Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Author assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

Epidemiology of Breast Cancer

Anne Zeleniuch-Jacquotte and Roy E. Shore

What is the frequency of breast cancer in the world?

Breast cancer is the most common cancer (22% of all new cases) as well as the leading cause of cancer deaths (14% of all cancer deaths) in women worldwide.¹ The number of new cases in 2000 was estimated to be 1.05 million and the number of deaths 370,000. Breast cancer is the most prevalent cancer in the world: in 2000, there were an estimated 3.9 million women alive who had had breast cancer diagnosed within the previous 5 years.¹

How does breast cancer incidence vary by country?

Incidence varies more than fourfold internationally, with high rates in all the more developed countries except Japan (i.e., North America, Northern and Western Europe, Australia) (Fig. 1–1). High rates are also observed in southern South America, especially in Uruguay and Argentina. In contrast, most African and Asian populations have low rates, whereas rates in Central America and Eastern Europe are intermediate.¹ The incidence of breast cancer is increasing in most countries, with the greatest changes where rates were previously low. Whereas the worldwide increase in incidence between 1990 and 2000 was about 1.5% per year, many low-risk countries recorded increases greater than this: for instance, 2% in Japan, and 3% to 5% in some areas of China.¹ Although part of these international and temporal variations may be spurious, owing to incomplete reporting and variable diagnostic practices, the consistent pattern of higher rates in certain regions suggests true differences in underlying breast cancer risk across nations.²

How does breast cancer incidence change in immigrant populations?

Breast cancer incidence among immigrant populations gradually changes from the incidence in the country of origin to approach the incidence in the immigration country.^{3–6} For instance, Asian Americans born in Asia, where incidence is low, are at lower risk for breast cancer than Asian Americans born in the United States but are at higher risk than Asian

women born and living in Asia.^{4,6} Breast cancer risk increases with the number of years lived in the immigration country, and in subsequent generations risk continues to increase and to approach the risk in native-born populations.⁶ However, the speed with which breast cancer incidence among immigrants and their offspring approaches that of their adopted country varies considerably from one ethnic group to another.⁷ Of additional interest, among Asian American women, immigrants from urban areas arrived in the United States with a 30% greater risk than immigrants from rural areas.⁶

International geographic variations in breast cancer incidence, in conjunction with the temporal changes in these rates and results of immigrant studies, have long indicated that lifestyle and environment play an important role in the development of breast cancer. However, a recent study that assessed the risk for breast cancer in women from various racial and ethnic groups living in California and Hawaii reported that, after adjusting for seven known lifestyle risk factors (ages at menarche, age at birth of first child, parity, age at and type of menopause (natural or surgical), weight, hormone replacement therapy use, and alcohol consumption), the risk for breast cancer was 65% greater in Native Hawaiian women and 11% greater in Japanese American women than in white women.⁸ These results suggest that genetic factors may also play a role, although other environmental factors, such as diet, could also explain these results.

What is the frequency of breast cancer in the United States?

Breast cancer is the most common cancer among American women, representing 32% of all new cancers (Fig. 1–2), and is the second leading cause of cancer deaths in American women, representing 15% of all cancer deaths, behind lung cancer (25% of all cancer deaths).⁹ On the basis of current incidence, it is predicted that one of every eight women in the United States will develop invasive breast cancer in her lifetime.¹⁰

In 2005, approximately 211,240 new cases of invasive breast cancer are expected to occur among women in the United States.¹¹ In addition, it is anticipated that 58,490 new cases of in situ breast cancer will be diagnosed in the same year. These numbers represent a sharp increase over the past 30 years. From 1970 to 2005, the number of invasive breast

Figure 1-1 Estimated incidence by country, age-standardized by world standard population. (Data from Parkin DM. Global cancer statistics in the year 2000. *Lancet Oncol* 2001;2:533–543.)

Figure 1-2 Sites of new cancer cases and deaths—2003 estimates. (Data from American Cancer Society. *Breast Cancer Facts and Figures 2003–2004* [Online]. Available: http://www.cancer.org/docroot/STT/content/STT_1x_Breast_Cancer_Facts_Figures_2003-2004.asp [accessed January 29, 2004].)

cancer cases increased by approximately 200% (from 69,000 to 211,240).^{9,12} This increase, however, is due in large part to the increase in the population of older women, who are at higher risk of developing the disease.¹³ In the same time period (1970–2003), the number of deaths from breast cancer also increased, but only by 33% (from 30,000 to 39,800), a result of early detection by mammography screening and improvements in treatment.

How has U.S. incidence changed over time?

To assess the temporal changes in breast cancer incidence, it is necessary to examine age-adjusted incidence that is independent of changes in the age distribution of the U.S. population. Such statistics are available through the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program, which has collected cancer incidence and survival data from population-based cancer registries since 1973 (<http://www.seer.cancer.gov>). Figure 1-3 shows the SEER age-adjusted incidence of invasive breast cancer from 1975 to 2000. Three distinct phases are seen: between 1975 and 1980, the incidence was essentially constant; between 1980 and 1987, the incidence increased by about 4% per year; between 1987 and 2000, the incidence (adjusted for delayed reporting¹⁴) increased by 0.6% per year.^{15,16} Using the 2000 U.S. standard population, the 2000 age-adjusted incidence was 135.1 per 100,000 woman-years.

The increase in invasive breast cancer incidence was not uniform across histologic types and estrogen receptor (ER) status. The incidence of ductal carcinoma appeared to remain essentially constant from 1987 to 1999, whereas the incidence of lobular carcinoma increased steadily.¹⁷ Also, most of the increase in breast cancer incidence appeared to be due to an increase in incidence of estrogen receptor-positive tumors,^{18–20} which was not accounted for by technical improvements or changes in tumor size, age, or nodal status.²¹

Figure 1–3 Incidence, age-adjusted to the 2000 standard U.S. population, SEER 1975–2000. (Data from Ries LAG, Eisner MP, Kosary CL, et al. SEER Cancer Statistics Review, 1975–2000 [Online]. Available: http://seer.cancer.gov/csr/1975_2000 [accessed January 28, 2004].)

The age-adjusted incidence of in situ breast cancer increased considerably over the past 20 years, with a 32.3% annual increase from 1982 to 1986 and a 6.1% annual increase from 1986 to 2000.¹⁶ This dramatic increase is largely attributable to an increase in ductal carcinoma in situ (DCIS),²² which between 1996 and 2000 accounted for 88% of all in situ breast cancer cases.¹¹ Between 1975 and 2000, the incidence of DCIS increased five times faster than the incidence of invasive breast cancer. In the same time period, the incidence of lobular carcinoma in situ (LCIS) also increased, but only twice as fast as the incidence of invasive breast cancer.¹¹

What are the causes of the increase in breast cancer incidence in the United States?

