limited life expectancy. Surgical intervention must be undertaken with the intention of avoiding future surgery. Surgical principles of management of pathologic fractures or impending pathologic fractures are as follows:

1. Curettage to remove all gross disease
2. Use of immediate rigid fixation consisting of internal fixation with polymethylmethacrylate (PMMA or bone cement) or cemented prosthetic replacement
3. Filling defects with bone cement
4. Adjuvant radiation or chemotherapy

Painful lesions and pathologic fractures should be referred to an experienced orthopedic surgeon for evaluation and treatment. Many patients without an actual fracture do not require surgery. Symptomatic relief is usually satisfactory with a combination of radiation and medical therapy. Patients at low risk for fracture or those who are poor surgical candidates can often be effectively managed with conservative means, such as bracing, casting, non-weight bearing, and radiation. Anatomic site may play a role in selecting treatment. Lesions in weight-bearing bones are often treated more aggressively than upper extremity lesions.

Prophylactic fixation is warranted for impending fractures in the following circumstances:

1. Fixation eliminates the need for narcotic analgesics or reduces pain.
2. Equally effective nonoperative treatments are not available.
3. Surgical treatment for the impending fracture would be significantly safer or more effective than surgery for an actual fracture.
4. Surgery permits mobilization and early return to function.

Pathologic fractures are best treated by operative fixation. Even if fractures can heal with nonoperative treatment, the protracted treatment time required for closed management is inappropriate because this period generally is increased by the presence of tumor. Primary goals are to allow immediate weight bearing and return to activity, not to promote fracture healing. Prosthetic replacement and stabilization with polymethylmethacrylate (bone cement) are frequently used. These techniques would be avoided in the treatment of non-neoplastic fractures. Tumor removal and bone stabilization best meet the goals of diagnosis, functional stability, and pain relief. In general, the metastatic deposit should be excised. Treatment includes intralesional (marginal resection or curettage) and extralesional (wide) excision. Intralesional curettage is usually performed in or around a fracture site at the time of stabilization. Extralesional excision or resection is usually

performed for a solitary metastatic deposit or for lesions that have destroyed a large segment of the bone with no cortices left for reconstructing with bone cement. It is the most effective way to achieve local tumor control. Cures are occasionally reported following resection of isolated bone metastases.

Surgical treatment of pathologic fractures is based on anatomic location, extent of the lesion, and condition of the patient. Surgery is indicated for most patients. Patients with a very short life expectancy (usually less than 2 weeks) or who are poor surgical candidates can be treated conservatively by stabilizing the bone with a cast or a brace and by providing sufficient medication for pain relief.

The surgical procedure is aimed at preventing the need for future surgeries. In general, one should choose a device (e.g., rods and nails, prosthetic replacements, and screws and plates) that will fix the entire bone and prevent complications should disease progression occur. Intramedullary devices are usually used for diaphyseal fractures or metadiaphyseal fractures in long bones. The bone proximal and distal to the lesion must be free of disease to allow secure fixation of the device in good bone. Adjunctive use of methylmethacrylate or bone cement enhances fixation, fills defects, enables immediate weight bearing and use of the extremity, and reduces the risk for hardware failure that requires reoperation. Amputation is rarely needed in the management of metastatic breast lesions to bone.

Whenever feasible, gross tumor should be removed so that tumor is not carried by the rod and implanted at a more distal site. Intramedullary rods can be placed through limited incisions with minimal blood loss and low risk for infection. Use of strong nails of wide diameter and supplementation with bone cement are preferred to prevent hardware failure for these types of fractures, which may require a prolonged time to heal or may never heal.

Cemented prosthetic replacement is indicated for pathologic lesions that affect the epiphyseal areas of the bone. They may also be used for select metaphyseal lesions, particularly those that extend into the epiphyses. Special prostheses with long stems permit fixation of the entire bone. Screws and plates have selected indications and in most instances are not recommended because they do not provide fixation for the entire bone.

Radiation therapy of bone metastases remains the principal surgical adjuvant. It should be delivered to the entire surgical field and along the length of any prosthesis or internal fixation device.^{23,27} This addresses tumor cells that have been spread by the surgical procedure along the intramedullary canal and soft tissues. Local tumor control helps prevent destabilization of the implant by preventing local tumor progression from affecting the structural integrity of the bone in which the implant is fixed. Postoperative radiation prevents local tumor progression that could affect the structural integrity of the bone and lead to implant failure.

SPECIFIC ANATOMIC SITES

Spine Lesions

The spine is the most common site of skeletal metastases. In a study by Toma and colleagues, the survival time of patients

with vertebral metastases was longer than that of patients with bone metastases to other sites.³⁴ Pain is the most common presenting symptom and may be secondary to intraosseous disease, spinal instability, vertebral compression fracture, epidural compression, or nerve root involvement. In about 5% of patients with widespread cancer, there is spinal cord or nerve root involvement. Neurologic involvement occurs in about 20% of patients with neoplastic involvement of the spine and may be the initial presenting symptom.^{35,36} Between 30% and 50% of the vertebral body must be destroyed before the damage is visible on plain films. Lysis of a pedicle may be the only radiographic finding in the early stages of vertebral involvement. MRI is warranted to detect extraosseous growth of tumor and epidural compression.

Surgical intervention is usually not needed for asymptomatic lesions discovered on bone scan. The indications for operative intervention include progressive neurologic compromise, intractable pain, recurrence of cord compromise following local irradiation, fracture with spinal instability, need for tissue diagnosis, and an impending fracture not responsive to radiation. The surgical approach should be based on the location of instability or epidural compression. The spinal canal is decompressed, and the spine is stabilized. Bone graft and bone cement are used to augment internal fixation. Radiation is recommended postoperatively. Further details about specific methods of decompression and stabilization are discussed elsewhere in this chapter.

Hip Lesions

The hip is the most common site of a pathologic fracture. This is because of the high incidence of metastases to this area and the high magnitude of forces concentrated in the hip area. Metastatic disease to the hip can involve the pelvis and acetabulum and the proximal femur. Complications caused by lesions to the proximal femur may arise from metastatic involvement of the femoral head or neck, intertrochanteric region, subtrochanteric region, or any combination. Surgical treatment of femoral head or femoral neck fractures entails endoprosthetic replacement, usually with a long-stem femoral component or total hip replacement. Prostheses permit rapid mobilization and weight bearing. Lesions in this region are not treated with internal fixation because of the poor quality of the bone and because of the risk that progression of the lesion can result in loss of fixation. Adequate pain relief and return to prefracture ambulatory status are successful more than 90% of the time. Long-stem prostheses are recommended to fix the entire femoral shaft, especially if there is coexisting disease distally that may progress or if the patient is at risk for additional metastases to the same bone in the future. This is especially necessary for patients in whom a prolonged survival is expected. Cemented stems have less risk for loosening and a lower incidence of postoperative thigh pain than do porous ingrowth stems, especially when adjunctive measures are used. Significant acetabular disease should be addressed during the same surgery.

Management of intertrochanteric and subtrochanteric fractures varies. Plate and screw fixation augmented with bone cement or second-generation femoral rods with fixation extending across the femoral neck have been employed successfully. Lane and colleagues have recommended long-stem cemented prostheses for metastatic involvement in any area

Figure 32–22 Plain radiograph demonstrating failure of fixation of a pathologic fracture of the left proximal femur. The patient presented 1 year earlier with a pathologic fracture of the proximal femur secondary to a breast cancer metastasis. Internal fixation was performed, and the patient underwent postoperative irradiation. The tumor progressed, and the fracture never healed. Ultimately, the hardware failed, and the screw penetrated the femoral head. This patient required a second surgery with placement of a long-stem cemented hemiarthroplasty. Whenever feasible, a curettage of the tumor, as well as fixation that does not rely on bony union, is recommended.

of the proximal femur.³⁷ This technique is reliable and avoids late failure of fixation from proximal progression of intertrochanteric and subtrochanteric lesions (Fig. 32–22). It also treats simultaneous lesions more distal in the shaft and permits early, rapid mobilization. In Lane's report, there were no instances of loosening or dislocation, and there were two infections (1.2%).³⁷ Long-stem cemented hemiarthroplasties are preferred (Fig. 32–23). A bipolar device lessens acetabular wear in cases in which metastases have not affected the acetabulum. Massive bone destruction is better addressed with a large special tumor prosthesis.

Lesions of the hemipelvis not directly involving the hip joint can generally be treated with modification of weight bearing and external-beam radiation. Avulsion fractures of the anterior superior and anterior inferior iliac spines, iliac crest, and superoinferior pubic rami are common and should be treated nonoperatively. Unstable pathologic fractures of the hemipelvis usually involve the periacetabular area. Periacetabular lesions are much more difficult to treat surgically. Surgical approaches are more complex and are associated with greater blood loss and a higher risk for complications. Most lesions in which the femoral head is not pushed into the pelvis can be treated with restricted weight bearing, medical treatment, and radiotherapy. Reconstructive techniques must transfer load-bearing stresses into structurally intact bone in the upper ilium and adjacent sacroiliac joint. This may be accomplished by use of multiple Steinmann pins, reinforced bone cement, and antiprotrusion devices (Fig. 32–24). When there is massive bone destruction, a saddle

prosthesis can be used. The saddle prosthesis articulates with the remaining ilium.³⁸

Femoral Shaft

Pathologic fractures of the femoral shaft are stabilized with intramedullary nails. Cement is used to add stability, prevent shortening, and decrease the risk for hardware failure. Coexisting disease in the proximal femur region should be addressed by using a cephalomedullary nail that provides fixation across the femoral neck in addition to fixing the femoral shaft or a long-stem hemiarthroplasty. Plate and screw fixation combined with bone cement is not preferred because of the risk for fracture proximal and distal to the plate and increased operative time. Intramedullary rod fixation is generally done by the open method; that is, the tumor-fracture site is exposed, the tumor is curetted, bone cement is injected proximally and distally, and the intramedullary rod is inserted. Immediate ambulation with full weight bearing is permitted a few days after surgery. Small lesions responsive to radiation may be treated before fracture by the closed method if the cortices are intact and there is normal proximal bone. The rod is inserted through a small incision at the greater trochanter and placed in an antegrade manner across the lesion to obtain good distal fixation.

Humerus

The upper extremity is less commonly involved with metastatic disease than the spine, pelvis, and lower extremities. Humeral fractures can be severely disabling, preventing patients from feeding themselves, attending to hygiene, and transferring with the use of external aids. Surgical stabilization is recommended for patients at risk for fracture and to permit rapid use of a crutch or walker in patients with concomitant lower extremity lesions. Humeral shaft fractures are amenable to intramedullary nails that may be augmented with bone cement similar to femoral shaft fractures. Pathologic fractures involving the proximal humeral metaphyseal regions, humeral head, or neck are amenable to long-stem endoprosthetic replacement. Shoulder function is limited following endoprosthetic replacement because of the need for muscle reattachment and rehabilitation in the presence of postoperative radiation. Pain relief is reliable, however, and a stable shoulder is provided for good elbow and hand function. Severe bone destruction of the proximal humerus with significant extraosseous extension of tumor may necessitate replacement with a tumor prosthesis. When patients have had mastectomies on the same side of the humeral lesion, postoperative edema is much worse after fracture stabilization. Elastic sleeves and gloves can be fitted by occupational therapists for assistance with this problem. Lesions of the distal humerus may require plate and screw fixation augmented with bone cement, crossed flexible intramedullary rods, a long-stem humeral and ulnar constrained elbow arthroplasty, or a distal humerus replacement with a constrained total elbow. Choice of implant depends on the degree of bone destruction and presence of coexisting disease within the remaining humerus.

B, MRI of same patient demonstrating extensive involvement of the acetabulum. C, The patient underwent fixation with a long-stem total hip replacement, antiprotrusion cage, bone cement, and Steinmann pins. The Steinmann pins transfer the forces across the hip into remaining intact bone of the ilium. The long-stem femoral component provides fixation for the entire femur that was also involved by metastases.

PROPHYLAXIS AND REHABILITATION

When is prophylactic surgery needed?

Patients with known metastatic lesions in bone may be at risk for developing a fracture through the affected bone because of weakening of the structural integrity. This is referred to as an impending fracture. There is no specific definition of an impending fracture, and the indications for operative treatment continue to be controversial. One strong indication includes lesions that are still painful after radiation especially, those with functional pain.

Criteria have been developed to estimate the risk for fracturing through a metastatic bone lesion and hence for providing the surgeon with indications for prophylactic surgical stabilization of the bone. Although criteria have been developed to estimate the risk for a patient's developing a pathologic fracture, retrospective analysis has shown that radiographic criteria alone do not accurately predict fracture.

Three common indications are as follows:

1. Lesion larger than 2.5 cm
2. Greater than 50% cortical destruction
3. Intractable pain attributable to the bone lesion

In a study by Keene and colleagues,³⁹ it was not possible to use defect size to predict pathologic fractures. A scoring system for assessing the risk for pathologic fractures has been proposed by Mirels and associates.⁴⁰ It is based on the following variables: site, pain, lesion size. In Mirels' classification, almost all patients with functional pain ultimately developed a fracture. The fracture rate was 5% in patients with lesions less than one third of the bone diameter and was 81% in patients with lesions greater than two thirds of the diameter of bone. In the 1960s, Beals and coworkers⁴¹ observed that 58% of breast cancer patients with well-defined lytic lesions larger than 2.5 cm involving the cortex of the femur developed pathologic fractures. Fidler⁴² showed a significant difference in the risk for pathologic fracture when there is greater than 50% destruction of the cortex regardless of the size of the lesion.

Is there a safe role for rehabilitation treatment?

Rehabilitation is often indicated for patients with skeletal metastases. Patients with a limited life span benefit the most from rapid restoration of function after treatment of metastatic bone disease. The indications for rehabilitation and the specific type of rehabilitation are dictated by the clinical circumstances, sites of lesions, potential for fracture, overall medical condition, and postoperative status. Patients who are being treated with radiation for an impending fracture of a weight-bearing bone can be taught crutch ambulation with non-weight bearing on the affected extremity. Patients receiving radiation also benefit from gentle range-of-motion exercises of adjacent joints to prevent radiation-induced contractures and to control swelling and lymphedema. Postoperative rehabilitation is indicated to mobilize patients and restore them to presurgical functional status. Patients may be eligible for acute rehabilitation depending on their overall medical condition, presurgical functional status, and degree of deconditioning. Patients who were active preoperatively and who sustain a pathologic fracture may have a rehabilitation course similar to patients who sustain a non-pathologic fracture. Patients who are poor candidates for acute rehabilitation (severely deconditioned and compromised) may be candidates for a more prolonged, less intense rehabilitation program at a skilled nursing facility or at home. In a study by Blunting and colleagues, the risk for pathologic fracture resulting from rehabilitation was found to be low.⁴³

Radiation Therapy for Metastatic Breast Cancer

John Rescigno and Anthony Berson

Breast cancer is the second leading cause of cancer death in women. About 39,800 women died of breast cancer in 2003, accounting for 15% of all cancer deaths.¹ Decisions about the use of localized therapy in the patient with advanced breast cancer can be complex. The primary goals of radiation therapy for metastatic breast cancer are alleviation of symptoms and improvement of functional status. Another benefit may be a modest improvement in survival in a small proportion of patients. Radiation often relieves localized symptoms such as pain. In other circumstances, although the patient is asymptomatic, impending problems, such as bronchial obstruction, cord compression, or bone fracture, can be prevented with radiotherapy. Decisions regarding the use of radiation therapy need to take into account the patient's prognosis, with the goal of obtaining durable control of symptoms within the patient's life span. Additionally, there is a subset of patients with minimal metastatic disease or chest wall recurrence in whom radiation might contribute to long-term durable control and possibly cure of the breast cancer.

What is the role of radiotherapy, and what are the optimal dose and fractionation for the palliation of bone metastases?

More than half of patients with metastatic breast cancer have bone as an initial site of metastasis. Two thirds of these patients present with metastatic disease limited to bone. Bone metastases tend to occur in patients with more well-differentiated, ER-positive tumors.² The relatively high frequency of bone metastases makes breast cancer the most common primary site in randomized studies of radiotherapy for the palliation of bone metastases.

Pain Relief

Long-term relief of pain is an important goal of radiation therapy, given the favorable prognosis of patients with metastatic disease to bone compared with other systemic sites. Radiation therapy is the mainstay of treatment for bone metastases. Local field radiotherapy is highly effective in relieving pain and preventing fractures and is typically associated with minimal side effects.

Mechanism of Pain Relief. The precise mechanism of relief of bone pain by radiotherapy is not known. The direct cytotoxic effects of radiation on tumor cells can provide shrinkage of tumor, decrease stretching of the periosteum, and allow for repair of bone with healing of microfractures and macrofractures. However, it is unknown whether tumor cell cytotoxicity is the primary factor in analgesia achieved with radiation. The fact that rapid pain relief may be seen at doses as low as 4 Gy (which is not expected to induce tumor shrinkage) suggests other mechanisms. It is likely that radiation also affects normal bone turnover through cytotoxic activity on osteoclasts and osteoblasts. In theory, cytotoxicity of radiotherapy on normal bone cells could lead to decreased production of cytokines that stimulate nociceptors, such as substance P, bradykinin, and prostaglandins, providing pain response at relatively low doses. In fact, radiotherapy pain response is correlated with suppression of osteoclast activity measured by urinary markers of bone degradation.³ The mechanism of radiotherapeutic analgesia may therefore have parallels to the mechanism of action of bisphosphonates.

Optimal Dose and Fractionation for Pain Relief.

Eighteen trials assessing fractionation and dose of radiotherapy for painful bone metastases have been published.^{4,5} Randomized trials comparing a single fraction of 8 Gy with multiple-fraction radiotherapy regimens (20 to 30 Gy in 5 to 10 fractions) reveal similar overall response rates. Pain relief is typically achieved 1 to 4 weeks after treatment, and the duration of response is 12 to 24 weeks. In pooled analyses of patients with varied primary cancers, about one third of patients with metastasis to bone had complete pain relief, and an additional one third of patients had partial relief of pain, irrespective of the dose fractionation used.⁴ Breast cancer is associated with higher response rates than non-breast cancer histologies. An important difference between an 8-Gy single-fraction treatment and higher dose fractionated treatment is that a significantly greater proportion of patients treated with the single fraction require retreatment (about 23% vs. 8%).⁴ However, more than 80% of patients with persistent or

recurrent pain secondary to breast cancer metastases respond to retreatment.⁶ Individual studies have found that remineralization based on CT density measurements is significantly better after 30 Gy in 10 fractions compared with 8 Gy in 1 fraction⁷ and that the actual pathologic fracture rate may be higher after 8 Gy in 1 fraction versus 24 Gy in 6 fractions (4% vs. 2%).⁸ However, the Radiation Therapy Oncology Group (RTOG) trial 7402 found a higher pathologic fracture rate with 40 Gy in 15 fractions compared with 20 Gy in 4 fractions (18% vs. 4%),⁹ suggesting that a dose of 40 Gy in 15 fractions may inhibit remineralization of bone and contribute to pathologic fracture risk and that the optimal total dose or dose per fraction should be less.

In summary, all trials of radiation fractionation for palliation of bone metastases suggest similar pain relief irrespective of the dose-fractionation schedule. However, radiation oncology communities throughout the world have been slow to adopt a single 8-Gy fraction approach. Reinterpretations of the randomized trial data taking into account analgesic use, need for retreatment, and complete response rates suggest that fractionated treatment to higher total dose leads to more complete and durable response.^{10,11} Problems with available data, including heterogeneity of primary cancers, patients, and prognoses; differing length of follow-up and time to assessment of response; failure to take into account analgesic use in most studies; varied and insufficient methods of pain evaluation; variable definitions of response; and variable and unspecified actual target dose are all reasons for skepticism in accepting the null hypothesis from the randomized trials of total dose and fractionation. However, the arms of the larger trials that included hundreds of patients are likely to be evenly balanced for known and unknown factors that could affect the results, and despite differences in methodology and reporting, the results of the trials are strikingly consistent.

Additional randomized trials using careful assessment of analgesic consumption and validated quality-of-life tools in more well-defined patient populations and stratified by single or multiple painful bone sites are warranted. To this end, the RTOG trial 9714 included 452 women with breast cancer and 445 men with prostate cancer.⁵ Pain response rates were similar with 8 Gy in 1 fraction compared with 30 Gy in 10 fractions. Overall response was 66% irrespective of the treatment regimen. The complete pain response was only 17%, without any difference between arms. In patients with one site of painful bone metastasis, the complete pain response rates were 18% with 8 Gy and 25% with 30 Gy ($P = .17$). One third of patients required no analgesic medication by 3 months after treatment. Response was the same irrespective of bisphosphonate use at the time of radiation. Acute grades 2, 3, and 4 toxicity were seen in 10%, 2.8%, and 0.2%, respectively. More patients experienced toxicity in the higher-dose arm (17% vs. 10%).

Should 8 Gy in 1 fraction be the standard treatment for women with painful bone metastasis from breast cancer? In patients with poor performance status and limited prognosis (e.g., less than 6 months), the convenience and relative ease of administration supports single-fraction treatment if the only goal of treatment is pain relief. For patients with a better prognosis, such as those with metastatic disease confined to bone, those with a long disease-free interval, or those naïve-responsive to systemic therapy, the frequent need for retreatment and indirect evidence suggesting improved complete

response and duration of response support consideration of higher doses such as 30 Gy in 10 fractions. Such a fractionation scheme might also be appropriate for patients at risk for fracture of weight-bearing bones (see later). Sites that could be associated with unique toxicity, such as the skull or joint spaces, may be better treated with 3 Gy or lower dose per fraction. For patients with an isolated bone metastasis, biopsy proof of recurrent breast cancer is usually warranted. Such patients can be considered for higher-dose radiotherapy with the additional goal of long-term durable control of disease (e.g., 35 Gy in 14 fractions or 40 Gy in 20 fractions).

Prevention of Pathologic Fractures

In addition to pain relief, prevention of pathologic fracture is a major goal of therapy, and assessment by an orthopedic surgeon is warranted for selected patients with good performance status who are at risk for pathologic fracture. Prediction of the risk for pathologic fracture is extremely difficult. Factors such as involvement of more than 50% of the cortex of long bones, lesions larger than 2.5 cm in the weight-bearing regions of the proximal femur, or avulsion of the lesser trochanter are commonly cited criteria for consideration of orthopedic stabilization before radiotherapy.¹² Involvement of the subtrochanteric femur over even a small area places the patient at risk for fracture. However, in a study of risk factors for fracture in breast cancer patients with proximal femur lesions, no clearly definable criteria could be established.¹³

A scoring system was developed to predict risk for pathologic fracture based on four factors: cortical involvement (less than half, one half to two thirds, and more than two thirds), site (upper limb, lower limb, peritrochanter), presence of pain (mild, moderate, severe), and lesion characteristics (blastic, mixed, lytic).¹⁴ For each factor, a score from 1 to 3 is given, and the scores are summed (minimum score, 4; maximum score, 12). Patients with a score of 7 or less have a low probability of fracture (5%) and can be treated with radiation alone. Patients with a score of 8 have a 15% fracture risk, and patients with a score of 9 or more have at least a 33% risk for fracture. Recent modification of the scoring system accounts for greater risk in patients with a lesion proximal to the lesser trochanter, a lesion in the proximal humerus, a breast cancer primary, lack of bisphosphonate therapy, and presence of osteoporosis.¹⁵ For patients who require orthopedic stabilization, radiotherapy is recommended postoperatively to improve functional recovery and to minimize the risk for prosthesis failure. Doses should be limited to 30 Gy or less in patients who have experienced long bone fracture so that healing is not inhibited.

What is the role of radiotherapy in the setting of bisphosphonate use?

Bisphosphonates reduce osteoclast activity and inhibit bone resorption. Bisphosphonate therapy has been shown in randomized trials to reduce the incidence of fractures, hypercalcemia, and the need for radiotherapy. There is also a trend toward reduction in the need for orthopedic surgery and in the risk for spinal cord compression. In a pooled analysis of patients with primarily breast cancer and myeloma who received bisphosphonate therapy, the need for radiotherapy

was reduced by one third (odds ratio, 0.67; 95% confidence interval, 0.57%–0.79%).¹⁶ None of the trials prespecified the criteria for administration of radiation.

Reports of the incidence of radiotherapy in patients treated with bisphosphonate versus control patients not receiving bisphosphonate are available from five randomized trials including 1625 patients with breast cancer.¹⁶ Combining these studies, radiotherapy to bone was used in 43% of control patients versus 33% of patients receiving bisphosphonate therapy. The continued significant rate of radiotherapy is a result of the complications from bone metastases for which bisphosphonate therapy is inadequate. The most common indication is pain before or during bisphosphonate therapy. Evidence is lacking to justify the use of bisphosphonates for rapid pain relief or as first-line therapy for bone pain. In a pooled analysis of studies that examined pain relief, fewer than 15% of patients achieved major pain relief after 12 weeks of therapy.¹⁷ Other indications for radiation include associated soft tissue masses, nerve root compression, pathologic fracture, and epidural disease. It is appropriate to consider radiotherapy complementary to bisphosphonate therapy analogous to the paradigm of combined-modality therapy for localized solid tumors: systemic bisphosphonates are most effective in preventing complications from asymptomatic or occult metastatic bone disease, whereas radiotherapy is most appropriate for the treatment of clinically apparent disease.

Can widespread bone metastases be treated with radiotherapy?

Other means of systemic treatment of bone metastases besides bisphosphonates, hormonal therapy, and chemotherapy include the use of hemibody irradiation and bone-seeking radioisotopes. Most patients with diffuse bone pain experience response of pain with hemibody irradiation, and 20% have complete response.¹⁸ Relief usually occurs within 1 week of treatment. Breast and prostate cancers respond better than other types of cancers. The treatment involves the administration of single-fraction or multiple-fraction radiotherapy to one half of the body, often followed about 2 to 4 weeks later (to allow for hematopoietic recovery) by treatment of the other half of the body. The body is typically demarcated at the level of the umbilicus, and the distal extremities and calvarium are excluded. A dose of 8 Gy has been used for the lower body, whereas a single-fraction dose of 6 Gy has been used for the upper body to limit the incidence of pneumonitis. Toxicity is less with customized shielding of nonosseous normal tissue. Treatment of the ribs can be accomplished with electrons, so that the normal underlying lung is not exposed. Treatment is associated with severe temporary hematologic toxicity in 10% of patients. Use of cytokine support is appropriate for patients with significant neutropenia after treatment. Vomiting is frequent, and premedication is indicated. Low-grade fever is common as well. Fractionated regimens are likely to improve the therapeutic ratio. For example, 17.5 Gy delivered in 2.5-Gy fractions has been used for treatment and prevention of bone metastasis complications with good effect and acceptable hematologic toxicity.¹⁹

Radionuclide therapy has also been used to treat widespread bone metastases and is the primary subject of a recent review.²⁰ A variety of systemically administered agents have

been developed. The two most commonly used agents are strontium 89 and samarium 153. Strontium 89 has a half-life of 50 days, and samarium 153 has a half-life of 1.9 days. The shorter half-life of samarium translates into a higher dose rate, quicker pain relief, and more rapid hematologic toxicity and recovery. Meaningful response is seen in about 80% of patients. A minority of patients will have significant flare of pain, which may correlate with improved response. Pain relief is maintained for an average of 6 months. Nadir counts are usually more than half of the pretreatment counts. After administration of strontium 89, nadir occurs by 8 weeks, and recovery occurs by 4 months. The time course of myelosuppression is about twice as fast with samarium 153. Therapy with samarium 153 should not be administered on the same day as a bisphosphonate, which competes for the same binding sites. Treatment is not suitable for patients with purely lytic disease and minimal uptake on bone scan. For patients with recurrent pain, treatment can be safely repeated after hematologic recovery.

The role of hemibody irradiation and radionuclides in breast cancer may become more limited with the widespread use of bisphosphonates and the availability of more effective hormonal agents and chemotherapy. More effective systemic therapy may shift the pattern of symptomatic progression later in the natural history of the disease when visceral sites become the predominant problem. Hemibody irradiation and radionuclide therapy are most appropriate for patients with diffuse bone pain refractory to hormonal therapy and chemotherapy, with a life expectancy of at least 3 months and satisfactory hematologic reserve.

What is the role of whole-brain radiotherapy in the management of brain metastases?

Although the median survival of patients with breast cancer after diagnosis of bone metastasis is about 2 years, the median survival after brain metastasis is generally 4 months.²¹ This is partly due to the direct effect of brain metastasis on function and survival. However, many patients develop brain metastases late in the course of their disease, when progressive extracranial disease dictates survival. Breast cancer is the second leading cause of brain metastasis, and about 15% of patients are diagnosed clinically. In randomized trials of therapy for brain metastases, typically more than half of patients have lung cancer, and less than one fourth of patients have breast cancer. Therefore, the specificity for breast cancer of brain metastases radiotherapy trials might be less than in trials of palliation of bone metastases.

Corticosteroids were first used in 1957 for the treatment of peritumoral edema associated with brain metastases from breast cancer.²² Median survival of patients treated with steroids alone is 2 months. The addition of whole-brain radiotherapy (WBRT) extends this time to 4 months. Most symptomatic patients have a clinical response with WBRT. The clinical response rate, degree of response, and duration of response depend on the extent of tumor and the severity of initial neurologic deficits. Breast cancer responds better than other primary cancers.²³ The most common WBRT fractionation is 30 Gy in 10 fractions over 2 weeks. In two randomized RTOG trials of more than 1800 patients with a variety of primary cancers, fractionation schedules of 20 Gy in 1 week,

30 Gy in 2 weeks, 30 Gy in 3 weeks, 40 Gy in 3 weeks, and 40 Gy in 4 weeks were tested.²⁴ No significant differences between the fractionation regimens were seen. Overall improvement in neurologic function was seen in about half of patients and maintained in more than three fourths of these patients. Normal functionality was achieved in one third of patients that were partly bedridden. Brain metastasis was the cause of death in 40% of patients. Additional randomized trials from the RTOG have shown no significant differences in outcome based on dose-fractionation schemes, including 30 Gy in 2 weeks versus 50 Gy in 4 weeks,²⁵ or versus a hyperfractionated regimen of 54.4 Gy at 1.6 Gy twice daily.²⁶ All regimens were associated with response of neurologic symptoms in most patients and a median survival of about 4 months. This result may be partly due to the heterogeneity of the patients enrolled in the trials, including patients with variable performance status, different primary tumor histologies, and the shortened survival that is most frequently dictated by progressive extracranial metastases. Recursive partitioning analysis of patients treated with a variety of dose-fractionation regimens suggests that factors unrelated to radiotherapy treatment parameters best predict survival: patients with a Karnofsky performance score (KPS) of at least 70, controlled primary tumor, brain as the only site of metastases, and age younger than 65 years were found to have a median survival of 7.1 months.²⁷

In patients who have undergone resection, the need for WBRT has been studied. Most patients have further failure in the brain at both the site of resection and remote sites in the brain. For example, in a randomized study of 95 patients who underwent MRI-defined complete resection of a solitary brain metastasis, 70% of patients had recurrence, including 46% who had relapse at the initial site of disease. Postoperative WBRT was associated with a three-fourths relative risk reduction in recurrence (resulting in an overall relapse rate of only 18%) and with decreased risk for death from neurologic causes.²⁸ Therefore, postoperative WBRT is recommended for patients who undergo resection of a solitary metastasis and who have controlled extracranial disease.

What is the role of stereotactic radiosurgery in the management of brain metastases?

The survival outcome with WBRT is poor, and up to half of patients will die from progressive brain metastases with the use of WBRT alone. Therefore, continued efforts to improve on the results of WBRT are needed. WBRT is increasingly being supplemented by more aggressive treatment directed at known sites of brain metastases using stereotactic single-fraction radiotherapy (“radiosurgery”), stereotactic multifraction radiotherapy, or surgical resection. Stereotactic radiosurgery delivers a focal high dose of radiation using three-dimensional treatment planning, often with MRI image fusion to contrast-enhanced CT image data, and a stereotactic localization device to aim multiple highly collimated beams. Sharp dose gradients near the edge of the tumor limit the dose to normal brain tissue. Therapy can be delivered with the Leksell gamma knife system, which consists of 201 small cobalt 60 sources all collimated to a single focal point. Another technology allows for linear accelerator-based treatment using a specialized cylindrical collimator placed onto the head

of the machine to aim a small radiation beam while the accelerator gantry moves in multiple arcs around a precisely localized target. Fractionated stereotactic radiotherapy can be done using mini-multileaf collimators and less invasive head immobilization and localization procedures.

Surgery or stereotactic radiation is likely to be associated with decreased risk for neurologic death and improved survival in appropriately selected patients. For example, surgically treated breast cancer patients with brain metastases have a median survival of about 16 months.^{29,30} The value of more aggressive treatment for patients with brain metastasis is clearly shown by two of the three randomized trials of surgical resection of solitary metastasis plus WBRT versus WBRT alone in patients with a variety of primary tumor histologies.^{31–33} Patchell and associates³¹ found improved local control (20% brain failure vs. 52% brain failure) and median survival (40 weeks vs. 15 weeks) with the addition of surgery. In another trial, surgery improved median survival from 6 months to 10 months.³² Another multicenter randomized trial of 84 patients did not reveal any advantage to surgical resection.³³ This may be due to the selection of patients with worse performance status or more extracranial disease, failure to achieve complete resection in some patients, and crossover of one fourth of patients receiving WBRT to surgery.

Selection criteria for radiosurgery are similar to those for surgical resection, that is—patients with solitary metastases, good performance status, and limited or responsive extracranial disease. Patients with surgically inaccessible lesions that are deep within the brain parenchyma or that involve Broca's area or the visual cortex can be safely treated with radiosurgery. Surgery is preferred for patients who are highly symptomatic and have accessible lesions because it provides more immediate relief of symptoms. Additionally, in the few patients with solitary brain metastases without extracranial disease, surgery is required for diagnostic purposes. About 10% of patients with good performance status and a solitary brain metastasis will have a diagnosis unrelated to the known primary cancer upon biopsy of the brain tumor.³¹

Radiosurgery may also be appropriate in patients with two or three brain metastases. In 68 women with metastatic breast cancer, Amendola and associates found that survival after radiosurgery was independent of the number of lesions (median survival, 7 months).³⁴ In a study of 248 patients with 421 brain lesions from a variety of primary cancers, there was only 11% progression within the radiosurgery volume at a median follow-up of 26 months. Surgery was required in 6% of patients for mass effect or steroid dependency secondary to radiation necrosis.³⁵ Mehta and colleagues reviewed more than 2100 lesions treated with radiosurgery to a median dose of 18 Gy and found that 86% of lesions were stable or responded.³⁶ A retrospective study of 122 patients who were eligible for surgical resection combined 37.5 Gy WBRT followed by a median radiosurgery boost of 17 Gy. An 86% brain tumor control rate was obtained, and the median survival was longer than 1 year, which compares favorably with results of trials of surgical resection and WBRT.³⁷ RTOG 95-08 randomized patients with one to three brain metastases to WBRT followed by a radiosurgery boost versus WBRT alone (37.5 Gy in 15 fractions). In patients with a single brain metastasis, survival was improved from a median of 4.9 months in the WBRT arm to 6.5 months in the WBRT plus radiosurgery arm.³⁸

Outcome after radiosurgery is similar to outcome after surgical resection. Radiosurgery, however, is minimally invasive and can be done on a purely outpatient basis. Patients can return to work or resume normal daily activities the following day. This contrasts with surgical resection, which requires hospitalization and inpatient recovery times that can significantly delay postoperative WBRT. Patient preference and physician bias will likely preclude a successful randomized trial of radiosurgery versus surgical resection.

WBRT is generally recommended before or after radiosurgery. In a multi-institutional retrospective study of stereotactic radiosurgery in the treatment of single brain metastasis, of 71 patients who had newly diagnosed brain metastases, the brain control rate at 1 year was 53% with radiosurgery and WBRT, as compared with 18% for radiosurgery alone.³⁹ However, salvage therapy with WBRT is possible after radiosurgery, and survival appears uncompromised with a deferred treatment strategy.⁴⁰ Patients with metastasis larger than 3 cm are best treated with WBRT as initial treatment because tumor control may be inferior with radiosurgery alone. Patients who respond to WBRT can be considered for radiosurgery.

Is there a role for radiosensitizers in the treatment of brain metastases?

Early trials of radiosensitizers such as misonidazole⁴¹ and bromodioxuridine⁴² yielded disappointing results. Temozolomide is an alkylating agent that is orally bioavailable and crosses the blood-brain barrier. It has been shown to yield higher response rates in combination with WBRT than does WBRT alone.⁴³ Whether this translates into improved quality of life and survival is yet to be determined. Motexafin gadolinium catalyzes the oxidation of intracellular ascorbate, glutathione, and protein thiols, depleting the cell of reducing metabolites. A randomized phase III study comparing motexafin gadolinium and WBRT versus WBRT alone found no difference in survival.⁴⁴ There was improved 6-month freedom from neurologic progression as judged by investigators but not by an independent events review committee. There did appear to be a benefit in time to neurologic progression in patients with lung cancer, who constituted most of the patients in this study.

The compound RSR13 is a synthetic allosteric modifier of hemoglobin that reduces the oxygen-binding affinity of hemoglobin and allows increased oxygen delivery to hypoxic cells. This agent was studied in combination with oxygen and WBRT versus oxygen and WBRT alone in 538 patients with multiple brain metastases (115 with metastatic breast cancer).⁴⁵ RSR13 was associated with improved survival for the entire study group ($P = .17$; $P = .01$ by Cox multivariate regression). In the subgroup of patients with metastatic breast cancer, survival was nearly doubled (4.6 months vs. 8.7 months). A study limited to metastatic breast cancer is planned to confirm these results.

In summary, no trials of a radiosensitizing agent have yielded improvement in survival over WBRT alone for a diverse population of patients with metastatic cancer to brain. Subsets of patients who might benefit have been retrospectively identified. Radiosensitizers remain an exciting area of research for patients with metastatic breast cancer to the

brain. Measurements of quality of life and neurologic outcome will need to be incorporated into future trials.

What is the palliative role of radiotherapy for other common sites of metastases?

Spinal Cord Compression

Breast cancer is the most common cause of spinal cord compression in women. Breast cancer is the underlying cause in half of women with spinal cord compression. Radiation therapy alone has most commonly been used for the treatment of spinal cord compression. Corticosteroids are initiated immediately before radiation. A total dose of 30 Gy in 10 fractions is appropriate, although shorter dose schedules have been employed with similar outcome.⁴⁶

Surgery is useful to establish a diagnosis if uncertain. Patients with acceptable performance status in whom bony retropulsion is likely to be the primary cause of neurologic deficit should also be treated with surgery. Patients with rapid deterioration of neurologic function or with high-grade cervical cord compression should also be considered for surgery. Patients with high cervical spine cord compression should be evaluated for atlantoaxial subluxation. If no or minimal subluxation is present, a stabilizing collar (e.g., Philadelphia collar) can be used before radiation therapy.

A prospective study of 275 consecutive patients with a variety of primary tumors found pain response in 82% of patients.⁴⁷ Three fourths of patients had preservation of ability to walk or recovery of function. Improvement in sphincter function was noted in 46% of patients with initial deficits. Patients with breast cancer and prostate cancer had better response than those with other solid tumors. Recovery of sensory or motor deficits is related to pretreatment neurologic status. Few patients with paraplegia or incontinence regain function with radiotherapy. In a study of 70 patients, two thirds of patients who were ambulatory at the time of radiotherapy remained ambulatory, whereas fewer than one third of patients who were initially nonambulatory regained function, and 16% of paraplegic patients regained the ability to walk.⁴⁸

Laminectomy rarely removes the bulk of the tumor, it fails to relieve pain, and it can destabilize the spine. However, vertebral body resection and radical decompressive surgery with postoperative radiotherapy was recently reported to be superior to radiotherapy alone in the only randomized trial of spinal cord compression conducted to date.⁴⁹ Patients with a single site of cord compression and a minimum 3-month life expectancy were enrolled. The trial was stopped early after 101 patients were enrolled. Patients who received surgery plus radiation therapy retained the ability to walk significantly longer (126 days vs. 35 days with radiation therapy alone). In a total of 32 patients who could not walk at the time of enrollment, 56% of those who received surgery and radiation therapy recovered the ability to walk, compared with 19% who received radiation therapy alone. Functional scores, maintenance of continence, and decreased use of steroids and narcotics were all improved in patients undergoing decompressive surgery versus radiotherapy alone. Survival was slightly better in patients undergoing surgery (median, 4.2 months vs. 3.3 months; $P = .08$). The threshold for

recommending surgery in patients with breast cancer may be higher because such patients generally respond better to radiation therapy. However, patients with neurologic deficit and life expectancy of at least 3 months should be considered for surgery based on the results of this phase III study.

Brachial Plexopathy

Extension of tumor from supraclavicular, infraclavicular, and axillary nodes into the brachial plexus can lead to devastating pain and loss of function of the upper extremity. Involvement of the lower plexus will affect the C7-T1 nerve roots and cause pain in the shoulder, arm, medial forearm, and fourth and fifth digits. Supraclavicular node involvement can cause upper plexus involvement and pain and numbness at the posterior arm, index finger, and thumb from involvement of C5 and C6 nerves. Occasionally, Horner's syndrome is present. The treatment of choice is local radiotherapy. Optimally, CT-based treatment planning is performed to target the full extent of disease and to avoid uninvolved tissue volumes such as the shoulder while providing adequate dose to the target. The rate of plexopathy secondary to radiation is expected to be less than 1% with a dose of 50 Gy using conventional fractionation. The response rate depends on the time from symptom onset to the initiation of radiation therapy, although most patients benefit from treatment, having reduction in pain and improvement in arm mobility. Re-irradiation is not possible after prior full-dose treatment because of the risk for brachial plexopathy from retreatment.

Choroidal Metastases

More than one third of intraocular metastases are due to breast cancer.⁵⁰ Uveal metastasis can be the initial manifestation of breast cancer metastasis in up to 16% of patients.⁵¹ Bilateral metastases have been noted in 38% of patients; about half of these are synchronous. The most common presenting symptom is decreased or blurred vision. Other presenting signs or symptoms include floaters and photopsia. Occasionally, symptoms can include diplopia, pain, uveitis, or headache. Indirect fundoscopic examination is used to

establish the diagnosis. Findings include detachment of the retina, usually posteriorly. The surface of the tumor may have a mottled appearance. Occasionally, hemorrhage and pigmentary changes may occur over the involved area. For single lesions, the appearance is similar to that of a primary ocular melanoma. Ultrasonography is useful in distinguishing between melanoma and metastatic disease. CT and MRI have a limited role in the diagnosis of ocular metastasis. Nevertheless, brain imaging should be performed because of a significant diagnosis of concurrent central nervous system (CNS) metastases. A 22% incidence of concurrent CNS metastases has been reported, with an additional 19% of patients diagnosed at a subsequent date.⁵² External-beam radiation therapy is usually recommended. Radiotherapy is indicated when there is secondary retinal detachment, impending or actual decrease in visual acuity, or rapidly enlarging tumor. In some situations, observation with close monitoring may be appropriate. The goal of radiation treatment is to encompass all of the choroid from the equator posteriorly, with a margin. Usually, radiation to the lens can be avoided by using a lateral field with a half-beam D-shaped block. For unilateral disease, a single lateral field is effective in delivering the dose to the eye while avoiding multiple pathways that could compromise subsequent palliative treatment in adjacent areas. Typical doses of radiation include 30 to 40 Gy over 2 to 4 weeks. External-beam radiation can provide local tumor control in up to 85% of cases. Initially, vision may deteriorate during or after radiation due to shifting subretinal fluid and retinal detachment.

Is there a role for definitive radiotherapy after locoregional recurrence or limited metastatic disease?

Locoregional recurrence of breast cancer after mastectomy remains a problem in more than 15% of patients undergoing mastectomy (Fig. 32–25). Risk factors for locoregional recurrence include lack of postoperative radiotherapy, large

Figure 32–25 A and B, Locally advanced breast cancer en cuirasse. From Steinfeld AD. Treatment of metastatic breast cancer. In Roses DF (ed): Breast Cancer. Philadelphia, Churchill Livingstone, 1999, p. 573.

primary tumor, lymph node involvement, presence of extracapsular extension, vascular or lymphatic invasion, involvement of the skin, and involved surgical margins. Patients usually present with an asymptomatic nodule or nodules in the skin or subcutaneously, often near the scar. Occasionally, recurrence has the appearance of an erythematous rash. Rarely, the skin and subcutaneous tissues are diffusely infiltrated and ulcerated (carcinoma en cuirasse; see Fig. 32–25). About half of patients have prior or synchronous presentation of distant metastases as a component of failure at the time of locoregional recurrence. For these patients, radiotherapy is generally directed toward palliation of symptoms. Morbidity from locoregional recurrence can be significant, with more than half of patients experiencing bleeding, ulceration, severe pain, upper extremity edema, or brachial plexopathy.⁵³ Therefore, local control of disease remains an important goal, and all symptomatic patients should be considered for radiotherapy. In patients who have not had prior radiotherapy, large fields encompassing the chest wall and regional nodes are necessary to avoid marginal failures. A dose of at least 50 Gy in standard fractionation is necessary to treat microscopic disease, and at least 60 Gy is needed for gross disease. Long-term local control can be achieved in more than 80% of patients who receive radiation therapy or surgical resection followed by radiation therapy.^{54,55} Patients who have had prior chest wall radiotherapy may be eligible for palliative re-irradiation with electrons, interstitial brachytherapy, or surface brachytherapy. Hyperthermia and photodynamic therapy have also been used with some success.

The fact that most patients with isolated locoregional recurrence ultimately experience relapse at distant sites has been a justification for an approach that assumes that all such patients should be treated with palliative intent only; consequently, such patients are often labeled as having stage IV disease. A corollary is that chest wall recurrence is only a marker of a definitive risk for distant metastasis and not a potential source of metastasis. However, in the era of improved systemic adjuvant chemotherapy, patients who might otherwise have experienced relapse at distant sites may manifest locoregional failure as the only site of failure. A subset of these patients can enjoy long-term disease control and possibly cure with the use of salvage radiation therapy.

A prerequisite of cure is durable control of locally recurrent disease. In a study of 121 patients who received chemotherapy for isolated locoregional recurrence, the 5-year disease-free survival was 35% for patients initially rendered disease free with local therapy and 13% for patients who were not disease free by the start of chemotherapy.⁵⁶ Selected patients with minimum-volume chest wall relapse have better survival, with up to half of patients remaining relapse free at 10 years after treatment of the local recurrence.^{57,58} Factors associated with long-term disease-free survival after chest wall recurrence include longer disease-free interval from mastectomy to local recurrence, negative nodes at initial diagnosis of breast cancer, resectable recurrence, and positive ER status.

Only one randomized trial has examined the use of systemic therapy after excision and radiation therapy for chest wall recurrence.⁵⁸ One hundred seventy-eight women with a disease-free interval of at least 1 year from initial diagnosis and low-volume isolated chest wall recurrence were randomized to receive tamoxifen versus observation after surgical resection and radiotherapy. Tamoxifen resulted in improved

disease-free survival, which was limited to reducing the risk for another locoregional relapse by nearly half (31% vs. 16%). The use of cytotoxic chemotherapy as “secondary adjuvant” treatment after resection and radiation of isolated locoregional recurrence has led to improved 5-year survival compared with local therapy alone in single-institution studies.^{56,59} The International Breast Cancer Study Group (IBCSG) 27-02 trial is testing whether systemic chemotherapy after surgical resection with or without radiation results in improved survival of patients who suffer isolated locoregional recurrence.

Advances in systemic therapy, including hormonal therapy, single-agent or combination chemotherapy, and molecular targeted therapy, are shifting the paradigm of treatment of metastatic breast cancer from palliation to long-term disease control. The radiation oncologist’s distinction between curative therapy and palliative therapy becomes less clear if the end point is long-term disease remission. For example, a patient with a solitary metastasis who responds to initial systemic therapy will usually ultimately have cancer recurrence and progression at that site, and consolidative radiotherapy can forestall or prevent relapse. In rare cases, patients with metastatic disease can remain in complete remission for more than 20 years.^{60,61} A study from the University of Texas M. D. Anderson Cancer Center of 134 patients with chest wall recurrence or isolated distant metastasis who were rendered disease free with surgery and, when possible, radiotherapy, were treated with systemic chemotherapy and achieved a 15-year disease-free survival rate of 24%.⁶² A more recent cohort of patients from the same institution found a 5-year disease-free survival rate of 59% with the use of multimodal therapy.⁵⁹ Another study of 60 patients with minimal metastatic disease amenable to local therapy followed by high-dose chemotherapy resulted in a 5-year relapse-free survival of 52%.⁶³ Although a significant proportion of patients in these studies had chest wall failure only, long-term survivorship was seen in patients who presented with distant soft tissue or visceral metastases.

Although metastatic breast cancer to the liver is usually associated with advanced and incurable disease, patients with metastatic disease to the lung may experience long-term survival with localized therapy. Of 467 patients with breast cancer selected for lung metastasectomy in the International Registry of Lung Metastases, the 15-year survival rate was 20%.⁶⁴ Multimodality treatment for asymptomatic metastatic breast cancer should be limited to patients with good performance status and an extent and distribution of disease that is amenable to surgery or radiation with the intent of rendering the patient disease free. Strict attention to the morbidities of therapy is important because most patients ultimately experience relapse at sites away from the clinically apparent surgical-radiotherapeutic target. Newer modalities such as intensity-modulated radiotherapy and extracranial body stereotactic radiotherapy limit the morbidity of treatment by more precisely targeting the metastatic tumor. Such focused radiotherapy techniques can be given with more convenient accelerated treatment regimens that avoid delays in full-dose systemic therapy. Additionally, analogous to stereotactic treatment of intracranial disease, extracranial radiosurgery and intensity-modulated radiotherapy may be viable alternatives to surgery and, because postoperative morbidity is avoided, more widely applicable than surgery in efforts to maintain durable control of clinically apparent metastatic disease.

Improved imaging modalities, including functional imaging, have the potential to enhance selection of patients who might benefit from aggressive combined-modality treatment of metastatic disease. Improved imaging will also allow increased targeting accuracy when used in conjunction with radiation treatment planning systems. Advances in systemic chemotherapy, radiotherapy delivery, and patient selection are likely to provide the foundation for increased use of radiation metastasectomy in the combined modality management of metastatic breast cancer. Improvements in disease-free survival, quality of life, and possibly overall survival can be anticipated in selected good-prognosis patients with metastatic breast cancer.

XI

Management of Pain for Metastatic Breast Cancer and Management of the Terminal Patient

Joseph Lowy

BACKGROUND

About 40,000 deaths resulted from breast cancer in the United States in 2004. Most of these patients and many of the patients who survive breast cancer experience considerable suffering. The suffering has physical, psychological (emotional), social (practical), and spiritual components. There is ample evidence that these aspects of suffering are not being addressed adequately by the medical profession.¹ *Palliative care* is the total care of patients with progressive advanced disease. It is concerned with all of the aspects of suffering and focuses on both the quality of life of the patient and the support of the family and those close to the patient. Terminal care is instituted when it is extremely likely that death will occur within a short period of time.

In his book *The Nature of Suffering and the Goals of Medicine*, Eric Cassell discusses a case of a patient with breast cancer:

The obligation of physicians to relieve human suffering stretches back into antiquity. Despite this fact, little attention is explicitly given to the problem of suffering in medical education, research, or practice. . . . Even in the best settings and with the best physicians, it is not uncommon for suffering to occur not only during the course of a disease but as a result of its treatment.

A 35 year old sculptor with cancer of the breast that had spread widely was treated by competent physicians employing advanced knowledge and technology and acting out of kindness and true concern. At every stage, the treatment as well as disease was a source of suffering to her. She was frightened and uncertain about her future but could get little information from her physicians, and what she was told was not always the truth. She was unaware, for example, that the radiation therapy to the breast (in lieu of a mastectomy) could be so disfiguring. After her ovaries were removed and a regimen of medications that were masculinizing, she became obese, grew facial and body hair of a male type, and her libido disappeared. When tumor invaded the nerves near her shoulder, she lost strength

in the hand she used in sculpting and became profoundly depressed. At one time she had watery diarrhea that would occur unexpectedly and often cause incontinence, sometimes when visitors were present. She could not get her physicians to give her medication to stop the diarrhea because they were afraid of possible disease-related side effects (although she was not told the reason). She had a pathological fracture of her thigh resulting from an area of cancer in the bone. Treatment was delayed while her physicians openly disagreed about pinning her hip.