The rapid increase in invasive breast cancer incidence between 1980 and 1987 was largely due to an increase in the incidence of small tumors (<2.0 cm), which more than doubled, while rates of larger tumors decreased.²³ The increase in incidence was also limited to the localized stage, whereas the incidence of breast cancer at regional and distant stages remained stable. These data suggest that the increase may be explained in large part by greater use of mammography screening, which detects small tumors, many of them too small to be palpable. The limited data available on mammography utilization before 1987 indicate that only 10% to 20% of women older than 40 years had ever had a mammogram (including for diagnostic purposes) by the early 1980s.²⁴ The rate of mammography screening has increased steadily since then. Data from the National Health Interview Surveys show that the percentage of women who reported having had a screening mammogram in the previous year was 17% in 1987, 33% in 1990, and 55%

in 2000.^{11,25} Although it may seem surprising that the incidence increased at a much slower rate after 1987 than in the 1980 to 1987 years whereas use of mammographic screening was still increasing sharply, this pattern is not unexpected for a screening procedure that detects early cases that would have been diagnosed in any case but at a later date: at the beginning of screening implementation, the incidence increases because screen-detected cases are added to symptom-diagnosed cases. However, later on, although the number of screen-detected cases keeps increasing as more women are being screened, the number of symptom-detected cases goes down (because some of them were detected earlier through screening), resulting in a leveling off (or even a decrease) in the overall incidence.²⁶

The strong increase in incidence of in situ breast cancer was especially pronounced among women 50 years of age and older,^{11,22} which is consistent with the age pattern of mammography screening.²² The larger impact of screening on DCIS than LCIS incidence was also anticipated because of the lack of specific radiologic criteria for LCIS, which is generally not detectable by mammography.²⁷

Are there causes other than mammography that explain the changes in U.S. incidence?

It has been argued that the increase in mammographic screening cannot entirely explain the increase in breast cancer incidence,⁵ and that changes in the profile of risk factors in the U.S. population also may have played a role.²³ In particular, changes in patterns of childbearing, with a trend toward delayed first birth and decreased parity, have been suggested as plausible causes of the rise in breast cancer incidence.²¹ Indeed, it has been estimated that later age at first birth and nulliparity account for 30% of breast cancer cases in the United States.²⁸ Although an increase in fertility rates was observed following World War II (baby boom), and this increase was shown to be associated with a reduction in breast cancer mortality in women born between 1924 and 1938,²⁹ a trend to lower parity and later age at first birth started in the 1960s, which would be expected to result in an increase in incidence. Oral contraceptives and hormone replacement therapy may also have contributed to the rise in breast cancer incidence because both exposures are associated with small increases in breast cancer risk during their use and for some time after cessation.^{30,31}

Changes in the distribution of risk factors could explain, at least in part, the variations in the temporal trends of the incidence according to histologic type and ER status: for instance, nulliparity appears to be more consistently associated with ER-positive than with ER-negative tumors, and increasing use of combined hormone replacement therapy³² appears to increase preferentially the risk for lobular carcinoma.^{33–36}

What is the risk for breast cancer in American men?

Breast cancer occurs infrequently in men, with about 1500 new cases diagnosed each year in the United States.³⁷ The lifetime risk for being diagnosed with breast cancer is 0.11% for

Figure 1-4 Five-year age-specific breast cancer incidence for white women (*open circles*) and African American women (*closed circles*) from 25 through 84 years of age by estrogen receptor (ER) status of breast cancer. (Data from Tarone RE, Chu KC. The greater impact of menopause on ER- than ER+ breast cancer incidence: A possible explanation [United States]. *Cancer Caus Cont* 2002;13:7-14.)

American men, in contrast to 13.5% for women,¹⁰ a 120-fold ratio.

What is the impact of age on breast cancer incidence?

The incidence for invasive breast cancer strongly increases with age. Overall, the increase in incidence with age is much steeper before than after 50 years of age, suggesting that menopause has a protective effect.³⁸ Furthermore, two recent studies, one in Denmark and one in the United States, have shown that only the incidence of ER-positive breast cancer increases after 50 years of age, whereas the incidence of ER-negative breast cancer stops increasing after 50 years of age^{39,40} (Fig. 1-4). These observations, suggesting that ER-negative tumors are more dependent on the premenopausal sex hormone environment than ER-positive tumors, need to be investigated further. An extensive review of the role of reproductive factors in the development of breast cancer is presented in Chapter 4.

What is the impact of race and ethnicity on breast cancer incidence?

Breast cancer is the most common cancer among women in every major ethnic group in the United States.⁴¹ However, the age-adjusted incidence varies greatly according to race or ethnic group. It is highest among white women (140.8 per 100,000 in years 1996-2000), lowest among American Indian or Alaska Native women (58 per 100,000), and

intermediate among African American (121.7 per 100,000), Asian or Pacific Islander (97.2 per 100,000), and Hispanic women (89.8 per 100,000).¹⁵ During 1992 to 2000, incidence increased overall in Asians and Pacific Islanders (2.1% per year), Hispanics (1.3% per year), and whites (0.9% per year) whereas rates decreased in American Indians and Alaska Natives (-3.7%) and remained stable in African Americans (Fig. 1-5).

White non-Hispanic women are more likely to present with localized stage breast cancer than African Americans (Fig. 1-6) and other racial or ethnic groups.^{15,42} Differences in mammography screening rates may explain this result, at least in part: in 2000, the percentage of women 40 years and older reporting having had a mammogram in the previous 2 years was 72% for white women, 68% for African American women, 63% for Hispanic women, 57% for Asian and Pacific Islander women, and 52% for American Indian and Alaska Native women.⁴³ However, the difference in mammography use between African American and white women decreased substantially since 1987.⁴⁴

Other differences in tumor characteristics in relation to race or ethnicity have been reported. SEER data show that, compared with non-Hispanic whites, tumors in African Americans are more likely to be hormone receptor negative and of medullary histology, two characteristics associated with poor prognosis, and are less likely to have a lobular histology, which is associated with lower mortality.⁴⁵⁻⁴⁸ Although data are limited, the risk for hormone receptor-negative breast cancer also appears higher in Native Americans, Asians or Pacific Islanders, and Hispanic whites 50 years of age or older than in non-Hispanic whites in the same age group, although not as high as in African Americans.⁴⁶

Figure 1-5 Incidence, age-adjusted to the 2000 standard U.S. population, by race and ethnicity, SEER 1975–2000. (Data from American Cancer Society. Breast Cancer Facts and Figures 2003–2004 [Online]. Available: http://www.cancer.org/docroot/STT/content/STT_1x_Breast_Cancer_Facts_Figures_2003-2004.asp [accessed January 29, 2004].)

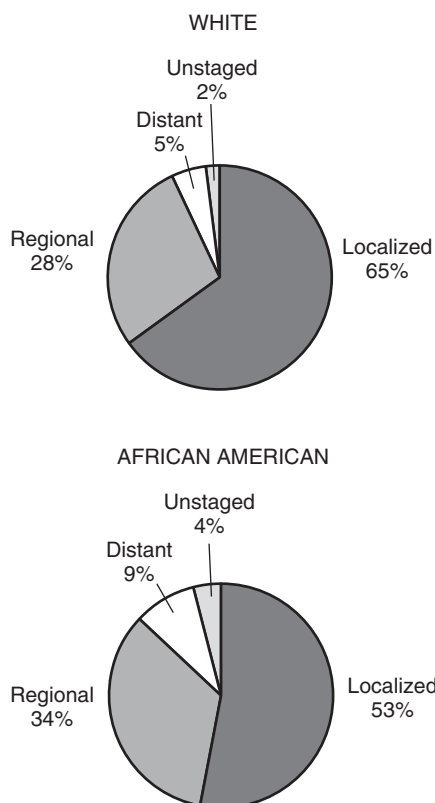

Figure 1-6 Stage distribution for African American and white women, based on patients diagnosed between 1992 and 1999. (Data from American Cancer Society. Breast Cancer Facts and Figures 2003–2004 [Online]. Available: http://www.cancer.org/docroot/STT/content/STT_1x_Breast_Cancer_Facts_Figures_2003-2004.asp [accessed January 29, 2004].)

Comparisons of the age-specific incidence in African American and white women show an unusual racial crossover in risk: up to age 40 years, African American women have a higher incidence than white women, whereas after age 40 years, rates for white women exceed those for African American women, and the disparity increases with age¹⁵ (Fig.

1–7). The incidence difference observed among older women appears to reflect racial differences in socioeconomic status⁴⁹ and related reproductive patterns⁵⁰: white women have a later age at menarche, fewer births, and a later age at first full-term pregnancy than African American women, all factors that are known to increase the long-term risk for breast cancer.

Differences in reproductive patterns in young African American and white women could also explain, at least in part, the excess risk observed in young African American women.^{51,52} It has been shown that pregnancy has a dual effect on breast cancer risk, with a transient risk increase for several years after childbirth, followed by a risk reduction in later years.^{53–55} African American women tend to have higher parity than white women,⁵⁶ which could contribute to their higher breast cancer incidence at ages younger than 40 years and lower incidence at older ages. Other factors possibly contributing to the higher premenopausal breast cancer rates in African Americans compared with whites are less breast feeding,⁵⁷ younger age at menarche,^{51,58,59} use of oral contraceptives at a younger age,⁵¹ and lower physical activity.⁵¹ On the other hand, African Americans have a younger age at first full-term pregnancy,⁵⁰ are more likely to be overweight or obese,⁶⁰ and are less likely to consume alcohol than whites,⁶¹ all factors that should lower their risk for premenopausal breast cancer, as compared with white women. Additional research to assess whether differences in known risk factor profiles are sufficient to explain the racial age-related crossover in breast cancer incidence is warranted.⁵⁰

What is the impact of place of residence in the United States on breast cancer incidence?

For several decades, mortality from breast cancer has been highest in the Northeast of the United States and lowest in the South.^{62,63} Rates are also somewhat higher in the Midwest and West than in the South.⁶² This pattern is more pronounced among postmenopausal than among premenopausal women, for whom little geographic variation was observed. A cluster analysis further suggested that the New York City–Philadelphia metropolitan area had a 7.4% higher mortality rate than the rest of the Northeast.⁶⁴ The elevated breast

Figure 1-7 Age-specific incidence for African American and white women, SEER 1996–2000. (Data from American Cancer Society. Breast Cancer Facts and Figures 2003–2004 [Online]. Available: http://www.cancer.org/docroot/STT/content/STT_1x_Breast_Cancer_Facts_Figures_2003-2004.asp [accessed January 29, 2004].)

cancer mortality observed in the Northeast has led to the suspicion that unknown environmental hazards, more prevalent in this region than in others, increase the risk for breast cancer of Northeastern residents. Two studies, though, showed that geographic variations in mortality or incidence could be accounted for, at least in part, by differing regional patterns of known risk and prognostic factors for breast cancer.^{62,65} One of the major contributors to the high rates of breast cancer in the Northeast was the tendency of Northeastern women to have first births at later ages.⁶⁶

What environmental exposures may affect breast cancer risk?

A number of studies have demonstrated that ionizing radiation causes female breast cancer. The studies range from the Japanese atomic bomb study,⁶⁷ to diagnostic x-rays,^{68,69} to studies of radiation treatment for benign conditions^{70,71} or cancer.⁷²

The studies show agreement that the dose-response relationship for breast cancer is approximately linear⁷³ and that radiation exposure in the first two decades of life confers several times more breast cancer risk than exposure in the adult years, whereas exposures beyond age 50 years confer little risk.⁶⁷ For irradiation at age 30 years, the excess relative risk for breast cancer increases about 1% per 1 cGy (1 rad).⁷³ Of special interest is the finding of a substantial excess of breast cancer in patients who had received on the order of 100 fluoroscopic examinations in the course of pneumothorax treatment for tuberculosis^{68,74}; these studies show that small dose fractions have a cumulative breast cancer induction effect similar to the risk one would expect if the total dose had been given as one exposure. The bottom line, however, is that most medical diagnostic radiation exposures with modern equipment and techniques are sufficiently low that any breast cancer risk from them would be undetectable.

It has been proposed that exposure to 60-Hz electromagnetic fields (EMFs) may confer risk for breast cancer by

inhibiting the synthesis of melatonin by the pineal gland, which, in turn, may result in higher levels of circulating estrogens, or by disrupting calcium homeostasis so as to increase oxidative stress and tumor-promoting protein kinases.⁷⁵ Most of the studies of residential EMF exposure and breast cancer risk in females have shown no association, including those studies that carefully included both the measurements and the electrical transmission wire assessments of home EMF exposure levels.⁷⁶⁻⁷⁸ Because electric blankets or heating pads are close to the body for extended periods of time, several studies have been conducted to evaluate whether EMF exposure from this source poses a carcinogenic risk to the breast. Nearly all studies of breast cancer and electric blanket use have been negative.⁷⁹⁻⁸⁴

In recent years, there has been concern over whether environmental chemicals that mimic or antagonize endogenous sex hormones (so-called endocrine disruptors) may have adverse effects on health. Human breast cancer risk from endocrine-disrupting chemicals has been studied largely for persistent organochlorine compounds, most notably PCBs (which were widely used in electrical transformers) and DDE (a metabolite of the insecticide DDT). Studies subsequent to the initial ones have generally not been positive,^{85,86} and meta-analyses of the several studies have shown no indication of an association of breast cancer risk with PCBs or with DDE.^{87,88} A study of occupational exposure to some 29 different estrogen-mimicking chemicals did not find any statistically significant associations with breast cancer, but it had limited statistical power.⁸⁹

More than 50 studies have shown that alcohol consumption is a moderate risk factor for breast cancer. Recent pooled analyses have found that the relative risk for breast cancer increases on the order of 7% to 10% for each additional drink per day on average, and the association is reasonably linear.^{90,91} The mechanism by which alcohol influences breast cancer risk appears to be primarily by increasing endogenous estrogen levels^{92,93}; hence, one might expect alcohol to influence hormonally responsive tumors. Although the data are not entirely consistent, alcohol consumption appears to be more

strongly associated with ER-positive and progesterone receptor-positive breast cancers than with others, as expected.⁹⁴ Similarly, alcohol use is more strongly associated with lobular breast cancer, probably because lobular breast cancer is more often ER positive and progesterone negative than is ductal breast cancer. There are suggestions that alcohol may confer greater risk for breast cancer among women who have genetic polymorphisms in the *CYP19* gene (which plays a key role in estrogen biosynthesis)⁹⁵ or in the alcohol-metabolizing genes, alcohol dehydrogenase III (*ADH3*)⁹⁶ or *CYP2E1*,⁹⁷ but these results require confirmation by additional studies.