She had come to believe that it was her desire to live that would end each remission, because every time her cancer would respond to treatment and her hope rekindle, a new manifestation would appear. Thus, when a new course of chemotherapy was started, she was torn between her desire to live and her fear that allowing hope to emerge again would merely expose her to misery if the treatment failed. . . . In common with most patients with similar illnesses, she was constantly tortured by fears of what tomorrow would bring. Each tomorrow was seen as worse than today, as heralding increased sickness, pain or disability—never as the beginning of better times.

This young woman had severe pain and other physical symptoms that caused her suffering. She also suffered from threats that were social and others that were personal and private. She suffered from the effects of the disease and its treatment on her appearance and her abilities. She also suffered unrelentingly from her perception of a future.²

Good palliative care addresses suffering in all of its forms and throughout the trajectory of illness. It should not be reserved for the terminal phase but rather should be increased proportionately as curative or life-prolonging therapy is reduced. Physicians are understandably focused on the cure and treatment of the disease of cancer. Disproportionate emphasis on treating the disease may undermine the goals of care for a patient with advanced breast cancer: the relief of suffering, optimization of quality of life until death, and focus on comfort in the terminal phase.

How significant a problem is pain in breast cancer?

Most patients with advanced cancer have significant pain. Portenoy and colleagues reported that pain was present in 63% of 246 patients undergoing active treatment for breast, prostate, colon and ovarian cancer. The pain was rated moderate to severe in 43% of patients.³ Despite the high incidence of pain in patients with cancer, this debilitating symptom remains underassessed and undertreated. Barriers to effective pain treatment, especially the use of opioids, must be overcome because up to 90% of cancer-related pain can be controlled with analgesic drug therapy in conjunction with nonpharmacologic methods.⁴ Successful treatment of pain is dependent on thorough assessment, judicious investigation, comprehensive management, and frequent reassessment. Diagnosis-specific treatment may be instituted if a specific etiology for the pain is established; however, nonspecific treatment of pain should take place before or without a specific diagnosis, if necessary.

How should pain be assessed?

A complete history of the pain includes location, duration, quality, intensity, and response to treatment. Pain should be rated using a verbal (0 to 10) or written pain scale.

The assessment strategy should be appropriate for the patient's functional status and expected survival. CT and MRI are time-consuming and inappropriate for a bedridden patient with days to live. However, a sophisticated diagnostic workup is indicated if the patient wants it and the expected information obtained is likely to change the treatment approach.

Pain can be both acute and chronic. This categorization of pain is of more than academic interest. Although acute pain is usually self-limited and responds to medical treatment, chronic pain (defined as lasting more than 3 months) is much more than a temporal extension of acute pain. Changes occur in both central neural processing and peripheral nerves. The results may include a decrease in objective signs of pain as well as development of such generalized symptoms as anorexia, malaise, sleep disturbance, and irritability. Good management of these patients demands attention to the effects that chronic pain has on the person suffering from it⁵ (Table 32–19).

Table 32–19 Common Causes of Pain in Breast Cancer

<p>Acute Pain Syndromes Acute pain associated with diagnostic and therapeutic interventions Acute pain due to procedures and postmastectomy pain</p>
<p>Acute Pain Associated with Anti-Cancer Therapies Pain associated with chemotherapy and infusion Pain associated with chemotherapy toxicity Mucositis and painful peripheral neuropathy Pain associated with hormonal therapy (hormone-induced pain flare in breast cancer) Pain associated with radiotherapy Early-onset brachial plexopathy</p>
<p>Chronic Pain Syndromes</p> <p>Bone Pain Syndromes Pain syndrome of hip, base of skull, and multiple bony metastases Back pain and epidural spinal cord compression</p> <p>Visceral Pain Syndromes Pleural, pericardial Liver Bowel obstruction Peritoneum</p> <p>Pain Syndromes Associated with Tumor Infiltration of Nerves Tumor infiltration of peripheral nerves Tumor infiltration of brachial plexus Tumor infiltration of meninges</p> <p>Chronic Pain Syndromes Associated with Cancer Therapy Postchemotherapy pain syndromes Chronic painful peripheral neuropathy Avascular necrosis or osteoporosis Postsurgical pain syndromes including postmastectomy pain syndrome Phantom breast pain Chronic postradiation pain syndrome Radiation-induced brachial plexopathy</p>

Table 32–20 Physiologic Types of Breast Cancer Pain

Type of Pain	Example	Character	Treatment
Somatic (nociceptive)	Bone metastasis	Dull, aching, focal	Nonopioid analgesics, opioids
Visceral	Intestinal obstruction	Dull, aching, throbbing	Nonopioid analgesics, opioids
Neuropathic	Brachial plexopathy	Burning, shooting, sharp	Nonopioid analgesics, opioids, adjuvants

From a physiologic standpoint, there are three types of pain: somatic (nociceptive), visceral, and neuropathic. Somatic pain develops once nociceptors in tissues are activated. Visceral pain results from involvement by tumor of thoracic and abdominal viscera and is not as well localized as somatic pain. Neuropathic pain results from injury to the peripheral or central nervous system and most commonly occurs as a result of tumor compression or infiltration of peripheral nerves, nerve roots, or the spinal cord. Surgical trauma and radiation-induced injury to nerves may also result in this type of pain. Neuropathic pain is often described as severe. Although there may be a constant dull ache or pressure, superimposed burning or shooting pains are often described (Table 32–20).

What is the approach to pain management in the patient with breast cancer?

The use of medications is predicated on the World Health Organization (WHO) analgesic ladder (Fig. 32–26). Mild to moderate pain may be treated with a nonopioid analgesic such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs). Opioids, however, are the mainstay of cancer pain management and should be used for persistent or moderate to severe pain. Opioid treatment and titration should be initiated with immediate-release products, often combined with acetaminophen or aspirin (including codeine, hydrocodone, and oxycodone). Persistent or more severe pain warrants the use of higher doses of oxycodone or tramadol, morphine, hydromorphone, fentanyl, and methadone.

Patients with chronic or anticipated chronic pain should receive around-the-clock dosing with longer-acting or continuous medications such as sustained-release morphine, sustained-release oxycodone, transdermal fentanyl, or, when appropriate, continuous infusion through the intravenous or subcutaneous route.

Patients who receive an around-the-clock regimen should also have available to them a short-acting opioid given on an as-needed basis for breakthrough pain. When possible, the breakthrough drug is the short-acting form of the maintenance drug. Short-acting oral opioids may usually be given every hour, whereas parenteral forms can be offered up to every 15 to 30 minutes. The initial rescue dose is usually about 15% of the 24-hour baseline dose; however, doses must be individualized.

Drug selection and doses are dependent on such factors as pain intensity, prior opioid use and adverse effects, preferred route of administration, and coexisting disease. For example, buildup of the toxic metabolites of morphine in the setting of renal disease makes hydromorphone and fentanyl the preferred agents for maintenance therapy in this setting. Initial doses are selected, and doses are titrated until good analgesia

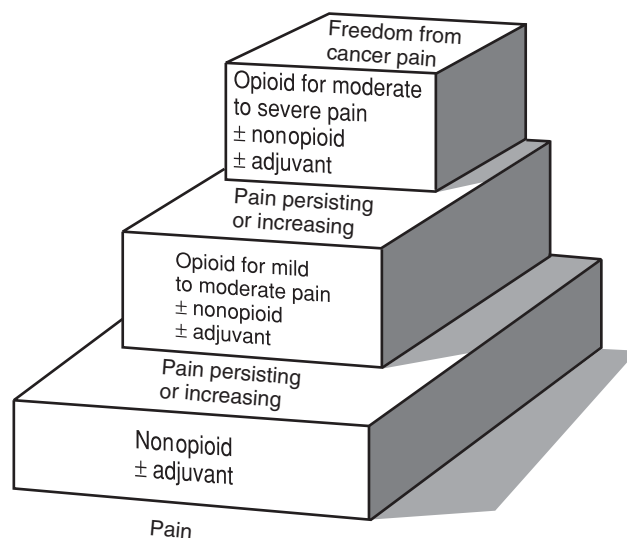

Figure 32–26 World Health Organization analgesic ladder. (From World Health Organization. *Cancer Pain Relief*, 2nd ed. Geneva, WHO, 1996.)

is reported or intolerable side effects occur. Dosing intervals may require adjustment. The total dose of opioid used over 24 hours is calculated, and the maintenance dose is changed accordingly so that patients require no more than several breakthrough doses daily.

Physicians should familiarize themselves with equianalgesic dosing guidelines and oral to parenteral relative potencies. Conversion of oral to parenteral doses and equianalgesic dosing for morphine and hydromorphone are illustrated in Figure 32–27.⁶

Transdermal fentanyl⁷ is a popular alternative to oral and other parenteral opioids. However, familiarity of its pharmacokinetics is essential for its optimal use. It is recommended that patients be stabilized on an oral opioid regimen (or conversion from patient-controlled analgesia [PCA]) by calculating the 24-hour dose of the opioid used and converting this to the equianalgesic dose of fentanyl. For example, a 100- μ g/hour fentanyl patch is about equianalgesic to 2 to 4 mg/hour of intravenous morphine. There is a delay of 8 to 12 hours in achieving effective analgesia the first time the patch is applied, so the prior form of analgesic should be continued for this period. Likewise, serum concentration falls slowly after the patch is removed. As a rule, dose changes should not be made more frequently than once every 72 hours, although some patients require a dosing interval of 48 hours. Given these limitations, transdermal fentanyl should be reserved for patients with stable pain, especially those unable to take oral medications. Short-acting rescue opioids must be available for breakthrough pain. Choices include oral short-acting opioids such

Drug	PO	SC or IV
Morphine	20 mg	Divide by 3 → 7 mg Divide by 20 → 1 mg
Hydromorphone	5 mg	Divide by 5 → 1 mg

Figure 32–27 Conversion of oral opioid doses to parenteral doses. (Data from Pocket Guide to Hospice/Palliative Care Medicine. Glenview, IL, American Academy of Hospice and Palliative Medicine, 2003, p. 80.)

as morphine (pill or elixir) and oral transmucosal fentanyl citrate, which is absorbed across the buccal mucosa.

Opioid adverse effects are common. They are gastrointestinal (nausea, vomiting, constipation), autonomic (xerostomia, urinary retention, and postural hypotension), central nervous system (drowsiness, delirium, respiratory depression, and myoclonus), and cutaneous (pruritus, diaphoresis). The four approaches to these side effects are (1) dose reduction, (2) specific therapy, (3) opioid switch, and (4) change route of administration.⁸ Constipation is the most common side effect of chronic opioid therapy. Patients should undergo routine prophylaxis with stool softeners and cathartics. Sedation may be counteracted with methylphenidate or dextroamphetamine. Small doses are initiated in the morning, usually with a second dose given at midday.

Which adjuvant analgesics are effective in cancer pain management?

Adjuvant analgesic drugs can be administered at any stage of the WHO ladder; however, severe pain warrants administration of a strong opioid immediately. Adjuvant analgesics may be used initially for mild pain or in addition to opioids for moderate to severe pain. Acetaminophen and NSAIDs are important first-line agents for mild to moderate pain control. The newer cyclo-oxygenase-2 (COX-2) NSAIDs are currently being studied, and there is some early evidence of their potential effectiveness in metastatic bone pain, as has been demonstrated with the older NSAIDs.^{9,10} Unlike opioids, NSAIDs and acetaminophen have a ceiling effect to their efficacy, so that increasing doses beyond a certain level does not result in a greater therapeutic effect.

Corticosteroids may provide effective analgesia in such varied situations as metastatic bone pain, pain related to nerve compression, pain from epidural spinal cord compression, and painful liver metastases.

Adjuvant therapy can be particularly helpful in the treatment of neuropathic pain. The tricyclic antidepressants have been used in a variety of chronic neuropathic pain syndromes, including postherpetic neuralgia and painful diabetic neuropathy. There is a growing body of evidence supporting the use of anticonvulsant drugs for neuropathic pain. In particular, gabapentin has been shown to be effective as an adjuvant to opioid analgesia for neuropathic cancer pain.¹¹

Other agents found to be effective as adjuvants include lidocaine and other antiarrhythmic-anesthetic agents given systemically, such as clonidine, baclofen, and *N*-methyl-D-

aspartate (NMDA) antagonists. The latter group includes dextromethorphan and ketamine. The ketamine produces analgesia in doses much lower than those needed to produce anesthesia. Also, methadone has anti-NMDA receptor effects.

Bisphosphonate compounds should always be considered in the setting of bone metastases. Pamidronate, 60 to 90 mg intravenous infusion every 2 to 4 weeks, has been shown to decrease pain, slow the growth of tumor metastases, and prevent fractures.¹²

When are interventional strategies indicated for cancer pain?

Patients whose pain is not adequately controlled with systemic analgesics or in whom side effects of these medications are intolerable may be candidates for interventional anesthetic techniques including spinal anesthesia and peripheral neurolytic blockade. Opioids, local anesthetics, and clonidine may all be administered for spinal analgesia. The epidural dose of opioid required to manage pain is about 10% of the systemic dose. Subarachnoid administration of morphine doses are as low as 1% of the systemic dose. In cancer pain, spinal opioids are most effective for patients with deep, constant somatic pain.¹³ Although effective, the use of spinal analgesia is invasive, highly technical, and costly because its delivery requires the use of indwelling catheters and pumps. This should be considered for use only in patients who have a prognosis of more than several months.

Neural blockade may be effective when pain is well localized. Local anesthetics can be injected in various locations, including the brachial plexus and pleural cavity. Newer techniques, such as radiofrequency ablation (RFA) therapy, are currently being studied for painful bone metastases¹⁴ and painful soft tissue tumors. In extreme circumstances, neurosurgical intervention may be considered. Techniques available include intracranial and spinal ablative procedures.¹⁵ The decision to employ any of these techniques is based on expected survival, pain location, and character and patient preferences.

Which nonpharmacologic methods of pain management are effective?

Good communication is the most important intervention for improved patient outcome. Patients must feel that they are being listened to. In addition to specific questions regarding pain assessment, they should be asked how else they may be suffering and what concerns they may have. To ensure true informed consent, the physician must discuss with the patient the important risks and benefits of, and alternatives to, all treatments (including chemotherapy) and procedures. The patients and caregivers should be educated about the high rate of effective pain control and the safety and effectiveness of opioids. Specialized cognitive-behavioral interventions may help patients develop skills to cope with pain and its secondary effects. These techniques include relaxation, imagery, hypnosis, reframing, distraction, structured support, and psychotherapy.¹⁶ Such nonpharmacologic strategies should be used in conjunction with pharmacologic treatment. Cognitive-behavioral skills are more difficult to acquire once

pain is severe or chronic. Physical methods such as massage,¹⁷ ice, or heat may be used at any time. There is a growing body of literature supporting the use of music therapy as a means to reduce pain intensity and related distress associated with pain.¹⁸ Other complementary therapies that have been demonstrated to be effective in cancer pain include acupuncture and transcutaneous electrical nerve stimulation (TENS). Pastoral and spiritual care, as well as group support, may be extremely effective complementary therapies and should be made available to all patients.

When is it appropriate to begin palliative and terminal care?

Palliative care is interdisciplinary and focuses on the management of physical, psychological, social, and spiritual issues. Terminal care begins when the patient is likely to die within days or weeks. Effective palliative care should be integrated into cancer care from the beginning, rather than reserved for the end of life. It is especially important that the oncologist inform patients whether the goal of treatment is cure or palliation. As with other cancers, patients with breast cancer overestimate the potential benefits of chemotherapy.¹⁹ This misunderstanding of the value of chemotherapy may interfere significantly with appropriate decision making. A survey of medical oncologists revealed little hesitation in recommending second-line treatments for breast cancer despite their lack of enthusiasm for benefit. This is consistent with the fact that medical oncologists are more likely than nonmedical oncologists to continue aggressive treatments for potentially small benefits.²⁰ Chemotherapy is frequently given within weeks of death despite the fact that, through abundant clinical research, the oncologist has accurate data concerning survival in patients with terminal disease. The avoidance of ineffective chemotherapy and redefinition of goals of care from cure to quality of life require awareness of prognosis.

The physician's ability to predict terminally ill cancer patients' survival has been evaluated in several studies. Overall, estimates tend to be overly optimistic.^{21,22} Multiple studies relate survival to performance status. The Karnofsky performance score (KPS) is the standard most often used. A KPS of less than 50% (patient requires considerable assistance and frequent medical care) suggests a life expectancy of fewer than 8 weeks.²³ This knowledge affords the treating physician the opportunity to help the patient modify goals of care to avoid futile attempts to prolong life with chemotherapy and focus on the alleviation of symptoms and distress and support for the patient and family. It is also a time to determine the patient's wishes with respect to advance directives and end-of-life care, if this has not yet been done.

Where do patients die, and when is referral to hospice appropriate?

When surveyed, 50% to 70% of cancer patients prefer to be cared for at home and to die at home, although as death approaches, some patients and relatives begin to express a preference for death in hospice.²⁴ In the United States, the Medicare hospice benefit was devised predominantly as home care for the terminally ill, with inpatient hospice available for

respite care, when necessary. Despite the availability of this benefit and, more importantly, the palliative care administered through hospice, most cancer patients in the United States continue to die in hospitals or other long-term facilities. Between 1991 and 1996, only 20.7% of women older than 65 years dying of breast cancer were enrolled in hospice (although the ratio of hospice use increased over those years from 11.1% to 27.1%).²⁵

What is expected during the terminal phase of a patient with breast cancer?

Common signs and symptoms in patients with advanced cancer include fatigue and generalized weakness, anorexia, pain, mental status changes, dyspnea, nausea, and vomiting. The proper management of these symptoms necessitates a thorough assessment and attention to physical and psychological factors. Cancer cachexia is a particularly troublesome symptom and, in breast cancer, has been shown to correlate with tumor bulk. Total parenteral nutrition does not improve cancer survival.²⁶ In the terminal breast cancer patient, the goals, risks, and benefits of artificial nutrition and hydration should be discussed with patient and family. Loss of appetite is natural and does not appear to contribute to patient suffering.

Most patients have their symptoms relieved by adhering to current palliative care guidelines for pain and other symptom control methods. Occasionally, refractory symptoms necessitate the use of induced sedation (also known as *palliative sedation* or *terminal sedation*). The three most common symptoms that result in the use of induced sedation are pain, agitation or delirium, and dyspnea. This extreme measure should be undertaken only for severe refractory symptoms in the setting of fully informed consent by the patient or health care proxy. Death is understood to be a possible side effect (double effect) because the primary goal is the relief of suffering.

When should advanced care planning take place?

All patients should be given the opportunity to express feelings about the type of care they would like to receive at the end of their lives. To do this properly, patients need to be informed of their status, prognosis, and range of available supportive measures. This information is often withheld or delayed for fear that the patient will lose hope. In general, however, patients want to know the truth about their diagnosis and prognosis. It has been shown that in the absence of prognostic information from their physicians, patients tend to overestimate their survival and express a preference for life-extending therapy. Patients who thought there was at least a 10% chance that they would not live for 6 months expressed a greater preference for comfort care.²⁷

Physicians are responsible for initiating discussions with patients regarding advanced care planning as a matter of routine. The patients should assign a health care proxy or durable power of attorney for health care in case they lose capacity to make decisions. A living will or written advance directive is also advisable to help direct care. Goals of care must be established as the patient's status changes. Early in a patient's care, remission or cure may be the goal. With advanced disease

progression, this goal may change to being home with family and ultimately to having a peaceful death.

Surgical Treatment of Patients at High Risk of Breast Cancer

Freya R. Schnabel

DEFINITION OF RISK

All women have a baseline risk for developing breast cancer. There is no immunity from the disease. However, there are known factors that increase a woman's risk for developing breast cancer over the baseline level, and they have been discussed in detail elsewhere in this volume. Risk factors for breast cancer stem from a variety of sources, including family history, reproductive factors, and environmental exposures. The care of women at high risk for the development of breast cancer is challenging and requires careful risk assessment and discussion of strategies to manage that risk.

It is clear that most women overestimate their risk for developing breast cancer. Anxiety, apprehension, and misinformation may alter a woman's perception of her risk. Therefore, it is the job of the clinician to clarify an individual woman's risk for breast cancer as precisely as possible, communicate that risk clearly, and explore the various approaches to assessing breast cancer risk to arrive at a strategy that is appropriate in each case at that particular point in time.

How can we quantify breast cancer risk?

Quantifying breast cancer risk provides advantages for both the patient and the clinician. Many women possess multiple risk factors for breast cancer that interact and combine to produce the overall risk for that individual. Quantifying risk allows individuals to compare their risks with known benchmarks. As interventions to modify risk become available, risk-benefit analyses can help define levels of risk that justify particular interventions.

The initial medical history taken from a woman being assessed for breast cancer risk should include detailed information concerning all established risk factors. Reproductive factors such as age at menarche, parity, age at first birth, and the use of hormone replacement therapy should be documented, along with breast-feeding history, because there may be some protective effect.¹ Prior history of benign breast disease should be explored, particularly a history of atypical hyperplasia or lobular carcinoma in situ. These conditions are

associated with a significant increase in breast cancer risk² and should be carefully confirmed, including review of pathologic material if necessary. A history of other malignancies should be sought. A prior history of Hodgkin's disease treated with mantle irradiation (including the neck, supraclavicular, infraclavicular, axillary, mediastinal, and hilar regions in one field) confers an increased risk for breast cancer to the survivor.³ Family history of breast cancer is an important aspect of breast cancer risk assessment. The patient should be queried carefully, and information regarding both maternal and paternal lines documented, including relatives' age at diagnosis, the presence of bilateral disease, and any incidence of ovarian cancer. In addition, some sense of the number of unaffected relatives may be helpful. A family history of breast cancer in a patient's single aunt is more significant than a history of breast cancer in one of six aunts. Similarly, a close relative who developed breast cancer at age 40 years has more significance than one who was diagnosed with the disease at age 90 years. A history of other cancers in the family, particularly ovarian cancer, is important. The combination of breast and ovarian cancer in a family is particularly predictive for an inherited susceptibility to these diseases. It may be helpful to draw out the pedigree to get a sense of the pattern of breast cancer in a family. This information should be updated periodically. Patients whose family history suggests an inherited genetic tendency for the disease should be referred for genetic counseling and testing because this will help clarify their risk more precisely.⁴

An individual woman may have multiple risk factors for breast cancer, and her overall risk will represent a complex combination of these factors. A variety of mathematical models have been used to quantify a woman's risk for breast cancer. The advantage of these models is the ability to use the risk estimate generated to facilitate communication with patients and present information in a manner that could be interpreted by the patient in a meaningful fashion.

The Gail model⁵ is probably the most widely used model for estimating breast cancer risk. This model was used by the National Surgical Adjuvant Breast and Bowel Project (NSABP) as a criterion for inclusion in the P-1 trial, which established the use of tamoxifen as a chemopreventive agent for breast cancer.⁶ The Gail model includes as variables the

patient's present age, age at menarche, age at first live birth, number of first-degree relatives with breast cancer, and number of benign breast biopsies, with a factor included to weight for the presence of atypical hyperplasia. The Gail model produces both a lifetime estimate for the risk of developing breast cancer and an estimate of the risk of developing the disease in the next 5 years. When discussing the results of a Gail model assessment with a patient, the lifetime risk can be compared with the widely disseminated 1-in-9 population risk estimate. The estimate of 5-year risk is extremely helpful because most patients are able to better understand this shorter term possibility. The Gail model is limited by the exclusion of family history beyond first-degree relatives. Particularly when the disease is seen on the paternal side of the family, there may be no affected first-degree relatives, thus resulting in an underestimate of risk by the Gail model.

The Claus model⁷ focuses on family history, includes both first- and second-degree relatives with the disease, and incorporates the age at which they developed breast cancer. The Claus model produces an estimate of the probability that a woman will develop breast cancer over a series of 10-year intervals. The Claus model provides a better estimate of breast cancer risk for women with extended family histories of the disease.

BRCAPRO⁸ is a new model intended to help evaluate a woman whose family history suggests an inherited susceptibility to breast cancer. This model produces a probability estimate that the individual woman will be found to carry a mutation in the *BRCA1* or *BRCA2* genes. Use of this model may be helpful to women considering genetic testing. Other models using sophisticated mathematical methods such as bayesian networks and including a multitude of risk factors are being actively developed. These models may provide a better estimate for individuals whose background contains risk factors from multiple sources.

How is a patient with inherited susceptibility to breast cancer evaluated?

The first step in evaluating an individual with the inherited susceptibility to breast cancer is identifying that individual. There are a number of inherited syndromes that include an increased susceptibility to breast cancer; hence, a detailed family history of all neoplastic diseases should be documented in women being evaluated for breast cancer risk. The most common inherited syndromes involving an increased risk for breast cancer are listed in Table 33–1. Families in which there

is an inherited susceptibility to breast cancer are recognizable by the presence of multiple generations with affected individuals, with early age at onset, more bilateral cases than would be predicted, and an increased incidence of other cancers, particularly ovarian cancer. The frequency of *BRCA1* and *BRCA2* mutations is increased in the Ashkenazi (Eastern European) Jewish population as compared with other ethnic groups.⁹ As a result, a lower threshold should be maintained for recommending genetic evaluation to women in this group.

When a pattern suggestive of inherited susceptibility to breast cancer is identified in a patient's family, genetic counseling should be offered.¹⁰ The process of genetic counseling is particularly important to allow patients to understand the level of risk they face, the decisions they may face regarding the risk for other associated cancers (particularly ovarian cancer), and the psychosocial ramifications of a positive result. Genetic testing should always be performed in the context of pretest counseling to ensure that the patient understands the above concepts and is prepared to accept and act on the results. A patient who is not prepared to accept and act on the results of genetic testing should not be tested. At the present time, there is no indication to test minor children because the information obtained from the testing will not benefit the child in any meaningful way at the time the results are obtained.

A special consideration in genetic testing is a woman who is newly diagnosed with unilateral breast cancer and whose family history suggests she may be a mutation carrier. In this setting, genetic testing before definitive cancer surgery may be indicated. Women with *BRCA1* and *BRCA2* mutations are at higher risk for the development of contralateral disease, and consideration would therefore be given to the performance of bilateral mastectomy, for treatment and prophylaxis. Testing for *BRCA1* and *BRCA2*, particularly in Ashkenazi Jewish individuals, can be done with a rapid turn-around and may affect the treatment of the newly diagnosed breast cancer in a woman whose family history suggests that she may be a mutation carrier.

Once the results of the genetic testing are available, a further discussion regarding the options for managing breast cancer risk should be conducted with the benefit of this updated information. In addition, the increased risk for other malignancies, particularly ovarian cancer, should be addressed. It is also critical that a patient understand that the failure to identify a mutation in the known genes does not imply a lower baseline risk and that there are almost certainly genes as yet undiscovered that play a role in a familial form of breast cancer.¹¹

Table 33–1 Hereditary Breast Cancer Syndromes

Syndrome or Disease	Inheritance	Sites/Tumors	Genetic Mutation
Breast-ovarian syndrome	Autosomal dominant	Breast, ovarian, prostate	<i>BRCA1</i>
Male breast cancer	Autosomal dominant	Breast, ovarian, male breast, pancreatic	<i>BRCA2</i>
Li-Fraumeni	Autosomal dominant	Breast, soft tissue, bone, brain, hematologic, adrenal	<i>p53</i>
Ataxia-telangiectasia	Autosomal recessive	Lymphoma, breast, ovarian, leukemia, oral cavity, stomach, pancreas, bladder	chr 11q22
Cowden's (multiple hamartoma)	Autosomal dominant (variable expressivity)	Facial trichilemmomas, papillomatosis of lips and oral cavity, thyroid nodules, gastrointestinal polyps, breast fibroadenomas	chr 10q22-23

What is the significance of atypical hyperplasias in breast cancer risk?

In dealing with patients with a history of benign breast disease, it is important for the clinician to recognize that most subcategories of benign breast disease confer no clear increase in breast cancer risk. Commonly observed cyclic breast pain and symmetrical bilateral nodularity on clinical breast examination do not imply an increased risk for malignancy. Typical fibroadenomas of the breast not associated with proliferative benign disease in the adjacent breast tissue are generally thought to have no association with subsequent risk for breast cancer.¹² However, seminal work by Dupont and Page established the association between certain categories of benign breast disease and an increased risk for breast cancer.² Benign lesions containing atypical ductal or lobular hyperplasia as defined by histologic analysis are associated with a relative risk of 4 to 5 for the development of breast cancer. Lobular carcinoma in situ (LCIS), also called lobular neoplasia, has been associated with a 6- to 9-fold increase in breast cancer risk.¹³ When atypical hyperplasia is combined with a family history of breast cancer, there is a synergistic effect, and there is an approximately 10-fold increase in breast cancer risk.² These data have been corroborated by other investigators, and it appears that when atypical hyperplasia is detected by cytologic analysis, the association with breast cancer risk is the same. Wrensch and colleagues analyzed nipple aspirate fluid for the presence of atypia and demonstrated a relative risk of breast cancer of approximately 5 in women with atypia diagnosed by this method.¹⁴ Fabian and associates performed random four-quadrant fine-needle aspirations of the breast for cytology and also documented a 5 times relative risk for breast cancer in women with atypical cytology.¹⁵ In this study, women with an elevated Gail model risk who had hyperplasia with atypia in their fine-needle aspiration samples had an observed breast cancer incidence of 15% at 3 years. Thus, it appears that cellular atypia in the breast is a meaningful marker for increased risk for breast cancer, particularly when combined with a background of elevated risk from other sources.

Ductal lavage represents an opportunity to evaluate for the presence of atypia in breast ductal cells and thereby help stratify an individual woman's risk for breast cancer.¹⁶ This relatively new technique involves cannulating the orifices of nipple ducts that produce nipple aspirate fluid with a double-lumen microcatheter, then irrigating the ducts to collect ductal cells for cytologic analysis. Atypia can be identified by this minimally invasive office-based method, with that information incorporated into the patient's breast cancer risk assessment. For many women, this objective data point, which is cell based and obtained in real time, may be an important aid in quantifying their breast cancer risk as precisely as possible.¹⁷ When added to a positive family history, these data may be the impetus needed for a patient to consider active risk modification interventions. It is particularly significant that in the NSABP P-1 trial, the subset of patients who benefited most from tamoxifen were those who entered the trial with a history of atypical hyperplasia.⁵ Individual patients can be offered ductal lavage on a yearly basis and their results tracked over time. Ductal lavage is becoming increasingly integrated into the comprehensive assessment of high-risk women as a tool for improved breast cancer risk stratification.¹⁸

What are the management strategies available for high-risk women?

The product of a comprehensive breast cancer risk assessment should be some statistical quantification of a woman's risk for developing breast cancer. This objective analysis may help to decrease the influence of anxiety and emotional factors on a woman's perception of her risk for breast cancer. However, it is important for the clinician to recognize that every woman will understand her risk for breast cancer in an individual manner, which may be governed by diverse issues such as the previous breast cancer experiences of friends and relatives and aspects of her own personality (e.g., qualities of being risk averse or risk taking in other aspects of her life). The discussion of breast cancer risk and risk management strategies is a dialogue, not a monologue, and the patient must participate. Breast cancer risk changes with time, and risk assessment should be periodically updated. There is no single strategy for managing breast cancer risk that is appropriate for every woman at any moment in time.

STRATEGIES

There are three major categories of strategies available to high-risk women: intensive surveillance, chemoprevention, and prophylactic mastectomy.

What is an appropriate surveillance strategy for high-risk patients?

Intensive surveillance should be offered to all high-risk patients, regardless of whether they undertake active risk reduction methods. The purpose of this strategy is to offer the patient every possible opportunity for the early detection of breast cancer. The benefits of such programs are not clearly established, although there are some data in the medical literature to support the effectiveness of this approach in early detection.¹⁹

Surveillance programs include the elements of breast self-examination, clinical breast examination, and breast imaging. Breast self-examination has become controversial, and the benefit to the patient has not been established in published studies. However, informing patients regarding the visible and obvious signs of breast disease (e.g. skin changes, change in breast contour) is good practice and prevents a patient from neglecting to bring an obvious sign to medical attention. Clinical breast examination is very important, particularly in young women, and we generally recommend clinical breast examinations every 6 months to our high-risk patients. Our approach to breast imaging for high-risk patients has evolved with time, as our understanding of the benefits and limitations of each technique has increased. Yearly mammography is recommended for all women after age 40 years. When caring for high-risk women, particularly those with a family history of breast cancer at a young age, the age at first mammography should be adjusted downward. Screening ultrasound may identify mammographically occult masses in high-risk women with dense breasts and has been increasingly integrated into clinical practice. There is also emerging evidence

in the medical literature to support the use of screening breast magnetic resonance imaging (MRI) for high-risk women. Although it is expensive and inconvenient, it appears that a small percentage of lesions will be detected by this method without producing recognizable signs by other imaging modalities. A paper from investigators in the Netherlands reviewed their experience with screening MRI in women known to be *BRCA1* and *BRCA2* mutation carriers.²⁰ In their experience, MRI detected invasive cancer more accurately than mammography; however, mammography remained superior in the diagnosis of ductal carcinoma in situ (DCIS). Despite the expense and the potential for generating benign biopsies, it seems clear that MRI should be offered to very high-risk women for the increased ability to detect breast cancer using this method.

What is the role of chemoprevention for high-risk women?

The NSABP P-1 trial provided a landmark in the management of women at high risk for developing breast cancer.⁵ This prospective randomized trial established the clear benefit of tamoxifen in reducing the risk for breast cancer development in high-risk women. Five years of treatment with tamoxifen provided an average of almost 50% reduction in breast cancer development (both DCIS and invasive disease) for women in the study. Of note, the subgroup that benefited most from tamoxifen was the group of women who entered the trial with atypical hyperplasia or LCIS. At this point, tamoxifen remains the one agent clearly demonstrated to reduce the risk for breast cancer in high-risk women.

The Study of Tamoxifen and Raloxifene (STAR) trial is a randomized prospective trial being conducted at present by the NSABP to evaluate the potential use of raloxifene in breast cancer risk reduction. Raloxifene, a selective estrogen receptor modulator like tamoxifen, is a Food and Drug Administration–approved treatment for osteoporosis. Early data support its efficacy in breast cancer risk reduction²¹; however, the results of the STAR trial will complete our understanding of the potential role of this agent in chemoprevention.

There is also ongoing research into other candidate agents for breast cancer chemoprevention. Aromatase inhibitors represent a promising category of agents under consideration for their effectiveness in breast cancer prevention.²² A recent study associated aspirin use with a reduction in the incidence of breast cancer.²³ Cyclo-oxygenase-2 (COX-2) inhibitors are also being studied for their potential use in reducing breast cancer risk.²⁴ As our understanding of the basic science of breast cancer development advances, we may anticipate additional possible interventions to reduce the risk for breast cancer in high-risk women.

What is the role of prophylactic surgery in the management of high-risk women?

Certainly, bilateral prophylactic total mastectomy provides a high-risk patient with the greatest possible reduction in the risk for breast cancer development. Hartman and coworkers reviewed the experience of the Mayo Clinic in prophylactic

surgery for breast cancer prevention and demonstrated a 90% reduction in breast cancer risk with this technique as performed between 1963 and 1993.²⁵ Many procedures, however, were performed for indications that might not be considered appropriate at this time, and many of the operations were done as subcutaneous mastectomies, which differs from the current standard. We might expect a greater degree of risk reduction with total mastectomy as the approach because the technique of total mastectomy should provide greater extirpation of at-risk breast tissue.

In our time, bilateral prophylactic total mastectomy is almost exclusively the province of those women at highest risk for developing breast cancer: women who are known *BRCA1* and *BRCA2* carriers. In those cases, the exquisitely high level of risk would seem to justify this intervention. Patients undergoing this procedure should also be offered the option of immediate breast reconstruction.

What modifiable risk factors should be considered in high-risk patients?

Some risk factors for breast cancer are clearly beyond a woman's control—for example, age at menarche and menopause and family history of the disease. However, there are other potential risk factors that are subject to modification by an at-risk woman. These include obesity, diet and exercise, smoking, and alcohol consumption.²⁶ These lifestyle factors may represent relatively small risks, but positive interventions may provide an individual with health benefits beyond any potential impact on breast cancer risk. Avoidance of risk-taking behaviors is another potential advantage to high-risk patients. The Women's Health Initiative provided clarification of the increased risk for breast cancer associated with combined estrogen-progestin hormone replacement therapy given to postmenopausal women.²⁷ Although hormone replacement therapy affords symptomatic relief for women suffering from significant menopausal symptoms, it also increases the risk for breast cancer and appears to increase the risk of some types of cardiovascular disease and should thus be viewed as a short-term strategy. For women at high risk for developing breast cancer, any intervention that will increase that risk further should be viewed with caution.

What is an appropriate surveillance strategy for associated ovarian cancer risk?

Women at high risk for breast cancer on the basis of putative or documented inherited genetic syndromes are also at risk for a variety of other malignancies, and they should be appropriately informed and screened. Women at high risk for breast cancer because of inherited mutations in *BRCA1* and *BRCA2* are also at increased risk for the development of ovarian cancer.²⁸ The estimated cumulative risk for developing ovarian cancer in a woman with a *BRCA1* mutation is 30% by age 60 years. The management of increased risk for ovarian cancer differs greatly from our approach to the management of women at high risk for breast cancer. At present, there is no effective way to diagnose ovarian cancer at an early enough stage that survival from the disease is increased. Neither screening ultrasound nor CA-125 testing has been shown to

reduce the mortality from ovarian cancer. Oral contraceptives afford some risk reduction and may provide an appealing option for younger women at risk for ovarian cancer.²⁹ However, there is some evidence that women who take oral contraceptives for long periods of time beginning at a young age may have an increased risk for breast cancer.³⁰ Women for whom fertility is not a concern most frequently opt for prophylactic bilateral oophorectomy, which may be performed laparoscopically. This procedure affords the patient dramatic risk reduction, but a small risk for primary peritoneal cancer remains.

Treatment of Unusual Malignant Neoplasias and Clinical Presentations

Alison Estabrook and Gladys Giron

Breast cancer does not always present clinically as a palpable mass or thickening in the breast tissue. It may mimic an infection, as in inflammatory breast cancer, or present as an irritation of the nipple (Paget's disease). It may present as an axillary mass. Some breast cancers are partially cystic (intracystic papillary carcinoma) and require careful clinical examination after aspiration. The breast can also develop sarcomas or lymphomas and can be the site of metastatic carcinomas. This chapter describes these unusual presentations and uncommon sarcomas and primary lymphomas.

PAGET'S DISEASE

What is Paget's disease?

It was not until after his retirement from the practice of surgery that Sir James Paget first reported 15 cases of chronic nipple ulceration in 1874. He described "a florid intensely red raw surface . . . like the surface of very acute diffuse eczema."¹ He proposed that chronic irritation was the cause of the malignancies diagnosed in these women within 2 years of initial presentation.² This rare condition of the nipple-areolar complex was later given the eponym of *Paget's disease*. It is reported in most series to occur in 1% to 3% of all breast malignancies. The classic histologic finding is that of Paget's cells within the epidermis of the nipple and areola. The origin of these cells is controversial and has spawned two theories of histogenesis. The first is the epidermotropic theory, in which malignant cells in the terminal ducts migrate to the nipple.³ The second is the transformation theory, in which epidermal cells of the nipple transform into Paget's cells. This latter theory assumes that Paget's cells are independent of the carcinomas found within the mammary gland in most cases.⁴ Immunohistochemical studies favor the epidermotropic theory, which is in keeping with the observation that essentially all patients are found to have concomitant malignancies of ductal origin.^{3,5,6}

How does Paget's disease present clinically?

Patients typically present with an erythematous, scaly or weeping eczematous lesion of the nipple (Figs. 34-1 and 34-2). This may be associated with bleeding. In later stages, there may be progression to erosion and ulceration with eventual effacement of the nipple-areolar complex. Subjectively, patients notice a change in sensation over the area such as burning and itching. Paget's disease involves the nipple first, before progressing to the areola. Sole involvement of the areola is not characteristic. The differential diagnosis includes inflammatory and malignant processes: eczema, psoriasis, other dermatologic conditions; florid papillomatosis; Bowen's disease; and amelanotic melanoma of the nipple.^{7,8} A delay in diagnosis often results because patients are initially treated with topical steroids for variable periods. When eczematoid changes of the nipple do not respond to such treatment promptly, Paget's disease must be excluded.

The diagnosis may be made with a punch biopsy of a representative area performed in an office setting but may require a wedge biopsy. Some authors report cytologic analysis of smears of the weeping fluid or blood, but this is not always diagnostic.⁹ Along with diagnosing the nipple-areolar lesion, attention must be paid to the remaining breast. Studies of mastectomy specimens have demonstrated that nearly 100% of patients with Paget's disease do have an underlying malignancy.¹⁰⁻¹² Less than half of these are palpable masses. The most common location for these carcinomas is central, but they have been reported in all quadrants. About 40% to 50% of patients with Paget's disease have no clinically detectable mammary mass.¹³ Most palpable disease is invasive carcinoma, whereas most undetectable disease is carcinoma in situ. Focal changes in the nipple-areolar complex, such as thickening or a retroareolar mass, may be detected on mammography, but typically this modality is most helpful in identifying concomitant tumors.¹⁴ Ultrasonography offers no further diagnostic advantage.¹⁵

What are the histologic features of Paget's disease?

The characteristic Paget's cells are identified in the keratinizing epithelium of the nipple epidermis (Fig. 34–3). Paget's cells are large round cells with abundant pale or clear cytoplasm, pleomorphic nuclei, and large nucleoli. They occur singly in the superficial epidermal layers and may form clusters in the basal layers.⁷ Associated invasive carcinoma is overwhelmingly of ductal origin. Accompanying intraductal carcinoma is characterized by comedo or solid growth patterns. Because comedocarcinoma is often associated with calcifications, this may be detected mammographically.⁷

Figure 34–1 Patient with biopsy-proven Paget's disease of the nipple, refusing standard treatment.

Histochemical characteristics suggesting a mammary origin for these cells include the distribution of carcinoembryonic antigen, cytokeratins, estrogen receptors, and *HER-2/neu* receptors.⁷

How has the treatment of Paget's disease of the breast evolved?

Traditionally, the treatment of Paget's disease has been mastectomy. In patients undergoing mastectomy for Paget's disease with an associated invasive carcinoma, postoperative prognosis and survival are directly related to the stage of the carcinoma. When associated with intraductal carcinoma, the 10-year survival rate after mastectomy has been reported as 100%.¹⁶

For patients with Paget's disease and extensive underlying carcinoma, total mastectomy with operative assessment of the axilla remains the standard approach. The axilla may be addressed with a sentinel lymph node biopsy followed by

axillary node dissection for positive metastatic lymph node involvement. Increasingly, patients are presenting with early-stage breast cancers and cancers that are nonpalpable and only detected radiographically. This has led to the acceptance of breast-conserving surgery for both invasive and in situ breast cancer. The use of conservation is being explored in appropriate cases of Paget’s disease.

Breast conservation approaches in the management of Paget’s disease include excision of the nipple–areolar complex with central segmentectomy, with or without radiation therapy. Table 34–1 summarizes current available reports of breast conservation approaches to Paget’s disease.^{4,11,17–24} Although numbers are small, the observed local recurrence rates are lower in more recent series, and mortality remains low.

Is breast-conserving treatment appropriate for Paget’s disease?

The application of breast-conserving surgery for Paget’s disease is similar to that for patients without this special clinical presentation. One obvious exception is the almost universal need for excision of the nipple–areolar complex, with its cosmetic implications. The foremost surgical goal is that of achieving negative margins. In most cases, an elliptic incision encompassing the entire nipple–areolar complex is necessary. A central cone of tissue is dissected out to a depth of at least 2 cm, or down to the chest wall. All margins must be inked and histologically evaluated. Emphasis again is placed on pre-operative assessment for a concomitant breast cancer that must be treated accordingly. Kothari and colleagues illustrated this point in a study of 70 women with Paget’s disease treated with mastectomy.²⁵ Only one third presented with a palpable mass, and of these masses, only 25% were confined to the retroareolar region. They then extrapolated that cone excision of the nipple alone would have resulted in incomplete excision

in 75% of the cases. Complete nipple resection with partial areolar excision may be possible in cases in which the areola is large and the extent of disease is small. The axilla should be evaluated surgically in patients with underlying carcinoma and extensive ductal carcinoma in situ (DCIS) with microinvasion. This may start with a sentinel lymph node biopsy.

Is radiation therapy required after breast-conserving therapy?

The decision to proceed with adjuvant radiation therapy depends on the extent of disease as determined by pathologic examination of the surgical specimen. Radiation therapists advocate postoperative mammography to rule out residual microcalcifications before proceeding with definitive radiation treatment, the standard in treatment of in situ and invasive breast cancer without Paget’s disease.¹⁷ In the subgroup of patients presenting with Paget’s disease of the nipple and no identifiable mammary malignancy, treatment should proceed as though there were underlying DCIS—that is, breast-conserving surgery followed by radiation therapy.

Cosmetic reconstruction of the nipple–areolar complex is delayed until all treatment is completed. A plastic surgeon should then be consulted to review the options available. Reconstruction most often entails a local “skate” flap with skin graft and subsequent tattooing. Other options include tattooing alone and composite graft from the contralateral nipple.²⁶

In our review of the treatment of Paget’s disease of the breast at Columbia-Presbyterian Medical Center between 1990 and 1997, 24 patients underwent breast-conserving therapy and 21 patients underwent modified radical mastectomy. Most of the patients treated conservatively presented without an underlying mass and had unifocal areas of DCIS. They were treated with a wide local excision performed through an elliptic incision including the entire nipple–areolar complex. Histologically negative margins were obtained in all cases. At

a mean follow-up of 82.5 months, three patients (16.67%) in the breast conservation group had developed a local recurrence within a median time of 24 months. At a mean follow-up of 90 months, three patients in the mastectomy group (14.3%) had recurrence within a median time of 23 months. The mortality rate was 16.67% for the conservation group and 22.2% for the mastectomy group. This long-term follow-up demonstrates that in carefully chosen cases, breast conservation with particular attention to negative margins results in local recurrence rates and overall survival rates equivalent to those of modified radical mastectomy.

UNUSUAL PRESENTATIONS

Inflammatory Carcinoma of the Breast

What is inflammatory carcinoma of the breast?

Haagensen described this presentation as “the most malignant type of breast cancer.”²⁷ The term *inflammatory carcinoma of the breast* was coined by Lee and Tannenbaum in their historic paper in 1924.²⁸ This term describes a constellation of signs and symptoms without any specific pathologic or radiologic features. Thus, it is primarily a clinical diagnosis. In a description of cases of inflammatory breast cancer (IBC) at Barnes Hospital, Ellis and Teitelbaum suggested that demonstration of dermal lymphatic invasion by tumor cells was necessary for the diagnosis to be made.²⁹ In the latest revision of the American Joint Committee on Cancer (AJCC) Staging Manual, IBC is defined as a T4d tumor corresponding to at least stage III disease. A patient must meet the clinical criteria for inflammatory cancer and have biopsy-proven cancer within either the dermal lymphatics or the breast parenchyma.³⁰

How does inflammatory carcinoma of the breast present clinically?

The frequency of IBC ranges from 1% to 10% in published series.³¹ Mean age at diagnosis of women with IBC is comparable to that of women with noninflammatory breast cancer. However, women with IBC present at a younger age than those with locally advanced cancer without inflammatory features.³¹ Patients often complain of pain or tenderness as a first symptom. The breast becomes enlarged, indurated, and erythematous.²⁷ Following presentation, the disease progresses rapidly. In his personal series, Haagensen noted an interval from onset of symptoms to diagnosis and treatment of 4 weeks, compared with 6.8 weeks for other types for breast cancer.²⁷

In general, the clinical diagnosis of IBC is made when a patient presents with sudden enlargement of the breast, erythema, and edema of the skin overlying the breast and chest wall with advancing disease (Fig. 34–4). The term *peau d'orange* is used to describe the orange peel–like appearance of the breast with enlarged pores in mostly dependent areas. The skin color may range from pink in the early stages to deep

Figure 34–4 Patient presenting with inflammatory carcinoma and painful upper extremity lymphedema.

Figure 34–5 Patient with inflammatory carcinoma manifesting with pink to violaceous hue predominantly centrally in the breast.

red-purple (Fig. 34–5). Haagensen believed only redness affecting more than one third of the skin of the breast could be regarded as significant in making the diagnosis.²⁷ We now know that a certain extent of skin involvement is not needed in diagnosing inflammatory cancer. There may be nipple retraction, and the nipple epithelium may become reddened and crusted with disease progression.²⁷ Most patients present

with a clinically positive axilla. About 50% have an associated palpable mass, but one commonly encounters diffuse induration with no obvious localized tumor. Table 34–2 summarizes the possible signs and symptoms encountered.

The differential diagnoses are numerous and are listed in Table 34–3. The most common misdiagnosis is of an abscess or mastitis and often leads to a delay in proper treatment. The average age of a patient with IBC is 52 years, and breast infections in this age group are rare. Therefore, a short course of antibiotics may be initiated, but only with close follow-up as the workup continues. Of note, this section deals with primary inflammatory carcinoma, which should be differentiated from secondary inflammatory carcinoma of the breast. The latter is recurrent carcinoma with inflammatory features not observed with the initial malignancy.³¹

Workup includes a thorough physical examination. A punch biopsy of the skin performed in the office under local anesthesia may confirm the presence of tumor emboli within dermal lymphatics. If a tumor is palpable, a core biopsy in the office setting, preferably through the same punch biopsy incision, will yield valuable information to guide therapy. If a mass is not palpable, ultrasonography may reveal a discrete mass, and an image-guided core biopsy can then be obtained. Ultrasonography will also show marked skin thickening, thickened Cooper's ligaments, edema of the subcutaneous space, pectoral muscle invasion, or axillary involvement.^{14,32} Although there are no pathognomic mammographic signs, ultrasonography can reveal skin thickening as well as thickening of the subcutaneous tissues, parenchyma, and retromammary fat.¹⁴ In a recent series from University of Texas M. D. Anderson Cancer Center, the mammograms of 26 women with primary inflammatory breast cancer were reviewed.³³ A mammographic mass was seen in only 4 patients (15%), and malignant-appearing calcifications were seen in 6 patients (23%). The authors then concluded that common mammographic findings for this presentation of breast cancer

**Figure 34–6** Inflammatory breast cancer. Tumoral emboli are seen in the dermal lymphatics.

include skin thickening, diffusely increased density, trabecular thickening, and axillary adenopathy. Masses and malignant-appearing calcifications were uncommonly seen. Mammography will aid in ruling out contralateral disease. Magnetic resonance imaging (MRI) of the breast has not been shown to offer additional benefit.³⁴

What are the pathologic features of inflammatory carcinoma of the breast?

It must be emphasized that the IBC does not constitute a separate histologic subtype of breast cancer. The clinically observed features thus described are the basis for the diagnosis and can be associated with any of the histologic subtypes of invasive breast cancer.

The gross pathologic features include large tumors or such diffuse involvement of the breast tissue that precise measurement is nearly impossible. Skin thickening is observed on specimen examination. In a 1978 review of IBC by Lucas and Perez-Mesa, the skin measurements averaged 2 to 8 mm, whereas normal breast skin thickness is 1 ± 0.2 mm.³⁵

Dermal lymphatic invasion by tumor cells may be seen microscopically but is not necessary for diagnosis (Fig. 34–6). Often, distinguishing between vascular and lymphatic emboli is difficult.³¹ There is no direct correlation between the extent of dermal emboli identified and clinical presentation or prognosis.³¹ Absence of dermal emboli has been reported in 50% to 60% of patients presenting with IBC.^{36,37} Most tumors in patients with IBC are estrogen and progesterone receptor negative with *HER-2/neu* amplification.^{31,38}

What are the current treatment recommendations for inflammatory carcinoma of the breast?