The weight of evidence from more than 35 studies, including the large Women's Health Initiative,⁹⁸ indicates that increased physical activity is protective against postmenopausal breast cancer.⁹⁹ At least 16 studies have found an inverse dose-response association, and the average decrease in risk among those who exercise regularly is 30% to 40%.⁹⁹ However, the seeming protective effect of exercise on breast cancer risk may be confounded with, or secondary to, associated variations in body mass index, because obesity is a known risk factor for breast cancer. Exercise may also be a surrogate for a composite of lifestyle factors that collectively diminish risk. The modest number of studies available on premenopausal breast cancer are more mixed in their results and probably indicate a smaller protective effect of physical exercise at premenopausal ages.^{98,100–102}

Although most studies suggest that regular use of nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin and ibuprofen, affords a modest protection against breast cancer risk, the case is not fully convincing because of a number of null results and conflicting evidence about whether the protective effect is limited to aspirin or includes all NSAIDs.^{103–105} More importantly, a randomized controlled trial is needed to ensure that the apparent beneficial effect of NSAIDs on breast cancer risk is not an artifact of lifestyle differences between users and nonusers.

What is the impact of family history on breast cancer risk?

One long-known feature of breast cancer occurrence has been the familial aggregation of the disease. The recent, striking advances in our understanding of the genetic basis for this familial aggregation are discussed in Chapters 2 and 20; the epidemiologic features of familial aggregation of breast cancer is briefly outlined here. A first question is, at the population level, what percentage of breast cancer is of heritable origin? One large study of monozygotic and dizygotic twin pairs estimated the heritability as 27%,¹⁰⁶ but statistically more appropriate analyses of those twin data and of large family-cancer databases in Sweden and among Utah Mormons suggest that heritability is on the order of 10% to 15%.^{107–109} If one considers only early breast cancer (<50 years of age), heritability is up to two times as high.¹⁰⁸

Several major studies have conducted more detailed analyses and agree that about 6% of breast cancers before age 55 years are linked to a family history of breast cancer in first-degree relatives.¹¹⁰ If one also includes any first-degree relative with a history of ovarian cancer and second-degree relatives with breast cancer, then about 13% to 15% of breast cancer

Table 1–1 Odds Ratios (Relative Risks) for Reported Family History of Breast Cancer among 2080 Breast Cancer Patients *cf.* 2058 Control Subjects, Ages 20–44 Years

Breast Cancer in Female Relatives	Odds Ratio (95% Confidence Interval)
First-degree relative	
Mother affected	3.1 (2.3%–4.2%)
Sister affected	3.1 (1.8%–5.3%)
Two or more affected	6.8 (2.5%–20%)
Second-degree relative	
Maternal grandmother/aunt affected	1.4 (1.2%–1.8%)
Paternal grandmother/aunt affected	1.6 (1.2%–2.0%)
Two or more affected	2.2 (1.4%–3.4%)

Data from Thompson WD. Genetic epidemiology of breast cancer. *Cancer* 1994;74:279–287.

cases before age 55 years have a positive family history. On the other hand, for breast cancers occurring at ages 60 to 80 years, only 3% to 5% have a familial component.¹¹¹ It is notable that about one third of the familial aggregation of breast cancer is not accounted for by *BRCA1* or *BRCA2* mutations; thus, there is clearly more to be learned about genetics and shared environmental factors in breast cancer.

Table 1–1 presents a summary of familial breast cancer risks in younger women from a large population-based study conducted by the U.S. Centers for Disease Control and Prevention.¹¹⁰ As expected for autosomal dominant traits, the elevation in relative risk is appreciably greater when a first-degree relative is affected than when only a second-degree relative is affected. Having more than one relative affected greatly increases risk. It is of interest that another major study, which showed a twofold breast cancer risk before age 40 years when a first-degree relative had breast cancer, also showed a 1.5-fold risk for breast cancer even after the age of 70.¹¹² Studies seem to disagree on whether having a relative with bilateral breast cancer confers more risk than having a relative with unilateral breast cancer.¹¹⁰ However, a woman with a family history of breast cancer is more likely to develop metachronous bilateral breast cancer than one with a negative family history.

The risk for breast cancer from a family history of several other cancers has been studied. Ovarian cancer in a first-degree relative appears to confer a breast cancer relative risk of about 1.5 to 2 overall, although the subset for whom the ovarian cancer is associated with *BRCA1* and *BRCA2* mutations may have much higher risks. There is some indication, although it is not firmly established, that a family history of prostate cancer or thyroid cancer may confer breast cancer risks of about 1.5 and 1.7, respectively.^{107,110} In contrast, a family history of endometrial cancer does not appear to confer breast cancer risk.

What is the impact of endogenous hormone levels on breast cancer risk?

Studies of reproductive risk factors and exogenous hormones and theories of the roles of various hormones in breast cancer are reviewed in Chapter 4. This section briefly summarizes results of studies on breast cancer risk in relation to endogenous levels of estrogens and androgens. These studies have

been conducted mostly in postmenopausal women because cyclic variations in estrogen levels among premenopausal women have made meaningful assessments difficult in large populations. Nine prospective studies have now reported on the association between circulating estrogen and androgen levels in postmenopausal women and subsequent breast cancer risk, and a pooled analysis of the original data of these studies (663 cases and 1765 controls) concluded that both estrogen and androgen hormones were strongly associated with risk.¹¹³ The breast cancer risk for women whose estradiol levels were in the top quintile was twice the risk of women whose estradiol levels were in the bottom quintile.

Similar results were observed for the other hormones studied, that is, estrone, estrone sulfate, androstenedione, testosterone, dehydroepiandrosterone, and dehydroepiandrosterone sulfate. As expected, the strongest associations were observed with free estradiol and estradiol not bound to sex hormone-binding globulin (SHBG), which comprises both free and albumin-bound estradiol, because only estradiol not bound to SHBG can readily enter cells. The hormone and breast cancer risk associations remained after subjects whose date of diagnosis was within 2 years of blood donation were excluded from the analysis. A more recent study showed that levels of sex hormones measured 5 to 13 years before diagnosis were elevated in breast cancer cases as compared with controls.¹¹⁴ The association of circulating estrogens with breast cancer risk appeared to be present regardless of whether the breast cancer was ER positive or ER negative.¹¹⁵

The New York University Women's Health Study also suggested that the contribution of androgens to breast cancer risk is largely through their role as substrates for estrogen production,¹¹⁴ whereas in the pooled analysis of prospective studies, androgens appeared to be associated with risk independently of estrogens.¹¹³ However, sorting out the role of estrogens and androgens is complicated by the high correlations between hormones and the fact that usually only a single hormonal measurement is available for each participant in epidemiologic studies, whereas the hormonal levels of interest are the long-term average levels.^{113,114}

How can the individual risk for developing breast cancer be estimated?

The lifetime probability of developing breast cancer (1 in 8 in women in the United States) is a striking statistic that conveys the public health importance of the disease. However, it is a valid estimate for a girl born today only if incidence and mortality remain unchanged over her lifetime,¹¹⁶ an unlikely assumption. Furthermore, it does not convey the fact that the longer a woman lives without breast cancer the lower her risk is over the remainder of her lifetime.¹¹⁷ Estimates of risk at different ages and for a more tangible time horizon, for example, the next 10 or 20 years, are more informative to women and their physicians, as well as more reliable.¹¹⁸ Table 1–2 provides such estimates, calculated with the method of Feuer and colleagues,^{10,114} for both African American and white women.

The estimates provided in Table 1–2 reflect the average risks for developing breast cancer in women from the general population. However, the risk is not homogeneous across women of the same race and age. Models to predict individual risk have been developed and can be useful decision-making tools

Table 1–2 Risk for Being Diagnosed with Breast Cancer in 10, 20, and 30 Years, Given that a Woman Is Cancer Free at Current Age, for White and African American Women

Current Age (yr)	White Women (%)			African American Women (%)		
	+10 yr	+20 yr	+30 yr	+10 yr	+20 yr	+30 yr
20	0.04	0.43	1.90	0.07	0.51	1.86
30	0.39	1.86	4.64	0.44	1.80	4.06
40	1.48	4.29	7.98	1.39	3.70	6.34
50	2.90	6.70	10.4	2.43	5.21	7.66
60	4.06	8.05	10.4	3.09	5.80	7.26

Data from Feuer E, Wun LM. DEVCAN: Probability of developing or dying of cancer software, version 5.0 [Online]. Available: http://www.seer.cancer.gov/faststats/html/dev_breast.html (accessed January 29, 2004).

for women considering preventive use of tamoxifen or prophylactic mastectomy.¹¹⁷ The most frequently used is the model developed by Gail and associates, for which a software program is available from the National Cancer Institute at <http://bcra.nci.nih.gov/brc/q1.htm>.^{119,120} Graphs derived from this model to estimate individual risks and corresponding confidence intervals have also been published.¹²¹ The Gail model estimates the chance that a woman with given age and risk factors who is screened annually will develop breast cancer over the next 5 years and for her lifetime. The risk factors taken into account are age, ages at menarche and first live birth, number of previous breast biopsies, presence of atypical hyperplasia on biopsy, and number of first-degree relatives with breast cancer. The model was shown to perform well for white women who receive annual mammograms.^{120,122–124} However, it has several limitations: it overestimates risk for women with infrequent mammography screening; it fails to take into account certain risk factors, such as the personal history of in situ breast cancer¹²⁵ or major genetic risks such as *BRCA1*, *BRCA2*, Cowden syndrome, or Li-Fraumeni syndrome^{125,126}; and it has been validated only among whites.¹²⁷ This simple model, though based on data easily obtained from the medical history, is quite useful and is currently being used to assess eligibility for the NSABP P-2 chemoprevention trial, a randomized study of tamoxifen versus raloxifene in women at high risk for breast cancer.

Several other models have been developed to predict breast cancer risk,^{128–130} but they focus on the family history of breast cancer in high-risk families and are not broadly applicable.^{117,131}

What is the survival from breast cancer in the United States?

Overall, survival from invasive breast cancer has improved in the United States: the 5-year relative survival rate was 86.6% for women diagnosed in 1995 versus 74.9% for women diagnosed between 1975 and 1979.¹⁵ The increase in survival likely results from both the “stage shift” toward increasing diagnosis at early stage, owing to greater use of mammographic screening, and therapeutic improvements.¹³² Factors influencing survival include age, stage at diagnosis, and race

(Table 1–3). For patients diagnosed between 1992 and 1999, the 5-year relative survival rate was slightly lower for women diagnosed before age 50 years (84.5%) than for older women (87.5%), which may be due to younger women's having tumors that are more aggressive and less responsive to hormonal therapy. Race and stage at diagnosis also affect survival rates (see Table 1–3). The lower stage-specific survival among African American women may be due to more aggressive tumors: tumors appear to be more often of medullary histology,⁴⁶ hormone receptor negative,⁴⁶ and of higher grade¹³³ in African American than in white women, all factors associated with poor prognosis. Less access to health care and differences in treatment may also be contributing factors.¹³⁴

What is the breast cancer mortality in the United States?

In the years 1996 to 2000, the female breast cancer age-adjusted mortality rates (per 100,000) were 27.2 in white women, 35.9 in African American women, 17.8 in Hispanic women, 14.9 in American Indian or Alaska Native women, and 12.5 in Asian or Pacific Islander women¹³⁵ (Fig. 1–8). Trends over time indicate that between 1970 and 1990, the mortality rate remained fairly constant among white women but increased among African American women, with an annual change of +0.9%. Between 1990 and 2000, the mortality rate decreased

in both white and African American women, but the decrease was steeper among white (annual percent change, –2.5%) than among African American (–0.9%) women. In these same years, annual percent changes were –1.1% in Hispanic women, –1.5% in Asian or Pacific Islander women, and +0.2% in American Indian or Alaska Native women. The overall decline in breast cancer mortality since 1990 has been attributed to both improvements in treatment and early detection. Several factors may contribute to the 30% greater mortality in African American than in white women. Although in recent years rates of mammography screening in African American women have been approaching the rates in white women, African American women tend to present with higher-stage disease than white women, raising the question of whether they receive screening at appropriate time intervals. In addition to higher stage, tumors in African American women present more often with poor prognosis characteristics than tumors in white women. Finally, differences in access to health care and treatment may also contribute to the excess in mortality observed among African American women.¹³⁶

CONCLUSION

The steady increase in breast cancer incidence observed in the United States in the 1980s appears to have subsided in the 1990s, whereas mortality has decreased since 1990.¹⁶ These trends are attributable, at least in part, to large-scale use of mammographic screening. It is important to emphasize, however, that early detection of breast cancer requires periodic screening, not just one-time mammograms.^{137,138} Adjuvant multiagent chemotherapy and use of antiestrogen therapy, such as tamoxifen, have also contributed to the decrease in mortality.¹³⁹ Further research is needed to assess differences in incidence and mortality in African American and white women as well as epidemiologic differences according to tumor characteristics.

Breast cancer remains the most common cancer and the second most common cause of cancer death in women in the United States. Incidence of breast cancer has been increasing in most countries, and the increases have been particularly rapid in several Asian countries where a “westernization” of

Table 1–3 Five-Year Relative* Survival Rates by Race, Stage, and Age at Diagnosis (1992–1999 SEER Data)

Stage	White Women (%)		African American Women (%)	
	<50 yr	≥50 yr	<50 yr	≥50 yr
Localized	95.0	98.4	85.7	91.9
Regional	80.8	80.2	66.3	65.7
Distant	32.6	22.2	19.5	13.0

*Relative survival rates are adjusted for expected mortality from causes other than breast cancer.

Data from <http://surveillance.cancer.gov/statistics/types/survival.html>.

Figure 1–8 Mortality rate, age-adjusted to the 2000 standard U.S. population, by race and ethnicity, SEER 1975–2000. (Data from American Cancer Society. Breast Cancer Facts and Figures 2003–2004 [Online]. Available: http://www.cancer.org/docroot/STT/content/STT_1x_Breast_Cancer_Facts_Figures_2003-2004.asp [accessed January 29, 2004].)

the lifestyle has been observed. These rapid changes, together with studies in migrants, underscore the importance of environmental factors in the development of the disease. However, to date, well-established “lifestyle” risk factors (later age at first birth, nulliparity, and family history of breast cancer) account for only about 40% of breast cancer in the United States. It is not clear that these risk factors may be altered, which limits their relevance for prevention.²⁸ The two most important modifiable risk factors known currently are to decrease alcohol consumption and increase exercise and physical activity. Additional research to identify modifiable risk factors for breast cancer, as well as to elucidate underlying biologic mechanisms, may help devise preventive strategies.