In 1943, Haagensen and Stout reported on the Columbia Presbyterian Hospital experience with IBC between 1915 and 1942, concluding that most patients had died of their disease

within a 2-year period.²⁷ Years later, Haagensen would comment that this collective experience and his own personal series taught him that IBC was incurable by radical mastectomy and that “limited irradiation and chemotherapy can be tried.”²⁷ This is still an aggressive form of breast cancer, with about 40% of cases presenting with metastatic disease and a median disease-free survival of less than 2.5 years.³⁸ After it became clear that mechanical and localized treatment alone could not eradicate metastatic tumor cells, treatment strategies changed, with radiation and chemotherapy combined with surgery becoming standard for these patients. The use of primary systemic therapy was first instituted in the 1970s and was soon followed by the demonstration of high tumor regression rates in patients with inoperable locally advanced cancer or IBC.³⁹

The current treatment approach involves establishment of a diagnosis and a thorough survey for metastatic disease, followed by the use of induction chemotherapy, surgery, and radiotherapy. The first report describing primary systemic therapy was published by the Milan group in 1978, wherein overall disease-free survival was 53% at 3 years, compared with 41% for a group treated with radiation alone.⁴⁰ An international expert panel recently described its collective experience in treating patients with locally advanced breast cancer, including IBC.⁴¹ They concluded that primary systemic therapy is indeed the standard treatment. A period of *in vivo* testing of response should last a minimum of three or four cycles. Patients whose cancers do not respond or who experience cancer progression during that time may be offered second-line neoadjuvant chemotherapy or immediate modified radical mastectomy. The authors point out that it is more appropriate to administer maximum chemotherapy before surgery and that it is unknown whether additional postoperative chemotherapy improves or worsens results. The international group looks to the future results of the National Surgical Adjuvant Breast and Bowel Project Trial B-27 and the European Cooperative Trial in Operable Breast Cancer for answers.

What is the extent of surgery for inflammatory breast cancer?

The surgical treatment is a modified radical mastectomy, with operative treatment being offered in all but the most advanced of cases. A topic of great concern and controversy is that of pathologic axillary staging. Clearly, the pathologic extent of lymph node disease cannot be assessed without an axillary node dissection before instituting chemotherapy. Such information can be useful for planning postoperative radiation therapy, although it is less of an issue for IBC than for locally advanced breast cancer. The use of pretreatment sentinel lymph node biopsy in this group is not established because most cases present with rather advanced clinical nodal status. A pretreatment pathologic assessment can usually be made easily with a fine-needle aspiration (FNA) of palpable nodes demonstrating malignant cells. Although there are published reports of breast conservation after preoperative chemotherapy and radiation therapy, this approach cannot be currently recommended.⁴²⁻⁴⁴ Reconstruction using autogenous tissue to either reconstruct the breast and missing skin or resurface the chest wall is often performed.

When is radiation appropriate in the treatment of inflammatory breast cancer?

Radiotherapy has been shown to provide improvement in locoregional disease control in patients with IBC.⁴⁵ Postoperative radiotherapy is an integral part of the standard treatment of IBC.^{46,47} Preoperative radiation therapy combined with neoadjuvant chemotherapy has not been established as standard at this time.⁴¹ Postoperative radiotherapy is administered to the chest wall and regional lymph node basins. Overall survival, relapse-free survival, and local recurrence rate were not affected by treatment sequence.⁴⁶

Future developments to improve the survival in patients with IBC will likely result from intensive chemotherapy and autologous hematopoietic stem cell transplantation.⁴⁸⁻⁵⁰ Additionally, future interventions may result from ongoing research on genetic determinants of IBC.³⁸

Breast Cancer Presenting with Axillary Metastases and Occult Primary Site

One of the most difficult clinical scenarios facing the clinician caring for breast cancer patients is that of the patient presenting with disease metastatic to the axilla without an identifiable primary site. The management of such a patient includes a careful, exhaustive workup to identify the primary site and recognition of the importance of locoregional control to the patient's ultimate course.

How is a patient with isolated axillary metastasis evaluated?

The incidence of breast cancer presenting with axillary metastasis and an occult primary is reportedly between 0.3% and 5% of all breast malignancies.^{51,52} In general, these patients present with one or more painless, enlarged axillary lymph nodes in the absence of a palpable breast mass. The differential diagnosis includes lymphoma, other primary site malignancies such as lung cancer, and an occult primary breast cancer. FNA biopsy can identify malignant cells and may rule out a lymphoma but may not rule out a nonbreast primary. A thorough history, physical examination, and chest radiograph are usually sufficient to exclude most other primary sources.⁵³ Further imaging studies and colonoscopy may be necessary. Contrast-enhanced computed tomography (CT) scans of the chest can be successful in identification of occult breast primaries.⁵⁴ A core biopsy or an open biopsy of the enlarged axillary lymph nodes is necessary to effectively rule out lymphoproliferative disorders, provide evidence of breast origin, and obtain hormone receptor status. FNA does not yield a sufficient amount of tissue.

A careful search for the primary lesion in the breast is required. Clearly, a carcinoma that has metastasized to the axilla without an obvious primary site may be aggressive in its biology despite a small size. Most of the classic studies of this clinical presentation were published before the current era of advanced breast imaging, and it behooves the clinician to take advantage of presently available techniques. Bilateral mammography, with particular attention to the ipsilateral breast, and comparison with previous studies is the initial step. A

sensitivity of 29% and specificity of 73% for mammography have been reported in this setting.⁵² Ultrasonography is the appropriate next step to try to identify masses not seen by mammography owing to tissue density. Kolb and associates reported that screening ultrasound found 17% more cancers than mammography alone in women with dense breast tissue.⁵⁵ The use of MRI in this setting was evaluated by Olson and colleagues.⁵⁶ Forty women with biopsy-proven axillary metastatic adenocarcinoma without evidence of a breast primary underwent breast MRI imaging with and without gadolinium enhancement. MRI identified the primary breast lesion in 70% of patients (28 of 40) and allowed breast conservation in 47% (16 of 40) in suitable cases. This modality has gained popularity and should be employed when radiologists experienced with the technique are part of the multidisciplinary team. Positron emission tomography (PET) scanning is another modality currently being used to help identify occult primaries.⁵⁷ Qualified radiologists should be available to interpret these results.

What is the appropriate management of the patient with an axillary metastasis and a clinically occult primary lesion?

If a primary lesion is identified, the management scheme reverts to the typical pattern for any patient of similar stage disease. Despite a comprehensive workup and exhaustive pathologic examination of a mastectomy specimen, the primary tumor may not be found in up to one third of cases.⁵⁸ Even if a primary lesion is not identified, the breast must be treated in some way. Failure to treat the ipsilateral breast leads to a rate of clinical tumor occurrence approaching 40% in some small series and 56% in a series reported from University of Texas M. D. Anderson Cancer Center.^{53,56,59} In the past, modified radical mastectomy was the standard therapy. The tumor yield of pathologic analysis of these mastectomy specimens reported in the literature varies from 30% to 70%.^{53,56,59} Axillary node dissection will reveal metastatic disease in lymph nodes. Most studies report a median of three to five involved lymph nodes found in removed axillary contents.^{53,60} Patients with four or more involved axillary lymph nodes are usually treated with chest wall irradiation after mastectomy.

Another treatment option is complete axillary node dissection followed by whole-breast irradiation to control local disease although the primary is occult. The report from M. D. Anderson cited earlier documented a 12% ipsilateral tumor recurrence rate in 25 patients treated with breast irradiation and no difference in survival than in patients who had undergone mastectomy.⁵⁹ The experience of Fourquet and coworkers at the Institut Curie in Paris was similar.⁵³ Of 44 patients treated with whole-breast irradiation between 1960 and 1993, 9 had local disease recurrence. All of these were treated with mastectomy. A retrospective series of 35 patients from Memorial Sloan-Kettering Cancer Center also documented equivalent 5-year survival rates in patients treated with mastectomy and those treated with breast irradiation.⁵¹ In summary, the available data suggest that primary breast irradiation following axillary dissection provides survival equivalent to that of modified radical mastectomy.⁵⁸

Patients with occult primary breast cancer and positive axillary disease are candidates for adjuvant chemotherapy and

radiation.⁵⁸ Prognosis has been reported as equivalent to or even better than prognosis for same-stage nonoccult breast cancers.⁵⁸

Radiation-Associated Breast Cancer

Who is at risk for radiation-associated breast cancer?

A variety of soft tissue neoplasms, including breast cancers, are known to be associated with radiation exposure. This has been demonstrated in women exposed through multiple chest radiographic examinations for follow-up of pulmonary tuberculosis, through spine films for scoliosis, or as treatment for acne, postpartum mastitis, neonatal thymic enlargement, and skin hemangiomas.⁶¹ Perhaps the most well-known association between breast cancer risk and nontherapeutic radiation is that of the atomic bomb explosions at Hiroshima and Nagasaki. Long-term follow-up of survivors has shown a proportional increase in risk with increasing dose of radiation exposure. This is illustrated by the 25% lower risk observed in Nagasaki, where the exposure was lower, than in Hiroshima.⁶¹

The improved survival of patients diagnosed with and treated for Hodgkin's disease has been accompanied by the development of second neoplasms as a long-term consequence.⁶²⁻⁶⁴ The cumulative risk for such a second malignancy is reportedly 10% to 20% at 20 years of follow-up.^{62,64} The most common solid tumor encountered in women in this setting is breast cancer.⁶²⁻⁶⁴ Affected patients likely received mantle irradiation. This is defined as including the neck, supraclavicular, infraclavicular, axillary, mediastinal, and hilar regions in one field⁶⁴ (Fig. 34-7). With mantle irradiation, the largest doses are delivered to the unshielded upper outer quadrants.⁶³

Travis and colleagues recently published the results of a series of 3817 female survivors of Hodgkin's disease diagnosed at or younger than age 30 years.⁶³ There were 105 cases of breast cancer. A radiation dose of at least 4 Gy to the breast was associated with a 3.2-fold increase in risk compared with those receiving lower doses. If the dose was increased to greater than 40 Gy, the risk increased eightfold. The increased risk was observed for at least 25 years after treatment. The use of alkylating chemotherapy agents decreased the risk for breast cancer when delivered alone or in combination with radiation therapy. This reduction appears to be related to

Figure 34-7 The field of radiation (including the mantle field) for Hodgkin's disease.

ovarian dysfunction and the resultant diminished hormonal stimulation of breast tissue. Van Leeuwen and colleagues similarly demonstrated a relationship between early menopause and a reduced risk for breast cancer in survivors of Hodgkin's disease.⁶⁵

There is evidence that patients with known *BRCA1* or *BRCA2* mutations are at increased risk for developing late second primary breast cancers following breast conservation and radiation. Haffty and colleagues obtained complete sequencing results of *BRCA1* and *BRCA2* genes in 127 women with breast cancer diagnosed at or younger than age 42 years who had undergone breast-conserving surgery and post-operative radiation therapy.⁶⁶ They identified 22 women with mutations in *BRCA1* or *BRCA2*. At 12 years of follow-up, the rate of ipsilateral breast cancer (49%) and contralateral breast cancer (42%) was statistically significantly higher than in the remaining 105 women with sporadic breast cancer (21% rate of ipsilateral breast cancer and 9% rate of contralateral breast cancer). Haffty also concluded that there is no increased risk for radiation-induced contralateral breast cancer in *BRCA1* and *BRCA2* patients because the rate of contralateral breast cancer was the same in mutation carriers undergoing mastectomy as in those undergoing lumpectomy and radiation.

What are the clinical features of radiation-associated breast cancer?

The risk for radiation-associated breast cancer is inversely related to the age at the time of exposure. Yahalom and associates reported that the highest risk is observed in patients treated between the ages of 10 and 20 years and manifests later in life.⁶⁴ Carmichael and colleagues reported that the age-related excess risk does not become manifest until 10 years after the exposure.⁶¹ These age-related effects support the theory that breast tissue is most susceptible to radiation damage during the early phases of breast development.^{61,63}

Most of these breast cancers arise within the field of radiation therapy.⁶² Although bilateral breast cancers have been reported, this is not the norm.^{61,62} Bhatia and coworkers reported that of 17 women who underwent irradiation, 5 had bilateral breast cancer.⁶² A report from Irvine Medical Center described a male with synchronous bilateral breast cancer following mantle irradiation for Hodgkin's disease and suggested that conditions associated with relative hyperestrogenism may further increase the risk in males.⁶⁷

What are the pathologic features and treatment of radiation-associated breast cancer?

There are no pathognomonic features of radiation-induced breast cancer. Most series do not address the pathology of these tumors. In their series of 16 patients treated for Hodgkin's disease, Bhatia and colleagues found that the majority of tumors were infiltrating ductal and lobular in histology.⁶² In their series of *BRCA1* and *BRCA2* carriers with breast cancer after lumpectomy and radiation therapy, Haffty and associates reported that most of the tumors were infiltrating ductal cancers.⁶⁶

Treatment is dependent on the characteristics of the breast cancer. Most clinicians would not advocate breast conservation because re-irradiation is often not possible. Deutsch and colleagues, however, reported the use of lumpectomy and breast irradiation for breast cancer in 12 women previously treated with radiation for Hodgkin's disease.⁶⁸ They reached the conclusion that such treatment is not contraindicated. There is presently no evidence that these tumors behave more aggressively or present at more advanced stages.

Certainly, long-term follow-up of patients who have been exposed to ionizing radiation is of utmost importance. Regular breast self-examinations and yearly clinical breast examinations are recommended. Although there is no consensus, current recommendations include baseline mammography 5 to 8 years after exposure and every 18 months thereafter.^{61,63} Ultrasonography and MRI may play a role in surveillance of these patients. The use of chemopreventive agents (tamoxifen or other selective estrogen receptor modulators [SERMs]) or oophorectomy may be indicated, especially in those with known genetic susceptibility.^{63,66} Bilateral mastectomy may also be offered in appropriate cases.

UNUSUAL NEOPLASMS

Intracystic Papillary Carcinoma

What is an intracystic papillary carcinoma?

In general, papillary breast lesions present a challenge to the clinician in terms of diagnosis, implications, and management. These lesions run the gamut from benign to invasive cancer. Solorzano and associates divide papillary carcinomas into noninvasive and invasive forms.⁶⁹ The noninvasive group is further subdivided into a diffuse form corresponding to the papillary variant of DCIS and a localized form corresponding to intracystic papillary carcinomas (IPC).^{69,70} IPC can be found in isolation or with intraductal carcinoma (DCIS) or frankly invasive disease.⁷²

How do intracystic papillary carcinomas present?

Most patients present with a palpable mass, although nipple discharge has been reported in 15% in one series.⁶⁹ The mean age of affected patients is reported to be in the sixth decade.^{69,71,72} Most are therefore postmenopausal.^{69,72} Imaging studies can provide some aid, although there are no pathognomonic findings. Mammography may show a cystic lesion with well-defined borders and an irregular contour, which may be obliterated in areas of invasion into surrounding breast tissue.⁷²⁻⁷⁴ Sonography can demonstrate a well-defined cystic mass with a shaggy, irregular growth arising from the cyst wall.⁷³ Although rarely used, pneumocystography may differentiate an IPC from a simple cyst by outlining inner wall irregularities.^{73,74}

The differential diagnosis includes benign cystic masses, carcinoma invading adjacent breast parenchyma containing cystic disease, or a high-grade solid carcinoma that has

undergone central necrosis.⁷² Benign cysts are common and are seen in perimenopausal women. Thus, when a cystic lesion is found in a postmenopausal woman who is not on hormone replacement therapy, suspicion for a malignancy is high.

The first step in diagnosing a cystic lesion is aspiration, because the fluid obtained may provide diagnostic clues. A cystic lesion is more likely to harbor a malignancy if frank blood or blood-tinged fluid is aspirated.^{72,75} Markopoulos and colleagues caution, however, that blood does not definitively make a cancer diagnosis, nor does its absence exclude one.⁷² In addition, simple cysts that recur repeatedly after aspiration of typical serous fluid should be investigated for possible intraluminal growths. Although cytology may reinforce the suspicion of a papillary neoplasm, the information gained is generally not adequate for complete characterization of the lesion and planning of definitive treatment. Core biopsy was inconclusive in about 30% in one series.⁶⁹ Levine and colleagues suggest using radiographic guidance to ensure adequate tissue sampling from any solid areas seen within or associated with cystic masses.⁷⁶ Recent reports suggest abnormal cytology of nipple aspirate fluid, and ductoscopy demonstrating irregular, friable areas corresponding to IPC may be useful for diagnosis.^{77,78} An excisional biopsy is usually needed for definitive diagnosis of an IPC. Frozen sections are also not definitive because these lesions may contain a spectrum of malignant change, and permanent histologic sections should be used to direct definitive surgical management.

What are the pathologic features of intracystic papillary carcinomas?

IPC has long been thought to develop from the epithelial lining of cysts. This theory has been challenged by those who believe that these tumors develop from the growth of ductal epithelium eventually obstructing the ductal lumen. The resulting cystic dilation then results in the formation of an IPC.⁷⁹ The gross appearance of these tumors varies according to the relative contributions by the cystic and solid components.⁸⁰ Larger tumors may contain clotted blood and floating papillary fragments.⁸⁰ Similarly, the microscopic appearance is varied. High nuclear grade and tumor necrosis are seen in aggressive tumors.⁶⁹ Associated DCIS or invasive cancer can be identified up to 40% of the time.⁶⁹ A high rate of estrogen receptor positivity is reported.⁶⁹

What is the treatment of intracystic papillary carcinoma?

There is no standard treatment regimen for IPC. Treatment must be individualized according to histologic findings and extent of disease. Carter and colleagues reported on 41 patients with IPC and found that IPC without associated DCIS or invasive carcinoma had an excellent prognosis.⁷⁰ Before this observation, all subtypes of IPC were lumped together, and thus most authors concluded that these lesions carried a poor prognosis and were best managed with modified radical mastectomies.⁶⁹ Although some have recommended local excision alone for IPC, others have demonstrated that these lesions have a potential for axillary nodal involvement and may lead to metastatic disease.^{73,81} For pure

IPC, there is a low likelihood of axillary lymph node metastases; hence, operative axillary staging is not recommended.⁶⁹ A retrospective review of 41 patients with IPC treated at M. D. Anderson Cancer Center reported no influence on recurrence or survival by the use of radiation therapy. There is no consensus regarding the use of chemotherapy, radiation therapy, or hormonal therapy.

Cystosarcoma Phyllodes

What is a cystosarcoma phyllodes tumor?

Cystosarcoma phyllodes (CSP) is an unusual fibroepithelial tumor of the breast, accounting for about 0.5% of all breast tumors and 2.5% of all fibroepithelial lesions.⁸² The tumor was given its name by Johannes Müller in the 19th century because of its gross fleshy appearance, resembling a sarcoma.⁸³ Some authors advocate the use of the term *phyllodes tumor* to include both the benign and malignant variants encountered.⁸³ The criteria for diagnosis, prediction of natural history, and appropriate management all evoke controversy.

How does cystosarcoma phyllodes present clinically?

Clinically, CSP can be difficult to distinguish from the more common fibroadenoma (FAD) of the breast. The average patient with CSP is in her 40s at the time of diagnosis, which is a later presentation than seen with FAD. Nonetheless, there is a well-described incidence of CSP in adolescents.⁸⁴ These tumors have been reported in males.⁸⁵ On physical examination, CSP most often presents as a painless, mobile, fleshy mass of the breast. A subset of patients will report the recent, rapid growth of a previously stable mass. This specific presentation may reflect the possible origin from a preexisting FAD in up to 25% of cases, as evidenced by histologic remnants of FAD.⁸⁶ CSP can attain very large sizes, with tumors up to 20 cm reported in the literature.⁸⁷ Any benign-appearing mass larger than 2 cm in diameter should have CSP included in its differential diagnosis. The presence of a rapidly growing, large breast mass in the absence of axillary nodal involvement raises the suspicion of this diagnosis.

On mammography, CSPs resemble benign lesions. They often have the appearance of FAD and may be associated with large, coarse calcifications.^{88,89} On ultrasonography, CSPs also resemble benign lesions. The presence of indistinct borders, heterogeneous internal echoes, and cystic spaces within a solid mass may be diagnostic of CSP.⁸⁹ MRI offers no advantage over ultrasonography other than providing the surgeon with information regarding possible chest wall involvement by the largest of tumors.⁸⁹

FNA may be helpful in suggesting the diagnosis but cannot definitively distinguish between CSP and FAD in all cases.⁹⁰ This modality is helpful in ruling out a breast carcinoma. Core needle biopsy can reliably provide a tissue diagnosis favoring a phyllodes tumor, thereby allowing better planned surgical management.⁹¹ If these modalities fail to distinguish CSP from FAD, a carefully planned incisional biopsy can provide the needed information.

What are the pathologic features of cystosarcoma phyllodes?

The gross appearance of this tumor is that of a single or multinodular, well-circumscribed mass lacking a capsule.⁸⁷ The tissue is gray to tan and may include areas of hemorrhage and necrosis.⁸⁷ Microscopically, a stromal component with expansion and increased cellularity is observed.⁸⁷ These tumors are further classified according to histologic characteristics into benign, low-grade malignant (borderline), or high-grade malignant.⁸⁷ The precise pathologic classification of a given tumor can be quite complex and is beyond the scope of this chapter.

What are the treatment and prognosis of cystosarcoma phyllodes?

Most CSPs behave in a benign fashion. The main feature distinguishing their behavior from other benign lesions is their propensity for local recurrence. Table 34–4 summarizes collected series of CSPs in the literature with observed rates of local recurrence following excision.^{92–98} The local recurrence rate is quite variable, partly owing to differences in extent of surgical resection undertaken. The cornerstone of the surgical approach to CSP is wide local excision with histologically negative margins. Locally recurrent CSP may show degeneration into more sarcomatous histology (resembling fibrosarcoma), resulting in a poor prognosis. In cases in which CSP and FAD cannot be pathologically distinguished preoperatively, the surgeon may choose to take a margin of normal tissue surrounding the lesion in an effort to avoid reoperation. Although this approach may overtreat the FAD, it is problematic only in that it may create a cosmetic deformity for the treatment of a benign lesion. When the diagnosis of CSP is made postoperatively, re-excision to obtain negative margins should be considered after discussion with the patient. The risk for local recurrence and the required surveillance is balanced against the need for further operation and potentially reduced cosmesis. Bulky disease may require simple mastectomy to achieve local control. Axillary node dissection is not

Table 34–4 Risk for Local Recurrence in Cystosarcoma Phyllodes (CSP)

Study	Incidence of Local Recurrence	
	Benign CSP (%)	Malignant CSP (%)
Treves & Sunderland (1951) ⁸⁶	4/37 (11)	0/18 (0)
Pietruszka & Barnes (1978) ⁹²	4/16 (25)	1/17 (6)
Hajdu et al. (1976) ⁹³	28/150 (19)	4/49 (8)
Contarini et al. (1982) ⁹⁴	3/22 (14)	3/16 (19)
Hines et al. (1987) ⁹⁵	4/15 (27)	6/10 (60)
Salvadori et al. (1989) ⁹⁶	1/24 (4)	13/30 (43)
Bennett et al. (1992) ⁹⁷	3/14 (21)	2/11 (18)
Christensen et al. (1993) ⁹⁸	7/36 (19)	2/18 (11)

indicated unless the tumor is associated with carcinomatous elements.

The risk for metastatic disease is confined to CSP classified histologically as malignant. The criteria for such a designation, as defined by Kessinger and associates, include assessment of the tumor margin, stromal overgrowth, cellular atypia, and number of mitoses per high-power field.⁹⁹ Although the histologic appearance of CSP does not clearly predict the clinical behavior, reported cases of metastatic CSP arose in lesions classified histologically as malignant.^{86,92,94,95} As with other sarcomas, metastases are hematogenous to the lung, liver, and bone as the most frequent sites of involvement. There is no consistently effective systemic therapy; therefore, metastatic malignant CSP is a uniformly fatal illness.⁹⁹

Primary Sarcomas of the Breast

What are primary sarcomas of the breast?

Primary soft tissue sarcomas of the breast represent less than 1% of all breast malignancies, with an estimated annual incidence of 44.8 new cases per 10 million women.^{100–103} A variety of subtypes are encountered. The most common are malignant fibrous histiocytomas, fibrosarcomas, stromal sarcomas, liposarcomas, and angiosarcomas. These tumors behave as sarcomas do elsewhere in the body. They are locally aggressive, and when they metastasize, it is through a hematogenous route. Because of their rarity, we must rely on retrospective case series. The result is a lack of comprehensive data regarding their optimal management.

How do primary sarcomas of the breast present?

Most primary breast sarcomas (PBSs) present as painless masses, often exhibiting rapid growth. The masses can be round or lobulated and may be fixed to the underlying chest wall. The mean tumor size in the literature is 4 to 5 cm, although tumors as large as 30 cm have been reported.^{100–103} Palpable axillary adenopathy is uncommon and when encountered usually represents reactive lymph nodes uninvolved by metastatic disease. A clinically negative axilla in the presence of a large tumor may be indicative of a breast sarcoma. Although uncommon, cases of involved lymph nodes have been reported in patients with distant disease at the time of presentation.¹⁰⁴ The differential diagnosis is age dependent. In young patients, giant FADs and unilateral advanced mastia are to be considered. In older patients, locally advanced breast carcinoma and phyllodes tumors are included in the list of possible diagnoses. The definitive diagnosis can only be made histologically.

On mammography, these lesions appear as round or lobulated nodular masses with smooth or indistinct borders, and they may have coarse calcifications associated with necrotic or vascular areas.⁸⁹ A liposarcoma might be considered in the case of a rapidly growing tumor with a fatty component as seen on mammography.⁸⁹ On sonography, these tumors may appear as hypoechoic nodular masses with smooth or indistinct borders, although a large variability is encountered.⁸⁹

Further experience is needed to determine the characteristics of these tumors on MRI.

What are the histologic features of primary breast sarcomas?

These tumors arise from the interlobular mesenchymal elements of the breast stroma.¹⁰⁵ Grossly, they are pale and fleshy and may contain hemorrhagic and necrotic areas.¹⁰⁵ The diagnosis of PBS can be made only after the specimen is adequately sampled to rule out the presence of in situ or invasive carcinoma.¹⁰⁵ Invasive carcinoma would lead to the classification of the tumor as a metaplastic carcinoma and not a case of PBS. The histologic classification of the sarcoma depends on the subtype.

What is the treatment of primary breast sarcomas?

A needle biopsy may not yield a specific diagnosis but may be suggestive of mesenchymal elements. As with extremity sarcomas, a well-planned incisional biopsy may be necessary to clarify the diagnosis. Once PBS is diagnosed, surgical intervention is the first and most important step in treatment.^{104,106} Many consider simple mastectomy the gold standard, but others reserve this for very large tumors.¹⁰³ In a retrospective series of 53 cases of PBS, Blanchard and associates noted no improvement in disease-free survival in patients undergoing mastectomy.¹⁰⁴ Because most primary breast sarcomas are unicentric, wide local excision with negative margins is considered appropriate treatment.^{104,107,108} Zelek and colleagues consider breast conservation acceptable in patients with low-grade tumors and in tumors smaller than 5 cm, as long as negative surgical margins are achieved.¹⁰³ These patients have the option of salvage mastectomy in the case of local recurrence, although this can be accompanied by distant disease.¹⁰³ Axillary lymph node dissection is not indicated because the nodes are rarely involved.

There is no consensus regarding the use of radiation therapy and chemotherapy. Postoperative radiation may be used in patients undergoing mastectomy because chest wall recurrences are observed.¹⁰³ In patients electing breast conservation, postoperative radiation therapy may be considered, especially in patients with microscopically close or positive margins refusing further surgery, those with high-grade tumors, and those with large tumors.¹⁰³ A small series from the National Institutes of Health (NIH) suggests a possible beneficial effect of postoperative radiation therapy in achieving local control.¹⁰⁹

It is not known whether postoperative chemotherapy affects long-term survival in patients with PBS.¹⁰³ As with sarcomas elsewhere in the body, PBS is thought to be poorly chemosensitive, with response rates on the order of 20% to 40%.^{103,108} There are studies indicating increased disease-free and overall survival rates with regimens using doxorubicin and epirubicin for sarcomas in general.^{110,111} How these regimens apply to breast sarcomas requires further investigation. Trent and coworkers recommend considering neoadjuvant therapy for tumors larger than 5 cm, followed by surgical resection, but most agree this requires further investigation as well.¹¹²

Size, histologic subtype, and grade have the greatest impact on overall prognosis.^{103,108,112} A report of 60 cases of PBS from the M. D. Anderson Cancer Center suggests that tumors smaller than 5 cm have a better prognosis, regardless of other tumor characteristics.¹⁰⁸ Many of the earlier series of PBS reported a very poor prognosis. This is attributable in part to the inclusion of angiosarcomas, which have a well-known poor outcome. Once angiosarcomas are removed from the overall group, the natural history of PBS is comparable to that of sarcomas elsewhere in the body.¹⁰³ Disease recurrence is observed as a local event or as distant lung metastases in most cases.¹⁰³ In most series, the 5-year disease-free survival rate is about 50%.¹⁰³

Angiosarcomas

What defines an angiosarcoma of the breast?

As discussed earlier, sarcomas are rare breast malignancies. Of this varied group of tumors, 0.04% is represented by angiosarcomas.¹¹³ Angiosarcomas of the breast are classified as primary or secondary. Secondary angiosarcomas are diagnosed in patients with a history of lymphedema or local radiation therapy. All other angiosarcomas are primary.

How do angiosarcomas of the breast present?

Primary angiosarcomas affect women in the second to fourth decades of life.^{114,115} Secondary angiosarcomas are diagnosed in patients with breast carcinoma treated with radiotherapy or followed by the development of lymphedema. Those affected are more commonly older than 50 years.¹¹⁴

A rare but well-known example of a secondary angiosarcoma is that of the lymphangiosarcoma arising in the lymphedematous, ipsilateral arm of women treated with radical mastectomy. This was first described by Stewart and Treves in 1948.¹¹⁶ More recently, secondary angiosarcomas are reported in irradiated mastectomy scars and after breast conservation.^{103,104,113–115,117} Although breast conservation, including postoperative irradiation, is increasingly popular, these tumors are uncommon, with about 100 cases reported in the literature.¹¹⁵ The latency period for secondary angiosarcomas is between 4 and 7 years.¹¹⁵ Although rare, secondary angiosarcomas have been described after segmental mastectomy alone and after breast irradiation alone or accompanied by chemotherapy without surgical intervention.¹¹⁴

There are no clinical features to distinguish primary from secondary angiosarcomas. Patients usually present with a superficial, painless, palpable mass or masses associated with a bluish discoloration. Patients may complain of ecchymosis of the breast in the absence of recent trauma. However, patients may present with no skin changes. Diffuse breast enlargement is also observed. As with other sarcomas, those in the breast spread through a hematogenous route, making axillary nodal involvement rare. The differential diagnosis includes benign lesions, postradiation telangiectases, and traumatic ecchymosis.¹⁰⁵ The diagnosis may be made with FNA, but an open biopsy is generally needed.¹¹⁴

Liberman and associates reviewed the radiologic findings of 29 women with biopsy-proven angiosarcomas of the breast.¹¹⁸ Mammographic findings included a solitary uncalcified mass in 52% of patients, with the remainder presenting with calcified masses, skin thickening, or no findings. Sonography was performed on five patients and showed single or multiple solid masses in four, with no findings in the other patient. MRI was performed in one patient and revealed low signal intensity on T1-weighted images but higher signal intensity on T2-weighted images. At this time, the MRI appearance of breast sarcomas is limited to a few case reports.⁸⁹

What are the pathologic features of breast angiosarcomas?

The violaceous skin color observed with angiosarcomas reflects the hemorrhage and vascularity associated with these tumors when located superficially.¹⁰⁵ Rosen describes the gross appearance as that of a friable, firm or spongy, hemorrhagic tumor.¹⁰⁵ Low-grade tumors have the appearance of normal endothelium. High-grade tumors are characterized by nuclear atypia and mitoses accompanied by hemorrhagic areas.¹¹⁵

What are the treatment and prognosis of breast angiosarcomas?

Once diagnosed, the treatment of angiosarcomas is complete surgical resection of the tumor with negative margins. In the case of postmastectomy angiosarcomas, this may require chest wall resection. For lymphangiosarcomas of Stewart-Treves syndrome, patients have been treated by forequarter amputation. Simple mastectomy and occasionally wide local excision are used to treat patients with secondary angiosarcomas after breast conservation.¹¹³ Axillary lymph node dissection is not indicated.

In a review of the English literature, Monroe and colleagues found that 55 of 75 patients experienced a local recurrence, most within 1 year following surgical resection.¹¹⁵ The surgical resection in these patients varied from wide local excision to extended radical mastectomy. Salvage procedures (ranging from mastectomy to chest wall resection) may be indicated because most distant metastases occur after local recurrence.¹¹⁵ The most common site of distant failure is the contralateral breast, followed by the lung.¹¹⁵

Radiation oncologists at the University of Florida recommend hyperfractionated postoperative radiation therapy with wide fields to achieve improved local control.¹¹⁹ In the case of angiosarcomas arising in previously irradiated areas, they recommend preoperative radiation therapy to allow removal of tissue at risk for radiation-associated complications and to allow for tissue flap coverage as needed. There is no consensus regarding the use of chemotherapy in the treatment of these tumors. Short-lived responses have been reported.¹¹⁹ Application of vascular-targeting agents may have a role in the future.¹¹⁵

These aggressive tumors have an overall poor prognosis. Higher tumor grade is associated with worse outcome. In a review of 118,115 breast cancer cases in patients treated with breast conservation, Marchal and colleagues found 9 angiosarcomas of the breast.¹¹⁴ At 32 months of follow-up,

only 1 patient was still alive. In the literature, the median survival from the time of diagnosis is a little more than 1 year. For a woman who has undergone breast-conserving therapy for the treatment of primary breast cancer, any new mass in the irradiated field, especially if pigmented and enlarging, must be viewed with extreme suspicion and excised for biopsy promptly.

Breast Lymphomas

What defines a breast lymphoma?

Breast lymphomas make up less than 0.5% of all breast malignancies.¹²⁰ This group of tumors is broken down into cases of primary breast lymphoma (PBL) and secondary breast lymphoma (SBL). The criteria used to make the diagnosis of PBL were introduced by Wiseman and Liao in 1972¹²¹ and are as follows:

1. The submitted specimen is adequate for analysis.
2. Both mammary tissue and lymphomatous infiltrate are present in the specimen.
3. There is no evidence of widespread disease or previous history of extramammary lymphoma.
4. Axillary nodal or bone marrow involvement is acceptable. All other lymphomas fall under the category of SBL.

How do breast lymphomas present?

The most common clinical presentation of a breast lymphoma is that of a painless palpable mass. Less common findings may include skin thickening and pain.¹²² The masses are larger than most breast carcinomas at the time of diagnosis.¹²³ Enlarged ipsilateral axillary lymph nodes are reported in 13% to 50% of cases.^{122,124} Associated B symptoms (fever > 38°C, weight loss > 10% total body weight over previous 6 months, and drenching night sweats) are unusual but have been reported in some series.^{123,125} Unexplained right-sided predominance is observed.^{123,124,126} Synchronous bilateral breast involvement is seen in 5% to 25% of cases.¹²⁷ When bilateral disease presents with rapid, diffuse enlargement in pregnant or puerperal women, the associated histology is that of a Burkitt's lymphoma with its attendant poor prognosis and rapid disease progression.¹²⁷ As with breast carcinoma, PBL is a disease of women, although cases in male patients have been reported.^{128,129}

The clinical presentation is nonspecific, and similarly, there are no pathognomonic mammographic features to distinguish breast lymphomas from other benign or malignant breast masses. Liberman and colleagues reviewed a series of 29 patients with breast lymphoma and found that only three cases had been detected only by mammography.¹²⁴ These three cases were identified as solitary masses. When discovered by mammography, breast lymphomas are solitary uncalcified masses, and observed axillary lymph node involvement is nonspecific.¹²⁴ Ultrasonography provides further nonspecific evidence of a solid mass. Other radiologic modalities, such as technetium scintigraphy and MRI, may be useful in making the diagnosis, but further experience is needed.^{123,130}

The diagnosis of SBL is made more easily because of concurrent widespread disease. The diagnosis of PBL is rarely made preoperatively, and most patients are thought to have breast carcinoma instead. FNA may be performed, and cytologic analysis can confirm the diagnosis, especially if coupled with flow cytometry.¹²⁷ Caution must be employed with this technique because the cytologic appearance of the lymphomatous cells may mimic lobular carcinoma.¹²² Excisional biopsy is required for precise histologic diagnosis, which can be aided by the use of cytokeratin staining.

What are the pathologic features of breast lymphomas?

There are no histologic features that serve to distinguish primary breast lymphomas from those found elsewhere. Most PBLs are of B-cell origin and are believed to arise from the breast equivalent of mucosa-associated lymphoid tissue (MALT). PBLs are further classified as diffuse large cell tumors predominantly, and SBLs are more commonly diffuse small cell tumors.^{120,122} Although rare, Hodgkin's lymphoma and T-cell lymphomas of the breast have been described.^{122,131}

What is the treatment of breast lymphoma?

After a breast mass has been proved to be a lymphoma, an evaluation of extent of disease is mandatory. This generally includes a chest radiograph; CT scan of the chest, abdomen, and pelvis; and bone marrow biopsy. For those found to have disseminated disease, the diagnosis of SBL is made, and systemic treatment proceeds accordingly.

For those found to have disease limited to the breast, treatment is dictated by histologic grade of tumor and stage of disease. For low-grade, early-stage tumors, treatment consists of local excision with or without radiation therapy.^{122,128} Chemotherapy is added in patients with high-grade, early-stage tumors because the rate of distant relapse can be as high as 70%.^{123,132}

Historically, PBL was associated with a poor prognosis and was treated by mastectomy with or without axillary node dissection followed by radiation therapy.^{122,133} Currently, we know that stage for stage, the prognosis is comparable to that of lymphomas at other sites, and radical surgery offers no advantage.¹³³ Five-year survival rates in the literature vary widely from as low as 9% to as high as 90% with appropriate treatment.¹²² The variation stems from differences in histologic subtypes, staging, and treatment in the retrospective series reported. Certainly, we must rely on such series because this is a rare breast malignancy.

Breast as the Site of Metastatic Lesions

Which neoplasms metastasize to the breast?

An estimated 211,240 new cases of breast cancer will be diagnosed in 2005, making this the most common site of primary malignancy in women.¹³⁴ In contrast, the breast is an unusual site of metastatic involvement. In the largest series to date,

review of records from the Pathology Department at the Royal London Hospital from 1907 to 1999 revealed 60 patients with secondary, nonmammary neoplasms of the breast constituting 3% of all breast tumors.¹³⁵ The most common tumors that metastasize to the breast are lymphomas, lung cancers, melanomas, renal cell carcinomas, and ovarian cancers. In childhood, rhabdomyosarcoma predominates.¹³⁶ Metastatic prostate cancer to the male breast has been described; however, in men with metastatic carcinoma to the breast, the lung is the most frequent primary site.¹³⁷

How do metastatic lesions to the breast present clinically?

The differential diagnosis clearly involves benign and malignant breast lesions. A degree of suspicion should be maintained in patients with even a remote history of nonmammary neoplasms because these lesions have been diagnosed simultaneously with the primary tumor and also up to 15 years after the initial diagnosis.¹³⁸ Most frequently, patients present with known disseminated disease, but the metastatic breast lesion may be the first manifestation of an occult primary tumor prompting further investigation.^{136,138,139} A well-defined, palpable mass is most common and can be associated with rapid growth.^{136,140} Multiple and bilateral masses have been described.¹⁴⁰ Some authors have noted inflammatory metastatic lesions from ovarian and gastric signet-ring cell cancers.^{138,141,142}

There are no pathognomonic radiologic features to distinguish this group of varied lesions from primary breast lesions. Mammography can reveal single or multiple discrete nodules. In the case of hematologic primaries, the metastases may appear as ill-defined nodules.¹⁴³ Sonographic findings similarly include single or multiple solid nodules with varied echotextures and margin definition.¹⁴⁴

What are the pathologic features of metastatic lesions?

FNA and core needle biopsy can provide accurate diagnosis of these metastatic lesions.^{139,145,146} Although the diagnosis depends on the primary site, Vergier and colleagues noted some histologic findings that might be helpful in recognizing metastatic lesions to the breast in general: (1) features atypical to primary breast carcinoma, (2) well-circumscribed tumors with multiple satellite nodules, (3) no intraductal component, and (4) numerous lymphatic emboli.¹³⁶

The type of primary tumors reported in the literature are varied and include papillary thyroid cancer, leiomyosarcoma, neuroblastoma, rectal cancer, gastroesophageal cancer, cervical and vaginal cancer, pancreatic cancer, and skin cancer. Melanoma is a common tumor encountered. A 30-year-old woman presented to our office with a painful, palpable mass of her left axillary tail. Noninvasive tests were not diagnostic, and after excision, the mass proved consistent with metastatic melanoma of unknown primary (Fig. 34–8). Arora and Robinson described 15 patients with cutaneous melanoma metastatic to the breast.¹⁴⁷ As with our patient, their patients were mostly in their 30s and premenopausal,

Figure 34–8 Metastatic melanoma composed of pleomorphic spindled and epithelioid cells with prominent nucleoli and cytoplasmic melanin pigment.

but in contrast, most had primary lesions identified in the upper extremity.

What is the treatment of metastatic lesions to the breast?

As mentioned earlier, FNA or core biopsy may suggest a non-breast primary.¹⁴⁸ Excisional biopsy may be required for confirmation. Extensive surgery is rarely indicated and should be reserved for appropriate patients in need of palliation of a painful, bulky disease. Treatment is determined according to the primary tumor. Although patients with secondary breast lymphoma may have a fair prognosis, patients with metastatic disease to the breast have a generally poor outcome because this is invariably a manifestation of widespread disease. Certainly, cancers with effective systemic treatment have a more favorable course.

Treatment of the Pregnant Patient with Breast Cancer

*Carol E. H. Scott-Conner, Peter R. Jochimsen,
and Joel I. Sorosky*

Two patients, not one, are involved when the clinician treats a pregnant or lactating patient with breast cancer. Concerns about individual mortality and the effect of treatment on the unborn or breast-feeding child lend a special poignancy and immediacy to the clinical decision-making process. This chapter defines the scope of the problem of breast cancer during pregnancy and lactation, discusses diagnosis and treatment, and summarizes current theories about the effects of pregnancy and lactation on mammary carcinogenesis. Benign breast lesions unique to pregnancy and the puerperium that can mimic breast cancer are described. Separate sections at the end of the chapter discuss the closely related issues of pregnancy after treatment for breast cancer and lactation after breast surgery.

SCOPE OF THE PROBLEM

How has pregnancy been regarded in the evolution of modern breast cancer treatment?

In 1896, Halsted reported performing a radical mastectomy on a lactating woman who subsequently survived for 30 years.¹ Harrington, in 1939, reported a 40% 10-year survival in a small series of node-negative women treated by radical mastectomy during pregnancy or lactation and stated that “the situation is by no means hopeless.”¹ These early successes, however, were eclipsed by the experience of Haagensen at Columbia-Presbyterian Hospital, who wrote, in 1943, that “carcinoma of the breast developing during pregnancy or lactation is so malignant that surgery cannot cure this often enough to justify this method of treatment.”¹ He reiterated this statement in subsequent publications until 1967, when he modified it to explain that although results were not as good as in nonpregnant patients, he no longer regarded pregnancy as an absolute contraindication to surgical therapy.²⁻⁵ By that time, several authors had reported small series of patients that suggested that although the disease tended to be more advanced at presentation, the prognosis in women with negative lymph nodes was similar to that in women who were not pregnant.^{1,6} Holleb and Farrow, reviewing the Memorial Hospital experience from 1920 to 1953, noted that there was a

poor prognosis when the axillary nodes were involved but that “one cannot state dogmatically that it is the pregnancy per se which accounts for the unfavorable results of treatment since the stage of disease is usually advanced.”¹ More recent data suggest a worse prognosis, but this crucial question remains unsettled and will be discussed later in the chapter.

Similarly, over the past several decades, scattered reports indicated that women who had been successfully treated for breast cancer could safely be allowed to become pregnant.¹ Each of these issues are discussed in detail in subsequent sections.

What is the definition of pregnancy-associated breast cancer?

Cancer of the breast diagnosed during pregnancy or within the first year after delivery is considered to be pregnancy-associated breast cancer (PABC). Some authors distinguish between cancer occurring during pregnancy and that occurring during lactation. However, because the period of lactation varies in length, 1 year after delivery has been accepted as the standard definition in most recent series.⁷

What is the incidence of pregnancy-associated breast cancer?

Carcinoma of the uterine cervix and breast cancer are the two most common malignancies diagnosed during pregnancy, each accounting for 25% of all malignancies so diagnosed.^{8,9} Because cervical cancer is the only malignancy for which routine screening is done during pregnancy, it is the most prevalent cancer in most series. In the United States, breast cancer complicates 1 in 3000 deliveries.^{8,10} The average obstetrician, if he or she attended 250 deliveries per year, would need to accumulate 40 years of clinical experience to encounter two or three cases of PABC.¹¹ This may lead to the perception that PABC is rare. When the subset of patients with breast cancer who are of childbearing age is considered, the incidence of PABC is about what would be predicted by chance, and the association no longer appears rare. If one assumes that the average woman has two pregnancies

between the ages of 25 and 40 years, she is pregnant for a total of 18 out of 180 months. She would thus be pregnant 10% of that time. The calculated incidence correlates quite well with the observed co-incidence of pregnancy with breast cancer in women of that age group in series from the United States, the United Kingdom, and other western European countries.^{1,4,12}

Similarly, if one estimates that 15% of women with breast cancer are of childbearing age, one would predict that 2% would have concurrent pregnancies.¹⁰ Once again, the prediction is fairly close to what is seen clinically. In a series from Finland, 0.9% of all carcinoma of the breast occurred during pregnancy, and PABC constituted 1.1% of a similar series from Canada.¹ In Nigeria, where breast cancer is a disease of primarily premenopausal and perimenopausal (rather than older) women, the incidence of PABC is accordingly higher, ranging from 10% to 19% of all patients with breast cancer.¹³ In contrast, breast cancer is considerably less common in India, and PABC is observed less frequently. Clinicians there suggest that breast cancer grows more rapidly when it occurs during the second and third trimesters or during lactation, compared with that seen in women who are not pregnant.¹ Similarly, in Japan, PABC makes up 0.76% of all breast cancer cases, with a suggestion of poorer survival and more advanced disease at presentation.¹⁴

When the probable latent or preclinical period of breast cancer is taken into account, it becomes likely that even larger numbers of young women with breast cancer have been pregnant at some time during the course of the disease, although they may not strictly meet the criteria for PABC. As early as 1956, T. T. and W. C. White wrote, "We believe that one-third of patients who develop breast cancer during the childbearing period will have pregnancy as a complication."⁶ Finally, as women in developed countries delay childbearing into their 30s and 40s, the incidence of PABC is predicted to increase.⁷ Birth rates among American women older than 35 years are the highest observed in 3 decades, at 41 births per 1000 for women between 35 and 39 years, and 8 per 1000 for those aged 40 to 44 years.

Are women with pregnancy-associated breast cancer more likely to have a positive family history?

In the Japanese series, a positive family history was three times more common among patients with PABC than in the general breast cancer population.¹⁴ To establish this association, however, the "third degree of relationship by blood" was required, whereas most series limit the association to first-degree relatives. Studies have reported no difference in rate of positive family history when compared with age-matched controls.^{2,6}

What are the implications of mutations of *BRCA1* and *BRCA2*?

Although the influence of family history on PABC has been difficult to establish, reports are beginning to appear detailing the possible implications of *BRCA1* and *BRCA2* mutations for pregnancy and mammary carcinogenesis, including

PABC. Johannsson and colleagues¹⁵ reported 10 pregnancy-associated breast cancers among *BRCA1* or *BRCA2* carriers, whereas only 2.7 would have been expected in the general population, for an odds ratio of 4.46. Subsequently, Shen and associates reported an excess proportion of allelic deletion at the *BRCA2* locus in 88% of patients with PABC, compared with 20% of controls.¹⁶

Early pregnancy has also been reported to increase the risk for breast cancer in *BRCA1* and *BRCA2* mutation carriers, compared with nulliparous carriers, providing a possible mechanism for this observation.¹⁷⁻¹⁹ This is thought to be consistent with other data showing that the wild form of these genes serves to regulate growth under conditions of hormonally induced proliferation. Women with mutations in either of these genes, lacking this growth-regulatory mechanism, may thus be uniquely vulnerable to the proliferative stimulation of pregnancy.

Although pregnancy appears to increase the risk for breast cancer among women who carry mutations of *BRCA1* or *BRCA2*, breast-feeding decreases the risk, at least in women with mutations of *BRCA2*.¹⁸ Again, the number of observations at the time of this writing is small.

Is there a higher risk for bilateral breast cancer?

Haagensen emphasized the need for careful follow-up of the contralateral breast and believed that women with PABC were at especially high risk for bilateral cancer.⁴ The incidence in the Columbia-Presbyterian series from 1915 to 1953 was 7.3%, but these were metachronous rather than synchronous bilateral lesions. Haagensen's statements, based on observations in a limited number of patients, were subsequently cited by numerous authors. Several other early uncontrolled series reported similar findings.¹ It appears likely that a strong effect among women who have mutations of *BRCA1* or *BRCA2* is obscured by the large numbers who do not. There are virtually no statistical data.

What physiologic changes occur in the breast during pregnancy and lactation?

Pregnancy induces both proliferation and differentiation of the mammary epithelium. Both lobular and alveolar growth occur.²⁰ Differentiation of the alveoli into mature milk-producing cells requires the stimulus of cortisol, insulin, and prolactin.²¹ Prolactin is the major stimulus to galactopoiesis, and levels of this hormone are markedly elevated during the later stages of pregnancy and lactation.^{20,21} Steroidogenesis in the fetal-placental unit does not follow the conventional mechanisms of hormone production within a single organ. Rather, the final products result from interactions and interdependence of fetal, placental, and maternal components that individually do not possess the requisite enzymatic capabilities. During pregnancy, prolactin is secreted by fetal pituitary, maternal pituitary, and uterus. The weight of the breasts approximately doubles. Blood flow increases 180%.²⁰ The increases in size, weight, vascularity, and density make detection of mass lesions difficult, both clinically and mammographically. The normal physiologic changes become

pathologically exaggerated in the gigantism that is extremely rarely associated with pregnancy.

EFFECTS OF PREGNANCY AND LACTATION ON MAMMARY CARCINOGENESIS

What physiologic changes occur during pregnancy that might favor tumor growth or induction?

Compounding the difficulties in assessment associated with the physiologic changes in the breast, an altered systemic milieu may play a role as well. Such a milieu might be potentially favorable to breast cancer growth. These factors include elevated hormone levels, changes in the breast that might render it more susceptible to carcinogens or to the spread of established malignancy, and the immunosuppressive effects of pregnancy itself.²²

Pure concentrations of all three major estrogen fractions (estrone, estradiol, and estriol) rise significantly during pregnancy. Estriol secretion is 1000 times normal, and estradiol and estrone are increased about 10-fold.²⁰ The steroid hormones cortisol and growth hormone are elevated by two to three times as well.²² Elevated cortisol levels may be responsible for some of the decreased cell-mediated immunity noted during pregnancy. Thymus-dependent lymphocyte levels are decreased in early pregnancy, in part due to increased cortisol. These levels recover after the 20th week of gestation. Human chorionic gonadotropin (hCG) is secreted by the syncytiotrophoblast. Despite reports concerning the suppressive effects of hCG and estrogens on cellular immunity, there is no increased incidence of malignancy in pregnant women. hCG exerts a dose-dependent protective effect on mammary carcinogenesis in animal models, and one case-control study showed that nulliparous women who had received hCG injections for weight control had a lower incidence of breast cancer than control women.²³

The complex interactions between the pregnant woman, the fetus, and the cancer are poorly understood from the immunologic standpoint. The fetus is an F1 hybrid that is tolerated by an intact immune system. Whether the immune system is, in fact, intact during pregnancy, is debatable. Both T-cell function and cell-mediated immunity are depressed during pregnancy. Germinal centers in pelvic lymph nodes are depleted. The acceptance by the mother of the fetus (which is indeed a foreign graft with paternal antigens) depends in part on a state of partial immunologic tolerance. There is no demonstrable deficiency in immunity to other foreign antigens such as those carried by tumor cells. Breast cancer is also a condition in which antigenic tissue is tolerated by the host. Although there is evidence that pregnancy depresses cell-mediated immunity through hormonal changes such as increased production of glucocorticoids, there is no clinical evidence that these changes result in more rapid tumor growth and metastasis.²⁴ This is in contrast to patients in the same age group receiving immunosuppressive therapy to promote acceptance of renal allografts, who have an incidence of malignancy 100 to 1000 times greater than age-matched controls.²⁵

Prolactin is significantly elevated. Although prolactin, when administered after a carcinogen, can promote tumor induction and growth in animal models of breast cancer, there is no evidence that it acts in a similar fashion in women with PABC.^{26–28} The clinical observation that women with bone pain from metastatic cancer occasionally obtain relief from prolactin suppression implicates prolactin as a possible promoter.^{27,28} In addition to hCG, the syncytiotrophoblast also secretes the glycoprotein human placental lactogen (hPL). hPL stimulates insulin growth factor I and induces insulin resistance and carbohydrate intolerance. Epidermal growth factor (EGF), a well-established mitogen, is also synthesized by the syncytiotrophoblast. Other growth factors produced by the human placenta include platelet-derived growth factor and transforming growth factor.