The Oncogenetic Basis of Breast Cancer

Ramon Parsons

What is the cause of breast cancer?

The cause of breast cancer cannot be explained by a single etiologic agent. Rather, the genesis of breast cancer can be viewed as the result of the accumulation of damage over many years to cells within the breast. Broadly speaking, two types of molecular trauma produce cancer: mutation of DNA and induction of cell proliferation.^{1,2} Mutation of DNA occurs within critical genes that are responsible for regulating cell growth, death, differentiation, and chromosomal replication. Mutations either activate or inactivate the affected genes. Proliferation, on the other hand, exerts its tumor-forming effects by promoting the expansion of a cell population.³ The induction of proliferation proceeds through two mechanisms. Mitogenic agents directly induce cell division and proliferation, whereas toxic agents induce proliferation in the surviving cells that repopulate an injured tissue.⁴

What is the genetic model of cancer development?

The genetic model of cancer development is based on the theory that the transformation of a normal breast cell into a breast tumor depends on the alteration of genes found in the normal cell.⁵ These genetic changes are induced by either internal or external factors. According to this theory, all breast cancers have a genetic basis for their pathogenesis. Thus, all the cellular insults that can lead to breast cancer, which include mutations, induction of proliferation, and induction of cell death, ultimately lead to the alteration of genes that control cell growth. Although the stimulation of proliferation does not directly result in the mutation of growth-control genes, it provides an environment for mutated cells to divide, acquire additional mutations, and outgrow their normal neighbors.

What agents lead to the genetic changes found in breast cancer?

The answer to this question is unclear. A simplified model compartmentalizes the potential causes of breast cancer into either internal or external causes¹ (Fig. 2-1). External

causes, which are defined as arising from outside of the body, fall into many types of environmental exposures. However, the identification of specific environmental agents associated with breast cancer has been slow. Moreover, the external agents that have been identified are associated with only a small proportion of breast cancers. These agents include radiation exposure during childhood (at high doses encountered during the treatment of Hodgkin's lymphoma and the atomic bombing of Japan) and cigarette smoking (among women who are slow acetylators of cigarette smoke carcinogens).⁶⁻⁸

Other poorly defined environmental agents affect breast cancer incidence as well. The rate of breast cancer varies widely throughout the globe.⁹ In general, an increased incidence is associated with a Western standard of living.¹⁰ Immigrant families from low-incidence countries that come to the United States experience an increase in breast cancer incidence within a few generations.¹¹

Internal causes of breast cancer, which are defined as cancer-causing agents arising from within the body, include a variety of extracellular and intracellular processes. The principal extracellular factor associated with breast cancer is estrogen. The extent of estrogen exposure over the course of a woman's life is a significant risk factor for breast cancer.¹² Early menarche, late menopause, and nulliparity are all associated with an increased risk for breast cancer. This is likely to be due to the proliferative response of breast epithelial cells to estrogen through the estrogen receptor.¹³ Regarding the intracellular processes, these include errors in DNA synthesis, which occur with each cell division.¹⁴ Occasionally, the resulting mutation is within a critical gene that allows a tumor to begin to develop. Thus, the known factors associated with an increased risk for breast cancer induce either mutation or proliferation of cells.

Perhaps the most basic internal cause of breast cancer is the inheritance of a mutated gene that increases an individual's risk for developing breast cancer.¹⁵ In this case, every cell in the body has an identical genetic alteration that substantially increases an individual's risk for breast cancer over a lifetime. Intriguingly, however, this genetic predisposition is not deterministic even in highly susceptible families; about 20% of carriers never develop breast cancer.¹⁶ Therefore, the development of cancer in predisposed individuals requires environmental insults as well.

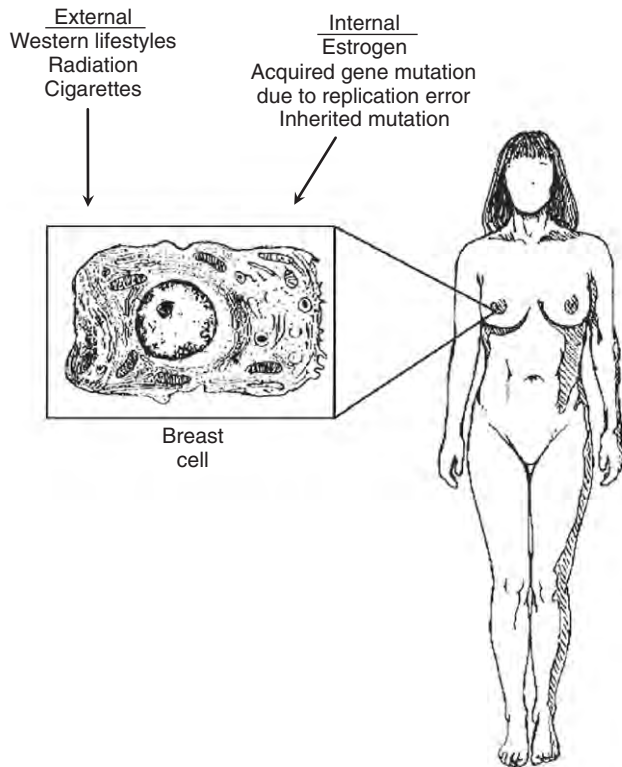

Figure 2-1 External and internal agents affecting tumor formation. External agents include radiation exposure, cigarette smoke, and a Western lifestyle. Internal agents include estrogen, acquired mutations due to replication errors, and inherited mutations. These agents slowly lead to the accumulation of genetic damage that may eventually result in a tumor.

What is an oncogene?

The word “oncogene” is derived from two Greek words: *onkos* for mass and *gignesthai* for birth, which is the etymologic root for the word “gene.” An oncogene has a more specific meaning than its name implies, however. Oncogenes are a class of genes that cause tumor growth when activated.² These genes behave dominantly because they promote tumor enlargement.

Oncogenes were first found to reside within retroviruses. The first example of such a retrovirus was discovered by Peyton Rous near the turn of the century.¹⁷ This virus was capable of causing tumors in chickens and is known as Rous sarcoma virus (RSV). Over 20 years ago, the *src* gene, which is the gene in RSV that is responsible for its tumorigenic activity, was found to be an activated form of a gene that is normally found in chickens.¹⁸ In effect, the virus had taken the *src* gene from the cell and modified it to produce tumors.

How are oncogenes activated?