The murine homologue of *BRCA1* is expressed at its highest levels in rapidly proliferating cells, such as breast tissue during puberty and pregnancy. Similarly, the expression of *BRCA2* is induced in the mammary gland during puberty and pregnancy. Reduction of *BRCA1* expression in vitro leads to accelerated growth, and overexpression leads to depressed growth, supporting a conceptual model in which this tumor suppressor gene negatively regulates proliferation.¹⁹

What is known from studies of experimental mammary cancer and pregnancy?

In a rat model, pregnancy enhances both tumor induction and growth, particularly when the animal is exposed to the carcinogen during the first half of pregnancy, when proliferation of breast tissue is maximum. Tumor expression is inhibited during the latter half of pregnancy, however, possibly by inducing differentiation in tumor cells.¹ Prolactin plays a significant role in tumor initiation and promotes the growth of diethylene anthracene-induced mammary tumors in mice. Its role in human breast tumorigenesis remains to be determined.^{26,28,29} Chinese boat women who nursed their infants only from the right breast (according to traditional practice) demonstrated a two to three times lower risk for cancer in the breast used for nursing than in the contralateral breast.²⁷ Additional information about hormonal factors is included in the subsequent discussion of pregnancy termination.

BENIGN LESIONS IN PREGNANCY THAT CAN MIMIC BREAST CANCER

What benign lesions are unique to pregnancy and lactation?

Although most of the benign breast tumors seen in pregnancy are the same ones seen in women who are not pregnant (e.g., fibroadenomas, lipomas, papillomas), they may be altered in size or consistency as well as histologic appearance by the hormonal stimulation of pregnancy and lactation. About 30% of the breast masses in one series were lesions unique to pregnancy and lactation (lactating adenomas, galactoceles, mastitis, infarcts).³⁰

The lactating adenoma (also called nodular lactational hyperplasia or lactating nodule) is a benign breast lesion unique to pregnancy and lactation.^{20,30-34} These histologic changes overlap and may include lactating changes in preexisting fibroadenomas.³⁰ The terminology varies, and it is difficult to compare older series or to get an accurate picture of the incidence. In one series of breast biopsies in pregnant women, 13 of 17 were lactating adenomas (with three fibroadenomas and one carcinoma).³⁵ Histologically, lactating adenomas are characterized by florid lactational changes with a tubuloalveolar appearance to the glands. There is considerable variability in size, which can range from 1 cm up to more than 5 cm.³¹ Some have suggested that the term should be reserved for lesions that closely resemble focal exaggerated changes similar to the physiologic hyperplasia of pregnancy and lactation.³² Microscopic foci of lactating adenomas and the less common tubular adenomas have been identified within fibroadenomas, raising the possibility that these lesions arise within preexisting fibroadenomas.^{31,36} Similar nodules have been described arising from ectopic breast tissue in the axilla and other extramammary sites, sometimes in association with drug administration (particularly hormones and antipsychotic or

antihypertensive agents) rather than pregnancy.^{31,32} The histologic appearance of florid lactational changes is shown in Figures 35-1 and 35-2, with comparison to in situ and invasive carcinomas of the breast.

Infarction of a fibroadenoma, a lactating adenoma, or hypertrophied breast tissue can occur during pregnancy.^{20,37-44} The typical lesion presents with an increase in size and tenderness of a preexisting mass, or simply as a new tender mass where none was noted previously. Typically, the lesion remains mobile, but it may become fixed to the overlying skin. Generally, these lesions are small, about 2 to 3 cm in diameter, and may be multiple.^{20,37} It is hypothesized that infarction occurs because of the increased metabolic demand associated with the hyperplasia of pregnancy.³⁷ The large "popcorn" calcifications, calcified fibroadenomas, seen on mammograms of older women may be the remnants of clinically unrecognized infarcts.²⁰ Histologic examination with conventional hematoxylin and eosin (H&E) stain may reveal only extensive necrosis with few or no residual glandular elements, leading the unwary to consider breast cancer as a possible diagnosis, especially on frozen section.^{38,39} Masson's trichrome or reticulin stain may be helpful in demonstrating residual

Figure 35-1 A, Lactational changes. Expanded lobules show hyperplasia and hypertrophy with an increased number of acinar units. (H&E, $\times 33$.) B, In situ and invasive carcinoma of the breast. (H&E, $\times 33$.) (Courtesy of Dr. Patricia Thomas.)

fibroadenoma architecture when only extensive necrosis is seen on H&E.^{38,39}

The main difficulty with these solid masses is the need to exclude malignancy. Large masses that do not regress after cessation of lactation may shrink with bromocriptine and may even require excision.^{40–42}

Galactocele are single or multiple nodules that contain retained milk (liquid if recent in formation, thickened if older). These palpable lesions are usually located peripherally in the breast. Sometimes fluctuance is elicited on palpation, and firm pressure on the mass occasionally expresses milk from the nipple.⁴⁵ Aspiration is both diagnostic and curative; if the lesion disappears totally and does not recur after aspiration of milky fluid, no further treatment is necessary.^{35,45,46} A typical mammographic appearance, owing to the mixed water and fat densities (with a fat–water level seen best with a horizontally directed lateral beam with magnification), has been described,^{45,46} but mammography is rarely necessary because the clinical picture is characteristic. The mammogram shown in Figure 35–3 demonstrates both a galactocele and a fibroadenoma in a lactating breast. Anything that obstructs the ductal system during lactation may cause a galactocele. Typically, these lesions occur at the cessation of lactation when milk is allowed to stagnate and inspissate in the ducts. The presentation may be delayed up to 6 to 10 months after cessation of nursing. Occasionally, a benign or malignant tumor is the cause of ductal obstruction, and this is why excision is advised if the lesion recurs after aspiration or if a mass persists.³⁴

Lactational mastitis may rarely progress to breast abscess. Although inflammatory carcinoma of the breast is no more common in PABC than in the general population of breast cancer patients, it is a sufficiently frequent occurrence that one should always biopsy the wall when draining a breast abscess.^{47–49}

Figure 35–3 Craniocaudal mammogram of lactating breast showing two benign lesions: a subareolar lactating adenoma (*single arrow*) and a galactocele (*double arrow*). (Courtesy of Dr. Donald Young.)

What is the significance of bloody nipple discharge during pregnancy and lactation?

Bloody nipple discharge is common during the latter stages of pregnancy and lactation and does not necessarily portend serious consequences. Classic studies by Kline and Lash^{50,51} included examination of nipple secretions of 50 women in the third trimester of pregnancy (4 of whom had a spontaneous hemorrhagic discharge). The authors demonstrated desquamated epithelial cells, similar to those seen with intraductal papillomas, and believed that pregnancy-induced changes in the ducts that led to the formation of delicate intraductal epithelial spurs, easily traumatized and shed, resulting in bleeding.^{50,51} These persisted for up to 2 months (and rarely, longer) after delivery.⁵¹

Nipple discharge cytology is unlikely to be helpful in this situation because the proliferative changes associated with pregnancy may be mistaken for those of a neoplastic process.^{34,43,50–54} There are no data available on use of ductal endoscopy, lavage, or ductography in this setting. If the bloody discharge persists more than 2 months after delivery, localizes to one duct, or is associated with a palpable mass, mammography and biopsy may be indicated to exclude breast cancer.⁵⁵ The presence of blood in the milk does not contraindicate breast-feeding. Typically, the bloody discharge ceases once breast-feeding is established.⁵⁴

DIAGNOSIS AND TREATMENT

How does pregnancy-associated breast cancer present?

Most cases of PABC present as painless masses, and up to 90% of these masses (as is true of the population as a whole) are found by the patient herself.⁵⁵ Occasionally, an infant will inexplicably refuse to nurse from a breast that is subsequently demonstrated to harbor a breast cancer, the so-called milk-rejection sign.^{55,56} Clearly, any breast mass warrants prompt attention, especially in a patient who is pregnant or lactating. Every effort must be made to reduce the delay between symptoms and diagnosis in PABC. A thorough breast examination should be an integral part of the initial prenatal physical examination. This should be done before the development of the physiologic breast changes enumerated earlier, which may conceal abnormalities. Delay in diagnosis may be minimized if both physician and patient are aware that breast changes may be manifestations of an underlying malignancy as well as normal alterations related to pregnancy and lactation. An enlarging mass that persists without regression, and other primary or secondary signs of malignancy (nipple retraction; fixation of mass to skin with or without skin thickening, dimpling, or fixation to underlying tissues; development of axillary lymphadenopathy) should be taken as indications of possible malignancy, and the diagnostic workup must be prompt given any of these findings. As in the nonpregnant patient, an occasional woman with PABC has extensive metastatic disease at initial presentation (sometimes with an occult breast primary).^{57,58}

How much delay in diagnosis occurs, and what are the implications?

Women with PABC generally have more advanced disease (larger tumors, a higher percentage of technically inoperable lesions, and a higher percentage of nodal involvement), and this has traditionally been attributed to delay in diagnosis. The literature on delay will be summarized here; subsequent sections discuss alternative explanations, such as a more aggressive biologic behavior of PABC tumors.

Although the regular antenatal and postpartum visits of the pregnant and nursing woman to her physician would seem to provide a unique opportunity for early detection, multiple series document significant physician- and patient-related delay.^{6,7,10,59} Average delays of 5 to 7 months are commonly reported, with isolated cases citing delays of up to 18 months.^{6,47} This problem has been noted in other parts of the world as well. For example, a series from Japan cited an average duration of symptoms of 6.3 months (1 month longer than controls).¹⁴ Difficulty in evaluating mass lesions within the gestating breast, reluctance to perform biopsy, inappropriately ascribing an inflammatory cause to a mass that fails to resolve with treatment, and inadequate follow-up by physician or patient have all been cited.⁷ Physical examination may be difficult because the breasts become hypervascular, engorged, and nodular. A discrete mass is often difficult to palpate. During lactation, malignancy, particularly inflammatory breast cancer, may be confused with mastitis (see previous section). Physician procrastination accounts for 60% to 75% of the delay in representative series,¹ but there is a substantial component of patient delay as well. In a series from Charity Hospital, New Orleans, 36% of pregnant or lactating women delayed seeking treatment for more than 6 months (compared with 19% for the overall Charity Hospital breast cancer population).^{1,10} Delay in diagnosis is frequently cited as a major reason for presentation with more advanced disease and hence lower survival in PABC, as has been shown in the general breast cancer population.¹⁰ Generalizing from what is thought to be known about the biologic behavior of breast cancer, Nettleton and coworkers⁶⁰ created a mathematical model to infer the risk for nodal metastases with PABC given an assumed tumor doubling time and delay. If tumor doubling time is assumed to be 130 days in their model, a delay of 6 months (the average delay cited in the series above) results in a 5.1% increase in the risk for nodal disease. If tumor doubling time is 65 days (i.e., a more rapidly growing tumor), a delay of 6 months in diagnosis raises the probability of nodal metastases by more than 10%.⁶⁰

Just as in the nonpregnant population, most breast lumps that pregnant and lactating women develop are not malignant. Rather than advocating more extensive use of open biopsy, greater use of fine-needle aspiration cytology (FNAC, as discussed subsequently) is suggested as an alternative way to evaluate these masses and avoid simply “watching” the lump.⁶¹

How useful are breast imaging modalities in the diagnosis of pregnancy-associated breast cancer?

Imaging modalities are primarily an adjunct in the workup of women who present with breast symptoms during pregnancy

and lactation.⁶² They are not currently used for screening purposes. Women who are lactating should be instructed to empty the breast of milk before breast imaging. This simple measure will decrease breast density and improve image quality somewhat.⁶³

Two questions must be answered to assess the usefulness of mammography during pregnancy: (1) Is the dose to the fetus acceptably low? and (2) Are the sensitivity and specificity sufficiently high?^{63,64} The estimated dose to a fetus from two-view film-screen mammography with abdominal shielding is about 500 μ Gy, which is acceptable.^{56,61} There are no reports of untoward effects from mammography to the mother or fetus. Thus, mammography can be safely employed.

Breast tissue does become radiographically denser during pregnancy and lactation, and this has traditionally been thought to limit the utility of mammography. However, as mammographic techniques evolve, the sensitivity and specificity of mammography during pregnancy have improved. In one study of 18 patients in whom both baseline mammograms and studies obtained during pregnancy and lactation were available, the density was not significantly increased in most.⁶⁴ In one early series, mammography demonstrated the correct diagnosis in 68% of pregnant women with breast cancer (compared with 74% of nonpregnant controls, also with breast cancer). In the same series, ultrasound demonstrated a suspicious mass in 93% of cases.¹⁴ In a series of patients with PABC from Memorial Sloan-Kettering Cancer Center in New York City, radiographic evaluation included 3 xeromammograms and 20 film-screen mammograms. Carcinoma of the breast was demonstrated as an uncalcified mass density in 4, a mass with associated calcifications in 9, calcifications only in 4, and a diffuse increase in parenchymal density with skin thickening in 1. Five studies were reported as “normal.” No unexpected second cancers were demonstrated.⁶³ Seventy-eight percent of mammograms in 23 women with PABC showed radiographic evidence of disease.⁶³

It has been suggested that ultrasound may be a preferred diagnostic modality, and several series have shown increased accuracy in confirming the presence of palpable masses in PABC.^{14,65} It too has its limitations and should be used primarily to differentiate cystic from solid masses. Figure 35–4 shows an ultrasound demonstrating two foci of ductal carcinoma in a lactating breast. These palpable lesions were readily demonstrated on ultrasound but were erroneously read as fibroadenomas. The corresponding mammograms are shown in Figure 35–5.

Magnetic resonance imaging (MRI) can be safely used during pregnancy. Both the energy modality and the contrast agent are approved for use. There are insufficient data at present to determine its sensitivity and specificity. When MRI is used during lactation, the woman should pump and discard breast milk for 2 days afterward to eliminate the contrast agent.

Because most PABC presents with a palpable mass, the role of imaging modalities in the evaluation of these patients remains extremely limited at present. As with any patient with a breast mass, radiology alone may not be trusted to unequivocally identify the true character of the lesion. Pathologic confirmation is necessary to state with confidence that a given mass is benign or malignant.

How should one approach the workup of the pregnant or lactating woman with a palpable mass in the breast?

First, it is important for the clinician to realize that cancer occurs in this population and has been reported in women as young as 16 years.⁵⁵ Masses discovered during routine examination or detected by the patient should be fully evaluated. Imaging studies may be used to obtain additional

Figure 35-4 Ultrasound of lactating breast. Two palpable abnormalities are shown as ill-defined 2.5-cm masses with central echogenicity (breast cancer, initially read as benign fibroadenomas). (Courtesy of Dr. Donald Young.)

information, but histologic confirmation of the nature of all solid masses is essential. Ultrasound is of assistance in differentiating cystic versus solid masses and may confirm the presence of a mass when physical examination is equivocal and the woman complains of pain or tenderness. The decision to follow a mass in a pregnant woman is fraught with hazard because physical examination becomes progressively more difficult with the increasing breast enlargement and vascularity as pregnancy progresses. A mass may seem to disappear when, in fact, it is enlarging and has simply become buried in the surrounding breast. Significant physician delay is noted in virtually all series of PABC, as discussed earlier in this chapter. More liberal use of FNAC and core needle biopsy may help avoid delay. In some cases, excision will be required for diagnosis.

How accurate is fine-needle aspiration cytology in evaluating breast masses in this group of patients?

Because the physiologic changes of pregnancy and lactation induce proliferation in the normal breast, the cytopathologist must be informed that the patient is pregnant or lactating. Benign breast masses that have enlarged under gestational or lactational influences frequently show changes that are easily confused with carcinoma of the breast if the cytopathologist is not aware that the patient is pregnant or lactating, or is unaware of the typical and atypical features of these benign lesions.^{61,62,66-69} Material obtained from aspiration of cysts or galactoceles may be similarly misleading.⁶⁸

The classic FNAC appearance of a lactating adenoma has been described by several authors and is illustrated in Figure

Figure 35-5 A and B, Mammograms of same case shown in Fig. 35-4. Lactating breast contains two clusters of microcalcifications (arrowheads). Histology demonstrated comedo-type ductal carcinoma of the breast. Calcifications shown on mammography may have been the source of the central echogenicity seen on ultrasound. (Courtesy of Dr. Donald Young.)

Figure 35-6 A and B, Diagnostic fine-needle aspiration cytology (FNAC) showing lactational changes. (Diff-Quik stain, $\times 100$.) C, Diagnostic FNAC of breast cancer demonstrates single atypical cells with intact cytoplasm and clusters showing marked pleomorphism. (Diff-Quik stain, $\times 100$.) (Courtesy of Dr. Patricia Thomas.)

35-6.^{48,61,66-70} The similarity of many of these changes has been emphasized, and it has been suggested that the term *breast tumor of pregnancy* be applied to the cytologic appearance.⁷⁰ Aspirates of benign lesions under the influence of pregnancy and lactation show large numbers of similar-appearing cells, nuclei with prominent nucleoli, some nuclear enlargement, cell dispersion, and a background suggestive of necrosis.⁹ Prominent cytoplasmic vacuoles may produce a foamy, wispy appearance, particularly well seen with a Romanovsky stain.⁹ During pregnancy, ball-like clusters of breast epithelial cells surrounded by myoepithelial cells at the periphery may be obtained at FNAC.⁹

In a large series of 214 FNACs performed during pregnancy or lactation, in which the diagnosis of malignancy was confirmed in all suspicious or positive aspirates and all patients with benign FNACs were followed clinically for a minimum of 1 year, there were only four nondiagnostic aspirates. FNAC diagnoses were benign lesions of pregnancy in 103, cysts or galactoceles in 26, fibroadenoma with secretory effects in 36, lactating adenomas in 2, and inflammation in 34. Eight FNACs were read as positive for carcinoma, and all were confirmed at biopsy. One additional biopsy was read as suspicious for carcinoma and proved to be carcinoma on biopsy.⁶⁹ Several smaller series have also demonstrated the utility of FNAC and confirmed that the preponderance of palpable masses is benign.^{36,66-68} The differential diagnosis of malignant breast lesions in this population includes not only ductal and lobular carcinoma but also other primary or metastatic lesions,

including non-Hodgkin's lymphoma.⁹ Although immunocytochemistry^{68,70} and electron microscopy (in a case with pleomorphic giant cells)⁶⁸ may aid in the diagnosis of difficult cases, this is rarely required by the experienced cytopathologist.

FNAC is also useful in confirming the benign nature of masses in extramammary sites, where ectopic breast tissue has enlarged under the hormonal influence of pregnancy and lactation or due to medications.^{9,31} Indeed, as has been stated by Novotny and associates, "FNA is useful in distinguishing benign breast masses of pregnancy from those with marked cytologic atypia requiring surgical biopsy and may minimize the delayed diagnosis of carcinoma associated with pregnancy."³⁶

What special precautions are required when breast biopsy is undertaken during pregnancy?

The special considerations associated with the administration of anesthesia during pregnancy are discussed subsequently. Breast biopsy may be performed under either local or general anesthesia. Procedures using local anesthesia are usually without risk to the fetus.⁷¹ The breast engorgement and increased vascularity associated with pregnancy may make the procedure technically more difficult, and some surgeons prefer general anesthesia for this reason.⁷² Fetal heart rate and tocodynamometric monitoring are easily employed in the later

stages of pregnancy and may provide an early warning of impending complications. The risk for spontaneous abortion has not been reported to increase, particularly if tocolysis is employed when necessary.⁷¹ Avoid supine positioning because this may cause caval compression. Rather, tilt the abdomen slightly to the left to allow the gravid uterus to fall laterally away from the inferior vena cava and prevent supine postural hypotension.

These women are at five to six times greater risk for thromboembolism than their nonpregnant counterparts, owing to a decrease in plasma fibrinolytic activity, an increase in all coagulation factors except factors XI and XIII, and a pregnancy-associated decrease in lower extremity venous flow. The use of prophylactic heparin, sequential compression stockings, or both is recommended. The prophylactic use of tocolytics is controversial because of the β -sympathomimetic side effects of tachycardia and pulmonary edema. Rather, close observation for uterine activity is recommended.⁷¹

In an early series of biopsies performed during pregnancy and lactation before availability of FNAC, most were benign lesions associated with pregnancy and lactation. However, even as recently as 1995, a series of 17 pregnant patients who underwent breast biopsy revealed just one carcinoma, and the authors recommended considering more extensive use of FNAC to diminish the number of open biopsies performed for benign lesions.³⁵ It is likely that subsequent series will reflect this trend (as has been true of breast biopsies in all women) and show a higher percentage of malignant lesions in patients actually undergoing open biopsy.

Even when clinical suspicion of carcinoma is high, there are advantages to confirming the diagnosis by FNAC or biopsy under local anesthesia, followed by a selective workup to determine the extent of disease. This allows time to discuss the options with the patient and plan definitive treatment.⁷

What should be done when breast biopsy is performed during lactation?

In lactation, as during pregnancy, open biopsy should be performed if FNAC is not useful in evaluating a clinically suspicious mass. The nursing woman should be advised to cease breast-feeding and allow milk production to dry up before biopsy. Cessation of lactation not only will eliminate the risk for milk fistula but will also decrease the vascularity of the breast.⁶⁶ Increased vascularity requires special attention to hemostasis, and local anesthesia may be difficult or impractical in these large, engorged breasts.^{7,72}

If the patient decides to continue breast-feeding, it is important to advise her of the risk for milk fistula or breast abscess. The breast-feeding woman should express as much milk as possible from the breast before surgery. It has been suggested that if the breasts are emptied early in the morning of the day the biopsy is to be performed, and the biopsy is done shortly thereafter, complications can be reduced.¹¹ After surgery, the infant may resume breast-feeding after a brief period of bottle-feeding.²¹ Unilateral weaning is another alternative and may present an acceptable compromise.⁷¹ A milk fistula is more likely to occur when central (as opposed to peripheral) lesions are excised.^{22,30,72} If a milk fistula occurs, meticulous attention to local cleanliness and dressing changes is important to avoid secondary infection. The fistula will

generally close spontaneously when breast-feeding is stopped.⁷² Dilated, milk-filled ducts communicate at the large duct level, and sepsis is a real threat if infection develops.⁷² The requirement for “tedious and meticulous hemostasis” is self-evident.⁷² The development of a breast infection or abscess after biopsy is all the more common in lactating women because of the nutrient medium the milk represents. Such an infection and the need for institution of antibiotics might well lead to the need to discontinue nursing permanently, much to the detriment of the mother and child.

Inflammatory breast cancer (see next section) may mimic an infectious process.^{47,49,73} For this reason, all abscesses or suspected abscesses that are surgically drained should have routine biopsy of the wall and any suspicious areas.⁶²

What distribution of histologic forms of breast cancer is encountered during pregnancy and lactation?

Generally, it has been stated that the various histologic types of breast cancer occur with similar frequencies in the gravid and nongravid state.^{74–76} Middleton and coworkers carefully reviewed the histologic findings in 39 patients who were pregnant at the time of diagnosis of breast cancer.⁷⁴ All tumors were infiltrating ductal carcinoma. Nine patients showed “a syncytial-sheeting pattern of growth with prominent areas of necrosis.” Ductal carcinoma in situ (DCIS) was found in 72%. One patient had a tumor consisting primarily of high-grade DCIS with multiple foci of microinvasion.⁷⁴ In a large multicenter series from Japan, invasive ductal carcinoma, mucinous carcinoma, and medullary carcinoma were found in similar rates in PABC and matched control cases.⁷⁵

Conventional wisdom held for decades that inflammatory carcinoma was more common in pregnancy and lactation. In one large case-control series, Bonnier and colleagues reported a higher percentage of inflammatory carcinoma (26%) than in nonpregnant controls (9%),⁷⁷ but most series have failed to confirm this. The incidence in other series has ranged from 1.4% to 5%.^{47,49,73} Other malignancies localized to the breast, such as Hodgkin’s and non-Hodgkin’s lymphomas, Burkitt’s lymphoma, other hematologic malignancies, metastatic tumors, and various kinds of sarcomas, may be encountered in this population.^{8,13,78–82}

When should termination of pregnancy be considered?

Prompt and thorough discussion of the options, implications, and patient’s wishes must precede any decision about the termination of pregnancy. Several conversations may be necessary before a satisfactory plan can be agreed on. This section is predicated on the assumption that the woman will want to continue the pregnancy and will deal solely with medical issues surrounding the advisability of termination of pregnancy. It is based primarily on studies that predated the availability of testing for *BRCA1* and *BRCA2* mutations. There are no data that would assist in decision making in this subgroup of patients.

Up through the 1950s and early 1960s, concerns over hormonal stimulation of tumor growth, poor survival, and lack of

effective systemic therapy of breast cancer led many to advocate therapeutic abortion when breast cancer was diagnosed during pregnancy.⁸³ Subsequent series demonstrated that therapeutic abortion not only failed to improve survival but also might even be detrimental.^{8,11,14,47,84} The finding of a high percentage of estrogen receptor (ER)- and progesterone receptor (PR)-negative tumors in most series of PABC dampened enthusiasm for pregnancy termination on theoretical grounds, with the possible exception of the aggressive, hormonally sensitive tumor discovered early in pregnancy.⁶² In a series from Japan, 93% of women diagnosed in the first trimester of pregnancy underwent therapeutic abortion.¹⁴ The major advantage appears to be that termination of the pregnancy allows full and complete treatment of aggressive or advanced disease with chemotherapy and, when necessary, radiation therapy, without consideration of the effect on the fetus.^{8,62}

It is difficult to interpret some of the data indicating a worse prognosis associated with pregnancy termination because there may be considerable selection bias (i.e., abortions were performed only in patients with more advanced or more aggressive tumors). However, even when this factor is taken into account, a suggestion persists that termination of pregnancy diminishes survival.⁴⁷

Animal experiments with carcinogen-induced mammary tumors suggest that the initial phases of pregnancy, which are associated with rapid proliferation and incomplete differentiation of mammary gland tissue, contribute to tumor initiation and promotion.^{85,86} Subsequently, full differentiation of tissues occurs, and in some animal models, this is associated with decreased susceptibility to carcinogenesis or inconsistent regression of established tumors. It thus has been hypothesized that termination of pregnancy might be deleterious because the breast has been subjected to the intense proliferative stimulus of early pregnancy without the subsequent stimulus to full differentiation.⁸⁵⁻⁸⁹ Additional indirect evidence is provided by epidemiologic studies suggesting that women with a history of induced abortion have an increase in risk for breast cancer (or presentation with more advanced disease),^{86,90} or that parous women with a family history of breast cancer develop tumors at an earlier age than nulliparous women with a similar family history.^{85,87,91,92} Data from the Nurses Health Study indicate that the consistent increase in breast cancer risk noted among women with a first-degree relative with the disease was exacerbated by pregnancy.⁸⁵ Much of this remains speculative; however, there is abundant clinical evidence to support the viewpoint originally expressed by Byrd and colleagues: "Faced with the alternative of terminating the pregnancy, we believe the evidence is that the cancer should be terminated."⁹¹ Medical recommendation to terminate a pregnancy should be based on whether the pregnancy will present a significant obstacle to effective therapy and whether the fetus will sustain harm as a result of therapy. Because the pregnancy itself has no effect on the course of the disease, the termination of pregnancy does not ameliorate the disease. Spontaneous abortions and prematurity are not increased in pregnant women with malignancy. Therapeutic abortion may be considered in the first or second trimester to treat metastatic disease promptly, particularly if the disease is ER positive.⁹⁰ Rapid advancement of disease during pregnancy may provide clinical evidence favoring therapeutic abortion in some cases.³⁰

How should breast cancer be managed when it is diagnosed during pregnancy?

The general principle is to treat the cancer and allow the pregnancy to proceed.^{72,93} There are exceptions to this, and treatment must be individualized in each case. The radiation component of breast conservation is generally not practicable during pregnancy because of the radiation exposure to the fetus. Surgery can usually be safely performed during pregnancy with minimal risk to the fetus and mother, particularly in the second and third trimesters of pregnancy. When compared with chemotherapy and radiation therapy, surgery appears least likely to affect the developing fetus. Thus, the traditional treatment for the technically operable breast cancer has been modified radical mastectomy, performed under general anesthesia. Several recent series have reported successful use of breast-conserving surgery during pregnancy, and this will be discussed in a subsequent section. Staging studies are used selectively, and an individualized decision about chemotherapy is made. Patients who present with advanced, technically inoperable disease may require neoadjuvant treatment with chemotherapy, radiation therapy, or both. Each of these issues is considered in more detail subsequently.

What are the risks of anesthesia during pregnancy, and what can be done to minimize these risks?

In the United States, 75,000 women (1.5% to 2.0% of pregnant women) every year receive anesthesia for a nonobstetric indication.^{72,94} Breast procedures are among the most common performed during pregnancy; other common procedures include appendectomy, cervical cerclage, ovarian cystectomy, and surgery for trauma.⁹⁴ During nonobstetric surgery, the fetus is at risk for preterm labor, teratogenesis (in early pregnancy), or diminished uterine blood flow, or from the disease process that necessitated the surgery in the first place.⁹⁴ In a large registry study, there was no increase in congenital malformations associated with nonobstetric surgery during pregnancy. The major problems included an increase in preterm births, an increased incidence of low- and very-low-birth-weight infants (due both to prematurity and to intrauterine growth retardation), and an increase in the number of infants born alive who die within 7 days of birth.⁹⁵ The risk for preterm labor appears to depend more on the surgical site (being greatest for intra-abdominal surgery, and less for surgery, such as modified radical mastectomy, that does not invade a body cavity) than on anesthesia per se.⁷² Surgery is generally safest during the second trimester, when organogenesis is complete and the risk for inducing preterm labor is less.⁸ Potent inhalational anesthetics such as halothane may provide some benefit by virtue of their relaxing effect on uterine musculature.⁷² The chance of aborting a pregnancy as a result of performing a mastectomy is generally estimated to be 1% or less.⁸

The physiologic changes of pregnancy that affect anesthetic management are listed in Table 35-1. Modified radical mastectomy is customarily performed under general anesthesia, although the use of high thoracic epidural anesthesia or

paravertebral blockade has been reported.^{21,96,97} Routine safety precautions are listed in Table 35–2. Major concerns for fetal safety include maintaining fetal oxygenation, preventing preterm labor, and avoiding teratogenic agents (during the first trimester). The incidence of failed intubations in parturients is estimated at 1 in 5000.⁹⁷ As previously noted, the risks for supine postural hypotension can be minimized by positioning the patient with a wedge under the right lumbar region to produce left lateral tilt. Maternal hyperoxia is not associated with any risk to the fetus and has not been reported to result in retrolental fibroplasia in the neonate; thus, preoxygenation and the liberal use of oxygen during the procedure are encouraged. However, maternal hyperventilation causes vasoconstriction, a decrease in placental intervillous blood flow, and an increased affinity of maternal hemoglobin for oxygen, all of which lead to decreased oxygen delivery. Hypercapnia, on the other hand, may result in fetal acidosis. Excess positive end-expiratory pressure (PEEP), by raising intrathoracic pressure, leads to a decrease in cardiac output. Uterine blood flow is directly dependent on maternal blood pressure, which should be maintained in a range normal for pregnancy.⁹⁴

Table 35–1 Physiologic Changes of Pregnancy that Affect Anesthetic Management

Increased blood volume with physiologic anemia of pregnancy
20% increase in RBC volume
40%–50% increase in plasma volume
Increased heart rate
Increased cardiac output
Supine postural hypotension
Elevated diaphragm
Decreased functional residual capacity
Increased oxygen consumption (10%–20%)
Chronic hyperventilation
Decreased PCO ₂
Decreased buffer base capacity
Normal pH
Increased fibrinogen
Increased platelet count
Prolonged gastric emptying
Hyperemic respiratory tract mucosa

Data from references 8, 22, 72, and 169.

The same drug characteristics that make particular anesthetic agents effective (high lipid solubility, low molecular weight, nonionized state, loosely bound to plasma proteins) also facilitate drug entry into the fetus across the placenta.²¹ Concerns about the teratogenicity and mutagenicity of anesthetic agents in human pregnancy appear unfounded. In large registry series, no increase in congenital malformations was noted after surgery under general anesthesia in the first and second trimesters.^{94–96}

What cancer staging studies should be done in the evaluation of the pregnant patient with breast cancer?

In general, the metastatic workup should be limited to those situations in which there is a high clinical suspicion of metastatic disease and in which documentation of disease would alter therapy.^{7,21,98} The fetal radiation exposure from a chest radiograph performed with abdominal shielding is minimal, and this test is generally performed.⁹⁹ The effects of radiation on the fetus are discussed subsequently, but the adverse consequences from total exposures below 5 cGy are generally thought to be extremely small.¹⁰⁰ When multiple studies are performed, the total dose may easily exceed this threshold, hence the need for extreme selectivity.^{1–6}

Alkaline phosphatase is normally elevated in pregnancy and is therefore an unreliable indicator of metastatic disease.¹ Ultrasound of the liver is preferable to computed tomography (CT) scanning.⁷ If ultrasound is equivocal or nondiagnostic, MRI is an alternative modality that has been used extensively during pregnancy since 1983 and is generally believed to be safe.¹⁰¹

The long bones and skull may be irradiated in a symptomatic patient, but a complete skeletal survey exposes the fetus to an unnecessarily large dose of radiation.⁷ The fetal dose varies from as low as 1 cGy for an extremity film to 300 cGy for hip films.³⁷ Generally, bone scanning is avoided in pregnancy because of low yield and potential fetal harm. However, if bony metastases are strongly suspected, bone scanning with ^{99m}Tc-technetium is preferable to skeletal survey provided certain precautions are taken to minimize fetal exposure.^{55,102} Because this agent was used for placental scanning before the

Table 35–2 Safety Precautions for General Anesthesia During Pregnancy

Risk	Safety Precaution
Aspiration	Oral noncolloidal antacids (e.g., sodium citrate) Administration of agent to increase lower esophageal sphincter tone and promote gastric emptying (e.g., metoclopramide) Assume full stomach Rapid-sequence induction Cricoid pressure during induction (Sellick's maneuver)
Hypotension due to aortocaval compression	15-degree wedge under right hip to produce left lateral tilt
Fetal acidosis or maternal hyperventilation	Monitor fetal heart rate Maintain normal maternal pH Avoid hyperventilation Avoid maternal acidosis
Preterm labor	Monitor uterine activity Use tocolysis if necessary

Data from references 8, 22, 94, and 169.

availability of ultrasound (for diagnosis of placenta previa), there is considerable clinical experience with its use in late pregnancy. Adequate hydration before and during the scan facilitates rapid washout of the isotope from the blood. Foley catheter drainage of the bladder during the scan and for 8 to 12 hours after the scan avoids accumulation of isotope in the pelvis and hence minimizes fetal exposure. Using these precautions, the fetal dose was reduced from 194 to 76 mrem in one study (calculated using phantoms).¹⁰² Once again, extreme selectivity is advocated.

What considerations govern the use of radiation therapy during pregnancy?

The fetus is extremely sensitive to both chemotherapy and radiation therapy. These effects are influenced by gestational age and dose and duration of therapy. A dose that produces fetal damage may not have perceptible effects on the mother. Death in utero can be manifested by fetal resorptions, spontaneous abortions, or stillbirths with or without malformations. Intrauterine growth retardation and prematurity are additional risks. Drug- or radiation-induced structural malformations may affect physical and mental growth and development as well as long-term viability.^{103–107} Subtle point mutations may occur in the developing fetus, producing altered coding for proteins and manifesting as disease only years later. An irradiated fetus may develop recessive traits (leukemia or Hodgkin's disease) that may only appear in the second or third generation of life. The embryo is the most radiosensitive stage of human life, and there are varying sensitivities within the tissues of the human embryo. Any irradiation of gonadal tissue involves genetic damage with no threshold below which mutations do not occur. The fetus is most sensitive to radiation in early gestation during organogenesis. It has been estimated that 1 cGy produces five mutations in every 1 million genes exposed. As previously stated, the maximal permissible fetal dose of radiation is considered to be 5 cGy.¹⁰⁸

In the preimplantation period, radiation produces an all-or-none effect in that it either destroys the fertilized egg or does not alter it significantly. The fetus is most sensitive to radiation at 18 to 38 days. During this period, doses of 10 to 40 cGy may cause visceral organ or somatic damage. Microcephaly, anencephaly, eye damage, growth deficiency, spina bifida, and foot damage have been reported with doses of 4 cGy or less, but cause and effect have not been reported with these lower doses. Knowledge of the effects of radiation therapy during human pregnancy comes from observations on the survivors of the blasts at Hiroshima and Nagasaki (dose difficult to quantitate) and from series of patients receiving head and neck irradiation for Hodgkin's disease (the dose used is about three fourths of the dose required for breast cancer, and the field is farther from the fetus), as well as very limited numbers of patients who have received breast irradiation during pregnancy.^{47,62,72,98,104–110} The risks include fetal demise, teratogenesis or mutagenesis, and mental retardation, and are dependent on total dose and trimester. To put these risks into perspective, it is useful to recall that between 30% and 50% of human embryos abort spontaneously, and there is an average incidence of 2.75% of major malformations at birth, which increases to 6% to 10% overall once all malformations and genetic disorders become manifest.¹⁰⁰ Therapeutic abortion

may be considered if the fetal dose exceeds 10 cGy during the first trimester. The risk for abnormalities is low for exposure less than 5 cGy and rises with dose as 10 cGy is exceeded.^{107,111} Population data obtained from atomic bomb survivors suggest that exposure at 8 to 15 weeks' gestation of 1 to 2 cGy doubles the frequency of severe mental retardation. From 4 to 17 weeks, the greater the dose, the smaller the brain and head size; beginning at a dose of 50 cGy, mental retardation increases in frequency with increasing dose.¹⁰⁶ The risk for teratogenesis or mutagenesis has been estimated at 1 in 1000 per 1 cGy of exposure. Exposure during later stages of pregnancy is less likely to cause abnormalities (because organogenesis is complete) but may result in more subtle problems such as sterility and subsequent development of malignancy in offspring.¹⁰⁷

Much of the data concerning consequences of in utero irradiation in the medical setting come from Dekaban,¹⁰⁸ who studied 26 women. The children with severe congenital malformations had been irradiated between 3 and 10 weeks' gestation. More than half of the children developed anomalies (microcephaly, retinal degeneration, skeletal and genital abnormalities, and cataracts) at 250 cGy. This dose, administered before 2 or 3 weeks' gestation, increased spontaneous abortions but did not lead to severe congenital malformations. At 10 to 20 weeks' gestation, the effects were less severe than at 3 to 10 weeks, but there were children born with microcephaly, mental retardation, and small size. After 20 to 25 weeks, there were no severe abnormalities, with anemia, pigmentary changes, and dermal changes being the only toxic effects. These data support the recommendation that abdominal radiation should be avoided during the first half of pregnancy.¹⁰⁸

An external radiation dose of 5000 cGy to the breast area exposes the fetus to at least 10 to 15 cGy and delivers several hundred cGy to the part of the fetus immediately below the diaphragm late in pregnancy.^{62,105} Because much of this dose comes from internal scatter of radiation within the body of the woman, abdominal shielding is only partially effective. The fetal dose depends in part on the total dose administered, the distance of the fetus from the field source, the field size, and the energy source.^{30,72} The fetal dose varies and must be individually calculated for each case.¹⁰⁵ Following a general guideline to limit the total fetal dose to 10 cGy, it becomes obvious that radiation therapy during pregnancy should be rarely employed if alternatives exist.¹⁰⁰

Older series and scattered case reports describe use of radiation therapy in addition to radical or modified radical mastectomy, without evidence of adverse fetal sequelae or palliation of large, fixed, technically inoperable breast cancers, or the inadvertent exposure of a woman not known to be pregnant at the time of therapy.^{47,104,107,109,110} Current practice emphasizes the use of chemotherapy rather than radiation therapy during pregnancy and reserves radiation therapy for special cases.

Can breast-conserving therapy be used during pregnancy?

As previously discussed, radiation therapy during pregnancy inevitably results in significant fetal radiation exposure, and its use is discouraged.^{62,72,100} However, breast-conserving therapy has been reported during pregnancy, most

commonly based on one of two strategies. In the first, wide local excision is performed at the time of diagnosis, with radiation therapy after delivery. Chemotherapy may be given in the interval between surgery and the initiation of radiation therapy. The little that is known about the long-term results is predicated on extrapolating the results from therapy in women who are not pregnant. In an alternative strategy, neoadjuvant chemotherapy is given and lumpectomy performed later. Concern has been raised that the risk for local failure may be increased in these women, because of the altered anatomy and physiology of the pregnant breast, with vascular engorgement and an active intercommunicating ductal system.^{67,72,107,112} Data are not available to support this concern, and an increasing number of small series support the use of breast-conserving surgery in pregnancy.^{113–116} Kuerer and colleagues reported on four patients who underwent breast-conserving surgery during pregnancy between 1995 and 1997.¹¹⁵ These women were treated initially either with lumpectomy and level I or II axillary node dissection, followed by CAF chemotherapy every 21 to 28 days during the latter part of pregnancy, or with chemotherapy followed by surgery. Radiation therapy was given after delivery.¹¹⁵ All women were alive with no evidence of disease at follow-up ranging from 33 to 55 months, and all pregnancies had normal outcomes. In a previous study, nine patients with PABC treated by BCS were compared with similar PABC patients treated by modified radical mastectomy, and outcomes were similar in stages I and II.¹¹⁴

There is additional evidence that selected patients who undergo breast-conserving therapy may benefit from chemotherapy before radiation therapy because long-term survival is predicated on distant disease failure rather than local failure.^{113–116} As this becomes more widely accepted therapy, the issue of timing of radiation therapy may become less crucial for most patients.¹¹² At present, it is judicious to limit the use of breast-conserving therapy to those women who want to preserve the breast and are otherwise suitable candidates, and to those who are diagnosed late in pregnancy (so that the delay in initiation of radiation therapy is minimized).⁷²

Can sentinel lymph node biopsy be used during pregnancy?

Isolated case reports document use of sentinel node biopsy during pregnancy. Little is known about whether the lymphatic pathways are altered during pregnancy. The radioisotope that is commonly used is approved for use during pregnancy, and fetal dose is acceptable. Lymphazurin (isosulfan blue) dye has not been approved for use in pregnancy, however. There are no large series documenting the predictive value of the technique.¹¹³

What considerations govern the use of chemotherapy during pregnancy?

General principles have been derived from experience treating primarily hematologic malignancies during pregnancy, with a more limited experience with solid tumors including breast cancer. Little is known about the use of chemotherapy for

breast cancer during pregnancy, but some general principles can be laid down based on experience treating other malignancies (primarily hematologic).^{112–120} All chemotherapeutic agents are theoretically teratogenic and mutagenic. Their use can result in fetal growth retardation, malformations, miscarriage, or fetal death. It is important to differentiate teratogenic and mutagenic effects from those related to an adverse uterine environment¹²¹ or to transmission of maternal toxicity (e.g., hematopoietic depression, infection, hemorrhagic diathesis, myocardial toxicity). There is also the potential for effects on future fertility, recessive mutations, and impaired neurologic development. Long-term effects on the fetus are generally unknown, and there exists a need for long-term observation.¹²² Material in the older literature is of limited relevance because lower doses of single agents were generally used, in contrast to modern practice.¹²³ Drugs used in combination, or chemotherapy combined with radiation therapy, may significantly increase the risk for fetal abnormalities.¹¹⁹

The physiologic changes associated with pregnancy directly affect the dosing and toxicity of chemotherapeutic agents. The usual increase in renal blood flow, glomerular filtration rate, and creatinine clearance may increase the clearance of drugs excreted by the kidneys. Amniotic fluid may act as a physiologic third space, effectively increasing the toxicity of certain agents (e.g., methotrexate) by delaying elimination. The physiologic increase in body water with the increase in plasma volume changes the volume of drug distribution. No human data on transplacental passage of antineoplastic agents are available,¹²⁴ but it is assumed to occur (especially with low-molecular-weight, highly lipid-soluble, nonionized, loosely bound drugs).⁸

The effect on the fetus is related to the particular drug, drug dosage, gestational age, and potential synergism if used with other drugs or with radiation therapy.^{7,125} The National Cancer Institute (NCI) maintains a registry of patients who receive chemotherapy during pregnancy and is tracking outcomes.⁸ Premature birth and low birth weight for gestational age are the most common complications and are probably underreported.^{7,8,122} In a manner similar to radiation, the effects during the first few weeks are mainly teratogenic; during the second and third trimesters, intrauterine growth retardation becomes dominant.^{60,98} The relative ease of identifying the sequelae of first-trimester exposure may have led to the perception that chemotherapy is safer during the later trimesters. More subtle effects, such as growth retardation, future development of neoplasms, or subtle abnormalities in neurologic development that might result from chemotherapy later in gestation, are not only more difficult to detect without careful long-term follow-up but also much harder to infer from animal studies.¹²² With that caveat, some general observations about timing and specific agents follow.

The risk for spontaneous abortion is high when chemotherapy is given during the first trimester. Similarly, there is a significant trend toward greater fetal abnormalities at this time. Thirteen women who received chemotherapy for breast cancer during the first trimester were followed to term. Of the five whose pregnancies continued to term, two had major malformations in the infants, four suffered spontaneous abortions, and four had therapeutic abortions.¹²⁶ Registry data support the concept that chemotherapy given before implantation has no effect on the developing fetus.¹²⁵ The blastocyst is resistant to teratogens in the first 2 weeks of

life; if not destroyed, a surviving blastocyst will not manifest any abnormalities from the teratogen. From the third to the eighth week of development (5 to 10 weeks' gestational age), there is maximal susceptibility to teratogenic agents. With the exception of brain and gonadal tissue, organogenesis ends by 13 weeks' gestation.

Most available data concerning chemotherapeutic teratogenicity and mutagenicity have been derived from laboratory animals.¹²⁴ Some generalities about specific agents that may be used in the treatment of PABC follow:

The risk of *alkylating agents* administered during pregnancy appears to be small, with no increased risk for congenital anomalies if given after the first trimester.

The *folate antagonists* aminopterin and methotrexate cause a high incidence of spontaneous abortion or fetal abnormality when administered during the first trimester. The effects vary with the dosage and the gestational age at time of administration. Limited data suggest that these agents are not harmful after the first trimester.

Although most *other chemotherapeutic agents*, including 6-mercaptopurine, azathioprine, 5-fluorouracil, alkylating agents, vinca alkaloids, doxorubicin (Adriamycin), and cisplatin, are known to be teratogenic in animals, there have been surprisingly few case reports of human fetal abnormalities resulting from the use of these drugs in the first trimester. Doxorubicin has been used in the later stages of pregnancy without reports of abnormalities.

Treatment with large doses of *corticosteroids* and cytotoxic agents, particularly during the last trimester of pregnancy, may produce neonatal bone marrow and adrenal gland suppression. Corticosteroids may be associated with cleft lip and palate.

Despite ample evidence of teratogenic effects and the potential for fetal wastage, there are many case reports of apparently healthy term neonates delivered despite administration of chemotherapy to the mother, even during the first trimester. The potential for teratogenesis exists but may be less than anticipated. It is obviously safer to avoid potential teratogenic exposure, but the decision to terminate a pregnancy must incorporate the social, religious, and ethical considerations of the patient and her family.¹²⁴

In addition to concerns about the effect on the fetus, administration of chemotherapy during pregnancy is fraught with hazard owing to risk for sepsis, bleeding during unplanned labor and delivery, and other complications.⁶² Delivery or cesarean section should be timed to avoid the chemotherapy nadirs, when bone marrow suppression is at a maximum. Timing of delivery may also affect the neonate because the placenta acts not only as a vehicle for drug delivery but also as the major route of drug excretion. Chemotherapy given shortly before delivery may not have been eliminated from the fetus by the time of delivery; the result may be prolonged drug presence in the neonate, who lacks the placental route of excretion.¹²⁴

With respect to the specific treatment of breast cancer, it is advisable to avoid agents that have been associated with a high frequency of anomalies, particularly when alternative regimens exist.¹²⁵ Concurrent radiation therapy increases the risk.¹²³ During the first trimester, cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) cannot be used,

owing to the toxicity of folate antagonists such as methotrexate. One series used the alternative cyclophosphamide, doxorubicin, and fluorouracil (CAF) regimen.¹²⁷ Because most women today are acutely aware of the damaging effect any drug may have on their unborn child, extensive counseling is needed. Such counseling must provide as much objective, scientific information as possible and avoid emotional bias.¹²⁰ The clinician may find it helpful to distinguish between the use of chemotherapy with curative intent and that for pure palliation. When cure is possible and the odds may be improved by adjuvant chemotherapy, modification or delay should be minimized. When cure is not possible, the goal should shift to the protection of the fetus.¹²⁷ Delaying chemotherapy until after delivery would seem to be the safest strategy and certainly provides the best protection for the unborn child, but it may do so at the expense of control of maternal disease because the greatest permissible time lapse before instituting adjuvant chemotherapy remains unknown.⁷² Data on the use of combination chemotherapy for breast cancer during pregnancy consist mainly of isolated case reports; information from a registry of such cases is sorely needed.^{109,123,128} A large retrospective French national survey identified 20 women who received chemotherapy during pregnancy.¹²⁹ 5-Fluorouracil, epirubicin, and cyclophosphamide were the agents most commonly used. One pregnancy resulted in a stillborn infant, and a second infant experienced intrauterine growth retardation, but overall, 95% of pregnancies resulted in live births with little related morbidity.

There are no data about newer chemotherapeutic agents such as taxol derivatives and trastuzumab (Herceptin). Tamoxifen may cause vaginal bleeding, spontaneous abortion, birth defects, and fetal deaths and should not be used during pregnancy.¹¹³ The aromatase inhibitors are similarly precluded from use in pregnancy.

How should breast cancer be managed when diagnosed during lactation?

“Breast cancer arising during lactation is just as emotional but management is less complicated as there is no fetus to consider.”⁴⁷ After delivery, the full range of therapeutic modalities is again available. The issues related to breast surgery during lactation have been discussed previously.

Breast-feeding during chemotherapy is contraindicated because antineoplastic agents may reach significant concentrations in breast milk.²² Although little is known about excretion of drugs in milk, it is assumed that small molecules pass freely.²⁰ Case reports document that chemotherapeutic agents such as methotrexate and cyclophosphamide are excreted in the milk and can produce neonatal neutropenia.⁵⁵

What is known about the hormone receptor status of pregnancy-associated breast cancer?

Older series of PABC that report ER and PR status indicate that a high percentage (up to 80%) of patients, studied with the older ligand-based receptor assays, were ER and PR negative.^{7,14,30,130,131} Two general hypotheses have been advanced to account for these observations: first, that ER levels are falsely

depressed or undetectable with standard assays in PABC; and second, that PABC tumors are truly ER negative because they fall into the subset of aggressive, largely ER-negative, tumors found in young women (whether or not they are pregnant).¹³¹ Difficulties with ER and PR assays during pregnancy are discussed here. The more general question of whether these represent a subset of more biologically aggressive tumors (and that ER and PR negativity is simply another manifestation of this biologic behavior) is considered later in this chapter. Indirect evidence favoring this second hypothesis comes from old data in which oophorectomy failed to improve survival in PABC.¹ These data are difficult to interpret owing to inadequate information concerning stage of disease, deficiencies inherent in the old ligand-binding assays, and the common practice of therapeutic abortion.

Older ligand-binding assays measured ER in the cytosol. High levels of endogenous estrogen not only may have saturated the ER-binding sites but also may have triggered migration of the bound ER to the nucleus. It is thus generally suspected that the high levels of circulating estrogens in PABC contribute to false-negative ER assays.¹ In addition, high levels of circulating estrogen and progesterone down-regulate ER levels and could physiologically suppress these below the levels detectable by the standard ligand-binding assay.¹³¹

PR is inducible by high levels of estrogen and less easily saturated by circulating progesterone. It has been suggested that the finding of a tumor that is PR positive but ER negative, particularly in a patient younger than 51 years, indicates that the ER determination is probably falsely negative. In the latter stages of pregnancy, when progesterone levels are at their maximum, PR may be masked, and it may be necessary to remove free progesterone from the plasma before assay. This appears to be less of a problem with PR because of the relatively low affinity of PR for progesterone.¹

Immunohistochemical testing has largely supplanted the ligand-binding assays. Middleton and coworkers reported the results of immunohistochemical testing on 39 patients with PABC (all invasive ductal carcinoma). ER was positive in 28%, PR was positive in 24%, and ER and PR were positive in 16%; these rates are similar to those of age-matched controls. *HER-2/neu* was positive in 28%, *p53* was positive in 48%, and a high Ki-67 was noted in 60%; again, all these rates are similar to those of age-matched controls.⁷⁹ Although prolactin receptors have been demonstrated in some ER-deficient tumors in rats,¹³² little is known about prolactin receptors during human pregnancy, and there is no evidence that the elevated prolactin levels associated with pregnancy stimulate tumor growth.