In humans, oncogenes are rarely activated by viruses. Instead, the activation is typically triggered by mutation of the gene, usually by one of three major mechanisms (Fig. 2-2). The first mechanism of activation was identified in the *ras* family of oncogenes; these genes are mutated in a variety of human tumors.¹⁹ A single amino acid alteration activates the *ras* protein product to continuously signal the cell to divide.²⁰ The *k-ras* gene is mutated in about half of all colon cancers.²¹

The second mechanism of oncogene activation occurs through chromosomal translocation, which was first observed

Figure 2-2 Mechanisms of oncogene activation. The three mechanisms of oncogene activation are depicted: amino acid alteration, translocation, and amplification. The level of transcription from their promoters is indicated by the 90-degree angle arrows to the left of each gene. More arrows indicate increased levels of transcription. *A*, Activation by point mutation leading to a new amino acid. *B*, Activation by translocation. The normal promoter of a gene is replaced by a very active promoter from another chromosome, which induces overexpression. *C*, Amplification. Multiple copies are present in tandem, each with a functional promoter. The level of amplification can be anywhere from 5-fold to 100-fold, as indicated by the symbol + (gene)_n.

in chronic myelogenous leukemia.²² The end result of a translocation is the overexpression of a protein that either stimulates cell division or prevents cellular death.²³ In the case of chronic myelogenous leukemia, the translocation of chromosomes 9 and 22 leads to the overexpression of the *bcr-abl* fusion protein, which is an active tyrosine kinase that signals the cell to divide.²⁴ Another important example is the translocation of chromosomes 14 and 18, which is found in follicular lymphomas.²⁵ This translocation leads to the overexpression of the *bcl-2* oncogene, which functions to prevent cell death. In general, by placing a strong promoter of gene transcription near an oncogene, translocations lead to gene overexpression and tumor growth.

The third mechanism of activation of oncogenes is amplification, in which multiple copies of a gene are reproduced in a single chromosome.²⁶ By increasing the gene dosage, the protein product of the gene is overexpressed within the cell. Genes activated in this way in breast cancer include the epidermal growth factor (EGF) receptor, *erbB-2/HER-2/neu*, *c-myc*, and *cyclin D1*, all of which stimulate cell division.^{27–30} Each of these genes is amplified in breast cancer; hence, amplification is the major mechanism of oncogene activation in breast cancer.³¹

How do oncogenes function in the cell?

Oncogenes can either stimulate cellular division or prevent cell death (Fig. 2–3). All of the genes that stimulate division have a role in transmitting a signal from a growth factor receptor to the nucleus to initiate cellular replication. Oncogenes of this type vary in their specific functions, whether they are receptors, guanosine triphosphate (GTP)-binding proteins, kinases, or transcription factors, but all stimulate the cell to leave a resting state (G_0) and enter the DNA synthesis (S) phase of the cell cycle.²⁰ *Bcl-2* and its homologues stimulate tumor growth by a completely different mechanism. These genes function to inhibit apoptosis or programmed cell death.³² Less is known about the cell death pathways, but they clearly function through a protease cascade to cleave nuclear DNA and destroy the nuclear and plasma membranes.²⁵

What is a tumor suppressor gene?

The concept of tumor suppressors is the result of two different branches of cancer research: studies of tumor cells in vitro and studies of families with a hereditary predisposition to cancer. The original in vitro studies of tumor suppression were derived from the observation that when a tumor cell was fused with a nontumor cell, the resulting fused cell lost its tumor characteristics.³³ These experiments were further refined by the observation that a single normal chromosome, when introduced into a tumor cell, could suppress the growth of the tumor cell. The interpretation of these findings was that normal cells have tumor suppressor genes that are inactivated in the tumor. A similar model of tumor suppressors was developed by Knudson for explaining the mechanism of inheriting a predisposition to retinoblastoma.³⁴ This model is based on the concept that with the exception of the sex chromosomes, people normally have two functional alleles

Figure 2–3 Mechanism of oncogenic stimulation of tumor growth. Oncogenes are depicted to signal (+) the cell to leave G_0 and commit to mitosis. In addition, they also inhibit (–) the induction of the cell death pathway (apoptosis).

(copies) of every gene. For a tumor to develop, both alleles of a specific gene must be inactivated.

What is Knudson’s hypothesis for tumor suppressor genes?

By comparing rates of retinoblastoma in predisposed families and the general population, Alfred Knudson proposed his “two-hit” model, in which both alleles of a gene must be inactivated before tumor formation can occur³⁴ (Fig. 2–4). In his model of tumor suppression, he proposed that the early-onset and multiple tumors found in familial forms of cancer could be accounted for by the inheritance of one defective allele. His insight was to realize that this inherited mutation was not sufficient alone for the formation of a tumor. He hypothesized that inactivation of the second healthy allele of the same gene was also necessary and could thus explain the dominant inheritance pattern found in families. Thus, both alleles are altered in the tumor. This is a paradox of genetics in which the mutated gene behaves dominantly during transmission in families but behaves recessively during tumorigenesis within the cell. With the prominent exception of the germline mutation of the *c-ret* oncogene in multiple endocrine neoplasia syndrome,³⁵ Knudson’s tumor suppressor hypothesis for retinoblastoma has proved to be broadly applicable to all of the tumor predisposition syndromes characterized to date.³⁶

Figure 2–4 Knudson's model of tumor suppressors. A pair of autosomal alleles (A and B) is indicated for individuals with (*left*) and without (*right*) an inherited germline mutation of a tumor suppressor gene. The inherited mutation is indicated by an X on allele A of the predisposed individual. Tumor establishment occurs much faster in an individual who is predisposed because only one further copy need be inactivated. In the individual without predisposition (wild type), the inactivation of both alleles is a rare event. The large deletion seen on the B allele is an example of loss of heterozygosity (LOH).

How are tumor suppressor genes inactivated?

Genes have now been identified not only for retinoblastoma but also for inherited predispositions to a variety of tumors, including those of the breast (see below), ovary, kidney, colon, skin, lymphocytes, and peripheral nerves.^{37–48} In all cases, one defective copy is inherited and the second copy is altered in the tumor. Many of these genes are also inactivated in sporadic tumors of people who inherit two functional alleles. Because mutation of both copies of the gene must occur somatically, sporadic tumors occur later in life and in a smaller proportion of nonpredisposed individuals. However, because sporadic tumors are much more common than familial tumors, somatic mutation is the most common form of tumor suppressor inactivation.

What is loss of heterozygosity?

In familial cancer syndromes, the mechanism of inactivation of the normal copy of a tumor suppressor usually occurs through loss of heterozygosity (LOH), which is due to the deletion of a large chromosomal region containing the wild-type tumor suppressor allele (see Fig. 2–4). In sporadic cancer,

LOH may be the first or second event in the inactivation of a tumor suppressor.

How commonly are tumor suppressors inactivated in sporadic tumors?

Mutation of tumor suppressor genes is by far the most common genetic alteration found in the tumors of nonpredisposed individuals. A handful of tumor suppressors are inactivated in a large fraction of nearly all invasive cancers regardless of organ of origin. The *p53* tumor suppressor is the most commonly mutated cancer gene.⁴⁹ The *p16/CDKN2/ARF* and *PTEN* tumor suppressor loci vie for second place.^{50,51}

Why are tumors clonal?

Unlike a model based on the relative simplicity of inheriting a single mutation in a tumor suppressor gene, Peter Nowell's model for the development of a solid tumor depends on the mutation of many genes.⁵² The model is based on two principles: (1) the principle of clonal expansion, in which a mutant cell with a selective advantage for growth will outgrow its neighbors; and (2) the principle that expansions occur in consecutive waves that result in the accumulation of multiple genetic alterations within the evolving tumor. Somatic mutations that take place with each advancing wave of tumor expansion occur in both tumor suppressor genes and oncogenes. In the case of tumor suppressors, both alleles must be inactivated during tumor development. For oncogenes, point mutations, amplifications, and translocations lead to activation. For a tumor to evolve, several distinct regulatory pathways must be compromised, including those regulating the cell cycle, apoptosis, and genomic stability. The clonal nature of a tumor allows for the accumulation of multiple growth disruptions within one cell. Because multiple independent mutations must accumulate within a single clone, the evolution of a tumor occurs over years to decades.