What is the prognosis of pregnancy-associated breast cancer?

The initial pessimism expressed by Haagensen has given way to the philosophy of treatment detailed above. Numerous studies over the past several decades have suggested that PABC tends to be more advanced at initial presentation but that it has an equivalent prognosis when patients are matched, by age and stage at diagnosis, with nonpregnant patients treated for breast cancer in the same institution at the same time period.^{5,7,8,10,11,13-19,47,133-136} Older series, with inconsistent staging and inadequate control groups, showed fairly consistently that patients with PABC presented with more advanced

disease, suggesting that this was the reason for a significantly worse observed survival. Subsequent series of patients reported over the next decade reiterated the message that stage for stage, survival was equivalent, but that patients with PABC tend to present with larger tumors and more advanced disease.^{7,11,91,134} This tendency to present with more advanced disease was largely ascribed to delay, as previously discussed. However, several studies published more recently suggest that this assumption may not be altogether correct. In 1991, Clark¹³⁴ reviewed his experience at Princess Margaret Hospital and noted that only 10% of patients presented with tumors less than 2 cm in diameter and that the 5-year survival of patients diagnosed during pregnancy was only 32% (regardless of nodal status; that is, node-negative patients had survival no better than node-positive patients). In several additional studies, poorer survival was shown in young PABC patients.^{135,137} In a careful review of the Memorial Hospital experience, Anderson and associates¹³⁸ matched young women with operable breast cancer according to pregnancy status and demonstrated that in the subset of patients younger than 30 years with stage IIIa cancer, survival was decreased compared with nonpregnant controls. The extent to which this poor prognosis represents treatment delay, a more aggressive biologic behavior, or another manifestation of the poor outcome experienced by young women who develop breast cancer is unknown.

Kroman and colleagues, in a retrospective cohort analysis of 5652 women with breast cancer who were age 45 years or younger at the time of diagnosis, found the prognosis to be worse when the woman had been pregnant within 2 years of diagnosis.¹³⁹ This adverse effect was not affected by age, nodal status, tumor size, or whether the woman received adjuvant chemotherapy.¹⁴⁰

Finally, in one careful study of pregnancy outcomes, there was a greater number of stillbirths, and live children were more likely to be born preterm or of low birth weight, suggesting a poor intrauterine environment.¹²⁶

Can breast cancer metastasize to the products of conception?

Concern that the breast cancer may spread to the unborn child has been termed one of the myths of PABC and is cited as a major patient concern.^{141,142} Metastatic spread to the placenta has been reported but is extremely rare, and spread to the fetus has never been reported (although such spread has been reported for melanoma, hematopoietic malignancies, hepatoma, and choriocarcinoma).¹⁴³⁻¹⁴⁵ At least 55 cases of placental metastases have been reported in the literature. Melanoma is the most common, accounting for about one third, followed by hematopoietic malignancies. Breast cancer accounted for 13% of cases, and the remainder were divided among lung, sarcomas, and various gastrointestinal malignancies.¹⁴³ Occasionally, placental metastasis is the only sign of metastatic disease and has been associated with a poor maternal prognosis in other malignancies.⁶² There are insufficient data to determine whether this is the case with breast cancer in particular.

Careful examination of the placenta is required, with histologic sections, even if the placenta appears grossly normal. It has been suggested that the actual incidence of placental

metastases is underestimated because the gross appearance is normal in up to 50% of cases with histologic evidence of spread.¹⁴⁶⁻¹⁴⁸ If metastases are found, the pathologist should document the extent of intervillous, intravillous, or fetal capillary involvement. Placental metastasis is generally found in conjunction with widespread metastatic disease. Fetal metastasis of other malignancies is usually associated with evidence of villous invasion or malignant cells within the fetal villous vessels.¹⁴³ Despite the lack of documented fetal transmission of breast cancer, close follow-up of the neonate has been suggested when these histologic findings are present.¹⁴³ Maternal breast cancer metastatic to the fetus has not yet been reported.

What are the ethical, psychosocial, and legal aspects of pregnancy-associated breast cancer?

At a time when the attention of both the woman and her family are focused on the future and on the prospect of bringing new life into the world, the woman and her loved ones must confront her own mortality. The diagnosis is unexpected and frightening, particularly since most patients with PABC are young and fall outside of the stereotypic “cancer patient” age range. There is a clear need for moral, emotional, and psychosocial support. The complexities of treatment of necessity involve multiple physicians from various specialties (obstetrics, surgery, and medical oncology, to name a few), and the team must develop a strategy that allows clear communication with the patient, ideally through a single professional.^{149,150}

In the treatment of PABC, there may be occasions in which the best interests of the patient and fetus are perceived as being contradictory. The clear legal trend in support of patient decision-making autonomy in virtually all other aspects of care stands in contrast to certain notable cases in which courts have been inclined toward “criminalization of maternal conduct” when actions are taken during pregnancy that might harm the fetus.¹⁴⁶ So far, these cases have been limited to lifestyle choices in which the actions of the pregnant woman were arguably analogous to actions giving rise to charges of abuse and neglect. The opposite is more often expressed by patients with PABC, who overwhelmingly seem to put the welfare of their unborn child first. Major concerns articulated by patients in one study included “living to see my child grow up,” receiving proper treatment for breast cancer, pregnancy making breast cancer worse, the possible effects of chemotherapy on the baby, and the “risk of not being there for my other children if I continue this pregnancy.”¹⁵¹ Women who become pregnant after treatment for breast cancer face additional worry about disease recurrence, ability to breast-feed, and health of the child.¹⁴⁸ Extensive needs for emotional support, reliable information, and patient advocacy may provide a special role for the nurse, allowing physicians to concentrate on medical aspects of care.^{112,128}

A separate set of ethical and legal issues arises when cancer therapy is anticipated to destroy ovarian function. Experimental therapies such as oocyte cryopreservation for subsequent reimplantation are being offered to women, without sufficient data to show success of the procedure in humans.

The American Society for Reproductive Medicine, citing the “desperate feelings of cancer patients and the special status of ovarian tissue containing oocytes,” noted the requirement that research in such areas adhere to the highest level of ethical and social sensitivity. When treatment can result in loss of ovarian function, it is essential that the risks and benefits of the treatment be fully explained to the patient to ensure that she had been given an adequate informed consent.¹⁵²

PREGNANCY AFTER TREATMENT FOR BREAST CANCER AND LACTATION AFTER BREAST SURGERY

Is it safe or advisable for a woman to become pregnant after treatment for breast cancer?

When Cheek⁸³ surveyed the opinions of 47 nationally prominent surgeons in 1953 (choosing this method because little was available in the literature on which to base an opinion), there was no clear consensus about the advisability of pregnancy after treatment for breast cancer. In 1960, in a series of 20 women who became pregnant after treatment for breast cancer, neither termination of the pregnancy nor allowing it to go to term could be shown to affect outcome. By the early 1970s, a consensus was beginning to emerge in the literature that the woman who had survived for 2 or more years without evidence of disease could become pregnant without adverse sequelae, and this has been documented in numerous studies.^{7,30,43,151-166}

As a general rule, cancer identified before conception should be adequately treated with appropriate follow-up before attempting pregnancy. Once successfully treated, few if any malignant diseases (other than those that require extirpation of the reproductive organs) absolutely preclude future pregnancy.

There are no prospective studies evaluating the effects of subsequent pregnancy on breast cancer patients. Although most recurrences occur within 2 years, many occur later. No studies have shown an adverse effect of a subsequent pregnancy even in patients with positive axillary nodes or patients whose pregnancy occurred earlier than 2 years after treatment.¹⁶⁴⁻¹⁶⁶ Two large retrospective studies address this issue and have concluded that subsequent pregnancy does not negatively influence breast cancer survival and may have a beneficial effect. In a retrospective review of the Swedish Inpatient Care Registry, there was no untoward effect of pregnancy on the outcome of invasive breast cancer. Women who became pregnant after treatment for breast cancer demonstrated a trend toward improved prognosis compared with women not subsequently pregnant.¹⁶⁴⁻¹⁶⁶ Sankila and colleagues¹⁶⁰ retrospectively reviewed data from Finland and concluded that survival rates of women who deliver liveborn children subsequent to the diagnosis of breast cancer are better than those who do not deliver. They speculated that this may be due to a “healthy mother effect” (i.e., that only women who feel well get pregnant) and that selection bias may play a significant role. However, the large number of patients (91) matched with 471 controls and the long follow-up are reassuring that

subsequent pregnancy does not have an untoward effect on survival. Abortion does not improve survival, and termination of pregnancy for medical reasons is therefore considered only in women with recurrent disease.²⁰

One review demonstrated that of women who are fertile after breast cancer, about 7% subsequently have children, and that the prognosis in this subset of patients was better than in the group as a whole.⁷³ Selection bias, the healthy mother effect, or sociologic factors may be at work.^{6,73} This is another area in which data obtained from a registry could provide information of inestimable value. Petrek¹⁶¹ has pointed out the difficulties in accumulating outcome data in these patients in the absence of such a registry and cautions that it is too soon to categorically pronounce it safe. There remains concern that the hormonal changes of pregnancy may stimulate dormant micrometastases.¹⁶¹

Adjuvant chemotherapy for operable breast cancer has a significant effect on subsequent fertility. Levels of follicle-stimulating hormone (FSH) and chronologic age predict ovulation reserve and reproductive potential. The risks for premature ovarian failure induced by chemotherapy can be estimated from a woman's age, the agent used, and the total dose.^{123,150} Alkylating agents such as cyclophosphamide cause direct amenorrhea through direct ovarian depression. The severity of the follicular depletion seems to be a function of the number and activity of follicles present at the initiation of chemotherapy. Prepubertal ovaries not yet under cyclic hormonal control seem protected against destruction from chemotherapy. The younger the patient, the larger the reserve of oocytes that are available after chemotherapy. Thus, return of menses and ovulation are largely a function of age, dose, and duration of therapy, rather than the particular agent.¹²⁴ Whereas cyclophosphamide is a major cause of ovarian failure, methotrexate and 5-fluorouracil in adjuvant ranges were not associated with ovarian failure. There are little data concerning doxorubicin.^{123,159} Adjuvant chemotherapy for breast cancer causes significant changes in ovarian function. Ovarian damage is the most significant long-term sequela of adjuvant chemotherapy in premenopausal women. The average rate of chemotherapy-related amenorrhea with CMF is 68%.¹¹⁷ About 50% of women younger than 35 years resumed menses after a full course of adjuvant chemotherapy in one study.¹²³

Why would a woman choose to become pregnant after treatment of breast cancer? The four major reasons cited by women in one survey were (1) desire for fulfillment of a cherished but interrupted goal (especially women who developed breast cancer after postponing childbearing or who were trying to become pregnant when they were diagnosed with breast cancer), (2) desire to regain a sense of normalcy, (3) as a way to reconnect, and (4) finally—why not? (i.e., that there are no data in the literature to suggest that it is a bad idea). Pregnancy subsequent to breast cancer treatment is a powerful stimulus to get well again.¹⁵¹ Balanced against a woman's natural desire to get well again, to go on with her life, and to accomplish a cherished goal is the desire to provide maximum assurance of an uncomplicated pregnancy and of continued health. Because most recurrences occur early, many advise delaying pregnancy for 2 to 3 years. There are no hard data to support this position, which seems to be based on common sense as much as anything else.²⁰ A series of 32 women who became pregnant after breast conservation (including radiation

therapy) has been reported; 30 live births resulted (with one low-birth-weight infant, but no other adverse outcomes).¹⁶⁸ In the absence of evidence of recurrent disease, women who become pregnant after breast cancer should be managed like any other pregnant women.²⁰

What are the options for hormonal control of fertility after breast cancer?

Little data are available concerning the safety of oral contraceptive use after breast cancer. Common sense would dictate that low-dose oral contraceptives might be a safe alternative for the woman who could be regarded as definitively cured.¹⁶² The U.S. Food and Drug Administration (FDA) cites estrogen-dependent neoplasia as a contraindication. Medroxyprogesterone acetate suspension by injection every 3 months may be an attractive alternative to estrogen therapy (oral megestrol acetate [progestin] is approved for metastatic breast cancer). The FDA, however, cites a previous history of breast cancer as a contraindication.

The roles of in vitro fertilization (IVF) and oocyte donation in women rendered sterile but cured of breast cancer are totally unknown.¹⁵⁹ One patient underwent successful IVF 6 years after treatment for node-negative breast cancer,¹⁵² and a second case report documented good outcome in a pregnancy produced from a donated oocyte.¹⁶⁴ Cryopreservation of autogenous oocytes for subsequent implantation is not currently advised in these cases.¹⁵³

Is breast-feeding possible after breast surgery or radiation therapy?

Prior breast surgery may influence the ability of a woman to breast-feed. Circumareolar incisions may disrupt the innervation of the nipple-areolar complex, and excision of breast parenchyma in the central regions disrupts terminal ducts.¹⁶⁷ If a woman becomes pregnant and attempts to breast-feed several months after biopsy of a central lesion (particularly a ductal excision), the breast will become engorged and may become infected.²⁰ It is important that women with prior breast surgery or radiation therapy be identified prenatally as being at potential risk for problems during lactation. Early intervention includes assessment of lactation potential and a carefully individualized plan of care to allow breast-feeding while ensuring that the infant's nutritional needs are met.¹⁶⁷

Radiation therapy results in diffuse tissue damage, including ductal shrinkage and lobular atrophy.^{164,167} The treated breast generally does not swell as pregnancy develops. Although breast-feeding from the contralateral breast is feasible, many women have been advised not to attempt subsequent breast-feeding because of concerns about possible mastitis. In a survey of 52 pregnancies after radiation therapy, 18 (35%) reported lactation from the treated breast, and 24.5% successfully breast-fed.^{163,168} Milk production is generally poor, and success rates have generally been lower in other series.^{163,164} There are no data to suggest that breast-feeding after treatment for breast cancer is in any way injurious to the infant if precautions are taken to ensure that the baby derives adequate nutritional intake.^{169,170}

Treatment of Male Breast Cancer

Colleen D. Murphy and Patrick I. Borgen

Male breast cancer is an uncommon disease, accounting for 1% of all breast cancers and representing less than 1% of all malignancies in men. In 2005, the American Cancer Society estimated 1690 new cases of male breast cancer in the United States, with an estimated 460 deaths from the disease. By comparison, in the same year, there were an estimated 40,410 deaths in women.¹

Male breast cancer was first recognized in ancient Egypt.² J. M. Wainwright³ first documented the lethality of male breast cancer in 1927. The first documented case of male breast cancer belongs to the 14th-century British physician John of Arderne,⁴ who discovered an enlarging mass beneath the right nipple of a priest in Colstone.

Before the 1990s, the incidence of male breast cancer remained stable.^{5–8} Since 1991, however, there has been an unexplained rise in incidence.^{9,10} By contrast, the incidence of female breast cancer has continued to increase across decades.⁶ The geographic distribution of male breast cancer correlates with that of female breast cancer, with the highest incidence in North America and northern Europe, and the lowest incidence in Finland and Japan. Most countries report an incidence of less than 1 per 100,000.¹¹

Like other rare conditions, discerning the epidemiology and pathogenesis of male breast cancer is challenging because of the limited data. In this chapter, we review the current literature to understand risk factors, presentation, diagnosis, and treatment options currently available for male breast cancer.

What are risk factors for male breast cancer?

Understanding the risk factors for male breast cancer is difficult because only small case-control studies have been performed and consensus data are lacking. The strongest and most consistently associated risk factors are age, family history, exposure to exogenous estrogens, abnormal testicular function, Klinefelter's syndrome, and radiation exposure^{11–34} (Table 36–1).

The incidence of male breast cancer increases exponentially with age^{5,7} but without the midlife decline in incidence characteristic of female breast cancer corresponding to the menopausal period.¹¹

Family history is a significant risk factor for male breast cancer.^{11,19,23} Several series have reported a family history of

breast or ovarian cancer in first-degree relatives of up to 22% of men with breast carcinoma who have not undergone prior genetic screening.^{35–43} In addition, data from the Surveillance, Epidemiology and End Results program have shown that men with a first-degree relative with breast cancer have nearly a fourfold risk for male breast cancer.⁴⁴

Male breast carcinomas are predominantly hormone sensitive, and it is believed that estrogen may play an etiologic role. Unfortunately, the actions of estrogen in the setting of breast carcinoma are not well understood.^{45–48} The strongest evidence for a causal role of estrogen in male breast cancer is suggested by the development of breast cancer in three transsexual men with histories of chronic oral estrogen intake.²⁸ Anecdotal cases of male breast cancer have also been reported in men treated with estrogenic hormones for prostate carcinoma.^{4,29,30,31} In addition, therapeutic treatment with digitalis, an estrogen-like drug, has been associated with male breast cancer.^{19,23}

Several case-control studies have suggested that testicular abnormalities are a risk factor for male breast cancer. It is hypothesized that testicular insufficiency leads to increased endogenous estrogen levels and, therefore, increased risk. Significant correlations have been made between male breast cancer and patients with a history of mumps orchitis,¹² gonadal injury,²⁶ inguinal hernia repair,²⁶ and undescended testes.¹³

One of the strongest risk factors for breast cancer in men is Klinefelter's syndrome, a condition resulting from the inheritance of an extra X chromosome. This condition is associated with testicular insufficiency, gynecomastia, and increased excretion of follicle-stimulating hormone. These individuals have low levels of androsterone, resulting in a high estrogen-to-androgen ratio. The frequency of this disorder has been estimated to be 1 to 2 per 1000 men.⁴⁹ About 4% of men with breast cancer have been reported to have this syndrome.⁵⁰ When compared with the frequency of breast cancer in the general population, it appears that breast cancer may be 20 to 66 times more common in patients with Klinefelter's syndrome.^{11,24,25}

Radiation exposure is a known risk factor for female breast cancer.^{29,51,52} There is similar evidence to suggest a link between male breast cancer and radiation exposure.^{32–34} Men with a history of childhood radiation treatments for thymic enlargement or pubertal gynecomastia are especially at risk.^{29,51}

Table 36–1 Risk Factors Associated with Male Breast Carcinoma

Demographic Factors High socioeconomic status ^{12–14} Race ¹⁵ Higher education ^{12,16} Jewish ancestry ^{12,13,17,18}
Lifestyle Factors Increased body mass index ^{14,19,20} Unmarried ^{11–14} Occupational exposure to electromagnetic fields ^{21,22} Employment in blast furnaces, rolling mills, and steel mills ¹²
Medical History First-degree relative with breast cancer ^{11,19,23} Klinefelter's syndrome ^{11,24,25} Testicular abnormalities ^{12,13,26} Liver disease ²⁷ Exogenous estrogen exposure ^{4,28–31} Radiation exposure ^{32–34} History of head injury ²⁶

Other risk factors implicated in male breast cancer are high socioeconomic status,^{12–14} single marital status,^{11–14} higher education,^{12,16} Jewish ancestry,^{12,13,17,18} race,¹⁵ liver disease,²⁷ increased body mass index,^{14,19,20} history of head injury,²⁶ exposure to electromagnetic fields,^{21,22} and history of working in blast furnaces, rolling mills, steel works,¹² and meat-processing plants.²³

Is gynecomastia a risk factor for male breast cancer?

Several case-control studies have reported a correlation between clinically apparent gynecomastia and male breast cancer.^{11,26} However, clinical gynecomastia is seen less frequently in the male breast cancer population than in the general population, suggesting that the relationship is not causal. Reports have shown that the incidence of clinically significant gynecomastia in male breast cancer patients ranges from 2.7% to 20%,^{29,36,53} whereas the incidence of gynecomastia in the general population ranges from 40% to 65%.⁵⁴

This argument is strengthened when looking at gynecomastia identified by histopathology. In a series from Memorial Hospital, Heller and colleague⁵⁵ found that 40% of cases of male breast cancer had a histopathologic diagnosis of gynecomastia. Similarly, Scheike and Visfeldt⁵⁶ noted in a series of 265 male breast cancer cases that clinical gynecomastia was present in 3.8% of cases, but microscopic gynecomastia was present in 26.6% cases. In a prospective study of 446 men with a histopathologic diagnosis of gynecomastia, no cases of male breast cancer were diagnosed at a median follow-up time of 22.2 years.⁵⁷ Of note, in 441 of these patients, unilateral excision of the breast tissue had been performed for diagnosis. Similarly, Lilleng and associates⁵⁸ reported that of 809 surgical biopsies for male breast masses, 96% were benign, with gynecomastia representing 91% of benign diagnoses.

In search of a biologic explanation of the relationship between gynecomastia and male breast carcinoma, a small number of studies have used molecular genetic and immunohistochemical techniques to examine tissue specimens containing gynecomastia and invasive male breast carcinoma.^{59–62} Using Comparative Genomic Hybridization, gains on chro-

Table 36–2 Genes Associated with Male Breast Carcinoma

Functional Class	Gene
DNA repair	<i>BRCA1</i> ^{41, 65, 66}
Cell cycle regulation	<i>BRCA2</i> ^{41, 65, 66}
Steroid hormone synthesis and regulation	<i>PTEN</i> ⁶⁷ <i>MLH1</i> ⁶⁸ <i>CHEK2</i> ⁶⁹ Androgen receptor ^{70–71} <i>CYP17</i> ⁷²

mosome 8q24 have been reported in both invasive male breast cancer and gynecomastia.⁶¹ Pepsinogen C and apolipoprotein D expression has been documented in gynecomastia, in situ male breast carcinoma, and invasive male breast cancers.^{61,62} Although these results suggest a relationship between gynecomastia and male breast cancer, further molecular genetic characterization is needed to prove or disprove a causal relationship.

Is there a genetic predisposition to male breast cancer?

In the past decade, inherited genetic mutations, particularly in the DNA repair genes *BRCA1* and *BRCA2*, have been identified as being partially responsible for familial breast cancer in women.^{63,64} Likewise, inherited genetic mutations have been associated with male breast cancer^{41,65–72} (Table 36–2). *BRCA2* is perhaps the most recognized gene associated with male breast cancer, although mutations in *BRCA1* have also been described. The most recent population-based studies of male breast cancer patients unselected for family history have identified *BRCA1* mutations in 0% to 11% and *BRCA2* mutations in 12% to 18%.^{41,65,66} The incidence of these mutations is highly variable among populations owing to regional differences in population genetics.⁷³ The risk for breast cancer conferred to men carrying a *BRCA* mutation is much greater than that of women carrying the same mutation.

Mutations in genes other than *BRCA1* and *BRCA2* have also been found in male breast cancer patients. A 10-fold risk for male breast cancer has been estimated for men carrying a specific deletion in the *CHEK2* cell cycle regulatory gene.⁶⁹ Mutations in genes important to steroid hormone synthesis including *CYP17* and the androgen receptor also have a high incidence in men with breast cancer.^{70–72} A mutant allele of the *MLH1* mismatch repair gene has been described in a patient with a family history of hereditary nonpolyposis colorectal cancer syndrome who subsequently developed breast cancer.⁶⁸ Germline *PTEN* mutations have been identified in male breast cancer patients with Cowden syndrome.⁶⁷ However, most male breast cancer cases have unknown genetic etiology.

Does male breast cancer present at a more advanced stage than female breast cancer?

Historically, male breast cancer patients present at more advanced stages than female breast cancer patients.^{55,74,75} The stage of presentation of male breast cancer patients from multiple studies was compared with the stage of presentation of

Table 36–3 Stage of Presentation of Male and Female Breast Cancer

female breast cancer patients at Memorial Hospital^{36,55,76–79} (Table 36–3). Distribution of stages 0, I, and II is largely similar in male and female patients. A large number of males initially present with stage III disease and T4 tumors. Therefore, delayed presentation and diagnosis continue to be of concern in male breast cancer.

What are the clinical features of male breast cancer?

Sixty to 90% of men with male breast cancer present with a subareolar mass.^{37–39,53,79–81} Nipple discharge is a presenting symptom in 5% to 15% of men,^{37,53} whereas skin ulceration is demonstrated in 7% to 10%.^{37,53} Paget's disease is present in only 5% of cases.⁸² The left breast is more frequently involved with carcinoma than the right breast.^{38,40,80} Bilateral carcinoma has been reported in up to 5% of patients^{29,37,83,84} and clinically evident lymphadenopathy is found in nearly 55% of cases.^{29,39,56,85}

The median duration of symptoms before diagnosis varies between 9 and 18 weeks in the United States,^{36,37,78} whereas a longer time from the onset of symptoms to diagnosis is reported in other countries.^{38,39,80,81} In the United States, the median age at diagnosis ranges from 58 to 65 years.^{36,37,55,79}

What is the appropriate workup of male breast enlargement?

Our approach to the evaluation of male patients with breast enlargement is outlined in Figure 36–1. Pertinent medical history is typically obtained, along with an assessment of risk factors including family history of breast or ovarian cancer, exposure to exogenous estrogens, abnormal testicular function, and prior radiation exposure. Alcohol intake is assessed, as well as medication use, with particular attention to those medications associated with gynecomastia. On physical examination, gynecomastia is characteristically concentric, tender, and rubbery in consistency. Although gynecomastia is more commonly a process that affects both breasts, it is occasionally unilateral. In contrast, cancer of the male breast is classically hard, irregular, eccentric, and nontender. Skin discoloration,

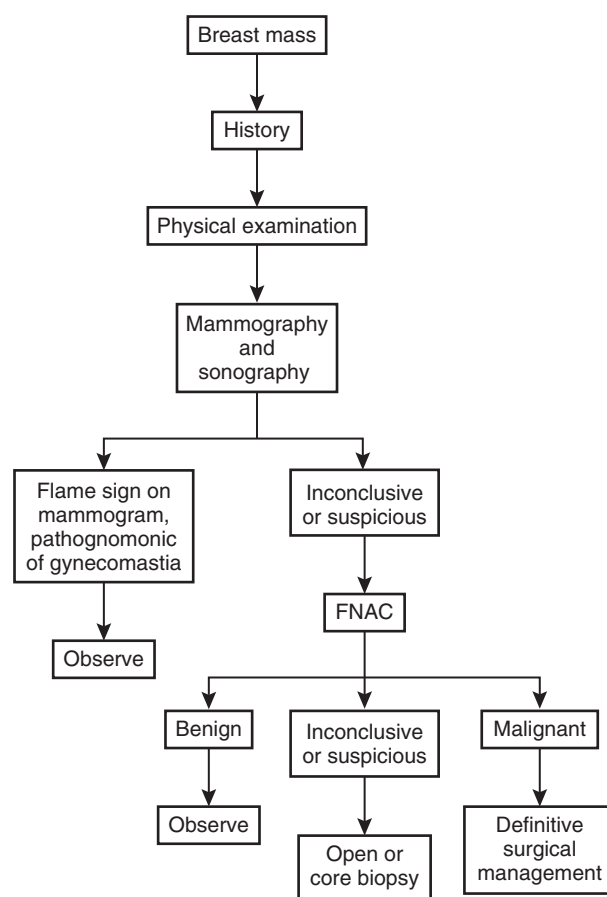

Figure 36–1 Algorithm for evaluation of male breast. FNAC, fine-needle aspiration cytology.

nipple ulceration, nipple discharge, and axillary adenopathy are concerning for malignancy and should be noted.

The differential diagnosis of male breast enlargement includes many benign and malignant processes, with gynecomastia being the most common cause of a male breast mass. The final histopathologic diagnosis of 187 men who underwent biopsy for breast mass is shown in Table 36–4.⁸⁶ Other reported benign causes of male breast mass include fat

necrosis,⁸⁶ abscess,⁸⁶ juvenile papillomatosis,⁸⁷ papilloma,⁸⁸ neurilemoma,⁸⁹ cavernous hemangioma,⁹⁰ fibroadenoma,⁹¹ spindle cell tumor,⁹² granular cell tumor,⁹³ leiomyoma,⁹⁴ and carcinoid tumor.⁹⁵ Malignant conditions other than infiltrating ductal carcinoma and ductal carcinoma in situ include multiple myeloma,⁸⁶ malignant lymphoma,⁸⁶ metastatic lung adenocarcinoma,⁸⁶ metastatic prostate carcinoma,⁹⁶ and metastatic melanoma.⁸⁶

Are radiology studies of value in diagnosis?

Recent studies suggest that mammography is both a useful tool to distinguish between malignant and benign male breast disease and an effective screening tool for the detection of contralateral cancer in patients with prior breast carcinoma (Fig. 36-2). A series of 104 prebiopsy mammograms of the male breast read by two independent radiologists blinded to

histopathologic diagnosis showed sensitivity of 92% and specificity of 90%.⁹⁷ For benign conditions, sensitivity was 90% and specificity 92%. In a retrospective review of 236 male patients who underwent imaging for male breast disease, mammography correctly identified 13 of 14 cancers.⁹⁸

These studies report the following frequencies of specific mammographic findings of male breast cancer: calcifications, 7% to 25%; retroareolar mass, 30% to 46%; eccentric mass, 54% to 60%; well-circumscribed mass, 23% to 60%; mass with irregular contour, 50% to 69%; nipple retraction, 43% to 58%; skin thickening, 21% to 58%; mass partially or completely obscured by gynecomastia, 21% to 50%.^{97,98}

On the mammogram, gynecomastia is classically identified by a flame-shaped glandular proliferation extending from the nipple into the fatty tissue of the breast.⁹⁹ This finding is pathognomonic of gynecomastia.

Ultrasound evaluation of the male breast is infrequently described. In a study by Yang and colleagues,¹⁰⁰ ultrasound examination of 8 patients with male breast cancer revealed that 50% of the carcinomas were complex cystic masses. In a study by Gunhan-Bilgen and colleagues,⁹⁸ ultrasound correctly identified 15 cancers in 14 patients; two of these cancers had small cystic components, whereas mammography missed one cancer in these patients. Their report also suggested that ultrasound is useful for determining the extent of skin and muscle invasion and axillary lymph node involvement. These studies suggest that the use of ultrasound and mammography together may increase the sensitivity for breast cancer detection over the use of either modality alone.

What is the role of fine-needle aspiration cytology?

Recent studies suggest that fine-needle aspiration cytology (FNAC) of the male breast is an important and reliable technique to distinguish between benign and malignant conditions. A combined series of diagnostic breast aspirations from 520 male patients performed at the Johns Hopkins Hospital, Memorial Sloan-Kettering Cancer Center, or University of Texas Southwestern Medical Center demonstrated overall sensitivity and specificity of 95.3% and 100%, respectively, with a diagnostic accuracy of 98%.⁸⁶ Similar results have been obtained from large studies performed at other institutions with dedicated cytopathologists.^{101,102}

What are the pathologic features of male breast cancer?

The pathologic features of male and female breast cancer are largely similar. Multiple series from the United States have shown that invasive ductal carcinoma accounts for 34% to 85% of male breast cancers, whereas tumors with a combination of invasive ductal cell and ductal carcinoma in situ constitute 18% to 48%.^{36,37,55,78} Intraductal carcinoma was the only diagnosis in 5% to 17% of cases.^{36,37,55,78} Medullary and tubular subtypes were identified in 1% to 2% of cases and inflammatory carcinoma in less than 1%.^{36,37,55,78,79} Lobular carcinoma is a rare diagnosis in male breast cancer because the male breast lacks the hormonal influences required to undergo lobular differentiation; however, anecdotal cases of

lobular carcinoma have been described in patients with Klinefelter's syndrome.¹⁰³ Case reports of male breast cancer with lobular carcinoma or lobular carcinoma in situ as a pathologic diagnosis should be questioned.

The presence of steroid hormone receptors is more common in male breast cancer than in female breast cancer. In most series, estrogen receptor positivity is as high as 80% to 85%, whereas progesterone receptor positivity approximates 75%.^{36–40,79,104,105} Although *HER-2/neu* is normally overexpressed in 20% of female breast cancers,¹⁰⁶ reports of its overexpression in male breast cancer are highly variable. *HER-2/neu* protein overexpression has been reported in 9% to 56% of male breast cancer cases in studies relying on immunohistochemical staining of the cellular membrane.^{107,108} Only one case of *HER-2/neu* gene amplification has been identified in studies using fluorescent in situ hybridization.¹⁰⁹

What is the surgical treatment of male breast cancer?

Radical mastectomy was the earliest performed surgical procedure for male breast cancer, and as with female breast cancer there is no difference in survival between modified radical mastectomy and the more morbid Halsted mastectomy.^{78,83,84,110} There are data to suggest that modified radical mastectomy offers no survival advantage over simple mastectomy, even in the setting of postoperative chemoradiation.⁷⁷ A role for radical mastectomy does exist when the tumor is fixed to the chest wall. Salvage mastectomy may be performed for locally advanced disease in medically unfit patients. Breast conservation is generally not applicable to males, owing to the small size of the breast.

The techniques of mastectomy and axillary dissection are essentially identical to those applied to female patients. Skin flaps should be developed to the same boundaries and should be of similar thickness in males and females. Axillary dissection should include levels I and II lymph nodes and is performed en bloc with the mastectomy.

Sentinel lymph node biopsy (SLNB) has been shown to be a successful technique for evaluating the axilla in male breast cancer patients. A study by Port and colleagues¹¹¹ showed successful identification of one or more sentinel lymph nodes in 15 of 16 male patients. SLNB is highly reliable in the hands of an experienced surgeon and is considered the standard of care for axillary evaluation of early-stage breast cancer in both male and female patients.

What is the role of adjuvant radiation therapy?

In female breast cancer patients, the goal of adjuvant radiation therapy is to improve locoregional control and overall survival in selected patients.¹¹² In female breast cancer, radiation therapy is typically given in the setting of breast-conserving therapy and to those patients considered at high risk for locoregional failure after mastectomy. The rationale behind adjuvant radiation therapy is the same in male breast cancer patients.

Studies examining the indications for radiation therapy in male breast cancer patients are limited. Anecdotal evidence

suggests a survival advantage in patients considered at high risk for relapse.^{113–115} Some data, however, suggest that the risk for local recurrence in early-stage disease is not reduced by the addition of radiation therapy.¹¹³ Until larger and better controlled studies are undertaken, the indications for adjuvant radiation therapy in male breast cancer patients remain uncertain.

What is the role of hormonal manipulation?

Orchiectomy is the oldest form of hormone therapy for disseminated male breast cancer.¹¹⁶ Orchiectomy has been reported to have a 75% to 80% response rate,¹¹⁷ stalling the progression of disease from 4 to 46 months.¹¹⁸ Other forms of surgical ablative hormone therapy, including adrenalectomy and hypophysectomy, are of historical interest only because of their associated morbidities.

Tamoxifen has become the most widely used hormonal therapy in male breast cancer.¹¹⁹ The earliest experience with tamoxifen was in the setting of disseminated disease, and there are data supporting its use as an adjuvant treatment in estrogen receptor-positive, node-positive patients. In a non-randomized trial of stage II and operable stage III patients, Ribeiro and Swindell¹²⁰ showed a 61% actuarial 5-year survival rate in tamoxifen-treated patients, compared with 44% for historical controls. In this same study, disease-free survival was 56% in tamoxifen-treated men, compared with 28% in the control group. Tamoxifen therapy may be used before or after orchiectomy, and failure to respond to one does not preclude a response to the other.¹²¹ Common side effects of tamoxifen include diminished libido in 29%, weight gain in 25%, and hot flashes in 20%. The effects produce an attrition rate of nearly 20% in male patients.¹²²

The selective aromatase inhibitor, anastrozole, is approved for first- and second-line treatment of female metastatic breast cancer. The first published case series of anastrozole therapy in five male breast cancer patients with metastatic disease showed disease stabilization without disease regression in three patients. This small series suggests that tamoxifen or orchiectomy is superior to anastrozole as first-line therapy for metastatic male breast cancer.¹²³

Other hormonal agents that have been used to treat male breast cancer include estrogen, cyproterone acetate (an antiandrogen with progestational properties), androgens, progestins, aminoglutethimide, and luteinizing hormone-releasing hormone analogues. All have been shown to have response rates ranging from 30% to 62%.^{117,124–126} Although data are lacking, these agents may be useful sequentially or in combination in patients who initially fail hormone therapy or in patients who experience relapse.¹²⁶

What is the role of adjuvant chemotherapy?

Owing to the low incidence of male breast cancer, only retrospective studies are available to determine the treatment benefit gained from adjuvant chemotherapy. The earliest studies of stage II and stage III patients receiving either (1) cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) or (2) 5-fluorouracil, doxorubicin, and cyclophosphamide (FAC) regimens showed a 5-year survival rate of 80% to 85%, which

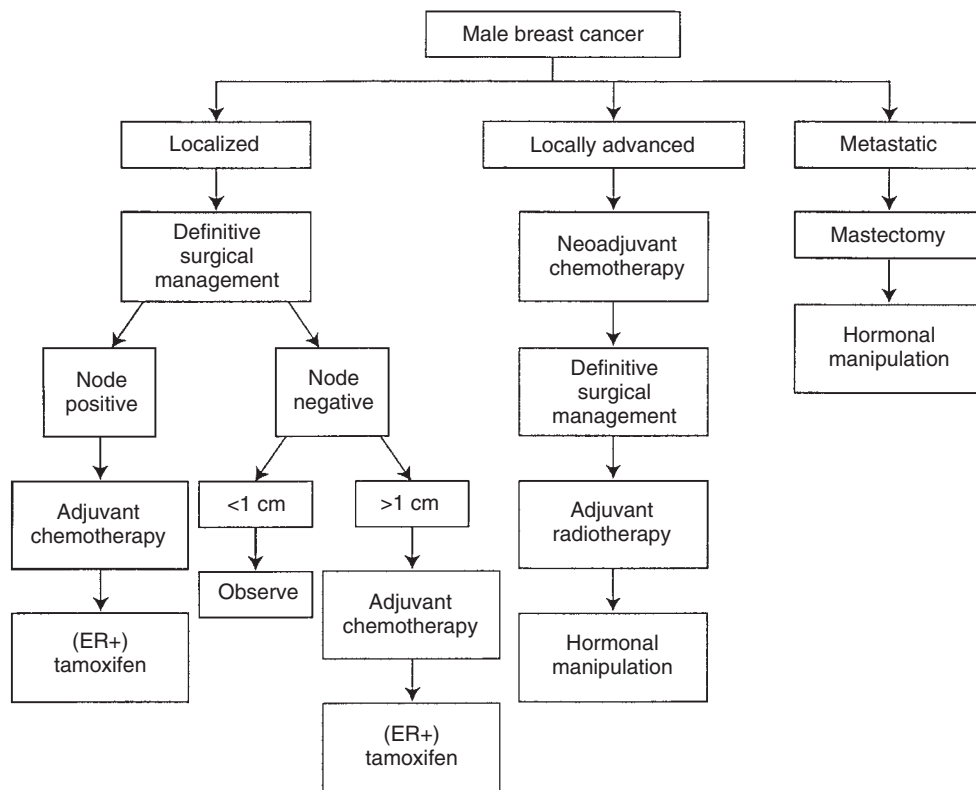

Figure 36-3 Algorithm for management of male breast cancer. ER, estrogen receptor.

is considerably higher than that of historical controls.^{127,128} In a study by Yildirim and Berberoglu,⁷⁷ both CMF and FAC chemotherapy provided a survival advantage in patients with operable disease. Other case series have failed to show a survival benefit from adjuvant chemotherapy,^{53,78} but the beneficial effects of chemotherapy in these patients may have been obscured by the high number of deaths due to comorbid conditions.

Trastuzumab, the monoclonal antibody against the epidermal growth factor receptor *HER-2/neu*, has been shown to improve survival beyond chemotherapy alone in female patients with breast cancers with *HER-2/neu* gene amplification. There is a single case report of a 52-year-old man who underwent radical mastectomy for pT4b breast cancer. He later developed a mastectomy scar recurrence and concomitant lung and thoracic spinal metastases that demonstrated *HER-2/neu* gene amplification. After receiving 9 months of trastuzumab therapy, he had partial clinical remission, including regression of pulmonary disease and stabilization of spinal metastasis.¹⁰⁹

There are currently no prospective randomized trials evaluating adjuvant chemotherapy in male breast cancer. Because male and female breast cancers are biologically similar, it is reasonable to follow treatment guidelines for female breast cancer until further data are available. Our approach to the management of male breast cancer is outlined in Figure 36-3.

What is the prognosis for male breast cancer?

Data from the largest and most recent retrospective studies of male breast cancer show overall 5- and 10-year survival rates

of 51% to 86% and 24% to 64%, respectively.^{36,37,39,53,78,109,129} Lymph node status is the strongest predictor of survival in all series: 5-year overall survival of lymph node-negative patients is 68% to 100%, compared with 47% to 73% for lymph node-positive patients.^{36,37,39,53,55,129} At 10 years, survival for node-positive patients is grimmer: 11% to 38%, compared with 46% to 79% for node-negative patients. Overall 5-year survival stratified by stage has been reported as 100% for stage 0, 83% to 100% for stage I, 63% to 83% for stage II, 45% to 74% for stage III, and 0% to 25% for stage IV.^{37,55,130}

Older literature reported a worse prognosis for male than female patients with breast cancer, which was attributed to the more advanced stage of disease at presentation.⁷⁴ Heller and colleagues⁵⁵ reported a markedly lower 10-year survival rate in node-positive males compared with node-positive females (11% vs. 43%), suggesting that when adjusted for stage, male breast cancer has a worse prognosis; however, in a study stratifying 130 node-positive patients by number of positive lymph nodes, male and female patients with breast cancer had similar prognoses.⁸⁵ Other studies have since supported this finding by suggesting that male and female breast cancers have similar disease-specific survival when compared by stage.^{37,39,40,131}

The most common sites of distant relapse in male breast cancer are bone, lung, brain, liver, lymph nodes, and skin.^{37,127} Reported distant relapse rates are 18% to 40%, whereas locoregional relapse rates are 5% to 19%.³⁷⁻⁴⁰ The mean time from initial diagnosis to distant relapse is about 26 months,^{74,132} and the average time from the diagnosis of metastasis to death is 8 to 26 months.^{74,132} About one third of patients develop metastatic disease.⁷⁴

What are prognostic factors?

The most important prognostic factors in male breast cancer are axillary lymph node involvement,^{36,37,53,77-79} tumor size,^{38,39,77,79,85,129} and hormone receptor status.^{53,78,103} Multiple studies have shown a survival advantage for patients with no involved axillary lymph nodes compared with those with positive nodes. In addition, a significant survival difference has been reported between patients with one to three positive lymph nodes and those with four or more.⁷⁸ Larger tumors and a delay in diagnosis of longer than 6 months from the onset of symptoms confer a survival disadvantage,³⁷ whereas hormone receptor-positive tumors confer a survival advantage.

Anelli and associates¹³³ analyzed 36 male breast cancers for *p53* mutations and detected mutations in 42%. This is similar to the incidence of *p53* mutations in female breast cancer. They did not show a significant correlation between *p53* mutation and survival. A study by Pich and colleagues¹⁰⁸ demonstrated that the combination of *c-erbB-2* and *p53* immunoreactivity significantly decreases survival in male breast cancer patients.

FUTURE DIRECTIONS

Male breast cancer is a rare disease. Creation of a national male breast cancer database could facilitate clinical observation of a large number of patients to evaluate adjuvant chemotherapy, radiation therapy, and hormonal therapies. Access to large numbers of patients with male breast cancer would also provide the biologic samples required for the identification of genes associated with familial and sporadic male breast cancer. This knowledge, along with the advances in radiographic imaging, could provide a better understanding of this rare disease.

Gynecologic Management of the Woman with Breast Cancer

John P. Curtin and Steven R. Goldstein

For many women, their gynecologist acts as the primary care physician and as such may be directly involved in the screening, diagnosis, and follow-up of women with breast cancer. The current residency competencies expectations include both didactic and clinical training in the teaching of breast self-examination, the principles of breast examination, workup of an abnormal breast examination, and knowledge of breast cancer treatment options. As discussed in the section of this chapter on selective estrogen receptor modulators (SERMs), gynecologists may also play a critical role in identification and management of preventive medications designed to reduce the overall incidence of breast cancer. This role has been embraced and promoted by the American College of Obstetricians and Gynecologists (ACOG). The ACOG committee opinion¹ emphasizes the following:

- Performance of breast examination, which is an integral part of the complete gynecologic examination
- Instructing patients in the technique of breast self-examination
- Ordering screening mammography
- Recognition that certain patients may be at higher risk because of family history
- Performance of breast diagnostic procedures when indicated

An ever-increasing role for the gynecologists is to provide expertise in the follow-up of women who have been diagnosed with breast cancer. As discussed in previous chapters, the number of cases of breast cancer has increased dramatically over the past 2 decades. With more than 200,000 new cases of breast cancer diagnosed in the United States annually and the majority of new cases now involving smaller lesions owing to increased awareness and improved screening, the number of women who report a history of breast cancer will continue to increase. These patients often have specific gynecologic problems and concerns related to their history of breast cancer or the treatment effects, and there is the continued need for routine gynecologic care.

GYNECOLOGIC CARE FOR THE PATIENT WITH BREAST CANCER

When should a patient consult with her gynecologist?

Patients should maintain their routine schedule for gynecologic examination during and after the diagnosis of breast cancer. A yearly gynecologic examination that includes at a minimum a review of medical history and focused examination should be done. The gynecologist must be sure to include a discussion of any acute changes following the treatment, including issues related to menopause, sexuality, and depression.² Young patients who continue to menstruate should be asked about future pregnancy plans and current contraception plans.³ For postmenopausal women or for those women who become menopausal during treatment, the most common questions involve issues of depression, sexuality, and management of menopausal symptoms. Although many young premenopausal women become amenorrheic during cytotoxic chemotherapy, the patient and physician should not assume that the patient will not regain her fertility potential after completion of chemotherapy. It is critical that patients continue to use contraception if pregnancy is possible.

What are the options for contraception after diagnosis of breast cancer?

Except for rare cases, hormonal contraceptives are contraindicated for women with a history of breast cancer. This includes oral contraceptives and injectable agents such as medroxyprogesterone acetate (Depo-Provera). In discussions with the patient, the gynecologist should determine whether the patient is interested in permanent sterilization or temporary contraception. If the patient desires permanent sterilization, two options are available for the woman (vasectomy can also be considered for the partner of a patient in a monogamous relationship). The first option for the patient is tubal ligation. This method is extremely successful (fewer than 5 to 10

failures per 1000 women sterilized) and can be accomplished on an outpatient basis. An added advantage for women with a history of breast cancer is the reduction in overall risk for ovarian cancer. The risk reduction associated with tubal ligation is about a 50% reduction in breast cancer incidence, equivalent to use of oral contraceptives for 5 years or longer.⁴

Barrier contraception with condoms and spermicide or diaphragm and spermicide is the most reliable option for the patient who is not ready to commit to permanent sterilization. The success rate for barrier methods approaches that of either an intrauterine device (IUD) or oral contraceptives, provided that the patient is highly motivated and regularly uses the chosen method of contraception regularly. An IUD may be considered as an alternative to barrier contraception; the efficacy rate is excellent. Before placement of an IUD, the patient must have recovered from any chemotherapy because chemotherapy-associated neutropenia may increase the risk for an IUD-associated infection.

For those patients who are closer to menopause or have a known *BRCA* gene mutation, a second option for permanent sterilization is a risk-reducing bilateral salpingo-oophorectomy (discussed later). This procedure reduces not only the overall incidence of gynecologic cancers but also the risk for a second breast cancer.

How are menopausal symptoms managed?

The standard treatment of menopausal symptoms remains use of estrogen replacement therapy (ERT). However, this therapeutic option is often contraindicated for women who have been diagnosed with breast cancer. In the past decade, there was an increase in the number of centers that proposed ERT (either alone or in combination with a progestin) for selected individuals.⁵ Studies that reviewed large population databases or small prospective trials were initiated to test the hypothesis that ERT could be safely administered to women after a diagnosis of breast cancer. However, in the past 2 years, several significant studies have been published that question the role of ERT in many women, especially those with breast cancer history. The Women's Health Initiative (WHI) has published a series of reports that have challenged the benefits and safety of ERT usage.⁶ More recently, a prospective study of hormonal replacement therapy in women with a history of breast cancer (HABITS) was stopped by the data safety monitoring committee because of a higher than acceptable rate of breast cancer recurrence or new primaries in the group of patients who were randomized to hormonal replacement therapy.⁷ The findings of these two studies taken together suggest that except for a rare patient who fails to respond to non-hormonal therapy, systemic ERT should not be prescribed for patients who have been diagnosed with breast cancer.

Patients who have significant hot flashes either from tamoxifen therapy or from menopause may be managed by other methods. Venlafaxine (Effexor) has been prescribed with reported success in lowering the intensity and frequency of hot flashes. The side effects can often outweigh the benefits.⁸ Many patients have tried nutritional or alternative medicine remedies with relief of symptoms. Generally, the use of alternative or complementary medications is safe, although some have raised the issue of the estrogenic effect of plant estrogens or phytoestrogens. Patients should always consult

with their treating physician before embarking on regular use of these agents.

Another common quality-of-life issue for menopausal women is vaginal atrophy; the most common complaints include vaginal dryness, lack of lubrication, and discomfort with intercourse. A number of nonprescription products have been marketed for the potential relief of these symptoms. Water-soluble lubricants have been reported to improve lubrication and decrease discomfort during intercourse. Vaginal moisturizers may also reduce the complaints related to dryness.

As described, the use of systemic estrogen is contraindicated in women with a history of breast cancer; however, in selected cases, topical estrogen may be used. Newer products, such as low-dose intravaginal estradiol delivery using a Silastic vaginal ring (Estring), have been studied in patients with prior diagnosis of breast cancer and significant symptoms of vaginal atrophy.⁹ These agents deliver a continuous dosage of estradiol to the vaginal epithelium. Although there is a small amount of absorption, the serum estradiol levels do not increase above the normal postmenopausal serum estradiol levels.

How does family history affect the gynecologic care of women with history of breast cancer?

As discussed in other chapters, about 5% of all breast cancers may be due to an inherited factor; in the United States, therefore, there will be about 10,000 cases of breast cancer annually owing to a hereditary syndrome.¹⁰ The importance of early identification of patients at risk is becoming increasingly important as new prevention and screening strategies are developed. Routine genetic testing for the most common genetic mutations is not warranted for the general population. The current recommendation is that a family history of breast or gynecologic cancer in one or more first-degree relatives should trigger a more thorough evaluation. First-degree relatives include sisters or mother. Multiple cancer cases in second-degree relatives (i.e., grandmothers, aunts, uncles, and cousins) should also raise suspicion, especially when all are linked to either the maternal or paternal side of the patient's family. There are several resources available that aid the clinician in assessing whether a patient may be at higher than average risk for carrying a gene mutation commonly linked to increased susceptibility to breast or ovarian cancer.

In the general population, the prevalence of identifiable gene mutations that will place the patient at increased risk for breast cancer is small. It is estimated that only 0.1% to 0.2% of the general population carries these genetic mutations. Routine testing of all patients has not been proposed; the patient who is referred for genetic testing is usually identified by family history or when newly diagnosed with a cancer. Some authors have suggested that if there is a 5% or greater chance of a woman's being a gene mutation carrier, testing to determine the presence or absence of known gene mutations is indicated. Estimates of prevalence of gene mutations based on family and personal disease characteristics are provided in Table 37-1.

The most common gene mutations associated with an increase risk of breast cancer are *BRCA1* and *BRCA2*; less

Table 37-1 Risk of *BRCA1* and *BRCA2* Mutations in Selected Populations

Family and Personal Disease Characteristics	Prevalence of Positive Test for <i>BRCA1</i> or <i>BRCA2</i> (%)
General population	0.1–0.2
Ashkenazi Jewish	2.0–2.5
Breast cancer at age < 36 yr	10
Breast cancer at age < 50 yr	6
Breast cancer, bilateral	15
Family history of breast cancer	5–15
Family history of breast and/or ovarian cancer	10–40

commonly, mutations of mismatch repair genes associated with hereditary nonpolyposis colon cancer (HNPCC) syndrome place the patient at increased risk. Individual practitioners have the option of providing the counseling and ordering the genetic tests directly or referring the patient thought to be at risk to a genetic counselor.

Patients with a more than 10% risk for a *BRCA1* or *BRCA2* mutation include those with breast and ovarian cancer within the same family at any age, particularly if within the same woman; a history of male breast cancer within the same family; multiple cases of early-onset breast cancer disease (age < 50 years) in the same family; and the presence of bilateral breast cancers.¹¹

How are patients followed once they are identified as being at risk?

Patients have three general options if they are at an increased risk for developing gynecologic cancer due to either known genetic mutation or suggestive family history.

Normal Gynecologic Care

The first option is to maintain normal gynecologic care and follow-up with no added screening studies or testing. For some women, this is acceptable and desirable. For most women, however, some additional testing or risk-reducing surgery is recommended.

Additional Screening Studies

If the patient elects to be followed and wants additional screening studies, the patient must be advised that currently there are no proven screening methods to detect early ovarian, tubal, or peritoneal cancers. Some studies have suggested that regular screening transvaginal ultrasound (TVUS) examination may detect earlier-stage ovarian cancer. Other studies have examined the utility of serum tumor markers. In the absence of a proven method, it has been recommended that patients at risk for gynecologic cancer be examined twice yearly and have TVUS one or two times per year combined with serum CA-125 determinations.

The evaluation of the patient with an abnormal imaging study should include a repeat physical examination. If the serum tumor markers were normal, a repeat and possibly expanded panel of tumor markers should be obtained. In

general, there should be a lower threshold for surgical intervention when the patient has a prior diagnosis of *BRCA* mutation. Although patients with *BRCA* mutation are at risk for developing metastatic disease involving the ovaries, in retrospective series of patients undergoing surgery for newly discovered ovarian mass, new gynecologic primary cancers are more common than metastatic disease.¹²

Given the lack of established screening methods, patients should be encouraged to enroll in prospective screening studies. These ongoing screening studies will hopefully clarify the emerging role of new serum testing as well as study the role of ultrasound evaluation.¹³

Risk-Reducing Surgery

Another option for patients at risk is to have a surgical procedure to remove the organs at risk. Because patients with *BRCA1* or *BRCA2* mutation are at risk for ovarian, tubal, and peritoneal primary cancer, surgery can reduce but not eliminate the potential for future *BRCA1*- or *BRCA2*-associated cancer.¹⁴ This recognition has resulted in a change in terminology that more accurately conveys the intent of the surgical procedure. Instead of a “prophylactic” bilateral salpingo-oophorectomy, the preferred term should be “risk-reducing.” The decrease in risk is difficult to calculate exactly, but data from clinical reports as well as from risk modeling suggest that the reduction in risk is greater than 90%¹⁵ (Fig. 37-1). This can be translated for the *BRCA1*-positive patient into the reduction from a 30% lifetime risk for ovarian, tubal, or peritoneal cancer to a less than 3% risk for peritoneal cancer after risk-reducing salpingo-oophorectomy.

When the decision is made to proceed with a risk-reducing salpingo-oophorectomy (RRSO), this can usually be performed as a laparoscopic procedure. The laparoscopic approach has the advantage of minimal discomfort and can be performed as an outpatient procedure. There is some debate as to whether removal of the uterus is indicated as part of the risk-reducing surgery. It is our practice not to perform routine hysterectomy at the time of the RRSO unless there is specific uterine pathology. Others have advocated for inclusion of hysterectomy at the time of RRSO because of the potential association of papillary serous endometrial carcinoma of the uterus with *BRCA1* and *BRCA2*.¹⁶ Other authors have postulated that any laparoscopic procedure removing only the tubes and ovaries would leave behind a small portion of the fallopian tube where the tube traverses the cornual region of the uterus.

Before the RRSO, the patient should be examined and have a recent TVUS and serum CA-125. Even if these tests are normal, there is still a small chance that at the time of the laparoscopic procedure, a small, clinically occult ovarian cancer will be discovered. A critical part of the consent process should include a discussion of the extent of surgery that the patient agrees to as well as the surgical capability of the surgeon. Processing of the specimen by the pathologist is also important, and the surgeon should communicate directly with the pathologist regarding the indications for RRSO.

The procedure is performed using a three- or four-trocar approach. The patient is placed under general anesthesia and laparoscopy initiated. It is our preference to use an open laparoscopic approach in all cases. After establishment of the pneumoperitoneum, a thorough inspection of the entire

Figure 37–1 Prospective study of two cohorts of women at risk for breast cancers or gynecologic cancers related to *BCRA*. The number of women diagnosed with either gynecologic or breast cancer was significantly reduced for those patients who elected to undergo a risk-reducing salpingo-oophorectomy. (Data from Kauff ND, Satagopan JM, Robson ME, et al. Risk-reducing salpingo-oophorectomy in women with a *BRCA1* or *BRCA2* mutation. *N Engl J Med* 2002;23;346:1609–1615.)

Number at risk

Salpingo-oophorectomy	98	69	36	17	11	4	0
Surveillance	72	44	28	16	9	5	1

abdomen is performed. This includes the peritoneal surfaces of the diaphragm and liver as well as the pelvis.

Rather than the typical pathologic examination of bilateral salpingo-oophorectomy specimens, the RRSO should be submitted to the pathologist in its entirety, with multiple sections obtained. Protocols for processing of these specimens have been published.¹⁷

Surveillance after RRSO is uncertain. Several reports have estimated that primary peritoneal papillary serous (PPPS) carcinoma following RRSO may be as high as 1 in 20 patients (5%). There are no accepted screening tests for these cancers; current ongoing studies are following patients with serial serum CA-125 determinations. There is no role for routine imaging studies such as ultrasound or computed tomography (CT) scans. As would be expected, most have a clinical presentation similar to that of epithelial ovarian carcinoma (EOC). The majority are stage III at the time of diagnosis. When the diagnosis is suspected, the workup should include CT scan imaging. Treatment is similar to that for EOC. The standard treatment includes initial surgical staging and debulking, followed by combination chemotherapy with carboplatin and paclitaxel.

Are additional gynecologic tests necessary when a patient has a history of breast cancer?

Unless the patient has specific complaints, the annual physical examination is sufficient. Patients should be followed with regular cervical cytology according to their own history and risk profile. The ACOG and the American Cancer Society have updated the cervical cytology screening recommendations. After age 30 years, patients who have had normal yearly Papanicolaou (Pap) smears can be followed with Pap smears every 2 to 3 years. Combining human papillomavirus testing with a Pap smear may allow for longer intervals between Pap smears, provided that both of the tests are normal. Patients do not appear to benefit from routine ultrasound examination or endometrial biopsy if on tamoxifen therapy.¹⁸

When do patients need to be concerned about tamoxifen-associated cancer?

In nearly all cases, endometrial cancer is associated with early warning signs. The most common sign is abnormal bleeding. For younger women, who may be menstruating normally, concerning changes could include periods that are heavier than usual or bleeding between periods. For postmenopausal patients, any vaginal bleeding should be a signal to both the patient and the physician that further evaluation is indicated. In addition, a persistent discharge should also be evaluated.

The most common reported cancer in patients taking tamoxifen is adenocarcinoma of the endometrium. This cancer is commonly associated with hyperestrogen states, including obesity, and unopposed estrogen replacement therapy. The risk for a tamoxifen-associated cancer depends on length of treatment.¹⁹ After 5 years of tamoxifen therapy, the risk for endometrial cancer is about 6 cases per 1000 women. Although this is an increase in the expected rate of endometrial cancer, it is important to remember the significant role of tamoxifen in reducing the chance of a second breast cancer or a recurrence of breast cancer. Most studies have shown that the cancers associated with tamoxifen are similar to other estrogen-associated cancers in that the cancers tend to be low-grade, early-stage cancers confined to the uterus.²⁰ These types of tumors are generally cured by surgery alone.

Less commonly, tamoxifen is associated with rare uterine tumors known as *uterine sarcoma*. Based on a series of case reports in the literature, in 2002, the U.S. Food and Drug Administration (FDA) added information to the tamoxifen label advising patients and their physicians that tamoxifen usage can be associated with an increased risk for uterine sarcoma. In a trial of more than 8000 women with an intact uterus who were randomized to either tamoxifen or a placebo, there were a total of 70 cases of endometrial adenocarcinoma; 53 cases of endometrial cancer occurred in the tamoxifen-treated patients, and 17 cases occurred in the placebo group. There were 4 cases of uterine sarcoma in the group of more than 8000 women; however, all 4 cases occurred in women

who received tamoxifen.²¹ It is important to remember that these tumors are rare and that the increased risk associated with tamoxifen, although significant, is still quite low. The symptoms of uterine sarcoma are similar to those of the more common adenocarcinoma. Unfortunately, uterine sarcomas can be more difficult to treat. Uterine sarcomas are more commonly spread beyond the uterus at the time of diagnosis, and the overall mortality rate is higher for uterine sarcomas than for adenocarcinomas of the uterus.

How should abnormal vaginal bleeding be evaluated?

The patient is usually examined in the office. If the patient has not had cervical cytology testing within the past year, a specimen is obtained. Any cervical abnormalities should be noted; if noted, a biopsy can be performed if necessary. In most patients, an endometrial biopsy is performed in the office. The preferred instrument is a small flexible suction biopsy instrument similar to the Pipelle device. For most patients, this procedure is associated with mild cramping, which can be minimized by giving the patient a nonsteroidal anti-inflammatory drug (NSAID) just before the procedure. When the biopsy is performed, the size of the uterus as well as the amount of tissue obtained (i.e., minimal versus abundant) should be noted. An endocervical biopsy may be omitted during the initial evaluation, but in the patient with persistent bleeding, this should be performed to rule out an endocervical lesion.

When the endometrial biopsy cannot be obtained in the office, consideration should be given to performing a dilation and curettage (D&C) under anesthesia. Indications for a D&C would include persistent bleeding or progressive growth in the thickness of the endometrium. The D&C is considered to be the best diagnostic procedure for patients with either persistent abnormal bleeding or postmenopausal bleeding. Many practitioners will also perform a hysteroscopy at the same time to better visualize the endometrium.

Ultrasound may be helpful in triaging patients, especially postmenopausal patients. If ultrasound demonstrates a thin endometrium with no areas of thickening or polyps, then close follow-up may be an alternative to D&C. As discussed later, sonohysterography may be an important diagnostic aid in the evaluation of the patient taking tamoxifen who is symptomatic. The interval for follow-up should be about 3 months.

GYNECOLOGIC EFFECTS OF SELECTIVE ESTROGEN RECEPTOR MODULATORS (SERMs)

SERMs are synthetic compounds that bind to estrogen receptors and exert estrogen-agonistic effects in some tissues (i.e., bone, lipid) while being estrogen antagonists in other tissues (i.e., breast). Currently, two SERMs, tamoxifen and toremifene, are employed for treatment of breast cancer; tamoxifen is also FDA approved for prevention of breast cancer in high-risk women. Raloxifene is a SERM approved for

prevention and treatment of osteoporosis in postmenopausal women. However, it sharply reduced invasive and noninvasive breast cancer in women with osteoporosis during 4 years of therapy compared with placebo²² and is currently being studied in a head-to-head comparison with tamoxifen in high-risk women (the Study of Tamoxifen and Raloxifene [STAR] trial). Other SERMs have had phase III trials suspended because of an increase in urinary incontinence and uterine prolapse.²³ Still other SERMs are in various stages of development. It appears that the gynecologic effects of SERMs are variable but obviously important in determining their utility for treatment or prevention of breast cancer.

Tamoxifen

Tamoxifen was the first clinically available SERM. Originally, it was referred to as “antiestrogen” because of its properties in the breast. Like other SERMs, it also exerts an antiresorptive effect on bone, thus improving bone mineral density in postmenopausal women as well as lowering total and low-density-lipoprotein cholesterol. It was developed in 1966 and FDA approved in 1978. It is the most widely prescribed anticancer drug in the world, currently with more than 12,000,000 woman-years of experience. It results in significant improvement in recurrence-free and overall survival rates in postmenopausal women with breast cancer.²⁴ In the middle to late 1980s, a series of letters to the editor and case reports started to suggest an association between endometrial carcinoma and breast cancer patients receiving tamoxifen.^{25,26}

What is the evidence that tamoxifen causes endometrial abnormalities?

The first prospective study was published in 1990 by Neven and colleagues.²⁷ They reported on 16 patients followed prospectively with hysteroscopy for 36 months. Eight of these postmenopausal patients maintained the atrophic, inactive endometrium that one would expect in such postmenopausal patients. Seven developed proliferation, including four polyps, and one developed adenocarcinoma.

Gal and associates²⁸ reported on 38 patients who were followed prospectively for just 12 months. Eighteen percent (7 patients) developed hyperplasia, causing the authors to recommend “periodic blind endometrial sampling.”

What is the role of transvaginal ultrasound?

At about the same time, TVUS had been introduced. The vaginal probe was employed in a variety of clinical settings. One early publication²⁹ described the use of TVUS before endometrial sampling in patients with postmenopausal bleeding. The maintenance of a thin distinct endometrial echo thinner than 5 mm was uniformly associated with lack of significant tissue (Fig. 37–2). Screening with TVUS has become the mainstay of current therapy in postmenopausal women with bleeding. A thin distinct endometrial echo has an extremely high negative predictive value (99%), and such patients can avoid endometrial sampling and its expense, discomfort, and risk.³⁰

Figure 37-2 Long-axis transvaginal ultrasound view of a postmenopausal patient with bleeding. This thin distinct endometrial echo has a 99% negative predictive value in excluding significant tissue.

Figure 37-3 Transvaginal long-axis ultrasound view of a tamoxifen-treated patient. The central uterine echo measures 18 mm. Previously, a picture like this was misinterpreted as “endometrial” thickening.

As a result of the newly discovered association of endometrial carcinoma and tamoxifen therapy, many tamoxifen patients were examined with TVUS. An unusual ultrasonographic appearance of the uterus in patients receiving tamoxifen was first reported in 1994.³¹ Some patients displayed bizarre heterogenous echo patterns centrally located in the uterus, which represent a loss of the normal junctional zone between the basalis of the endometrium and the proximal myometrium. This was being misinterpreted as endometrial thickening on ultrasound. When viewed with saline infusion sonohysterography, such changes are often shown to be microcysts, which represent dilated cystic atrophic glands that can be located in the basalis of the endometrium, in the proximal myometrium, or even within polyps (Figs. 37-3 to 37-5).

A collective experience with tamoxifen was published by Schwartz and colleagues in 1998,³² who found a 27% incidence of polyp formation, a 4% incidence of carcinoma, and a 9% incidence of proliferation or hyperplasia. Only 25% of tamoxifen patients maintained a thin endometrial echo 5 mm

Figure 37-4 Same patient as in Figure 37-3 when viewed with saline infusion sonohysterography. The sonolucent (black) area centrally located is the fluid that has been instilled. The endometrium surrounding the fluid is thin, compatible with inactive atrophic change. The small sonolucencies under the surface epithelium represent microcystic change and are dilated atrophic cystic glands in the basalis of the endometrium and the proximal myometrium. The endometrium is outlined by calipers and is thin, measuring 2.8- and 2.5-mm, respectively.

Figure 37-5 Hysteroscopy of the patient whose transvaginal ultrasound is pictured in Figure 37-4. Notice that the surface functionalis of the endometrium is thin and pale, compatible with atrophy. Coarse vessels are also typical of atrophic changes. There are noticeable blebs compatible with the microcystic change seen on ultrasound.

or smaller, although ultimately 59% of patients demonstrated atrophic endometrium but often required sonohysterography to prove it. In that report, a surveillance algorithm of patients receiving tamoxifen therapy was proposed. Unenhanced TVUS was performed. If the endometrial echo remained thin and distinct, measuring 5 mm or less, inactive atrophic endometrium was assumed, and follow-up was undertaken at appropriate intervals. If the central uterine echoes were thickened, the patient was interrogated with saline infusion sonohysterography. If there was thin endometrium surrounding the fluid and less than 3-mm single-layer measurements, with or without microcystic change, the patient was deemed to have inactive atrophic endometrium and followed at appropriate intervals, whereas any abnormal endometrial findings,

Figure 37-6 Saline infusion sonohysterogram of a tamoxifen-treated patient. A large centrally located polyp is seen. Small areas of microcystic change are seen within the polyp (arrows). The endometrium surrounding the fluid is thin, compatible with atrophy.

Figure 37-7 Operative hysteroscopy of the patient in Figure 37-6. Notice that the large tamoxifen-induced polyp has a similar surface appearance to that in the patient depicted in Figure 37-5.

more than 3-mm single-layer endometrial thickness, or focal lesions such as polyps were evaluated under direct vision by hysteroscopy (Figs. 37-6 and 37-7).

Should tamoxifen patients have ongoing endometrial surveillance?

In 1996, the Gynecologic Practice Committee of the ACOG issued an opinion relative to tamoxifen and endometrial cancer,³³ in which they stated,

Women with breast cancer should have annual gynecologic examinations, including Pap test and bimanual rectal vaginal examinations. Any abnormal bleeding, including bloody discharge, spotting, or any other gynecologic symptoms should be evaluated thoroughly. Any bleeding or spotting should be investigated. Practitioners should be alert to the increased incidence of endometrial malignancy. Screening procedures or diagnostic test should be performed at the discretion of the individual gynecologist.

However, in April 2000, the same gynecologic practice committee altered its opinion.³⁴ At that point, they stated that

... because screening tests have not been effective in increasing the early detection of endometrial cancer in women using tamoxifen and may lead to more invasive and costly diagnostic procedures they are not recommended.

Is there a role for pretreatment screening?

This controversy about appropriate endometrial monitoring and surveillance of breast cancer patients treated with tamoxifen needs to be reexamined in light of research published by Berliere and coworkers.³⁵ Their initial publication involved 264 postmenopausal women with newly diagnosed breast cancer. They all had baseline TVUS. If the endometrial echo was larger than 4 mm, outpatient hysteroscopy with biopsy was performed. Seventeen percent of these asymptomatic postmenopausal women had baseline lesions (almost entirely polyps). All polyps were removed, and all patients were treated with tamoxifen. The incidence of atypical hyperplasia was significantly higher in the group that was abnormal initially and then treated ($P = .009$). Berliere's group updated their data several years later.³⁶ At that point, 575 patients with breast cancer had been studied up to 5 years, and 16.6% had endometrial polyps before tamoxifen therapy. In the group with no initial polyps, which is referred to as "squeaky clean," 12.9% developed polyps, and 0.7% developed atypical hyperplasia. In the group that had initial polyps removed and then were treated with tamoxifen, 17.6% developed benign polyps, and 11.7% developed atypical hyperplasia. Thus, there appear to be two distinct groups of women newly diagnosed with breast cancer in the postmenopausal state: those with initial polyps and those without initial polyps. The group with initial polyps represents a high-risk group, with 18 times the risk for developing atypical hyperplasia of the endometrium on tamoxifen therapy and with 1.5 times the risk for developing benign endometrial polyps subsequently. Such systematic pretreatment screening can identify the high-risk group. These patients may require ongoing surveillance, whereas the low-risk group may not and can be followed according to the ACOG Gynecologic Practice Committee Opinion.

What about SERMs and breast cancer prevention?

Breast Cancer Prevention Trial

In 1992, the National Surgical Adjuvant Breast and Bowel Project (NSABP) launched a prevention trial using tamoxifen. A total of 13,388 women aged 35 years or older who were deemed at high risk for breast cancers were enrolled at numerous sites throughout the United States and Canada. The overall incidence of breast cancer in the tamoxifen group was 3.4 cases per 1000, compared with a breast cancer incidence in the placebo group of 6.8 cases per 1000.³⁷ The trial was stopped 14 months before its planned completion because the Data and Safety Monitoring Board felt it was unethical to continue to allow one half of the participants, deemed to be at high risk for developing breast cancer, to continue to take placebo in view of the dramatic reduction of both invasive and noninvasive breast cancer in the tamoxifen-treated group.

Table 37–2 Black Box Warning Added to the Labeling for Tamoxifen by the FDA in 2002

NEW TAMOXIFEN LABELING: HEALTHY PATIENTS ADVERSE EVENTS				
	Tamoxifen	Placebo	RR	CI
Endometrial adenocarcinoma	2.2/1000 pt years	0.71/1000 pt years	Not given	
Uterine sarcoma	0.17/1000 pt years	0.00/100 pt years	Not given	
Stroke	1.43/1000 pt years	1.00/1000 pt years	1.42	(0.82–2.51)
Pulmonary embolism	0.75/1000 pt years	0.25/1000 pt years	3.01	(1.15–9.27)
BENEFICIAL EFFECTS				
Breast cancer	6.49/11000 pt years	3.38/1000 pt years	0.49	$P < .00001$

CI, confidence interval; RR, relative risk.

The trial, however, made available for the first time large-scale information about the effects of tamoxifen on healthy women. Previously, all studies of tamoxifen had been in women with breast cancer. The overall relative risk (RR) for endometrial cancer associated with tamoxifen therapy in healthy women was 2.53 (95% confidence interval [CI], 1.35%–4.97%). However, when further analyzed by age, the RR in women older than 50 years was 4.01 (95% CI, 1.70%–10.90%), whereas the RR in women aged 49 years or younger was 1.21 (95% CI, 0.41%–3.60%). Although menopausal status was not reported, this arbitrary breakdown into women younger than 50 years and older than 50 years is the closest thing to a premenopausal and postmenopausal group because the average age of menopause is 51.4 years.

In October 1998, based on these trial results, the FDA approved tamoxifen for the primary prevention of breast cancer in women at high risk for the disease. They recommended that the use of tamoxifen be limited to high-risk women because of the potentially serious side effects seen in the clinical trials, especially in women older than 50 years. The FDA did not actually determine high risk, but it made the recommendation that the decision to use tamoxifen as a prophylactic chemopreventive therapy needed to depend on a thorough evaluation of a woman's personal, family, and medical history; her age; and her understanding of the assessment of the risks and benefits of treatment.

What are the uterine effects of tamoxifen in women who do not have breast cancer?

In the NSABP's prevention trial, there were 15 cases of endometrial cancer in the placebo group.³⁷ Fourteen of these were revealed to be International Federation of Gynecology and Obstetrics (FIGO) stage I, and one was revealed to be FIGO stage 4. All 36 cases of endometrial carcinoma in the tamoxifen group were FIGO stage I. In May 2002, updated data from the trial were presented on 8306 women with an intact uterus with a median follow-up of 6.9 years and on all those who used tamoxifen for at least 2 years.³⁸ It revealed adenocarcinoma in 53 cases of tamoxifen therapy (52 FIGO stage I, 1 FIGO stage III), compared with 17 cases in the placebo

group (16 FIGO stage I, 1 FIGO stage IV). Furthermore, there were 4 cases of uterine sarcoma in the tamoxifen group and no cases in the placebo group. Therefore, in 2002, the FDA added a "black box warning" to the label of tamoxifen that was directed at the use of breast cancer prevention and not treatment. This warning is summarized in Table 37–2.

Raloxifene

Like tamoxifen, raloxifene is also a SERM. It is a benzothio-phenone derivative, unlike the triphenylethylene family from which tamoxifen is derived. Raloxifene, not unlike tamoxifen, was originally investigated as a treatment for advanced breast cancer. Preclinical studies as summarized by Hol and associates indicated that raloxifene had an antiproliferative effect on both estrogen receptor–positive mammary tumors and estrogen receptor–positive human breast cancer cell lines.³⁹ In the 1980s, however, a small phase II trial revealed that raloxifene had no further antitumor effects in postmenopausal women with advanced breast cancer in whom tamoxifen therapy had failed.⁴⁰ After information had surfaced about the neoplasia-inducing capabilities of tamoxifen on the uterus of postmenopausal women,²⁷ there was renewed interest in raloxifene.

What are the effects of raloxifene?

Raloxifene has SERM-like properties in that it has estrogen agonistic activity on bone remodeling and lipid metabolism. It was FDA approved for prevention of osteoporosis in postmenopausal women in December 1997. Its indication was extended to treatment of osteoporosis in October 1999. In terms of its effect on the endometrium of postmenopausal women when compared with placebo,⁴¹ there were no differences in endometrial thickness, endoluminal masses, proliferation, or hyperplasia. Raloxifene did not cause endometrial hyperplasia or cancer and was not associated with vaginal bleeding or increased endometrial thickness as measured by TVUS. However, in this, the only study of raloxifene with the uterus as the primary end point, women with any endometrial abnormality were excluded from the study. The study was a

1-year trial whose objective was to “analyze uterine effects of raloxifene in a general population of postmenopausal women with a normal endometrial at baseline.” By excluding women with any endometrial abnormality, this becomes a study of low-risk women. Thus, a 5% incidence of polyps in 1 year in the group taking 60 mg of raloxifene must be compared with a 12.9% incidence of polyps in Berliere’s low-risk tamoxifen group,³⁶ which had an average follow-up of more than 2 years (range, 1 to 5 years). The lack of any hyperplasia in the raloxifene group and the 2% incidence in the placebo group in this raloxifene uterine safety study needs to be compared with the 0.7% hyperplasia in the Berliere data. Thus, the utility of this uterine safety study with raloxifene may be diminished. Still, at 1 year in those women with a clean endometrium to begin with, there was no estrogen-like effect, and raloxifene did not behave significantly differently from placebo.

The published results from the Multiple Outcomes of Raloxifene Evaluation (MORE) trial provide a “real-world” experience with raloxifene in the endometrium.⁴² There was no pretreatment selection. After 4 years, the RR of endometrial carcinoma with raloxifene compared with placebo was 0.91 (95% CI, 0.31%–2.70%). The only comparator for tamoxifen in women not already diagnosed with breast cancer was the RR of 4.01 (95% CI, 1.7%–10.90%) in the women older than 50 years in the NSABP prevention trial. Thus, any concerns about raloxifene in the endometrium brought by the uterine safety study, excluding the seemingly high-risk patients, are easily quelled by the real-world data comparing the MORE trial and the NSABP prevention trial.

What are other gynecologic effects of SERMs?

Pelvic Organ Prolapse and Urinary Incontinence

Levormeloxifene was a SERM developed by Novo Nordisk (Princeton, NJ) for the purpose of treatment and prevention of postmenopausal osteoporosis. Structurally, it is related to ormeloxifene used in India as an oral contraceptive under the name Centhroman since the 1980s. In 1998, levormeloxifene was in phase III trials that were suspended after 10 months because of adverse events that were mainly gynecologic but also gastrointestinal and genitourinary.²³ The RR for uterovaginal prolapse with levormeloxifene compared with placebo was 3.44 (95% CI, 2.13%–5.56%). The RR for urinary incontinence was 4.99 (95% CI, 3.55%–7.00%). Furthermore, the RR for having an unusual ultrasound appearance, discussed above with tamoxifen, was 14.96 (95% CI, 8.60%–26.00%). Those patients reporting leukorrhea as an adverse event had a RR of 14.30 (95% CI, 9.60%–21.51%). Postmenopausal atrophy of support elements is a precipitating factor in the development of genital prolapse. It is unclear whether this is simply an aging phenomenon or related to estrogen deprivation. No randomized trials exist. The pathogenesis of pelvic organ prolapse and urinary incontinence are poorly understood. Associated factors include increased age, increased parity, smoking, obesity, and chronic obstructive pulmonary disease. Connective tissue is weakened in aging as a result of decreases in collagen content.

Neither tamoxifen nor raloxifene has been associated with pelvic floor relaxation. In a post hoc analysis based on about 7000 postmenopausal women who had an intact uterus when

they entered the study, 3 years of raloxifene therapy was associated with a significant reduction in the risk for pelvic floor surgery (50%).⁴³ The mechanism by which SERMs affect pelvic floor relaxation is not clear. The presence of estrogen receptors in pelvic floor tissues indicates that this region is a target for estrogen and may respond to SERMs. Similar to the known effects on collagen metabolism in bone tissue, SERMs may also affect tissue remodeling in the pelvic floor.

Genital Tract

Several studies suggest that tamoxifen has estrogenic effects in the vagina. In a study comparing postmenopausal women who had breast cancer with healthy, age-matched controls, the vaginal pH in the tamoxifen-treated group was significantly lower and was comparable with the pH levels in fertile women. Two thirds of tamoxifen-treated women had well-estrogenized vaginal smears, compared with none in the control group.⁴⁴ In the NSABP prevention trial, tamoxifen was associated with an increase in vaginal discharge that caused leukorrhea that was “moderately bothersome or worse” in 29% of patients, compared with 13% in the placebo group.³⁷ Although the effects of raloxifene on the vaginal mucosa have not been studied directly in clinical trials, raloxifene has not been associated with symptoms related to vaginal atrophy, including vaginitis, leukorrhea, or dyspareunia.⁴⁵ Droloxifene, another triphenylethylene derivative in the tamoxifen family, has also been associated with an increase in vaginal discharge.⁴⁶

Unusual Ultrasound Appearance

The unusual ultrasound appearance mistaken for endometrial thickness was also found in a phase II trial of levormeloxifene. In that study, 65% of all women treated with levormeloxifene had an endometrial thickness above 8 mm after 12 months, compared with 0% in the placebo group. Endometrial biopsy at 12 months, however, revealed no cancers or hyperplasias, 18% “weakly proliferative,” and 59% inactive or atrophic endometrium.

Idoxifene was also found to produce a dose-related “thickening” on TVUS, although 99% of endometrial biopsy results were benign or atrophic.⁴⁷

It is most likely that these reported increases in endometrial thickness with levormeloxifene and idoxifene are similar sonographically to the tamoxifen effect discussed earlier, although in those trials, no sonohysterography was performed.

Vasomotor Symptoms

A higher incidence of hot flashes has been reported with tamoxifen therapy than with placebo. Among postmenopausal women taking tamoxifen, 16% sought treatment for vasomotor symptoms.⁴⁸ Extremely bothersome hot flashes also were common in the tamoxifen-treated group of the NSABP trial.³⁷

In an integrated analysis of five randomized placebo-controlled trials, younger, healthy postmenopausal women receiving raloxifene has a significantly higher incidence of hot flashes (25%) than those receiving placebo (18%); however, that trial excluded women with severe vasomotor symptoms.⁴⁹ Furthermore, there was no therapy difference for the severity of hot flashes or for the discontinuation of therapy because of the hot flashes. Increased incidence of hot flashes in the

raloxifene treatment group was observed only during the first 6 months of therapy. In older postmenopausal women with osteoporosis, the overall incidence of hot flashes was lower but still significantly different between raloxifene (9.7%) and placebo (6.4%).⁵⁰ Hot flashes also had been associated with toremifene, idoxifene, and raloxifene, all triphenylethylene derivatives.^{51–53}

Summary

SERMs have played an important role in breast cancer treatment and more recently chemoprevention. In the future, existing as well as newly developed SERMs can be expected to be important pharmacologic agents in breast cancer prevention and treatment. The gynecologic effects of such SERMs vary from compound to compound and differ in premenopausal and postmenopausal patients. Decisions for use of such agents must take into account a patient's menopausal status, presence or absence of a uterus, and risk for developing new-onset breast cancer or breast cancer recurrence.

Needs of Breast Cancer Patients and Their Families: Psychosocial Adaptation

Karen L. Weihs, Kelsey Menehan, Mary Politi, and Jane Lincoln

Care of the breast cancer patient involves preserving her quality of life as well as providing good medical care. Each health care professional contributes to the breast cancer patient's personal experience of illness and return to health through the quality of her or his relationship with the patient. When a woman with breast cancer is treated as a unique individual who can participate actively in her own care, the stage is set for an outcome that satisfies both the patient and her treatment team.

Relationships are fundamental to the patient's quality of life with breast cancer. We use the biopsychosocial model to organize our thinking about the multiple levels of relationships that influence the patient. This model presumes that the patient is part of a dynamic system through which pressures and changes reverberate and in which there are many resources for handling threats and solving problems. Awareness of the stresses and resources that emanate from each level of the system will help optimize patient care along with improving the quality of life for the patient and her family. Professional care providers are likely to enjoy making a difference in patients' overall well-being.

In this chapter, we discuss four levels within the biopsychosocial model.¹ These are the patient's relationships to (1) her body, (2) her self, (3) her family members and close significant friends, and (4) her community. Experiences at each of these levels affect the other levels and call up responses to stabilize the system. For example, the distress of the patient when she discovers that she has breast cancer and must have surgery calls up comforting and protective responses from her family members. A husband who is pained by his wife's distress might accuse her surgeon of acting too slowly or of giving incomplete information. If the surgeon understands that this is not primarily a response to himself or herself, but a misguided attempt by the husband to protect his wife, the surgeon will feel less distressed and more able to offer comfort to the husband, who may, in turn, be able to comfort his wife.

The relationships between levels of the biopsychosocial system are easily identified. Breast cancer, a change at the

level of the patient's body, provokes emotional distress and alienation from her body, a change at the level of the patient's self. These changes reverberate to the level of the family, with the husband feeling a deep need to protect his wife and to vent his anger that the surgery will "damage" his wife and their sexual relationship. His reactions cannot be stabilized in the usual way within the family because of his wife's distress; therefore, the stress is directed to the next level up, the surgeon and the medical community. Clearly, the surgeon who takes the husband's attacks personally has fewer options for action than the surgeon who sees the husband as part of a powerful system, which is reacting to protect itself from threat.

More than for men, women's identity and self-esteem depend on the well-being of their family members and close friends. Conversely, changes in the family resulting from the breast cancer's impact on the patient are a major source of stress for patients. Among three measures of a patient's social support, family interaction was the strongest predictor of patients' psychological well-being in a prospective study of 661 early-stage breast cancer patients by Bloom.² Studies indicate that husbands also experience distress when their wives are diagnosed with breast cancer, sometimes more than their wives themselves.^{3,4} When the breast cancer recurs, this phenomenon is even more salient.³ Spousal distress can greatly affect the patient's response to breast cancer.

Thinking in terms of a cancer-related system rather than simply considering one individual with cancer allows clinicians to identify both risk factors and resources at each level of the system. For example, at the most basic cellular level, a cancer in an advanced stage with limited treatment options or a cancer with an unpredictable course is associated with higher risk to the psychological and social adjustment of the individual, and by extension her family and her broader community. However, it is not a one-way effect. The systems model presumes that high-risk characteristics at each of the other levels can also have an impact on the cellular level, perhaps accelerating the progression of the cancer or hindering recovery.

PERSONAL CONSIDERATIONS

Do psychosocial differences affect breast cancer progression?

Any formulation of cancer as a systems phenomenon necessarily raises the long-debated issue of connections between psychosocial characteristics and disease outcome. Most research on this topic has examined risk and protective factors in prospective longitudinal trials. Associations can be determined by such studies, but causal attributions cannot be made unless intervention trials demonstrate that changes in these risk and protective factors predict improved disease outcome.

The strongest evidence of a psychosocial risk factor for breast cancer progression is the patient's perception of dependable emotional support. However, results from studies that explore the role of "social support" during the year after breast cancer diagnosis as a protective factor against recurrence or mortality have been inconsistent, probably owing to variation in the definition of social support.

Studies that focus on the size of the patient's "social network," without consideration of her actual reliance on these individuals, have not found that it predicts future disease status.⁵⁻⁷ In one of the strongest of these studies by Reynolds and colleagues⁸ of 1011 women with newly diagnosed breast cancer, the researchers failed to find a significant effect for a measure of total contact with friends and relatives in predicting survival.

Other studies focus on functional social support, defined by the way support is used and how its recipient perceives it.⁹⁻¹¹ There is some evidence of improved disease outcome in association with breast cancer patients' satisfaction with support, but results of these studies are inconsistent.

Finally, some studies focus on dependable relationships, measured as the number of friends and relatives on whom the patient feels she can rely for support or help.^{5,12,13} The study by Reynolds and colleagues⁸ also measured the number of reliable supportive relationships by asking women about family members, friends, or other individuals with whom they could talk about the illness or about other personal problems. They found that women reporting fewer reliable supportive relationships were significantly more likely to die of breast cancer.

Dependable support from one's spouse or intimate partner has recently been shown to predict improved survival in breast cancer patients.¹⁴ Marital status, however, is not a reliable predictor of disease outcome.^{11,15}

The preponderance of evidence from studies of social support and breast cancer suggests that any protective benefit from social support is likely to be related to the patient's sense that she has dependable supportive relationships. A precise definition of social support is needed to allow an accurate assessment of its role in breast cancer progression.

Very severe depressive symptoms, occurring in about 2% of breast cancer patients who meet criteria for the diagnosis of major depressive disorder, have also been linked to decreased survival.^{16,17} In contrast, numerous studies find no association between normative elevations in emotional distress during the early stages of breast cancer and disease progression.^{9,11,12,18-21} However, differences in the way women *process* this distress are related to differences in its duration²² and in disease

outcome. For example, Weihs and coworkers¹⁴ studied 79 breast cancer patients and found that coping through acceptance of emotions leads to decreasing distress between 12 and 36 months after diagnosis, and this pattern predicted longer survival after 7 years of follow-up. Healthy adaptation to breast cancer involves initially elevated distress followed by declines in distress over time. Such adaptation appears to be influenced by patients' coping processes and is likely related to disease outcome.

There is some evidence to support a "type C" biobehavioral cancer risk pattern,²³ with behavioral features including the repression or suppression of emotions (particularly anger), avoidance of conflict, overcooperation, unassertiveness, compliance with external authorities, high social desirability, and self-sacrificing. Weihs and associates²⁴ have documented a relationship between shortened survival after breast cancer recurrence and excessive emotional restraint as well as intense psychological distress.

Hurny²⁵ has postulated that reliance on a linear cause-and-effect model may be an inappropriate method of investigation because it does not take into consideration the complexity and circularity of mind-body-environment interactions. Even so, the fact that many of the so-called type C behavioral risk factors correlate with an outdated, but still enduring, societal norm in regard to women's submissive roles and self-negating behavior should be of concern to, and perhaps a focus of intervention for, health care practitioners in oncology. Clinical intervention research, although still in its infancy, is beginning to show not only behavioral changes but also changes in immune functions, at least of a temporary nature, related to psychological interventions.

Cancer is a very complex disease, and its multifaceted nature—along with the associated fear—tends to invite oversimplification. One way to counter unhelpful reductionism is to think of "risk factors" and "protective factors" rather than "causes." Risk factors can be genetic, environmental, psychological, or behavioral. Helping patients and their families build up their protective factors, while limiting known risk factors, may in the long run contribute more to their health than searching for singular causes of illness. A physician using the biopsychosocial model would certainly do no harm in "prescribing" such things as the appropriate expression of emotions, stress management, and the activation of patient's support networks alongside biomedical interventions such as surgery, chemotherapy and radiation therapy.

How does the diagnosis of breast cancer affect a woman's relationship to her body?

Cancer poses a threat to the woman's sense of bodily integrity and her conceptions of body image and sexuality. It is not uncommon for women with breast cancer to report that they feel betrayed by their bodies. For some, this translates into feeling unsafe in the world—strange, alone, odd, suddenly unlike everyone around them. Some women develop panic-like symptoms in the body—constriction in the chest, difficulty breathing, heightened startle response, a sense of dissociation from the body. These symptoms usually diminish as the woman adjusts to the diagnosis and mobilizes to receive treatment,^{19,26} but the immediate impact on her relationship to her body, to her self, and to others can be profound.

Research has shown that women undergoing breast-conserving surgery might maintain a slightly healthier body image than those undergoing mastectomy,^{27,28} but findings are conflicting. Some researchers have shown the opposite.^{29,30} Age might contribute to a more positive body image following a mastectomy because studies have found that older women who undergo mastectomy can cope well psychologically.³¹ It also may be true that women who identify as lesbians do not feel the distress about body image that heterosexual women do. One study, which compared coping issues, found less distress about body image, but an equivalent number of issues regarding sexuality, in lesbians as in heterosexual women.³²

How is a woman's sexuality and sexual functioning affected by breast cancer?

Research on the impact of breast cancer on women's sexuality is in an early stage, although recent literature has begun to explore the issue.^{28,32–35} Moreover, the subject of sexual adaptation is often not addressed in the oncologist's office. Breast cancer surgery and treatment remain an invasive and physiologically distressing sequence of events, although the emergence of breast-conserving techniques has ameliorated some of the effects on body image and sexuality.^{27,28} The study by Kemeny and colleagues³⁶ of 83 patients randomized to mastectomy versus breast-conserving surgery showed that breast-conserving surgery, to a greater extent than mastectomy, preserved body image and integrity, protected feelings of sexual attractiveness and desirability, and contributed positively to the woman's perceptions that her sexual partner's reactions are unchanged as a result of treatment. These findings were consistent with those in Steinberg and associates' earlier study of 46 patients who underwent modified radical mastectomy compared with 21 patients who underwent lumpectomy and radiation,³⁷ and with a study of 99 Scandinavian breast cancer patients.³⁸ Breast reconstruction techniques have succeeded in returning to the woman a tangible sense of bodily integrity. Even so, patients report that lack of sensation in the new breast can be distressing. For example, one woman, after having bilateral mastectomies and reconstructions, described her chest, not without some humor, as having "two grapefruits attached." Chemotherapy and radiation treatment also affect the body's physiology in a way that can result in sexual morbidity. Most chemotherapeutic agents cause premature menopause, with its associated hot flashes, vaginal dryness, and loss of libido. Women attending several support groups at George Washington University reported mixed responses to vaginal lubrication products; for some, sexual activity was still painful. This disincentive, added to a lack of desire, discouraged them and their partners from renewing sexual relations.

One recent study suggests that problems with body image and sexual functioning may persist for many breast cancer survivors months or even years after treatment has ended. Of 784 breast cancer survivors from the greater Washington, DC, and the Los Angeles areas who responded to a mailed survey about their sexual attitudes, practices, relationships, and general well-being, 35% reported that breast cancer had a negative impact on their sex lives. Twenty-four percent were uncomfortable with the changes in their bodies; 26% no longer felt sexually attractive; 70% reported problems with lubrication; and 25% reported pain with intercourse more

than half the time. The women who experience negative body image, premature menopause, and symptoms of emotional distress following treatment may be at particular risk for sexual dysfunction.³⁹

In a follow-up study by the same researchers, of 472 patients from Los Angeles and 662 patients from Washington, DC, the most important predictors of sexual health were vaginal lubrication, emotional well-being, positive body image, quality of the partnered relationship, and absence of prior sexual problems with the partner.³³

How does a partner's response to changes in sexuality affect the breast cancer patient?

The woman's adaptation to breast cancer is influenced not only by her own conceptions and beliefs about her body and her sexuality but also by the beliefs of her significant others and the greater society. Perceptions of body image correlate with sexual adaptation.⁴⁰ Traditional views of women in our society have tended to focus on certain ideals of attractiveness, often focusing on the breasts as a prime asset and object of desire. Although many women and men have eschewed such ideals, the cultural overlay remains strong. If a woman's emotional investment in her breasts is essential to her self-esteem, her feelings of loss and reduced self-worth will be disproportionately experienced. A minority of men—primarily those who receive a sense of reflected self-approval from a "beautiful" woman—may have disproportionately negative reactions to the loss of or disease in their partners' breast.⁴¹

Even men who adapt well to the changes wrought by breast cancer and who give their partners support may struggle with overwhelming fears about losing the woman they love. In a study of spouses 18 months after their wives' breast cancer diagnosis, 27% of men reported distress characterized by fear of disease recurrence, difficulty communicating their feelings about breast cancer, or changes in their sexual relationship with their wives.⁴² A similar longitudinal study of 143 pairs of patients and their significant others documented significant psychological distress in a substantial minority of significant others up to 1 year after the patient's initial diagnosis.⁴³ Feelings of depression and dependency and the belief that such feelings should not be shared with their partners can result in the man's unconscious withdrawal both physically and emotionally as a means of self-protection. A member of a support group for spouses of breast cancer patients at George Washington University Cancer Center confessed that he was afraid to talk to his wife about his fears because he didn't want to upset her. "I'm supposed to be strong for her. I can't let her see how scary this is." With the group's help, he was able to articulate his concerns and eventually told his wife how he felt. The wife confessed that she too had been holding back, for fear of upsetting her husband. Being able to "practice" talking with his wife in the group enabled this husband to reestablish comfortable communication and intimacy.

Which patients are at risk for experiencing significant diminished sexuality?

Not all women experience changes in their sexual self-concept or behavior as a result of the cancer experience. Schain's⁴¹

review of the literature suggests that women at extremely high risk for difficulties and in need of early intervention are women who (1) are young and have high emotional investment in their breasts, (2) have not had the children they hoped for or consider having children a major life goal, (3) may have been sexually abused, (4) did not get the treatment of their choice, (5) have few areas of gratification and sources of self-esteem outside of intimate interaction, (6) have a history of substance abuse, (7) have a history of psychiatric morbidity, and (8) have had multimodal therapy.^{40,41} Infertility is often induced by chemotherapy, although patients of younger age and those who do not receive chemotherapy may escape treatment-related premature menopause.⁴⁴ The threat of infertility looms until treatment is complete, however, and creates distress.

The sexual issues of single women with breast cancer are receiving more attention as the age at which women marry increases and the age at which women are diagnosed with breast cancer decreases. The impact of the cancer on single women's sexuality and sexual activity differs according to their life goals and expectations. Some single women report intense grief at the loss of fertility and the ability to have children. Other issues involve whether and how to tell potential sexual partners or significant others about the diagnosis and its implications. The demise of significant relationships seems to occur more frequently with unmarried women, although it is true that some marriages break up in the aftermath of a cancer diagnosis. Single women face a difficult challenge in maintaining a secure emotional attachment or initiating emotional attachment. The sexual and relational issues of lesbian or bisexual women with breast cancer have not been explored adequately. Only recently have national studies of women's health begun to incorporate information on sexual orientation.^{32,45}

What are the psychological stresses on the patient before a definitive diagnosis?

The period of uncertainty after finding a lump and before diagnosis can be the most stressful period of the entire cancer experience. Northouse and colleagues⁴⁶ found significant emotional distress in more than 200 women awaiting breast biopsy. Some studies suggest that fear of cancer itself is the primary stressor; others report the focus of concern to be the possible loss of the breast. Whatever the reason, women experience tremendous anxiety in this anticipatory phase. The danger here is that the fear will become so overwhelming that women will defend against it through denial, suppression, or avoidance and delay consulting a doctor.

Some researchers use the term *neglected breast cancer syndrome* to refer to this pattern of ignoring or denying breast cancer.⁴⁷ The researchers found that women with this syndrome often seek treatment because of symptoms of locally advanced disease, rather than self-discovered lumps or abnormal mammograms. When they do seek treatment, they behave in erratic, unpredictable ways, often denying or delaying treatment recommended by their physicians. It is important for these patients to be followed by a mental health professional in order to address issues such as fear, denial, and distrust that arise in breast cancer treatment.

What are the most common responses when a woman is told she has breast cancer?

The woman's response to hearing the words "You have cancer" vary according to the perceived nature of the cancer, the manner in which she is told the news,⁴⁸ her earlier experience with cancer, her defense mechanisms, the social support provided by those close to her, and her philosophy of life. Some patients respond with shock and disbelief and may later report that they heard no other information after getting the bad news, so overwhelming was their emotional reaction. Others display an almost stoic reaction, as if the diagnosis were inevitable. Health practitioners often experience anxiety when telling the news and are concerned about giving a proper response to whatever the patient's reaction.

Fallowfield and colleagues²⁹ studied 101 women with early breast cancer (T0–2, N0–1, M0) who were randomly assigned to mastectomy or breast conservation. They found that patients who perceived that the information they were given about diagnosis and treatment was inadequate were more likely to become anxious or depressed. In this study, contrary to some others, anxiety states and depressive illness, or both, were high in women who underwent mastectomy (33%), but not as high as in women with breast conservation followed by radiation therapy (38%). The authors concluded that radiation therapy itself carries considerable psychological morbidity.

Being told the diagnosis in the absence of a close friend or family member increases the psychological morbidity. For this reason, many oncologists make it a point to deliver information about the illness and treatment options over the course of several office visits, so that their patients have time to assimilate it. Patients are encouraged to bring a spouse, partner, family member, or friend to appointments—for emotional support, but also for another set of ears to hear important information. Some patients take notes or ask their doctor for permission to tape-record their conversations so that they can review later. More and more, patients are finding the information they need through the Internet, the American Cancer Society, or the National Cancer Institute. It is important for health care professionals to understand that the patient's efforts to overcome anxiety may manifest in incessant information gathering on one end of the spectrum, or in psychic numbing that can impede the necessary assimilation of data important for treatment decision making on the other.

How does defensiveness affect a patient's adaptation to a breast cancer diagnosis?

The adaptation process may include a number of defensive postures that have been traditionally characterized as pathologic in the psychoanalytic literature, including suppression, repression, and denial. We have noted how denial can be destructive if it hinders a person from receiving treatment in a timely manner. But denial, and the related defense mechanisms that alter the perception of reality, can serve very important functions as well. "[Denial] is positive and an advantage to the person to the degree that it allows the

reality to be integrated without too much disturbance to an individual's psychic equilibrium. It is also positive to the degree it contributes to an individual's potential to counter maladaptive tendencies to give up, and not fight to live and do well".⁴⁹

Rather than trying to confront what appear at first glance to be maladaptive defensive patterns, the clinician can attempt to expand the range of coping mechanisms open to the patient.⁵⁰ He or she can encourage patients to seek information, to take direct action in gaining control of their situation, and to activate their support networks, among other coping strategies.⁵¹

How does the woman's relationship with her physician and other health care professionals affect her adaptation to the breast cancer experience?

In adapting to the cancer experience, the woman's relationship with her surgeon, oncologist, and others on the health team is of critical importance. Benson⁵² wrote that the interaction between physician and patient was one of the crucial elements in the placebo effect, or the body's ability to heal itself. Harris and Templeton⁵³ also discuss that positive interactions between physicians and patients can facilitate improved physical and mental health.

One potential barrier to a patient securing a workable attachment to a surgeon or medical oncologist is a perceived societal power differential between patients and physicians—and more particularly between women and men. A certain godlike mythology still attaches itself to the role of physician, despite the changes in the health care system wrought by managed care and the increased activism of patients as medical consumers. Women patients may inadvertently accept a more passive, subordinate role, allowing the oncologist, who is usually a man, to make important treatment decisions. This can be an adaptive arrangement for some patients, eliminating anxiety and simplifying the decision-making process, and a comfortable role for some doctors who perceive themselves as parental figures. But most patients today prefer a more active role in their health care, and most physicians look forward to having the patient act as a partner.

Lesbian women face significant barriers in communicating honestly with their physicians. Many lesbian women are not comfortable disclosing their sexual orientation, and the standard medical history taking questions presumes heterosexuality and often corners the responder, as in "Are you sexually active?" and the follow-up question, "Which form of birth control do you use?" Health care providers' reactions to disclosure of a homosexual orientation ranged from "embarrassment and discomfort to patronizing attitudes, outright hostility, and refusal to treat."⁴⁵ Some lesbian women may not be getting the routine care they need, including regular breast examinations and Papanicolaou smears, because of these barriers. It is not difficult to establish a comfortable setting for any sexual orientation. Helpful traits for clinicians included showing a willingness to listen; appearing to be accessible, attentive, and open; treating the patient respectfully; using neutral language (such as "partner" or "mate" rather than "boyfriend" or "husband"); taking time

during the visit; and showing gentleness during the physical examination.⁴⁵

How can the physician enhance the physician-patient relationship?

Although there are no definitive models for the ideal physician-patient relationship, several guiding principles can be gleaned from a review of the literature. Patients' main communication issues revolve around maintaining a sense of control, seeking information, disclosing feelings, and searching for meaning.⁵⁴ Because the disease is so frightening and unpredictable, patients need interpersonal and environmental contexts that allow them to regain a sense of communication competence and therefore control.^{55,56} For the physician, establishing consistent patterns of interaction with patients may be one of the means of enhancing their patients' sense of control. If patients are communicated with and treated in predictable ways, they will feel they are handling their illness more competently.

A moderate level of self-disclosure of feelings is key to healthy adjustment of cancer patients. It is important for physicians to remember that self-disclosure serves several important purposes: (1) it allows for catharsis, or draining of the tension and anxiety, (2) it allows people to receive feedback from others that normalizes the cancer experience, and (3) it enhances problem solving. The most effective response to patients' self-disclosure is simply "listening" or "being there."⁵⁴ In a qualitative study of 15 women living with breast cancer, Harris and Templeton⁵³ found that active listening was the most helpful characteristic for physicians to demonstrate when communicating with their patients. Further disclosure can be prescribed by referral to a support group.

On the health professional's side of the transactional process, literature points to three areas of communication that are important: (1) imparting information, (2) communicating hope, and (3) sharing control. Health care professionals struggle with what and how much to say to patients about their condition as well as how to say it in a way that is both honest and hope enhancing. In addition, they must deal with the growing complexity of a health care system in which various "players" have input and influence in the treatment process. No longer is the physician in complete control of health care decisions. Fortunately, sharing of control benefits the patient, allowing for the distribution of power in provider-patient relationships and the regaining of a sense of personal control.

In the end, the physician-patient relationship often defies easy formulation. It is as unique as the two individuals involved. What is important is that it be grounded in mutual trust and respect.

What are the most common diagnosable mental disorders among breast cancer patients and what are the warning signs?

Adjustment disorders are the most common psychiatric diagnoses in breast cancer patients, followed by depression and anxiety. Studies suggest that about 25% of patients with breast

cancer experience depressed feelings significant enough to affect their daily functioning.^{21,57} For most patients, these feelings lessen in a few weeks as their coping skills become activated and as they reconnect with people who care about them. It is important not to downplay severe depressed feelings, however, especially if they persist. Women who have had a premonitory clinical depression are more susceptible to the stress of a cancer diagnosis and treatment and are at greater risk for a depressive episode.²¹

A study of 205 newly diagnosed breast cancer patients assessed at 3 months after diagnosis found that 15% of patients experienced marked distress with a wide range of possible symptoms, including anxiety, depressed mood, social withdrawal, or unexplained physical complaints. Women with stressful life events in addition to breast cancer were found to have a greater likelihood of high emotional distress, ranging from 17% to 37% of patients, depending on the magnitude of their other stressors.¹² A history of depression or suicidality and regrets regarding the past are also associated with high vulnerability to psychiatric disorders and require early mental health interventions.^{12,58} Mental health treatment is indicated if the patient's social, occupational, or academic functioning is impaired, or if the distress is not alleviated by supportive interactions with family, friends, or a breast cancer support group. Women who are isolated and who anticipate little emotional support from others in response to their breast cancer are more vulnerable to mental illness.⁴³ Women who are unhappily married, divorced, or widowed are particularly vulnerable.³⁸ Therefore, patients who cannot name a confidant or who say they have little personal support should always be strongly encouraged to participate in a support group and should be referred for mental health care as soon as psychological distress is reported.

Although most women have adequate inner resources and family and social supports to take them through this most devastating of life experiences, some are at higher risk for depression because of social isolation. A prospective study of 458 working-class women⁵⁹ found that women without a confidante were 30% more likely to suffer a major depression within 2 years after a severely stressful life event. Furthermore, studies report that depression in chronic illness is associated with increased morbidity and greater overall disability.⁶⁰

Some women find themselves preoccupied with thoughts of death after receiving a breast cancer diagnosis. This is an expected response when one is confronted with a potentially life-threatening illness. Cancer is still associated with death for the general public, although today nearly half of people with cancer are cured or live with the disease for many years. Thoughts of death should be carefully differentiated from suicidal ideas or plans, which are much less common but require direct action. Physicians need to ask directly about suicidality when their patients mention thoughts of death. A statement such as "Some people feel so bad that they think they'd be better off dead. Have you been feeling that way?" can be used to avoid insulting the patient with such inquiries. Women with a plan for suicide should not leave the physician's office but should be seen directly by a psychiatrist to ensure safety and to begin appropriate treatment.

Supportive, problem-focused psychotherapy is indicated for adjustment disorders.⁶¹ Psychotherapists with a range of backgrounds including psychiatry, psychology, social work,

and mental health nursing can provide this treatment. It is preferable to refer patients to mental health providers with some experience in medical settings who can integrate the patient's illness experience with her psychiatric treatment. Physicians should develop a collaborative relationship with a mental health professional or group, which allows a smooth referral to be made. Such referral practices make it more likely that the patient's emotional problems will be adequately addressed. When a woman's surgeon, oncologist, or other medical treatment provider recommends that she see a specific mental health professional, the patient is much more likely to follow the suggestion than she would be if only a general recommendation of psychotherapy or psychotropic medication is made.

When are antidepressant medications indicated for breast cancer patients?

Depressive disorders and anxiety disorders in breast cancer patients should be treated with antidepressant medications as well as psychotherapeutic interventions. Moderate to severe symptoms of anxiety or depression that persist for more than 2 weeks require a thorough review of psychiatric symptoms to determine their breadth and severity. If persistent depressed mood or loss of pleasure in all life activities is accompanied by thoughts of suicide, diminished ability to think or concentrate, or feelings of worthlessness or excessive guilt nearly every day, the patient may be suffering from a major depressive disorder. It is important to make this diagnosis because treatment can markedly reduce suffering and associated work, social, and family problems. Depressive disorders left untreated can result in hospitalization or even suicide. Fatigue, changes in weight or appetite, and trouble getting to sleep or staying asleep are also signs of major depressive disorder, but surgery, chemotherapy, and radiation therapy can induce these symptoms in many breast cancer patients. When they are combined with moderately severe sadness or lack of interest in life, however, they are also indicators of the need for treatment of a depressive disorder.

Some nonpsychiatric physicians elect to provide pharmacologic treatment without psychiatric consultation for depressive and anxiety disorders in their patients. Such pharmacologic intervention needs to continue for at least 6 months in order to prevent psychiatric morbidity. A physician who treats depressive disorders must maintain a close relationship with the patient in order to monitor symptom response to treatment, to interpret side effects, and to help patients to tolerate side effects until the full therapeutic antidepressant effect occurs. After the initial treatment response, patients should be seen at least monthly to monitor ongoing effectiveness and to strongly encourage continued medication compliance. Some patients believe that their symptom relief indicates that they can stop the treatment. However, just as stopping antibiotics for a severe wound infection after 5 days of treatment would undermine the full resolution of the infection, so too does stopping antidepressant treatment undermine the full resolution of a depressive disorder.

Bupropion is the preferred medication for starting treatment of depression in women who are sexually active. Although the serotonin-reuptake inhibitors fluoxetine, sertraline, paroxetine, citalopram, and escitalopram are often the

first-line antidepressants used by general physicians and can reduce depressive symptoms, as many as one third of patients who take them experience changes in libido or anorgasmia as a side effect.⁶¹ The *Handbook of Psychiatric Drug Therapy, 4th Edition*,⁶² is a very good reference for the pharmacologic treatment of patients with psychiatric disorders.

When is anxiety a symptom warranting psychiatric intervention?

Patients who describe re-experiencing a highly traumatic event, such as being told they have breast cancer, may be suffering from an acute stress disorder. Re-experiencing involves feeling as if or dreaming that the trauma is happening again, some time after the actual occurrence. More than one third of breast cancer patients experience some of the symptoms of a stress disorder, including intrusive thoughts and symptoms of increased arousal. Trouble sleeping was found in 36%, and easy startling and hypervigilance were found in 27% of patients in a recent study of 160 patients with stage I breast cancer diagnosed 4 to 12 months before assessment.⁶³ Stress disorders of a more chronic nature are often related to past experiences of violence or sexual abuse. Women with such histories may be more vulnerable to psychiatric symptoms at the time of a breast cancer diagnosis. Persistence of intrusive thoughts, hyperarousal, sleep disturbance, and avoidance of medical care facilities for more than 8 weeks indicate that psychiatric evaluation and treatment are needed.

Women with anxious temperaments that predate the breast cancer and involve chronic worry, muscle tension, fatigue, chest tightness, or pain are at risk for flooding with these symptoms when they receive the cancer diagnosis. Such symptoms can be effectively treated with antidepressants. These drugs are preferable to benzodiazepines because they are equally effective while free of the risk for drug tolerance or dependence. Short-term benzodiazepine use for 1 to 2 weeks, however, can be very helpful while antidepressant medications are becoming effective. Alcohol abuse and dependence are prevalent in women with anxiety disorders and should be considered at the same time as any diagnostic assessment for anxiety disorders.

What is the role of support groups?

The ultimate challenge to a person's sense of place in the world is to know that she will die "before her time." Support groups can enhance patients' sense of control over their lives despite loss of control over the cancer. They can help women recognize and become more tolerant of strong, painful feelings, at the same time revealing and discarding unhelpful beliefs about not complaining and "toughing it out alone." Many patients believe it is unacceptable to speak of one's possible death from cancer because such talk might indicate loss of hope and a morbid preoccupation with negative outcomes. If they do speak of their fears, they are often silenced or pathologized by those they open up to, including health care providers and virtually everyone in their social networks. As Spiegel⁶⁴ wrote: "Paradoxically, we observed that when patients openly discussed the most serious issues [in group], such as dying and death, their fears were detoxified. They

came to realize that they feared the process of dying more than death itself. They were able to parse the fear into a series of problems: pain control, participation in medical decision-making, [and] making the best possible use of remaining time." A belief system that rigidly dictates positive thinking at all costs gives way to an empowering sharing of common fears in a group context that enhances coping and strengthens the patients' hold on the time remaining.

Some oncology clinicians routinely prescribe participation in a support group for women with breast cancer, regardless of the patient's degree of social support. The importance of support groups for maintaining one's quality of life has been documented. One study, for instance, found that participation in a breast cancer support group contributed to an improvement in psychological well-being, and this improvement continued 1 year after participating in the group.²⁶

A more startling finding was a correlation between participation in weekly group therapy and increased longevity for women with advanced breast cancer. In a study that began at the time of their onset of metastatic breast cancer, 88 women were randomly assigned to either a professionally led, weekly group therapy or to no systematic psychosocial care. At follow-up 7 years later, the women in the intervention group had an average survival time of 36 months, compared with 18 months' average survival for the controls.⁶⁵ A study by Cunningham and coworkers⁶⁶ also found that women with metastatic breast cancer who "worked through" their feelings during supportive expressive group therapy benefited with better psychological well-being and longer survival.

A more recent study by Goodwin and colleagues⁶⁷ involved 235 women with metastatic breast cancer who were randomly assigned to supportive-expressive group therapy or no systematic psychosocial care. Adherence to the intervention methods used by Spiegel and associates⁶⁵ was rigorously enforced. Women assigned to supportive-expressive therapy had greater improvement in psychological symptoms and reported less pain than women in the control group. The psychological intervention did not prolong survival.

What can be concluded, then, about the effect of supportive expressive group therapy? It clearly benefits women who are distressed and in pain by reducing these symptoms. Whether it increases longevity will not be determined until further research is available.⁶⁸

What is the impact of confronting death for the breast cancer patient?

Thinking excessively about death can contribute to depression and despair, but an honest confrontation with the reality of one's mortality can also have positive benefits. The sociologist Ernest Becker⁶⁹ postulated that our scientific society's insistence on "denying" the reality of death has led to a kind of psychic numbing. The "heroic" individual, according to Becker, is one who embraces more of the ambiguities and pain of life, not less. "Taking life seriously means that whatever man [or woman] does on this planet has to be done in the lived truth of the terror of creation, of the grotesque, of the rumble of panic underneath everything. Manipulative, utopian science, by deadening human sensitivity. . . falsifies our struggle by emptying us, by preventing us from incorporating the maximum of experience."

Numerous cancer patients have reported that a brush with death helped give meaning to their lives. They feel motivated to live life more fully, to appreciate each moment, to do now what they might have put off until tomorrow, to confront old hurts and resolve them. In short, their lives are enriched by the cancer experience.⁷⁰ On the other hand, there are some women who resent the suggestion that they must have a life-altering spiritual experience as a result of having breast cancer. As one breast cancer survivor aptly put it, “Cancer is a growth, not a growth experience.”

What are the particular challenges faced by women who experience a recurrence of their cancer?

A recurrence forces the woman and her close significant friends and relations to revisit previous stages and renegotiate the psychological landscape. The return of cancer shatters hopes that the initial cancer was cured and heightens fears that this time the cancer will be fatal.⁷¹ The recurrent phase of cancer has been reported as one of the most stressful phases over the entire course of illness.⁷² Patients report shock and depression, anxiety and powerlessness, fears about death, disability, and pain, and a sense of injustice at the renewed assault of the cancer.⁷³ On the other hand, women bring to the experience of a recurrence the knowledge gained from their previous cancer journey. They know the intricacies of the health care system and how to marshal their inner resources and social supports to meet the new challenge.

Breast cancer recurrence affects the functioning of relationships between patients and their partners.⁷⁴ Women’s adjustments are affected by the amount of symptom distress, hopelessness, and emotional support they perceive in themselves as well as the amount of emotional distress they perceive in their partners. Husbands’ adjustments are affected by their own health problems and by feelings of hopelessness as well as by the symptom distress they observed in their wives.⁷¹ Other family members can also experience a reduced quality of life in response to a recurrence, which can be influenced by the degree of hardness in the family.⁷⁵ A family-focused approach to the care of women with recurrent disease that includes their partners and their family is recommended as each member in some way influences the adjustment of the others.

What is the impact on the breast cancer patient of contemplating a recurrence?

The possibility of recurrence is an ongoing mental health concern for most breast cancer patients regardless of prognosis. After treatment ends, many patients report feeling vulnerable because they are no longer actively “doing something” about their illness. Trigger points for anxiety about recurrence seem to intensify in relation to anniversary events (date of original diagnosis, date of surgery, date of completion of treatment), suspicious symptoms (particularly those that mimic feelings at the time of the original illness), any illness or change in health (particularly weight loss or fatigue), illness in a family member, recurrence or death of a fellow survivor, or times of

particular life stress. To combat anxiety related to recurrence, patients can employ behavioral actions such as connecting with support systems, planning pleasurable activities, seeking professional counseling when needed, providing support to others, and learning and using relaxation techniques. Cognitive-emotional approaches include recognizing that trigger points exist and that anxiety fluctuates, enjoying life one day at a time, reframing feelings, and reflecting on positive changes that have resulted from the illness.⁷⁶

How do people’s belief systems affect their ability to handle the psychosocial impact of cancer?

Cancer challenges people’s assumptions about life and their place in it. A breast cancer patient brings her beliefs about the world and her place in it to her experience of cancer and uses those beliefs to shape its meaning to her life.⁷⁷ Belief systems can assist the patient to weave the changes brought by cancer into the tapestry of her life, strengthening her identity, helping her to affirm: “I am a survivor, therefore I can overcome this.” Conversely, belief systems can impair the patient’s ability to cope with each aspect of cancer, sapping hope from a woman who believes “once more, I am a victim of a cruel world.” The concept of meaning derives from a person’s unique perception of her place in the world; these perceptions give a sense of coherence to life in the face of loss, change, and personal upheaval.⁷⁸ The search for meaning is a powerful component of coping and a method of reasserting cognitive control,⁷⁹ for example, a patient might decide that “I did not need this experience, and did not cause it, but I can and will learn from it.” One study found that positive meaning ascribed to the pain of cancer, such as viewing it as a challenge, was associated with lower levels of depression.⁸⁰ Other studies found that a belief that control of the illness experience was within the control of the individual patient herself was associated with a positive “fighting spirit,” an attitude associated in previous studies with longer survival, whereas the belief that external factors were in control of the illness was associated with anxious preoccupation about cancer.^{81,82}

Can a patient’s beliefs about life and about cancer hinder the adaptation process?

Misguided beliefs about cancer causation can be damaging to patient adjustment. A cancer diagnosis challenges people’s assumptions about “the way life ought to be.” One such assumption is that doing the “right” things—eating right, doing good deeds, believing correctly—will shield them from negative life events. These beliefs have deep roots in religion and in every culture, with more recent offshoots found in some of the popular writings about the mind–body connection. The news of a breast cancer diagnosis can often set patients on a life review in search of a deficiency that caused the cancer. They are encouraged by much of the cancer self-help literature, such as Siegel’s⁸³ million-selling *Love, Medicine and Miracles*, and sometimes by well-meaning friends or family. The most common concern voiced by patients seems to be that an inability to deal well with stress might result in

impaired immunity against cancer, and yet the relationship between stress and cancer is far from clear. A related belief states that cancer is, on some level, a psychological event. Writer Susan Sontag⁸⁴ wrote a polemic against such ideas, protesting that “People are encouraged to believe that they get sick because they (unconsciously) want to, and that they can cure themselves by the mobilization of will. . . . Psychological theories of illness are a powerful means of placing blame on the ill.”

It is helpful to inform patients that our very human natures yearn for theories of causation. Finding “reasons why” provides a buffer against the random danger we all face. However, the search for the cause of a particular woman’s breast cancer may divert emotional energy away from constructive coping with the urgent treatment decisions and tasks at hand. Patients can be encouraged to shift their focus toward reducing the negative impact of cancer in the present. There is evidence that social support from family, friends, or support groups counteracts the effects of stress, buffering people against negative life events and contributing to improved health and disease resistance.¹⁶ Health care providers can reassure patients that the connections between mind and body are extremely complex indeed.

Breast cancer patients can use the mind–body literature for health-strengthening techniques, while setting aside self-blaming messages. Emotional well-being can be enhanced through new and old techniques such as yoga, biofeedback, meditation, and visualization, and from support groups. A patient can always use the cancer event as a catalyst for changing the things about her life that she already wanted to change. This “wake-up call” phenomenon, often remarked on by cancer survivors, is one of the ways in which positive meaning and purpose can derive from the cancer experience and serves to enhance rather than undermine personal power and life coherence.

The Danish writer Isak Dinesen said, “All sorrows can be borne if you can put them into a story or tell a story about them.”⁸⁵ Health care providers can assist patients in integrating their cancer experience into their life story in a positive, creative way, and listening to the statements patients make during clinic or hospital encounters is an important first step.

Are there long-term psychological consequences of having had breast cancer?

The psychological impact of the illness may continue well beyond the end of treatment. A study of 127 women with breast cancer⁸⁶ found that the illness not only added to ongoing life stress but also increased the negative events or difficulties in other areas such as relationships with family and external stressors (e.g., education, work, housing, money, crime). The women continued to experience a higher level of perceived “threat” to their well-being in these “nonhealth” categories in each of the 3 years after their cancer diagnosis than they had reported before the diagnosis. However, it is important to keep in mind that most women cope well with the disorder, and factors such as emotional expression, social support, and psychosocial interventions can help minimize the negative effects of breast cancer.⁸⁷

FAMILY CONSIDERATIONS

How does the diagnosis of breast cancer affect the patient’s family?

Different families feel the reverberations of a woman’s cancer very differently. Carter and McGoldrick⁸⁸ suggested that the individual, the family, and the illness each have a “life cycle,” and how and at what stage these intertwine will determine the overall impact on the psychosocial system. The degree of disruption to the family system is affected by a number of factors, the most significant of which are (1) the timing of the illness in the life cycle, (2) the nature of the illness, (3) the openness of the family system, and (4) the family position of the ill family member. More recently, Veach and Nicholas⁸⁹ discussed a similar view of family development. They highlighted the unique stressors faced by families, depending on the clinical course of the cancer as well as the stage of the family life cycle. Using these views, a woman in her early 40s with breast cancer is out of sync with the expected natural process of illness and possible death. At this phase in the life cycle, the woman is at her peak in terms of family responsibilities and productivity; all things being equal, her illness leaves a gap in family functioning that is difficult, if not impossible, to fill. At the same time, the woman’s adolescent daughter is at the life stage of moving away from the cocoon of family. The unique course of the illness can add additional stress to the individual and the family system, particularly if there are unexpected complications, debilitation, or an increased possibility of death. The significance of the ill person in the family constellation will contribute to the degree of distress. Understood in terms of functional role and the degree of emotional dependence of the family on the individual, the woman’s significance is practically beyond measure.

Most families mount a resilient response, despite the suffering that is universal for those living with cancer.⁹⁰ They report feeling closer to one another after marshaling resources to fight the disease.^{56,91} Although many families report this positive response, the physical and emotional pressures during the different stages of cancer can strain family relationships, even among families who cope well with cancer.^{3,90} Multiple investigators have reported that about one third of adult cancer patients, their spouses, and their children have clinically significant distress and psychosocial dysfunction.^{92,93} Some families of cancer patients express psychological distress as much as, if not more than, the patients themselves.^{94,95}

The quality of the family environment affects the outcome of its members. Family environments experienced as cohesive and low in conflict include family members who are less distressed and have better coping than patients, partners, and children whose families are detached or high in conflict.^{42,90,96} The latter family characteristics have also been linked to behavioral disorders in children whose parents have cancer.⁹⁶ The importance of family function for the psychological adjustment of its members becomes evident when it is assessed along with physical disability in the same patient population. Family function has a much greater effect than physical disability on the patient’s mental health.⁹⁷

Families whose members have the best mental health are likely to perceive their family environments to be cohesive and expressive, without the burden of excessive conflict. Research has shown that high emotional expressiveness and cohesion in family relationships predict better psychological adjustment to cancer in all family members.⁹⁸⁻¹⁰⁰ Correlations of depression and anxiety among family members suggest that something shared by members of the same family influences the mental health of its members. Some attributes of the family may also influence the course of the biologic disease process. It is not yet clear whether the latter attributes are the same as those that correlate with psychological adjustment.

Cancer poses the risk for separations and losses that can best be contained in relationships that are secure. Psychological adjustment depends on adaptation of family relational processes in response to these threatened separations and losses that are related to cancer. The specific nature of the cancer threat, because of its potential for loss and separation, can set in motion either constructive or destructive transformations of family relationships. These transformations occur through the activation of attachment and care-giving relationships, which give rise to new forms of communication, joint problem solving, mutuality, and, at times, intimacy.¹⁰¹

How do family beliefs about illness affect patients' and family members' adjustment?

Family beliefs about illness may help or hinder adjustment. A family's belief system may need to expand during the time of acute illness; for example, if the patient has always been the children's primary parent, and she is profoundly debilitated by chemotherapy, the father/husband will need to expand his underutilized competencies for parenting, and the mother/wife/patient will need to let go of some control over this area in their family life.¹⁰² Ideally, a renegotiation of roles should occur so that flexibility can replace time-worn routine in the household. The cycles of treatment require families to make ever-changing adjustments to the energy level of the patient, which should be made without denying the reality of fatigue at one extreme, or infantilizing the recovering patient at the other. These changes pose challenges to the most supportive and communicative of families.

The research of Reiss and colleagues¹⁰³ on chronic illness in families has shown that long-term accommodation of the family to illness can endanger other family priorities and lead to a neglect of normative family developmental issues. Particularly for the family of a woman with recurrent, advanced, or "chronic" breast cancer, belief systems may need to be examined so that the needs of both the well and the ill are validated, thus sparing the family the additional burdens of guilt, resentment, and truncated development. A working metaphor that Reiss' team found useful in removing guilt from the family dynamic was to view the illness as a 2-year-old tyrant who disrupts family life with excessive demands and threatens catastrophe if demands are not met. They¹⁰³ found it important to "separate the patient from the illness and to place all family members, including the patient, on the same team, a team whose joint task it is to evaluate current coping strategies and to experiment with more equitable and satisfying coping responses." In this era of outpatient mastectomies

and home hospice care, families will assume more of the responsibility for medical care; programs to support family coping are needed to produce good medical outcomes with the use of fewer traditional medical resources.

How should information about the cancer be conveyed to children and other family members?

Children can sense when something is not right in their family environment. A child has a right to know about anything that affects the family as cancer does. The question is, how and at what level of detail should children be told? Knowledge of children's normal growth and development can be a guide in this regard. Very young children are dependent, are present oriented, and have a limited grasp of concepts. Breast cancer in the mother threatens their sense of predictability and consistency of nurturance. Thus, a seemingly selfish response of "Who will fix my breakfast?" when told of his mother's illness is normal for a 4-year-old. School-aged children, with their growing understanding of concepts and language, have the capacity to see their mother's illness as separate from them and may be curious about it. Children at this age also can engage in the magical thinking that may lead them to believe that they did something to cause the illness. Older school-aged children view death as a natural biologic process and have concerns about its effect on their own lives. Young teens and adolescents generally feel that they are not vulnerable to their mother's death. They will be challenged by the conflicting drives to pull away from the family toward independence and draw closer as they accept more responsibility for care giving.⁸⁹

At the most basic level, children of all ages need to know (1) what has happened, (2) what will happen next, (3) that they did not cause the cancer, (4) that there is hope, even though they are upset now, and (5) that they are and will be loved and cared for.¹⁰⁴ Parents should feel free to communicate feelings as well as facts because that gives permission for children to acknowledge their own scary feelings. The first explanation can be as simple as the following:

I have a sickness. It is called cancer. The doctor is giving me medicine to help me get well. Sometimes I will feel sick or tired and sometimes I will be just fine. Dad will help me take care of you until I feel better.

Being sick makes me feel sad. You are a help. But it's OK for you to feel sad or angry or happy or whatever. Our feelings change but love is always there.

Listening to children's responses to the initial explanation will let parents know what the children can handle. Then parents can follow up with further explanation or ask their children if they're worried or have other questions.

One study showed that some children are not told about their mother's breast cancer until after surgery, if they are told at all.¹⁰⁵ The study also found that older children are often told about their mother's breast cancer earlier, and are provided with more information, than younger children.¹⁰⁵ It is important for health care professionals to support mothers in communicating with their children in the early phases of breast cancer, in age-appropriate ways.

As for telling other family members, the woman should not feel compelled to tell everyone right away. She may begin by telling the people with whom she feels most safe. Women report that concern about how people will react often delays their disclosure: "I'm having a hard enough time with this. I don't want to have to comfort someone else." In reality, family members react very differently to bad news. Some do get upset. Some people react in fear. Others, in their compulsion to help, offer unwanted advice or "war stories" from others' cancer experience, unintentionally increasing distress. The woman can be reassured that she need not feel responsible for people's reactions and assume the caretaker role. Recruiting her partner or a close friend to help in giving the news can be a significant buffer.

What are the particular psychosocial risks for children of breast cancer patients?

In most cases, mother-child relationships tend to stay strong or grow stronger following breast cancer. In interviews with 78 breast cancer patients, Lichtman and colleagues¹⁰⁶ found deterioration in only 12% of the relationships. Problems with children were more likely when the patients had a poor prognosis, more severe surgery, poorer psychological adjustment, and to a lesser extent, more difficulty with radiation therapy or chemotherapy. Interestingly, the mothers' relationships with their daughters were at a significantly greater risk than were their relationships with their sons. Seventeen percent of the patients reported that their daughters were fearful, withdrawn, hostile, or rejecting; only 8% reported having problems with their sons. Their fear of inheriting breast cancer and the mother's demands on the daughter for support were judged to be major contributing factors to the difficulties with adolescent and preadolescent daughters.

In another study of daughters of breast cancer patients, Wellisch and colleagues¹⁰⁷ reported that daughters who were adolescents at the time of their mother's illness had greater adjustment problems later on than daughters who were either latency age or young adults. Girls of this age group had greater feelings of discomfort about their mother's illness and more often changed their long-range life plans as a result of the experience. They also reported less sexual satisfaction later on in adult life.

How does the experience of breast cancer shape a woman's definition of self and her role within her family?

Many women are socialized to care for others, and caring for oneself can seem like a disavowal of an appropriate concern for other people. Requesting time and specific kinds of attention from others may represent for the woman with breast cancer a loss of role, such as manager in the family and provider of emotional sustenance.

A woman's struggle to see herself as a unique individual in the presence of breast cancer is shaped by ongoing changes in self-image for women in contemporary Western cultures. Carol Gilligan¹⁰⁸ described dilemmas in women's perceptions of themselves as they move toward defining themselves in their own terms. Gilligan and Belensky¹⁰⁹ found that women

who cope well with illness defined self-care as one of the aspects of their ability to be a caring person. In this schema, caring for others and caring for oneself are no longer in conflict but instead become an integrated part of one's core identity. Gilligan and Belensky¹¹⁰ describe this critical step in women's adult development to be the transition from a conventional feminine role in which "goodness" is self-sacrifice, toward a truthful acknowledgment of oneself as deserving of the consideration one grants others. They call this evolution a movement from goodness to truth.

The urgent need for self-care often brings women with breast cancer to an awareness of the deception inherent in the feminine role of selflessness. They become aware of the destructiveness to self and other which that deception breeds. "The incongruity between the experience of self and the demands of role generates the movement from an understanding of self and other through roles, to an understanding of self and other beyond roles."¹¹¹ Weingarten,¹⁰² a family therapist who has had breast cancer, described growth beyond the traditional parental role. In her book, *The Mother's Voice: Strengthening Intimacy in Family Relationships*, she described how breast cancer stimulated her realization that her children have strength to care for her and that she can be closer to them by being more genuine in disclosing her own needs along with attending to theirs.

What impact does the diagnosis of breast cancer have on a woman's relationship to the community?

Breast cancer patients and family members draw their perceptions of cancer from the attitudes of the larger society, their own ethnic group, their religious-spiritual community, their work community, and their own families of origin. The experience of illness cannot be adequately understood without understanding the larger cultural context. At the societal level, for example, a diagnosis of cancer still engenders fear and stigma, despite advances in the understanding of the disease, and this can be a hindrance in seeking and receiving treatment. McGoldrick and colleagues¹¹² wrote that the medical model's emphasis on diagnosing and curing disease often renders it inattentive to the patient's or family's perception of what is wrong and that this inattention accounts for at least some of the noncompliance, dissatisfaction with clinical care, and treatment failure experienced.

A woman's social network provides many positive resources as well. It acts as a buffer during times of crisis, protecting her from potential declines in physical and emotional well-being.^{9,10,98,99} Weihs and associates¹⁵ identified the provisions of social integration, nurturance, reassurance of worth, a sense of relative alliance, and guidance. No relationship can adequately furnish all provisions, but a network of relationships can. Social support is multifaceted and serves multiple functions, yet the underlying thread is that support reinforces the individual's sense of worth and being loved.

Of what influence are ethnic factors in the detection and treatment of breast cancer?

Certain ethnic groups suffer disproportionately from breast cancer. For example, the incidence is lower but mortality rates

are higher for breast cancer in African American women than in women of other ethnic groups.¹¹³ Studies that establish risk factors for breast cancer often do not include minority groups, however, making it difficult to determine the causes for these group differences. Many researchers believe that ethnicity is not an independently significant risk factor for breast cancer survival; factors such as age, socioeconomic status, stage of disease, and treatment are more important to consider in all ethnic groups.¹¹⁴

Attitudes toward health and illness are also influenced by ethnic factors. Zborowski's classic study¹¹⁵ of 146 Jewish, Italian, Irish, and white Anglo-Saxon Protestant veterans hospitalized with painful physical illnesses found marked differences among the ethnic groups in response to pain and in their expectations of treatment. Through the use of structured interviews, the research demonstrated that Jewish and Italian patients tended to complain about their pain, whereas the Irish and white Anglo-Saxon Protestants did not. The Italians worried about the effects of their pain on their immediate situation, but once the pain was relieved, they easily forgot their suffering. The Jewish patients feared anything that stopped the pain, such as a pill, because they felt it would not deal with the real source of the problem. The Irish patients did not expect a cure, were fatalistic, and did not complain or even mention their pain.

African Americans tend to use more emotional restraint than their European American counterparts, a factor that may be associated with decreased survival time in women with recurrent breast cancer.²⁴ Higher emotional constraint in African Americans than in European Americans has been attributed to their predicament as members of a nondominant social group. This negative effect of racial discrimination on health has begun to be documented for other medical conditions.¹¹⁶ African Americans enter a medical establishment designed by and for European Americans, for which they are sometimes not socialized. However, they must perceive the nuances of that system, of themselves, and of other people in it, in order to obtain medical treatment. In this context, intense effort to control oneself and to determine and meet others' expectations is understandable and probably advantageous.

Discussion of cancer is considered taboo in some African American southern communities. This taboo is based on a view of cancer as a minion of fate, which is active, powerful, and impossible to stop.¹¹⁷ As a result, family and friends who might discuss the patient's cancer with her may consider such behavior to be tempting fate.

Further study of emotional constraint and control is needed to clarify the ways in which African American women may be emotionally overtaxed in obtaining social support and medical care when they have cancer.

What are the socioeconomic and class issues related to breast cancer?

Poverty has been associated with late diagnosis of cancer, barriers to treatment, and lower survival rates.¹¹⁸ Studies show women from more deprived areas are less likely to get breast cancer but experience poorer survival than women from less-deprived areas.¹¹⁹ Several barriers prevent poorer women from receiving mammograms and participating in breast cancer

early-detection programs, including high costs, limited availability to screening, physician referral requirements, fear of breast cancer detection, fear that detection will necessitate mastectomy, mammogram-related pain, and fear of radiation, which can affect their survival rates. One study showed that screen-detected cases of breast cancer had a better prognosis at diagnosis, regardless of the socioeconomic status of the patient.¹¹⁹ Thus, increasing access to screening, helping poorer people to finance breast cancer care, and providing culturally sensitive cancer education programs might improve the survival rates for lower income groups.

Health care professionals also report numerous obstacles in providing cancer care to poor people: (1) fatalistic beliefs and attitudes among their peers regarding the prevention, control, and curability of cancer, (2) processes and systems that discourage providers from making referrals, and (3) limited access to resources to serve the needs of the disadvantaged. Strategies to enhance the delivery of care and services include greater involvement in community cancer control efforts, more focus on issues of poverty in medical training, more public advocacy for access to health care for all people, and the creation of delivery systems that better accommodate the needs of the disadvantaged. As one health care provider testified: "Our clinics could be of major assistance in screening patients for prevention and early detection of disease. These facilities need to be more accessible, and they need to require a minimal amount of their time per visit."¹²⁰

In what ways does religious affiliation affect the woman's experience of breast cancer?

Religious beliefs and affiliation can play a key role in how a woman understands and copes with breast cancer. We have examined earlier how belief systems both are challenged by the cancer experience and provide needed succor. For African Americans, in particular, concepts of health and religion are closely meshed. Spirituality has been found to be a major resource for managing illness and stressful life events.¹²¹ One study found that African Americans use prayer and spirituality as the primary source of support in coping with breast cancer.^{122,123}

In other ethnic groups, religion and spirituality can also play a role in coping with breast cancer. One study of 39 women living in or near Ottawa, Canada, found that religion and spirituality can help patients to understand their illness, to strengthen their relationships, and to foster their support networks.¹²⁴

An exploratory study found that women with metastatic breast cancer who rated spiritual expression as important had greater numbers of circulating white blood cells and total lymphocyte counts (both helper and cytotoxic T-cell counts) than those who were not as spiritually expressive, even after controlling for demographic, disease status, and treatment variables.¹²⁵ Although the mechanism for this relationship is not clear, the study indicates that there may be both physical and mental health benefits of spirituality in breast cancer patients.

Clinicians must work to understand their patients' religious beliefs and the role of their religious community in their experience of cancer. The community aspect of religious belief offers an important social and spiritual "holding space" for

many in coping with their illness. The relationship of social support to overall health and well-being has been well established in the literature, and religious communities are key sources of that support. Churches and synagogues also can be important centers for community education about cancer. Some African American churches have nurse auxiliaries that can provide education about the importance of cancer prevention and early detection. These “insiders” have been quite successful in recruiting members to screening programs.¹²⁶

WORKPLACE CONSIDERATIONS

What are the most important workplace issues for women with breast cancer who work outside the home?

Most women who enter the cancer clinic for treatment will have at least a part-time job outside the home. The workplace is an important component of most women’s social network and provides resources, both emotional and financial, for weathering the cancer experience. The world of work is also a significant stressor for many women who are balancing the demands of home and career. The most important workplace issues for women with breast cancer are preserving income and access to health insurance benefits and setting a realistic pace at work during the acute phase of treatment.

Many people, both patients and employers, remain ignorant of the reality of breast cancer treatment, from the overall good prognosis to the odd rhythm of treatment side effects that leave many patients too ill to work for several days out of each chemotherapy cycle. Ignorance can translate into discrimination by employers based on expectations of negative outcome and, conversely, unrealistic expectations for normal productivity by the patients themselves. *Working Woman*¹²⁷ conducted a survey of 500 patients who continued to work while receiving treatment. Twenty five percent of the patients said that their job responsibilities were cut or that they were demoted, denied promotion, or passed over for a raise. Seven percent said they were fired as a result of their cancer. This survey also polled managers and colleagues and found a far more pessimistic view of the impact of cancer on job performance than the patients had.

People who have no first-hand knowledge of the improvements in breast cancer treatment and prognosis will not understand that most patients in active treatment can still perform adequately on the job and will resume previous performance ability following treatment. This survey revealed that 60% of the cancer patients undergoing treatment were able to maintain their regular hours during treatment. The challenge for society is to minimize the job stressors of those 60% as they undergo treatment and to protect the jobs and health insurance benefits of the sicker 40%.

How much and to whom should breast cancer patients reveal details of their medical condition?

Legal experts recommend that patients tell their supervisor soon after learning their diagnosis, thus setting the tone for

open communication.¹²⁸ This period just after diagnosis is often the most anxiety provoking as women begin to gather opinions and make decisions about treatment. Once a course is chosen, patients need to learn about the likely side effects of treatment from their oncologists, and again inform supervisors of what may happen. In breast cancer support groups, women have learned that some patients are unable to work for 4 or 5 days after an infusion of doxorubicin despite antiemetics and rehydration therapy, whereas other women feel a slight nausea and miss only 1 day. Once patients have experienced their first treatment, they will have a better sense of how to pace their work lives (and home lives) around the dictates of side effects and fatigue.

Even when fully informed about the physical toll of treatment, patients may have unrealistic expectations of their ability to perform at work. Breast cancer is a blow to self-esteem, and although women may try to minimize the impact, certain biologic realities will intrude on their best intentions to maintain as “normal” a schedule as possible. Conscientious working women will experience the dilemma of not wanting to be excluded by coworkers from important tasks, yet not feeling “totally there” either. Well-meaning advice to “take it easy” does not validate the importance of women’s jobs to their self-esteem and ignores the pressure to minimize cancer treatment’s impact on household income. A woman’s self-esteem may be tied to a social role of being the reliable one in both family and workplace. To preserve health and minimize guilt, roles and expectations in general need to be flexible during treatment and renegotiated during recovery.

What legal or legislative measures protect breast cancer patients’ rights in the workplace?

Four laws protect breast cancer patients in the workplace: the Americans with Disabilities Act (ADA) of 1990, the Family and Medical Leave Act (FMLA) of 1993, the Health Insurance Portability and Accountability Act of 1996, and the related Consolidated Budget Reconciliation Act of 1985 (COBRA). Under the ADA, cancer is considered a disability and requires that employers who have 15 or more employees provide “reasonable accommodation” of the disability, which may include flexible work hours or leave policies, unless the accommodation would impose “undue hardship” on the employer. The Family and Medical Leave Act handles temporary, serious health conditions like cancer (or cancer in a spouse or child) for employees who have completed 1 year of service for at least 25 hours per week and who work for employers with 50 or more employees. The FMLA allows up to 12 weeks of unpaid leave in a 12-month period. The FMLA allows leave to be taken intermittently, which is particularly useful for breast cancer patients who may need to stay home for a few days out of every month during chemotherapy. The FMLA allows for up to 1 week absence per month for 12 months and allows a shorter workday; if medically required, a worker can reduce the workday from 8 hours by increments of 1 hour (a useful strategy for accommodating weeks of daily radiation therapy after lumpectomy).

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 is most relevant to breast cancer survivors who are making a job change. It protects workers who have

been covered under a group policy for a minimum of 18 months from losing health insurance, ensuring "portability" without waiting periods or preexisting condition limitations. This law should help with the "job lock" many cancer survivors experience. If the breast cancer survivor moves to a job that does not offer group health insurance, the law gives the right to purchase individual coverage; however, it does not protect against unreasonably high premiums for individuals outside of groups. The COBRA requirements (passed in the Consolidated Budget Reconciliation Act of 1985) allow individuals to keep their coverage after leaving an employer group for 18 months and protect against high premiums during that period.

Individual states are passing health insurance reforms, and survivors may want to consider a move to a state in which access to health insurance is facilitated, especially if they cannot find coverage in their current situation. Supporting advocacy groups like the National Coalition for Cancer Survivorship are also an important option for expanding breast cancer survivors' rights.

CONCLUSION

The cancer experience challenges not only the individual woman but also her entire network of affiliations, relationships, and support. Yet even as the experience reverberates through the system, numerous resources can emerge to help her mount a resilient response. Clinicians who are alert to the many levels of relationships that affect the woman's life will be able to accompany her more fully and helpfully as she fills gaps and calls forth resources in a successful adaptation to breast cancer.

Rehabilitation and Nursing Care

Jean Lynn

Nurses in a collaborative multidisciplinary setting are the indispensable members of breast health teams that develop supportive strategies to meet the growing demand for comprehensive, service-oriented care. The nurse's involvement includes, but is not limited to, patient triage, patient and family education, psychosocial support, administrative responsibilities that include financial and clinical management, and ultimately, patient advocacy.¹

The nurse can also have an impact on breast cancer awareness in the community. She or he can offer lectures to increase awareness about early detection, screening guidelines, and risk factors and can promote the legislative and political agenda as a breast cancer advocate. Involvement with professional organizations and breast cancer advocacy groups complements the nurse's clinical skills, which, in turn, enhance the care of the breast cancer patient. This role expansion is an asset to the nurse and hence to the other members of the breast health team.

Nursing and patient advocacy go hand in hand. The continued increase in rates of breast cancer has become a very political issue, and consequently, nurses have become involved not only as participants in the breast cancer advocacy movement but also as partners in research, both as scientific reviewers and as a resource to investigators.

The period between the diagnosis of breast cancer and the selection of definitive surgery is an extremely stressful time for the patient. Because breast cancer treatment is highly complex and is a paradigm for multidisciplinary care, the nurse is instrumental in providing emotional and physical support for the woman and her family. Furthermore, nurses can play an essential role in providing continuity of care and individualized treatment plans for each patient. Ideally, the nurse becomes the *patient's navigator*. The nurse helps to educate the patient and her family about all aspects of treatment, follow-up, and subsequent therapy. Preoperative teaching is an integral component of the patient's preparation for and recovery from surgery.

The following text describes how the nurse can effectively care for the newly diagnosed breast cancer patient.

ADDRESSING PATIENT CONCERNS

How can a nurse reassure a patient who has just been diagnosed with breast cancer?

Most often, women want to get treatment started as soon as possible. The nurse can help to reassure the patient that breast cancer is *not* an emergency. Breast cancer may be present for 5 to 8 years before a tumor becomes clinically apparent, either by physical examination or by mammography. A woman with a new diagnosis of breast cancer should explore all her options before making decisions about her therapy. In most cases, waiting several weeks for definitive treatment will not compromise the long-term prognosis.

The nurse should explain that there is no known cause of breast cancer. Although there are many factors associated with an increased risk for developing the disease, about 75% of women who are diagnosed with breast cancer have no known risk factors. When breast cancer is detected early (<1 cm in size), long-term survival is greater than 90%. In fact, even though the incidence continues to rise in the United States, the mortality rate from breast cancer remains steady, and this rate experienced the first decline in 50 years in the early 1990s.² The nurse should promote positive thinking, guide the patient to gather information, and help her process the information.

What should nurses tell patients who seek to learn more about their disease?

The nurse should encourage the patient to incorporate her family or support network into the information-gathering phase of her treatment. Breast cancer is often a family issue. Encourage the patient to have another person with her when she visits with the physician. If that is not possible, a tape recorder might be helpful for information gathering. The patient should realize that breast cancer encompasses a broad

spectrum of lesions with varying patterns of behavior. Therefore, there is no “one way” to treat breast cancer, and the patient should not compare her treatment with that of other women. Each breast cancer behaves differently, and the physician and nurse should provide the patient with information about the specific type of breast cancer she has and explain in detail the rationale behind her personalized treatment plan.

If the patient has access to a computer, there is a myriad of information on the Internet. (See “Internet Resources for Breast Cancer.”) In addition to the informational pamphlets provided by the American Cancer Society and the National Cancer Institute, many books are available for the patient with a new diagnosis.

How should the nurse explain the various treatment options to the patient?

The nurse should emphasize that women are encouraged to become empowered with information that will help them participate in the decision-making process. Evidence-based decisions are the standard of care. The nurse should have up-to-date knowledge about the *evidence* supporting the choices that are being presented to patients. If there is no evidence to support a recommendation, the nurse should be able to discuss clinical trials that the physician feels may be appropriate for the patient.

Most often, women are not sure what type of questions to ask. The Susan G. Komen Foundation has provided a very useful pamphlet entitled “Questions to Ask the Doctor about Breast Cancer.”³ The Susan G. Komen website (www.komen.org) also has an interactive video titled *Anatomy of Breast Cancer*, available in English and Spanish, that the patient can refer to for additional information. The nurse should be prepared to discuss the answers to the questions in the pamphlet, which will complement the information already provided by the surgeon. Several of these questions are addressed in the following list:

1. *What are my treatment options? What is the surgeon recommending for me and why?*
2. *What are the potential risks and benefits of these procedures?*
3. *Will the tumor be analyzed for estrogen and progesterone receptors?* This is important information because it will help the oncologist who prescribes the definitive systemic therapy. When a tumor is estrogen or progesterone receptor positive, the tumor cells are binding to estrogen, progesterone, or both, and these hormones are promoting tumor activity.
4. *Will other special tests for HER-2/neu and proliferation rate be done on the tissue?* How this test is performed is as important as the information it provides. The most accurate method is the fluorescence in situ hybridization (FISH) test to determine *HER-2/neu* status. If the tumor is *HER-2/neu* positive, the oncologist will recommend an anthracycline-based chemotherapy regimen with or without trastuzumab (Herceptin) therapy.
5. *In addition to the radiation therapy, will I need additional treatment with drugs if I have breast-conserving surgery?* The surgeon will most likely not be able to give a definitive answer until the immunohistochemistry analysis (which detects molecular markers [proteins] in breast

tumors) is performed on the sentinel lymph node or the axillary node dissection, and the complete pathologic examination of the tumor is completed.^{4,5}

6. *Is breast reconstruction something I should consider?* There is no time limit on this decision; hence, the woman should not feel pressured into making this decision until she is ready to do so.
7. *Should I consider a prophylactic mastectomy?* Most surgeons do not recommend this procedure, except in unusual circumstances. For many women the peace of mind that comes with not having to worry about breast cancer recurrence is very comforting, but the patient should understand that prophylactic mastectomy does not provide a 100% guarantee. In many cases, not all of the glandular tissue is removed. In most cases, however, mastectomy does reduce the risk for a second primary tumor.
8. *Is it necessary to evaluate the lymph nodes when treating breast cancer?* Most often, yes, if it is an invasive cancer. The nurse should explain that if the patient has a preinvasive cancer, there is no need to perform an axillary node dissection. However, if the preinvasive cancer is extensive, a sentinel lymph node biopsy may be performed. When lymph node dissection is performed, instruction about care of the affected arm will need to be incorporated into the preoperative teaching (Table 39–1).
9. *How long will I need to stay in the hospital? Will I need nursing care at home?* Generally speaking, most patients are in the hospital for a period of 6 to 23 hours. Ideally,

Table 39–1 Precautions for Patients Who Undergo an Axillary Node Dissection

If the sentinel lymph nodes are positive for cancer cells, the surgeon will proceed with an axillary node dissection to determine whether the nodes have any cancer cells.

Lymph nodes are located throughout the body. They filter fluids, proteins, and bacteria that are in our bodies. Occasionally, the removal of lymph nodes causes an ineffective filtering of this fluid, which sometimes results in edema (fluid accumulation) in the arm. This happens in a very small percentage of patients. The following guidelines have been established to help prevent lymphedema from occurring. It is important to review these guidelines and to incorporate them into your daily life:

1. Practice good skin hygiene; use lotion after bathing. When drying the arm, be gentle but thorough.
2. Avoid venipuncture, injections, and infusions into the affected arm.
3. Wear protective gloves when working outside or with water or cleaning products and during all activities that might result in injury to the affected arm.
4. Wear sunscreen to protect against sunburn, and use insect repellent to protect against bites and stings.
5. Do not cut hangnails or cut nails too short; do not push cuticles back to the nail bed.
6. Exercise and use the affected arm; full range of motion and return of strength should return within 2 months.

If a cut, insect bite, or other break in the skin occurs, wash the area with soap and water, use an antiseptic, and cover with a sterile dressing. Watch for any signs of infections, warmth, redness, pain, and/or tenderness.

Contact a physician immediately if an infection develops in the affected arm. She or he will most likely prescribe an antibiotic.

From Precautions for Patients Who Have an Axillary Node Dissection [pamphlet]. Washington, DC, The George Washington University Breast Care Center.

the nurse should see the patient for preoperative teaching a few days before the scheduled procedure. If this is not possible, the nurse should be sure that the patient receives written information about the proposed procedure, and the nurse should have a telephone consultation with the patient. Alternatively, patients may wish to correspond by e-mail. A written documentation of this correspondence is then placed in the patient's chart. Unless the patient has specific physical limitations, home nursing care is not necessary.

10. *Are there any special precautions or side effects from the axillary node dissection in addition to the lymphedema precautions?* Although special care is taken to prevent damage to the intercostobrachial nerve of the affected arm, many patients experience numbness in the armpit and inner arm down to the elbow. Sensation usually returns to the affected arm within several months, or perhaps even up to a year. Some patients indicate that the numbness never diminishes completely. When the numbness starts to dissipate, many patients experience a "pins and needles" sensation in the arm. This is quite common and reflects nerve regeneration. The nurse should instruct the patient to refrain from shaving with a razor in the affected armpit, because of the lack of feeling in that area; she should instead be instructed to use an electric razor to prevent cutting herself.
11. *What is radiation therapy?* The nurse can explain that radiation therapy is the use of high-intensity x-rays directed at the breast tissue to kill off any microscopic cells in the breast. This is given to prevent local recurrence of the breast cancer in the affected breast. The treatment is spaced over a period of 5 to 7 weeks. The nurse can also explain that before the treatment begins, the patient is "simulated." This procedure entails having the patient lie down on a hard table, with the affected arm hyperextended, which may be uncomfortable if it has been only a few weeks since surgery. This procedure takes about an hour; the technologists place markings on the breast surface to serve as landmarks for the daily treatments. These markings may be tattoos, which are permanent. The patient may request a nonpermanent marker, in which case the markings may fade and will require reapplication or touch-up during the treatment process. The simulation procedure is the longest session of radiation therapy. The actual time in treatment generally lasts only 20 minutes. An extra "boost" of radiation may be given to the area of the breast where the primary tumor originated. As detailed in Chapter 26, the usual dose of radiation is 5000 cGy, with a daily dose of 180 to 200 cGy/day. The nurse can suggest that the patient bring a book or portable music source to pass the time and should reassure the patient that the technologist is always within hearing distance and she is never alone.
12. *How soon will I begin radiation treatments?* This will depend on what the medical team decides is best. In any event, radiotherapy will not begin until the patient is completely healed from surgery.
13. *How many treatments will I receive?* The nurse can explain that the patient will be receiving treatments on a daily basis for about 20 minutes a day over a period of 5 to 7 weeks. Although this is an interruption of the patient's daily schedule, it is a relatively short period of time in the major treatment plan. Most women work full-time while receiving their therapy and schedule their appointments early in the morning, on their lunch hour, or after work. Once treatment is begun on a particular machine, the patient will have to stay with that machine for the duration of her therapy.
14. *What are the side effects of radiation therapy?* Although many women tolerate radiation therapy to the breast without any significant side effects, the nurse should inform the patient that one side effect from radiation may be fatigue due to the cumulative effect of radiation toward the third to fourth week of therapy. This usually subsides several weeks after radiation therapy is completed. Other side effects may be some breast tenderness and soreness, which gradually disappear over time; however, the irradiated breast may never feel completely normal compared with the other breast. Some women also describe "shooting pains" within the breast after receiving radiation that may or may not disappear. Another common side effect is skin redness, the "sunburn" effect. This side effect is more pronounced in fair-skinned people and usually subsides with time. As the redness goes away, there may be a darkening of the skin, and the pores can become enlarged and more noticeable. Fibrosis (thickening) of the breast tissue is a significant long-term effect. If the axilla has been irradiated, the patient may be prone to the subsequent appearance of lymphedema because the radiation compounds the scarring from surgery. The patient will also be unable to lactate from the irradiated breast.
15. *What should I do for my skin when receiving radiation therapy?* The nurse should advise the patient to follow these guidelines:
 - a. Wash with mild soap (e.g., Dove, Neutrogena, Basis).
 - b. Do not wear deodorant on the affected side because deodorants usually contain aluminum, which can interact with the radiation. Use cornstarch or talc-free baby powder as an alternative to deodorant. Health food stores may also have deodorant alternatives.
 - c. Shave only with an electric razor. There will be no feeling or sensation in the armpit area because of nerve manipulation, and you might cut yourself without realizing it. This could increase the incidence of lymphedema or infection.
 - d. Do not use any over-the-counter creams or lotions without checking with the nurse or physician in radiation therapy. Avoid direct sunlight to the area, and use sunscreen (SPF 15 or higher).
 - e. Avoid tight bras or underwire bras. Wear a sports bra if possible.
 - f. Use only unscented hydrophilic creams such as Aquaphor, Biafine Unscented, 99% to 100% pure aloe vera gel (with no added perfumes or dyes), or Radiacare gel or gel pads.

Although radiation therapy is generally used for women who choose breast-conserving therapy, some women may require it after a mastectomy to help prevent local recurrence.

What other information should patients receive preoperatively?

Before surgery, the physician may order several radiographs or blood tests to evaluate for metastatic disease. Routine labora-

tory tests include a complete blood count, which measures hemoglobin and hematocrit (red blood cell production). Other tests include liver chemistries and perhaps tumor marker studies as a baseline. A chest radiograph will be done, and the physician may order a bone scan and a computed tomography (CT) scan of the abdomen, depending on the clinical stage of presentation of disease. These are done to evaluate the lung, liver, and bones, which are the most common sites for breast cancer to spread. These tests may provoke some tension and anxiety, but they are performed to get a thorough overall picture of the patient and to have an established baseline from which to prescribe the most appropriate therapy.

The patient should be instructed before surgery that she will meet with the anesthesiologist. Encourage the patient to share any concerns she may have and to inform the anesthesiologist of any over-the-counter medicines, especially herbal medicines, that she may be taking.

Patients are admitted to the hospital on the day of surgery and usually stay in the hospital from 6 to 23 hours, depending on the type of surgery performed. On the day of surgery, the patient should wear a loose-fitting blouse that buttons down the front for the trip home. This will facilitate dressing because she should not need to raise her arm over her head owing to the incision in or near the axilla. She should also be instructed not to wear jewelry or contact lenses or to take any valuables with her to the hospital. If she is taking medications, advise her to check with the anesthesiologist to see if they must be taken on the morning of surgery. Also, if patients have dentures, hearing aids, canes, or walkers, these items should be labeled with the patient's name and placed in a secure area during the surgery.

How should nurses instruct patients during the postoperative period and adjuvant therapy?

It is unlikely that any side effects will occur, but patients should be made aware that there is potential for the following problems.

Seromas: These are fluid collections beneath the surgical site.

Fluid leakage from the drain: If the drain is not functioning properly—that is, if the suction device is malfunctioning—fluid may accumulate beneath the incision. If the patient notices that fluid accumulation has ceased in the drainage bulb or canister, the nurse may assess whether the tube is blocked with a clot and may then gently “milk” the tubing to clear the blockage.

Infection: If there is any fever or swelling (edema) around the drain site or incision, the patient should contact the physician immediately.

What care is required during the postoperative period?

Pain should be controlled before patient discharge. The nurse can explain to the patient that there will be some discomfort in the axilla. A prescribed pain medication or over-the-counter analgesic should be used. The nurse should encourage the

patient to take rest periods, pace herself, and seek the support of friends and family during the first 2 weeks after the operation. Usually, many people are willing to help out. Suggest that a friend organize dinner meals for the next couple of weeks.

Exercises are commonly advised following breast surgery, usually beginning 24 hours after the drain has been removed. Exercising may be uncomfortable, and ibuprofen or acetaminophen may be taken before commencing exercise.

Most women are so busy that they do not “have time” for breast cancer. Obviously, there is no good time to have breast cancer, but it is also unrealistic to think that patients' schedules can be resumed as if nothing has happened. Encourage patients to allow time for processing this event. Support groups are very helpful. If a patient does not have access to a support group, the nurse may suggest an online support group provided through the Wellness Community by a licensed social worker (www.thewellnesscommunity.org). It is comforting for many women to talk to others who are undergoing the same experience.

What might nurses convey to patients about systemic treatments?

After surgery is completed and all the information has been obtained from the breast tumor, a consultation with a medical oncologist will be scheduled to discuss the possibility of adjuvant hormonal therapy, chemotherapy, or a combination of the two. The following questions are similar to ones that may be asked of the nurse.

Will I receive hormonal therapy?

The nurse should explain that if the tumor is estrogen or progesterone receptor positive, hormonal therapy may be prescribed by itself or in addition to chemotherapy and radiation. Hormonal therapy is used to prevent recurrence of the tumor and to reduce the patient's risk for developing a contralateral or ipsilateral breast tumor. Tamoxifen blocks tumor cells from binding with estrogen and stops tumor growth. Tamoxifen has been the gold standard for decades, but newer studies show that for postmenopausal women, aromatase inhibitors such as Arimidex are becoming the treatment of choice.⁶ Although tamoxifen is well tolerated, it has side effects: hot flashes, decrease in libido, depression, vaginal dryness, and irregularity in the menstrual cycle. Patients, especially postmenopausal women, may also be at increased risk of thromboembolytic events. Women taking tamoxifen may also be at a slightly increased risk for developing cataracts. Other eye problems that have been reported are corneal scarring and retinal changes. Some benefits of using tamoxifen are that it increases bone augmentation and has a beneficial effect on coronary heart disease. Even though tamoxifen is an anti-estrogen drug, patients can still become pregnant while taking it. The nurse should instruct patients to use birth control while taking tamoxifen. There is also a risk for developing endometrial cancer. Therefore, annual gynecologic examinations should be performed.

In premenopausal women, tamoxifen stimulates the ovaries, which in turn increases estrogen and progesterone levels and may increase the incidence of ovarian cysts and stimulate ovulation while blocking estrogen in the breast. Side

effects of aromatase inhibitors include hot flashes, arthralgias, fatigue, and occasional nausea. Women taking aromatase inhibitors are also more prone to fractures. The nurse should inform the patient about appropriate calcium intake (1200–1500 mg/day), and a DEXA (dual energy x-ray absorptiometry) scan should be obtained prior to initiating treatment with an aromatase inhibitor. Vaginal dryness is a side effect of both of these therapies. Over-the-counter vaginal lubricants (e.g., Replens, Astroglide) can be used to alleviate this symptom. The usual course of therapy for tamoxifen and aromatase inhibitors is 5 years.

Will I have chemotherapy?

To many patients, chemotherapy sounds frightening, and questions about it are usually asked in the preoperative stage. To treat breast cancer aggressively and effectively and to decrease the possibility of a recurrence of the breast cancer or of a second primary cancer, chemotherapy is the most effective treatment we have at this time, in addition to surgery and radiation. The patient probably knows someone who has had chemotherapy in the past and whose memory of this experience is unpleasant. The side effects of chemotherapy are more manageable now than they were in years past. New medications minimize nausea and vomiting, and most women are able to work full-time while they are receiving chemotherapy.

How does chemotherapy work?

The nurse may explain that cancer cells proliferate at an uncontrolled rate. The cell division process is interrupted by chemotherapy, so that the cells cannot continue to multiply and divide. The drugs chosen to treat breast cancer have been shown to be effective against breast tumors through previous clinical trials. These drugs interfere with the cell division at different points in the cell cycle. This is why a combination of two or three drugs may be chosen as part of the treatment regimen.

Most women who undergo adjuvant chemotherapy tolerate it quite well. Because the chemotherapy affects fast-growing cells (i.e., tumor cells), it often affects other healthy, fast-growing cells in the body. These include the hair, the lining of the mouth, the lining of the gastrointestinal tract, and the blood cells in the bone marrow. The most devastating side effect for many women is hair loss.

Hair loss does not occur all at once. It is a gradual process that begins most often about 2 to 3 weeks after chemotherapy is administered. Many of my patients have shared that the hair loss occurs first in the pubic area and then on the head. Of course, this process depends on the drugs that are prescribed. Assurances that the hair will grow back do not necessarily diminish the patient's sense of loss. Some women have stated that they would endure more of the other side effects to avoid this one. When the hair does resume its growth, it takes about 3 months to grow in; most often, the hair is fine and is initially curly or wavy.

If the patient is likely to receive a drug that will definitely cause hair loss, the nurse should tell the patient where she can purchase a wig. It is very important to purchase a wig before the onset of hair loss. If the patient is receiving chemotherapy, the Look Good Feel Better Program of the American Cancer Society can help her with cosmetics application and styling of her wig. It is a half-day of pampering, and many women enjoy it.

How are chemotherapy side effects managed?

Although the nurse can facilitate access to resources and education, educating the patient to advocate for herself is just as important. Patients should be encouraged to ask questions. As the patient begins treatment, the nurse can teach her about the following:

1. *Keeping track of blood counts.* Blood counts are monitored on a weekly basis to evaluate the impact the chemotherapy has had on the bone marrow. The goal of chemotherapy is to give the maximum amount of drug in the shortest period of time, but at the same time, not to compromise the patient so that she will be susceptible to infection. If white blood cell counts fall below a certain point, patients can be more susceptible to infection. Therefore, the physician may prescribe filgrastim or pegfilgrastim to be used with chemotherapy. Filgrastim or pegfilgrastim is administered to stimulate the bone marrow to produce white blood cells.
2. *Eating a well-balanced diet.* Patients who are undergoing treatment always ask questions about food. The patient should avoid foods that are high in fat. This may be difficult to do on some days because the medications may cause patients to be hungry. Patients may experience waves of nausea and find that snacking on crackers or other light foods helps to alleviate this feeling. It is not uncommon for patients to gain weight while they are on chemotherapy. Other side effects that are not unusual include alterations in taste. Certain odors or food aromas may precipitate a wave of nausea. It is hard to predict just who will experience these symptoms, but patients who do should keep a record of the symptoms so they can avoid these foods in the future.
4. *Avoiding alcohol.* It is best not to drink alcohol. The drugs being given to the patient are metabolized in the liver, which is where alcohol is also metabolized. Liver enzyme values will also be monitored.
5. *Learning the dosage of drugs.* The drug dosage is determined by the patient's height and weight (body surface area). If the patient should gain or lose weight while on chemotherapy, the dosage may be changed. When chemotherapy is started, the patient should ask what her body surface area is, and what is the dosage of each drug being prescribed. Each time she receives chemotherapy, she should check the dose with the nurse.
6. *Chemotherapy-induced menopause.* If the patient is premenopausal, the chemotherapy may precipitate an early menopause. This depends on the patient's age at diagnosis. In some women, menstruation becomes irregular during chemotherapy. When chemotherapy is finished, the menstrual cycle may return to normal. Menopausal symptoms include hot flashes, vaginal dryness, sleep disturbances, mood swings, and decreased libido. The decrease in libido is also experienced while patients are undergoing chemotherapy because of alteration in body image, fatigue, and nausea. Because it is not advisable to use estrogen replacement therapy for these symptoms, other alternatives including vitamin E (400 IU daily) and the use of selective serotonin reuptake inhibitors (SSRIs; paroxetine and fluoxetine), venlafaxine, or gabapentin may also be prescribed.⁷ As mentioned previously, the nurse should instruct the patient about using calcium supplements to help prevent

osteoporosis. The recommended dose of calcium for postmenopausal women is 1500 mg per day. The body can absorb only 500 µg at a time, so the supplements should be spaced out throughout the day. Low-dose vaginal estrogen is also used to help with vaginal dryness. Vagifem 25-µg tablets and an estradiol vaginal ring (Estring) are the most commonly prescribed medications that provide a local estrogenic effect. Vagifem tablets are inserted 1 tablet intravaginally each day for 14 days, then 1 tablet twice weekly thereafter. Estring is inserted into the upper third of the vaginal vault and is worn continuously for 3 months. Estring releases estradiol, approximately 7.5 µg over 24 hours. Side effects from both of these medications may include headache, vaginal spotting or discharge, allergic reaction, and skin rash.

The above therapies should be combined with an exercise routine such as walking or swimming to achieve maximum benefit.

How might breast cancer affect sexuality and intimacy?

Many women at the time of diagnosis may have a strong need for intimacy; others, conversely, may withdraw from their partner. As mentioned earlier, breast cancer is a life-changing event in a woman's life. Sexual arousal may take longer because of the side effects from medications and other treatments. Libido may not be very strong because of physical and emotional stress. Women may feel that they have become unattractive to their partners if they have had a mastectomy or have alopecia. However, the sexual health of the woman is important to the process of recovery. Some women may not feel comfortable initiating the discussion of side effects and what other women undergoing therapy have experienced. Chances are that if the nurse initiates the discussion, the patient will be relieved to be asked.

How is a prosthesis selected?

A Reach to Recovery referral should be made preoperatively. This allows more time for the American Cancer Society to match the woman with a volunteer who has had a similar experience. These volunteers are often able to offer their perspective on the healing process. They will also bring a temporary (cotton) prosthesis and a mastectomy bra for the woman who has not had reconstruction. The surgical healing process takes about 6 weeks, after which the patient can be fitted for a permanent prosthesis. Permanent prostheses vary in size, weight, texture, and—most significantly—price. The physician will provide a prescription for a breast prosthesis. Most health insurance plans cover from 50% to 80% of the total cost. If the patient needs financial assistance in procuring a prosthesis, the American Cancer Society has resources to assist the patient. The Reach to Recovery program will also provide a list of stores that sell prostheses.

When the woman is ready to have a fitting for a permanent prosthesis, she should make an appointment. The fitting takes about an hour, and she should not feel rushed. The breast tis-

sue needs to be matched in weight to give a good body alignment. Mastectomy bras will also be needed. These, too, may be covered by insurance.

The nurse should become familiar with the shops in the area and visit them before making referrals. If the nurse can establish relationships with the fitters, it facilitates streamlining the care for women needing prostheses.

What are the interventions for menopausal symptoms?

As more young women are diagnosed with breast cancer, premature menopause is becoming more common. These symptoms affect the woman's quality of life and can be very uncomfortable.

Hot Flashes

Hot flashes are the most common side effect. The physiologic mechanism responsible for menopause is poorly understood. Some scientists postulate a pulsatile release of luteinizing hormone secreted from the ovary. This accompanies the decreasing levels of estrogen just before menopause. This release of luteinizing hormone may cause an alteration in sympathetic tone, causing vasodilatation, perspiration, and changes in blood flow, temperature, and heart rate. Hot flashes usually begin as a feeling of pressure in the head, neck, and upper chest and back that spreads to the entire body. The range and duration of hot flashes may vary; a woman may experience as few as one a day or as many as three an hour. Hot flashes interrupt sleep, causing irritability and insomnia. The good news is that hot flashes usually decrease with time as onset of menopause approaches.

To manage hot flashes, the nurse should provide the following suggestions:

- Wear absorbent cotton clothing.
- Dress in layers that can be removed as needed.
- Lower the thermostat.
- Avoid caffeine, spicy foods, and alcohol.
- Exercise regularly.
- Learn relaxation techniques.
- Record the number of hot flashes each day, and report this to the nurse or physician.

Nonhormonal interventions may include the following:

- Vitamin E, 400 IU twice a day (no side effects at this dosage)
- Black cohosh (over the counter in capsule form)
- SSRIs (paroxetine and fluoxetine)
- Antihypertensives (transdermal clonidine)

Atrophic Vaginitis

A drop in estrogen levels results in decreased elasticity of the vaginal wall. The vaginal lining becomes thinner and more fragile, and the pH becomes more alkaline, causing a woman to be at risk for vaginal or urinary tract infections. There is also decreased vaginal lubrication, which leads to dryness and dyspareunia.

Interventions for vaginal dryness include warm baths to alleviate vaginal itching and discomfort. Douches, feminine hygiene sprays, perfumed soaps, and perfumed toilet paper should be avoided. Over-the-counter agents are available to

Table 39–2 Drain Care after Surgery: Instructions for the Patient

After your surgery, you will notice a bulblike drain connected to tubing coming from your incision. This device suctions and collects fluid from the incisional area. The drain promotes healing and reduces the chance of infection.

The drain will be in place for 5 to 10 days after surgery. (The time varies from surgeon to surgeon.) You will most likely be discharged from the hospital with the drain in place. Your nurse will review the care of the drain with you. Remember to empty the drainage bottle every 12 hours or as often as directed. Refer to these instructions as needed:

1. Obtain a measuring cup to collect the fluid, and then wash your hands thoroughly.
2. Unpin the bottle from your dressing or your shirt.
3. Remove the rubber stopper from the bottle. Turn the bottle upside down, and squeeze the contents into the measuring cup. Empty the bottle completely, and keep a record of the amount of fluid in the measuring cup. *Note:* To prevent infection, do not let the rubber stopper or top of the bottle touch the measuring cup or any other surface.
4. Use one hand to squeeze all the air from the bottle. With the bottle still compressed, use your other hand to replace the rubber stopper. Do this to make sure the drain suction works well.
5. Pin the bottle back on your dressing or your shirt to avoid pulling it out accidentally. Wash your hands again (see Fig. 39–1).

From Drain Care after Surgery: Directions and Information [pamphlet]. Washington, DC, George Washington University Breast Care Center.

counteract vaginal dryness. For everyday dryness, Replens, Gyne-Moistrin, Lubrin vaginal suppositories, Astroglide, or K-Y Jelly (or other water-soluble lubricant) may be used. Pharmacologic interventions include Estrin and Vagifem tablets.

Vaginal Discharge and Yeast Infections

Vaginal discharge most often represents a yeast infection. It is exacerbated by factors that normally increase vaginal discharge, such as diabetes, antibiotic therapy, and extreme stress. Interventions include the use of Monistat, Femstat, or Diflucan.

Breast Self-Examination

After the acute phase of treatment is over, most women may benefit from individualized instruction in breast self-examination. The MammaCare method is a highly effective step-by-step program using the vertical strip technique. Certification to teach this technique can be obtained from the Mammatech Corporation (Gainesville, FL). Nurses can call 1-800-626-2273 for more information.

What are the long-term rehabilitation issues?

Although the diagnosis of breast cancer may pose adjustment issues later in life, it is important for women to try to find an appropriate balance. As breast cancer survivors, patients can become advocates for other women like themselves, either by volunteering for the Reach to Recovery program of the American Cancer Society or by becoming involved with other breast cancer support organizations. The National Breast Cancer Coalition, a grassroots advocacy effort, is a good

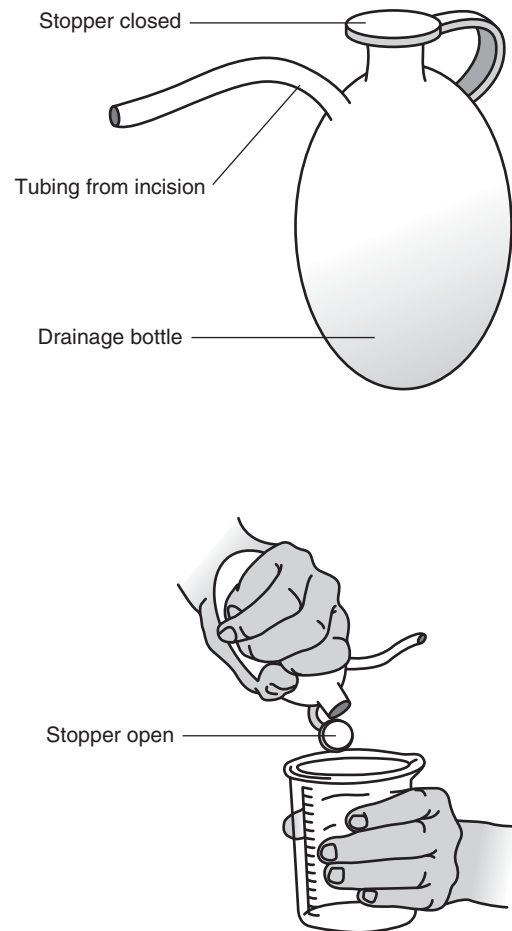

Figure 39–1 Postoperative drainage bulb. (From Drain Care after Surgery: Directions and Information [pamphlet]. Washington, DC, George Washington University Breast Care Center.)

example of how survivors have become advocates for themselves and other women. It has been very successful in securing money for breast cancer research and is influential on Capitol Hill, where breast cancer policy and legislation are initiated.

The nurse's role in the surgical setting is quite challenging, but it can be very rewarding. Roles continue to evolve as new treatment strategies become available. Promoting quality cancer care is the best gift nurses can provide to their patients. In addition to the Quality of Care Standards position by the Oncology Nursing Society, the National Breast Cancer Coalition Fund released the *Guide to Quality Breast Cancer Care* in 2002.⁸ This is a comprehensive guide that provides excellent information for the breast cancer patient. This guide can be obtained free of charge by calling 1-866-624-5307 or through their website, www.natlbcc.org.

How should patients be instructed in drain care after surgery?

See Table 39–2 and Figure 39–1 for patient instructions on drain care after surgery.

Pendulum Exercises

While standing, bend forward at the hips, and allow the affected shoulder to hang loosely in front of the body. Place the uninvolved hand on a table or chair for support.

Swing the arm in a clockwise circle, beginning with small circles and gradually increasing the size. Make 10 circles, then make 10 circles in a counterclockwise direction.

Swing the affected arm side to side across the chest 10 times in each direction.

Swing arm forward and backward as far as possible without any pulling at your incision.

Wall Climbing with the Fingertips

Stand facing the wall, and extend the affected arm directly in front of you so that your fingertips touch the wall (at arm's length from the wall). Creep up the side of the wall with your fingertips, taking a step toward the wall as you reach higher and higher up the wall. Repeat the procedure going down the wall, but taking a step backward this time.

Repeat the above procedure, but this time position yourself perpendicular (at a right angle) to the wall so that the affected arm extends sideways up the wall. Keep your trunk straight, not leaning toward the wall or shrugging your shoulders. Place a pencil mark on the wall each day, and try to go a bit farther every day.

Figure 39-2 Patient exercises to be performed after breast-conserving surgery or mastectomy. (From Breast Care Center. Washington, DC, George Washington University Medical Faculty Associates.)

What postoperative exercises should patients perform after breast-conserving surgery or mastectomy?

See Figure 39–2 for patient exercises to be performed after breast-conserving surgery or mastectomy. Patients should be advised not to start active range-of-motion exercises until they have been instructed to do so by their surgeon.

Medicolegal Issues in Breast Cancer Diagnosis and Treatment

Jay A. Rappaport and Andrew I. Kaplan

OPENING STATEMENT

According to the last Annual Report of the National Practitioner Data Bank (NPDB), the central repository of information regarding malpractice payments made on behalf of physicians nationally, during calendar year 2002, 80.6% of new reports concerning malpractice payments were physician related, with the median and mean malpractice payment amounts totaling \$150,000 and \$275,094, respectively.¹ Significantly, diagnosis-related payments were the most frequently reported (36.7% of all payments).¹

Although there is no comprehensive database tracking the basis, theory, and result of all medical malpractice claims in the United States, the Physician Insurers Association of America (PIAA), an association of more than 50 medical malpractice insurance carriers, regularly compiles malpractice claims data from more than 20 member companies to publish reports on national trends involving malpractice claims, particularly those involving breast cancer. According to the PIAA's *2000 Research Notes*, the average indemnity paid on breast cancer claims has consistently increased over the past 15 years. The average indemnity paid on breast cancer claims from 1990 to 1994 was \$224,509, whereas the average indemnity from 1995 to 1999 was \$231,596. Of note is the fact that the average indemnity paid for breast cancer claims over the entire 15 years from 1985 to 1999 was \$251,505, well above the average indemnity of \$163,743 for *all other malpractice claims made during that time period*.²

In fact, the most recent data accumulated by the PIAA suggest that the allegation of an error in the diagnosis of breast cancer has become the most prevalent condition precipitating medical malpractice lawsuits against all physicians. More than 41% of all claims involving breast cancer result in an indemnity payment to the claimant/patient. The latest figures released by the PIAA indicate that overall indemnification for all breast cancer malpractice litigation averaged \$438,000 in 2002, a 45% increase in the corresponding figure from 1995.³ Quite obviously, the public perception that earlier diagnosis virtually guarantees a cure, combined with the belief that clinical evaluation and mammography should be 100% accurate, has led to a deluge of claims for failure to diagnose breast

cancer and a concomitant willingness by juries to compensate patients for those perceived failures.

Medical professionals are certainly familiar with a wide variety of stressors, uncertainties, and hurdles inherent to the practice of medicine, and the practitioner has learned and developed methods and algorithms to deal with them. When physicians are named as defendants in a lawsuit, however, it is akin to entering a foreign land without a passport or an appreciation of the language. It drags practitioners outside the medical arena and subjects them to forces over which they have little, if any, control and often even less knowledge.

The patients who bring such suits, particularly in the realm of breast cancer litigation, have their own significant stressors and anxieties. Both sides going forward must understand this fact. It serves no one to engage in characterizations of those who sue, or those who are sued.

This chapter seeks to raise questions and, whenever possible, to suggest answers as to why the national court system has seen such a steady influx of claims alleging practitioners' failure to diagnose and treat breast cancer in a timely fashion and the manner in which that influx has caused, and should cause, physicians to take stock in and accommodate their methods of practicing medicine in an increasingly litigious environment. Through our own experiences as medical malpractice litigators and through the analysis of jury verdicts and insurance claims made and paid in lawsuits arising from claims of failure to diagnose and treat breast cancer in a timely manner, we aim to enlighten the reader as to the legal theories and hurdles applicable to such claims and the medical theories most often elucidated and litigated by the patients who bring them. Although it is neither our intent nor our desire to offer suggestions as to the clinical management of patients, at the conclusion of this chapter, we offer suggestions as to the manner in which the practitioner may be proactive in both preventing and defending exposure to malpractice litigation.

What is malpractice?

We have always found it instructive, whether discussing the matter with physicians or laypersons, to educate the listener

(or, in this case, reader) as to the charge delivered by the court to the average jury member sitting in judgment in a medical malpractice action, just before commencing deliberation. The *Pattern Jury Instructions* define malpractice as follows:

*Malpractice is professional negligence and medical malpractice is the negligence of a doctor. Negligence is the failure to use reasonable care under the circumstances, doing something that a reasonably prudent doctor would not do under the circumstances, or failing to do something that a reasonably prudent doctor would do under the circumstances. It is a deviation or departure from accepted practice.*⁴

A doctor who renders medical service to a patient is obligated to have that reasonable degree of knowledge and skill that is expected of an average specialist who performs or provides that medical service in the medical community in which the doctor practices.

The law recognizes that there are differences in the abilities of doctors, just as there are differences in the abilities of people engaged in other activities. To practice medicine, a doctor is not required to have the extraordinary knowledge and ability that belongs to a few doctors of exceptional ability. However, every doctor is required to keep reasonably informed of new developments in his or her field and to practice medicine or surgery in accordance with approved methods and means of treatment in general use. A doctor must also use his or her best judgment and whatever superior knowledge and skill he or she possesses, even if the knowledge and skill exceed that possessed by the average specialist in the medical community where the doctor practices.

By undertaking to perform a medical service, a doctor does not guarantee a good result. The fact that there was a bad result to the patient, by itself, does not make the doctor liable. The doctor is liable only if he or she was negligent. Whether the doctor was negligent is to be decided on the basis of the facts and conditions existing at the time of the claimed negligence.

A doctor is not liable for an error in judgment if he or she does what he or she decides is best after careful evaluation, if it is a judgment that a reasonably prudent doctor could have made under the circumstances.

If the doctor is negligent—that is, lacks the skill or knowledge required of him or her in providing a medical service, or fails to use reasonable care in providing the service, or fails to exercise his or her best judgment, and such failure is a substantial factor in causing harm to the patient—then the doctor is responsible for the injury or harm caused.

Breast cancer litigation is a form of tort litigation wherein a patient, termed the *plaintiff*, brings the action accusing a physician, the *defendant*, of a civil wrong. That civil wrong is negligence—failure to act as a “reasonable person,” or to adhere to a particular standard of care. Negligence by a professional is termed *malpractice*; by a physician or hospital, *medical malpractice*. The burden of proving every essential element that constitutes malpractice in any given case remains with the patient from institution of the proceeding until the verdict is rendered and judgment entered.

In medical malpractice litigation, the standard of care arises from the physician’s responsibility to possess and apply that reasonable degree of skill, learning, and ability ordinarily possessed by physicians within the community in which he or

she practices. The standard of care within the community in which the defendant practices changes on a case-by-case basis; prior trial court decisions in similar actions have no precedential or binding effect. Thus, there is no set “standard of care” adherent to the management of patients with breast disease, nor could there be one. In each individual situation, it is the duty of the fact-finder—the jury (and occasionally of the appellate courts, in situations in which the jury’s decision is inconsistent with the facts or the law presented)—to determine just what the applicable standard of care is in any given situation and to determine whether the defendant physician met that standard.

To establish a claim for civil negligence, there must first be proof of a duty owed (a physician–patient relationship). That relationship arises any time a physician undertakes to diagnose or treat conditions of the patient’s breast, whether it be during examination within the confines of the office, in rendering advice over the telephone while “on call” for a colleague, or even in the performance and interpretation of mammography, despite the rarity of the interpreting radiologist’s actually meeting the patient at all. In fact, according to the most recent PIAA statistics, radiologists are the specialists most frequently named as defendants in malpractice litigation, accounting for 33% of all claims. Obstetrician-gynecologists are second at 22.8%, and surgeons are third at 10.6%.⁵

Once it has been established that a duty to render appropriate care exists, the next prong in establishing a claim for medical malpractice lies in proving a *breach of duty* (commonly defined as a departure or deviation from good and accepted practice or care). Whether the physician breached is a determination made by the jury based on the medical evidence in the case and the testimony of the witnesses. More often than not, it is the testimony and the credibility of the expert witnesses in the case on the subjects of standard of care in the community and whether the particular practitioner on trial adhered to or departed from that standard that influence a jury’s decision. Those experts are subject to cross-examination by opposing counsel, not only on the medical testimony given on the stand but also on their qualifications and credibility, and in the face of inconsistent sworn testimony they may have given previously on similar topics in other courts of law.

Medical treatises or guidelines applicable to the period of treatment at issue, as well as the defendant’s own prior testimony, publications, and office protocols, may also come into play in the jury’s analysis. Most courts adhere to the common rule that a text or treatise must first be acknowledged as authoritative in the field before it may be read to the jury, but once acknowledged as such, it may be used to establish that the defendant practitioner deviated from the authoritative standards as set forth within the publication and thus committed malpractice.

Most attorneys who select juries on behalf of patients will tell those juries that they are not claiming that the practitioner acted, or failed to act, intentionally, or that they are “bad” doctors. Instead, they allege one act, or series of acts, of malpractice as isolated incidents of breach of care in a longer history of good practice. Without a “bad result,” meaning without injury, there is no case, but every jury is charged that a bad result, in and of itself, is not evidence of malpractice. It is not the result that legally determines whether there was negligence. Practically speaking, however, a jury faced with a bad

result will undoubtedly consider that result in the exercise of deliberation.

An error in medical judgment is not evidence of malpractice, either. In context, the use of the word *judgment* here has a specific meaning. Judgment comes into play in the arena of malpractice litigation where, and only where, there are two (or more) ways for a physician to approach a situation. If there are two ways to deal with the situation, each acceptable in the medical community, the choice by the physician of the one over the other is the exercise of judgment, and if exercised appropriately, the physician can be defended, even if the chosen treatment failed.

Many a practitioner has attempted to defend an allegation of malpractice by asserting that an exercise of judgment cannot constitute negligence, and many a tribunal has allowed the pursuit of just such a defense. In reality, however, almost every action involving a physician's decision making as it pertained to a patient could conceivably be defended as such, and so the courts have attempted to limit the defense of judgment to those situations in which the practitioner had two very real and very acceptable treatment options available and chose one over the other to the unfortunate but unpredictable detriment of the patient.

In that regard, jurors are cautioned against casting *their* judgment on the defendant physician based on outcome, but rather are directed to consider what the physician had in front of him or her at the time care was rendered and decisions made. The reason for this directive, as would appear to be obvious, is that in hindsight we are almost all correct. Even claims brought against radiologists for the misreading of mammograms, which come as close as any case can to a question of accurate interpretation, are not immune from hindsight analysis because of the unique nature of breast imaging. The difficulty of getting the exact same view twice, the nature of the image, particularly of dense breasts, and the requirement of significant experience and ability can place these cases in the realm of hindsight as well. Any radiologist can tell you it is easier to spot a cancer on mammography once you know it is there.

The third, and most essential, prong in establishing medical malpractice—particularly in the realm of breast cancer litigation—is causation. It must be shown that the practitioner's action or inaction was the competent producing cause of injury to the patient. In other words, the burden is on the patient to prove that, *more likely than not*, earlier or alternative diagnosis or treatment would have positively affected outcome. Thus, it is not the patient's burden to establish that appropriate care would have resulted in cure (though in some situations that is the very allegation made); rather, it is enough to establish that it would have affected the quality and duration of life to the patient's benefit. So significant is the subject of causation that it maintains its own Pattern Jury Instruction. Proximate cause is defined in the *Pattern Jury Instructions* as follows:

*An act or omission is regarded as a cause of an injury if it was a substantial factor in bringing about the injury, that is, if it had such an effect in producing the injury that reasonable people would regard it as a cause of the injury. There may be more than one cause of an injury, but to be substantial, it cannot be slight or trivial. You may, however, decide that a cause is substantial even if you assign a relatively small percentage to it.*⁶

Acknowledging, then, that a delay in diagnosis, even a negligent delay, may not affect the patient's ultimate outcome, the law interposes the evidentiary requirement of "proximate cause" on plaintiffs seeking monetary damages in medical malpractice cases. Technically, if a physician's negligence did not cause harm, as it were, the patient should be unable to make out what is known as a *prima facie*, or sufficient on its face, case of medical malpractice that will survive dismissal at the close of plaintiff's evidence rather than reach the deliberation of the jury. In reality, however, rare is the action in which medical negligence is proven yet the claim dismissed by court or jury. As will be discussed further, the public perceives that earlier and accurate diagnosis alters outcome, and the public is often unwilling to forgive the practitioner who has breached the standard of care or accept that "it didn't make a difference."

The final prong in establishing a claim of medical malpractice, and perhaps the most obvious one, is that the patient must have sustained an actual injury as a result of the practitioner's malpractice in order to obtain reward for financial damages. Although punitive or punishment damage awards are rare, juries are instructed that under the appropriate circumstances, they can award noneconomic damages for pain and suffering as well as loss of consortium or society (an award made for harm to a close relationship, such as with a spouse or child). Indeed, it is common for a patient's spouse to be named as co-plaintiff in a malpractice action, to seek redress for loss of society, comfort, and companionship due to the injuries alleged, and to obtain remuneration in significant amounts in those cases in which a jury determines that plaintiffs have proven their claims.

Economic damages such as loss of earnings incurred to date and in the future, medical costs, rehabilitation and therapy costs, and out-of-pocket expenses for goods and services can be granted as well, and often constitute a hefty portion of the fees awarded. The fact is that cases involving allegations of negligence in the diagnosis and treatment of patients with breast cancer often involve devastating injuries, both emotionally and financially, to those who bring suit. In fact, according to the PIAA, the average award in medical malpractice actions involving breast cancer is second only to those cases involving brain damage suffered by infants at or around the time of delivery.⁵

As a caveat, although the burden of proof in all cases rests on the party asserting the claim, the defense, alternatively, must prove those issues raised by the defense, which are deemed *affirmative defenses*, and which must be set forth in the initial answer to the complaint. Perhaps the most significant of these affirmative defenses in the realm of breast cancer litigation is termed *culpable conduct*, or more correctly, *comparative negligence*, which is conduct by the patient that caused or contributed to her own damages and may reduce the ultimate verdict by the percentage of that culpability. In the area of breast cancer litigation, this usually means that the patient did not follow an instruction, which, if followed, would have improved her outcome or prognosis. Because in many instances in this area of litigation, the patient has died from her disease or likely will, this defense is one approached with care and trepidation. The patient's attorney will no doubt attempt to portray the defense and the doctor as "blaming the patient." Thus, to be effective, not only must such a defense be medically valid, but, as will be discussed further in this

chapter, the basis for the defense must be well documented in the defendant physician's records and, preferably, supported by the records of the other nonparty treating practitioners.

Who sues whom and why?

Statistical analysis reveals that although most breast cancer occurs in women older than 50 years, most malpractice suits regarding breast cancer are brought by women younger than 50 years. In fact, according to the PIAA's *2002 Breast Cancer Study*—a data-sharing study of 450 paid malpractice cases in which the central allegation cited a delay in the diagnosis of breast cancer—the average age of claimants in breast cancer litigation is 45 years, with 68% of claimants younger than 50 years and 33% younger than 40 years.⁵ Patients younger than 40 years accounted for 47.5% of the claims in which wrongful death as a result of missed diagnosis was pled.

By the same token, research reveals that the average indemnity payment for younger plaintiffs was significantly higher than that for older patients. Patients younger than 40 years accounted for 33% of claims made and 42.9% of indemnity reported. The average indemnity for patients younger than 30 years was \$603,537, and younger than 40 years, \$508,606, compared with an average award of just under \$300,000 for patients between the ages of 50 and 70 years.⁵ Almost one third of patients (31.3%) had a family history of breast cancer, and most patients—55.1%—were premenopausal.⁵

That younger patients bring the majority of claims and recover the largest awards for those claims stands to reason, particularly given the nature of malpractice litigation. In terms of awards, juries are given wide latitude, within certain established parameters, in determining damages, both economic and noneconomic. Life expectancy *had timely diagnosis been made* is a significant factor in the determination of compensation, not only for future loss of earnings but also for deriving the almost incalculable compensation for the loss of months, days, or weeks with loved ones left behind. Patients with young children inevitably garner more significant indemnity for the potential loss of parental guidance occasioned on their offspring.

The overwhelming majority of malpractice claims related to breast cancer involve failure to timely diagnose, as opposed to less frequently seen claims such as iatrogenic injury, unnecessary mastectomy, or burns related to radiation oncology. We undertook a simple Lexis/Nexis analysis, which revealed that of the 20 judicial decisions rendered in breast cancer matters at both the state and federal levels since January 2003 (not only jury verdicts but also decisions rendered on pretrial discovery issues), the underlying facts reflected that 16 of the 20, or 80% of the cases reviewed, revolved around allegations of a failure to timely diagnose and treat breast cancer. Two cases involved injuries secondary to radiation, and the other two alleged the unnecessary performance of mastectomy.⁷

Of the 17 jury verdicts or settlements in breast cancer litigation reached and reported to the *National Jury Verdict Reporter* in 2004, over the preceding 2-year period, 15 of the 17—or 88%—were matters involving radiologists or surgeons, and only one involved anything other than a failure to diagnose breast cancer in a timely manner.⁷ Five of the 17 matters resulted in jury verdicts between \$1.5 and \$5.25 million, with an average jury verdict of \$2,144,375. Only 3 of the

17 cases reported resulted in verdicts in favor of the defendant at the conclusion of trial. Ten of the 17 plaintiffs, or nearly 60%, were younger than 50 years, and two women younger than 50 years accounted for the two highest reported verdicts of \$5.25 million and \$4 million. The overwhelming majority of cases reported involved misread mammograms, and more than 50% also involved patients whose self-detected lumps had been diagnosed as benign or fibrocystic.⁷ Given the difficulty in defending against public perception and intrinsic sympathy for the patient and her family, it is not difficult to understand why most breast cancer claims settle before a jury can price them.

Increased awareness of breast health, particularly the encouragement of earlier and more regular self-breast examinations, has led to not only earlier diagnosis of suspicious lesions but also increased awareness of their presence. Nonetheless, statistics seem to support that practitioners are often unimpressed with the presence of a painless, self-discovered mass in patients younger than 50 years, particularly those that have had a negative or equivocal mammogram. According to PIAA's report, in 58.9% of breast cancer claims, the patient found the lesion herself. In 38.7% of the cases, the patient's presenting symptom at the first physician visit was a lump in the breast, yet 24.4% of all patients in the study—110 of the 174 claims for which the patient presented with a specific complaint of a breast lump—were initially diagnosed with a benign condition such as a cyst, fibrocystic disease, or benign lump.⁵ By way of comparison, the second most prevalent physical finding on examination in the cases cited, after palpable mass, was "pain in breast," and this appeared in only 16.2% of cases.⁵ As will be discussed in the ensuing section, the practitioner must do more, particularly in the younger patient, to ensure the benignity of any palpable lesion appreciated by the physician or patient.

Accordingly, the specialists most often named as defendants in the cases cited (both by PIAA and in the informal survey by the authors) were radiologists, followed by obstetrician-gynecologists and surgeons.⁵ Obviously, the most common allegation against radiologists was the failure to properly interpret mammography—at first blush, perhaps, somewhat surprising given the continued advancement and sensitivity of the technology. This may, however, also be reflective of the increased use of screening mammograms that, when used in hindsight, may be deemed by a plaintiff's expert to depict an undiagnosed mass, suspicious microcalcifications, or quality too poor to merit accurate and reliable interpretation.

For surgeons, obstetrician-gynecologists, and general practitioners, the most common theme in breast cancer litigation continues to be *physical findings failed to impress*, which PIAA found in 44% of claims, followed by *failure to refer to specialist for biopsy* in 40.5% of cases involving obstetrician-gynecologists or general practitioners.⁵ Medically, this is equally unsurprising.

As mentioned, younger patients have lower indicia of suspicion for breast cancer from the moment they walk into the examination room. Doctors are less likely to order a biopsy or strict follow-up for younger patients, who are statistically less likely to have breast cancer. In addition, younger patients have denser breast tissue, which can obscure or obstruct the performance of physical examination as well as mammography. Pregnancy, breast-feeding, and hormonal changes can also cause changes in breast tissue, and—absent a family history of

breast disease—younger patients are often poorer historians of breast health and less likely to seek medical attention expeditiously on the first potential signs of concern or irregularity.

Public perception cannot be discounted in its impact on breast cancer claims and verdicts. In this context, we would point out that even though there are extant studies that seem to indicate that delay, at times, does not affect outcome, this is a “hard sell” to jurors, indoctrinated as they are by campaigns that indicate that early detection saves lives. Once a patient or a potential juror accepts such a theory as truth, then, by definition, any delay is “bad,” meaning that the delay in diagnosis is a compensable item of damages.

Clearly, survival is not the same as cure, but once a patient and a juror hear “survival” rates discussed in the examining room or the courtroom, the natural inclination is to tune out the pessimistic evidence of the natural biology of cancer and tune into the optimism of early detection and timely treatment in effectuating “cure.” Well-publicized advances in technology benefit the practitioner and patient alike but also indoctrinate the mindset that failure is unacceptable. Accuracy at all times becomes mandatory and is, of course, impossible to achieve, particularly in those situations in which the patient maintains a level of responsibility for failure to heed the clinician’s recommendations or warnings.

A patient’s attorney will almost always argue that the response of the practitioner—radiologist, surgeon, gynecologist, or general practitioner—to complaints or findings was not nearly aggressive enough in the face of a potentially deadly yet curable disease. The mammography warranted magnification; the cyst warranted aspiration; the lump warranted biopsy, the pain required referral; her complaints necessitated follow-up in 3 months, not 6 months or a year. As long as the public perceives or misperceives that earlier diagnosis of breast cancer virtually guarantees a cure and that any delay in diagnosis is a death sentence—even in the face of objective medical expert testimony to the contrary—the number of malpractice claims related to the failure to diagnose breast cancer in a timely way will continue to rise, as will the rate of compensation for those claims, accordingly.

What is a physician to do?

Fortunately, many of the issues of the actual practice of breast care are, and should be, designed to avoid delay, and although it is an issue more for the practitioner than for the lawyers who represent them, the concept of “delay avoidance” ultimately inures to the benefit of the practitioner in the courtroom as well as the examination room.

At the outset, it is imperative for all physicians to be aware that the most important requirement of effective defense in litigation is documentation. If a fact, finding, or recommendation is not documented, the issue of its existence becomes almost purely one of credibility, a contest between the healthy physician or institution against the individual, frequently ill, patient. In context, it is important to realize that the physician will have many patients and will have seen many of them between the incidents complained of and the lawsuit. The patient, however, will have only one thing to recall: her own treatment.

This is not to say that the patient’s recall will be at all times accurate or that the physician’s will not be. However, common

sense dictates that in this area the patient has an advantage, which can be reduced or removed by appropriate, thorough documentation. It is not really enough to say, “I always do it.” If “it” is important enough to “always do,” it is important enough to *always document*.

Documentation of a pertinent finding or recommendation and the fact that it has been conveyed to the patient or appropriate physician serves not only to contemporaneously establish the nature and purpose of treatment recommended and given but also to aid in the practitioner’s legal defense months or years down the road, when memories have faded or have become biased by health problems and when credibility between the parties is at issue. Documentation of pertinent family histories, all breast complaints, and tactful notification of the risks of undiagnosed breast cancer for patients who do not follow up is mandatory in maintaining a complete chart.

Jurors have a natural inclination to accept what is written in a medical record as truth, or to at least provide the documented medical chart with the preferential inference of accuracy. In this way, communication and documentation truly go hand in hand. The passage of time, the backdrop of litigation, the sympathy afforded an ill patient or her family, and the suspicion of a physician’s presumed self-interest can all be countered by a medical record replete with pertinent findings and recommendations entered contemporaneously with treatment, long before the prospect of litigation was ever entertained.

Insofar as charting is concerned, as time has passed, the charting requirements of the various insurance programs, both private and government, have increased to the point at which computer assistance has become available and may well become standard. It is not our purpose to deal in depth with this issue, but some observations are in order.

The practitioner and counsel are always advantaged by the maintenance of a complete chart. By *complete*, we mean one that contains all notes by the physician, all reports received, and, importantly, all memoranda that have to do with follow-up. Given the prevalence of claims against radiologists, documentation of the receipt and comparison of prior studies and inclusion of copies of those reports in the chart are extremely helpful. Telephone messages received should be acknowledged in the chart (stapled to a page is always good), and the response to them documented.

In addition to documenting all recommendations, documentation of the physician’s thought process, including the diagnoses and tests considered and ruled out, as well as why, provides credible explanations of the judgment applied to potential jurors down the road. Documenting follow-up on any and all recommendations is imperative. A physician might recommend mammography, a mammographer might recommend sonography, a sonographer might recommend biopsy, and all three (or two, if the mammographer also performs sonography) might recommend a breast surgeon be consulted. On the next visit, a follow-up note can, and should, be generated. Did the patient comply? If not, why not? If so, when? Again, the testimony that “I always ask” is not as effective as a note documenting that the question was asked and a response received.

Some patients do not return after a recommendation for treatment or consult is made. Because most of these recommendations are or should be timed (mammogram “next week,” for example), a follow-up system that accounts for the

receipt of an appropriate report or consult note is helpful in countering the subtle, and sometimes not so subtle, indication by the patient's attorney that the physician in question did not care or, worse, abandoned the patient. These allegations are based on the unspoken but real supposition that in medical matters patients have given up the skills and knowledge they use in their everyday lives and have become dependent on the special skills of others. Because most jurors are patients as well, this argument holds weight and can sway opinion. Accurate documentation of a patient's reluctance to follow recommendations, pursue treatment, or keep appointments can help to counter the allegation that any delay was necessarily occasioned by the physician.

We believe that documentation of findings is an area with which most physicians are familiar. It is in the area of absence of findings where we find cases that are sometimes difficult to defend. Although the patient might complain of a mass or other abnormal finding, that finding at times cannot be, or is not, replicated on the physician's examination. Because there would be no suit without a later finding of a mass, a lesion, or the like, the inevitable allegation is that the malignancy was, in fact, the previously "missed" mass.

Here is where documentation can be of great assistance. A clear and accurate picture (literally, a drawing) of the area indicated by the patient will do much to assist in the defense of these cases, presuming, of course, that the malignancy is not where the patient initially felt a mass. To defend cases such as this, however, more is needed than good documentation. Appropriate referral (to a mammographer, sonographer, breast surgeon) is the best defense for the primary care physician, whether obstetrician-gynecologist or internist. If there is one lesson to be learned from the PIAA study, it is that a breast mass should always be resolved, whether it be by aspiration, biopsy, or appropriate referral. For the physician who receives the referral, the above rules for documentation apply, presuming nothing is found.

As an aside, we may be asked why we suggest that a physician go through these steps for something not clinically felt or appreciated. The answer lies in the reality that many jurors will believe that a patient is more familiar with her body than the physician is and, concurrently, that we are dealing with a common (an often-cited statistic is that one out of nine women will suffer breast cancer) disease. If a disease is "common" and life threatening, an attorney will argue that its mortality demands that any and all steps be taken to rule it out, and this argument is a telling one.

In terms of mental approach, despite cliché, the courtroom is not a theater or a sports arena. There are, indeed, both theatrical and sports analogies used in the description and practice of the litigation process, but these analogies are often suspect. Using them, however, is helpful in developing the concept of breast cancer litigation and the appropriate litigation mindset.

Language is important to all of us, and in the courtroom it is particularly important. In the context of litigation, however, it takes a back seat to attitude. This is why physicians are directed to consider themselves as fact witnesses, not "defendants," and that they are not to "defend" their case, which is the responsibility and province of counsel. The reasons for this are multifactorial. First, once words such as defense are being used, we are in the realm of the lawyer, not the realm of

the doctor. The simple reality is that the defense of a breast cancer case is the attorney's job, whereas the careful and truthful rendition of the facts and circumstances surrounding the incidents in question is the witness' job, be that witness another treating physician or the defendant.

It must be understood that sympathy is the unacknowledged, impermissible (the court will advise the jury not to use sympathy in its determinations) factor that must be recognized and controlled when possible. The physician defendant will not engender sympathy in the presence of the usual breast cancer sufferer or in the presence of the grieving family. Thus, any attitude other than professional commitment and concern works against the physician as a witness.

This does not mean that true sincerity, or caring, cannot be shown. It is antagonism toward the process, or the participants, that must be avoided. Thus, whereas the sporting arena analogy with its theme of two sides in competition is comparable, it is often, ultimately, counterproductive. Similarly, the "courtroom as theater" analogy distracts. Jurors, increasingly more sophisticated and litigation savvy, will detect actors and disregard them. Conversely, they will respond to a knowledgeable professional who presents without obvious ego, calmly indicating facts and opinions that bolster the reality of the defense.

Communication is the key element in establishing credibility and rapport with a patient and in gaining a patient's trust. In the breast cancer cases that we have litigated, invariably, either at the time of her deposition or at trial, the patient sets forth the basis for bringing suit: "He didn't tell me a thing." "She ignored my complaints." "He showed no compassion." "She never told me I needed a follow-up appointment." "No one ever suggested mammography," or "ultrasound," or "aspiration," or "biopsy." The list is endless, but it always centers on the patient's underlying mistrust of the physician for failing to simply and accurately convey pertinent findings and recommendations in a professional and timely manner.

As clichéd as it may seem, the "relationship" between physician and patient is often a key determining factor in whether a patient chooses to pursue legal remedy against a physician, irrespective of whether a cancer was "missed" or a departure from appropriate care occurred. The way the patient views her relationship with the physician matters.

By the same token, we often encounter, in the course of litigation, prior, contemporaneous, and subsequent treating physicians who we believe would be appropriate parties to the action, but for the patient's refusal to sue them. Our ability to implead these physicians, where applicable, is irrelevant for the purposes of this discussion, but, ultimately, it is our experience that the patient's rationale for excluding these physicians as party defendants is directly related to the basis for suing the party defendants: "He was the only one who was straight with me," or "I love Dr. Brown. She really listened to what I had to say." Rare is the patient who will pursue litigation against a physician with whom she has developed a relationship of mutual trust, courtesy, and respect.

It is certainly not the rule, but quite often a physician's honesty and ability to "connect" with the patient can overcome the inclination to sue for even the most damaging of medical errors. In fact, from the perspective of trial preparation, a physician's ability to build a rapport with his or her patients—and, specifically, what types of people or patients an individ-

ual physician best connects with—can assist counsel in determining what types of people would be preferential jurors.

SUMMATION

It has been neither the purpose nor the intent of this chapter to presume to advise physicians on practicing “good medicine,” because that is the responsibility of the practitioner. Rather, it is our desire to address the recurrent themes in this area of litigation and to alert the reader to the pitfalls and potential perils that exist in the hopes of avoiding them. Although practicing with “litigation in mind” is distasteful to most physicians, the fact is that the prevention and the defense of a potential malpractice suit begin long before the patient retains an attorney and files a complaint.

In a society obsessed with litigation and saturated by the legal news media, physicians can no longer afford to remain ignorant of the legal ramifications of their actions or inactions. National financial constraints render malpractice insurance coverage and potential health maintenance inclusion or exclusion for individual physicians or physician groups precarious at best and often dependent solely on the number of malpractice claims *instituted* against the physician or entity, irrespective of the merits of those claims.

Just as preventive medicine affords the patient optimal opportunity to avoid disease, so too does the practice of preventive medicine afford the physician optimal odds for avoiding litigation. Quite simply, the best way to avoid litigation is to consistently render care that is in accord with good and accepted standards and to render care that is consistently care-

ful; to communicate and to document; and to update not only one’s medical education but also one’s knowledge of the law as it applies to one’s specialty and the practice of medicine as a whole. It is not necessary that the physician practice with litigation in mind, but it is imperative that the physician not ignore the prospect of litigation entirely.

In terms of preventing litigation, the role of physician as compassionate caregiver should not be underestimated. Reality informs us, however, that even thoughtful physicians who communicate well can be and are sued. As verdict awards increase, even the most conscientious of practitioners may ultimately find themselves in the role of defendant.