What is genomic instability?

In general, the rate of mutation is low within genes (for any given gene, mutations occur once in every 1×10^6 cell divisions).⁵³ Based on the low frequency of mutations in the genes of a normal cell, tumor formation should be an extremely rare event because it would require occurrence of several rare events within a single cell during the course of a lifetime. Because tumor formation is a common occurrence, however, it is believed that the rate of gene mutations must be increased during the clonal expansion of a tumor. This increase in the rate of mutation is known as genomic instability.

A great deal of evidence currently supports the theory that tumors become genomically unstable during their development.⁵⁴ Tumor cells inactivate pathways that normally ensure that errors in the genetic code are repaired. Thus, the frequency of genetic alterations increases in the tumor cell. The result of this increased genetic instability is that cells within a tumor acquire mutations that allow them to outgrow their neighbors.

What causes genomic instability?

Three major systems are involved in preserving the integrity of the genome during each replication cycle. The first major system depends on the cell's various biochemical mechanisms for replicating and dividing (the cell cycle system).⁵⁰ The coordination of the different phases of the cell cycle—G₁, S (synthesis), G₂, and M (mitosis)—is orchestrated by a variety of gene products, which include the cyclins (A, B, D, and E) and their respective cyclin-dependent kinases (CDKs) (Fig. 2–5A). Aberrant overexpression of cyclin E has been shown to increase genomic instability.⁵⁵ CDKs are regulated by CDK inhibitors, which are capable of blocking the cell's progress through the cell cycle in response to signals from within and without the cell. Also included in the cell cycle system are the various replication enzymes and the mitotic spindles that function to reproduce a daughter genome and separate the two genomes into daughter cells. Mistakes or inappropriate signals in any of these pathways can lead to genetic damage.

The second major system is composed of the various repair pathways that fix genetic alterations once they are detected (the DNA repair system). These include the ultraviolet (UV) excision repair system and the double-strand break repair system, which repair external DNA damage, and the mismatch repair system, which repairs mismatches generated during DNA replication.^{56–58}

The third major system comprises the checkpoint control pathways of the cell (the checkpoint system)⁵⁹ (Fig. 2–5B). These pathways monitor the genome for alterations that affect

its integrity and can regulate the cell cycle and DNA repair systems. Alterations can be due to external mutations from ionizing radiation or from errors in replication during S phase or the separation of chromosomes during mitosis. Checkpoint pathways respond to these alterations by inhibiting the cell's progress through the cell cycle and coordinating the assembly of the proper DNA repair machinery. In effect, these pathways stall the cell to give it an opportunity to repair itself before proceeding to the next phase of the cycle.

The best characterized checkpoint pathway in humans is induced by ionizing radiation. The *ATM* gene encodes a protein kinase that senses genetic damage and transmits this information to other checkpoint proteins in the cell by phosphorylating them.^{60,61} *ATM* is able to activate a large number of different checkpoint and repair pathways. In one of these pathways, *ATM* transmits a signal to *p53*, a transcription factor and tumor suppressor, to induce the expression of the CDK inhibitor *p21*, which arrests the cell in the G₁ phase of the cell cycle.⁶² In the absence of functional *ATM* or *p53*, the arrest in response to DNA damage is impaired. Alternatively, DNA damage can induce programmed cell death (apoptosis), a process that is *p53* dependent.²⁵ In addition, the *ATM*–*p53* pathway appears to regulate checkpoint controls in other phases of the cell cycle. In particular, *p53* has a role in monitoring the fidelity of mitosis.⁶³ In the absence of *p53*, chromosomes segregate aberrantly, and cells soon become polyploid.⁶⁴ Another branch of the *ATM* pathway regulates the cell cycle without the help of *p53*. In this branch, DNA damage activates *ATM*, which phosphorylates the checkpoint kinases (*CHK1* and *CHK2*), key kinases that in turn

Figure 2–5 Regulation of the cell cycle and its checkpoints. *A*, The phases of the cell cycle G₁, S, G₂, and M are regulated by a series of cyclin protein–cyclin-dependent kinase (CDK) complexes that are synthesized and degraded at discrete times. The D cyclins are induced by mitogenic stimuli and remain elevated as long as the cell is cycling. They are potently inhibited by the CDK inhibitors *p16* and *p21*. Cyclin E is the critical cyclin for entry into S phase and is tightly regulated by *p27*, a CDK inhibitor, and also responds to *p21*. Cyclins A and B are involved in shepherding the cell through S phase, G₂, and mitosis when they are degraded. *B*, The best understood checkpoint in the mammalian cell cycle is the response to high-energy radiation. The ensuing DNA damage is detected by the *ATM* gene, which signals *p53* to induce *p21* and arrest the cell in G₁, induces arrest in S and G₂, or by a different pathway signals the cell to undergo apoptosis; *p53* is clearly a nodal point in the cell's response to DNA damage.

phosphorylate the *CDC25* tyrosine phosphatases to induce their inactivation.⁶⁵ After their inhibition due to *CHK1*, *CDC25* tyrosine phosphatases no longer remove a critical phosphate residue from CDKs to activate cyclin-CDK complexes in different phases of the cell cycle. Yet another branch of the *ATM* pathway mediates the repair of double-strand DNA breaks. To respond to DNA damage, this branch depends on the *BRCA1* protein.⁶⁶

Genes involved in the regulation of the cell cycle, checkpoint, and DNA repair systems frequently behave as either tumor suppressor genes or oncogenes when mutated. Alterations of these genes lead to an increase in genomic instability. These include *cyclin D*, *p53*, *ATM*, and the mismatch repair genes *hMSH2* and *hMLH1*.^{59,67} Cells with aberrations of either *p53* or cyclin D are permissive for gene amplification of other genes.⁵⁰ Cells with inactive *hMSH2* or *hMLH1* have an increased frequency of point and frameshift mutations.^{43,67} Finally, as mentioned above, a cell deficient for *ATM* or *p53* is unable to properly repair DNA damaged by ionizing radiation.⁶² All of these genes are components of one of the major cellular systems for preventing genetic damage.

What are the different forms of familial breast cancer?

There are several forms of familial breast cancer.¹⁵ Familial early-onset breast-ovarian cancer is an autosomal dominant disease that usually affects those at risk before 50 years of age and is typically due to *BRCA1* mutation. Breast cancer without ovarian cancer can be seen in families as well and is associated with either *BRCA1* or *BRCA2* mutations. This form of disease also has an early onset and is associated with male breast cancer in families with *BRCA2* mutations.

How were the *BRCA1* and *BRCA2* genes discovered?

Large extended families with autosomal dominant patterns of inheritance of breast cancer risk were the impetus for genome-wide scans to find breast cancer susceptibility genes. Because no knowledge of the function or location for such a hypothesized gene existed, DNA was collected from the blood of as many family members as possible and subjected to linkage analysis. With linkage analysis, the DNA from both affected and unaffected individuals is characterized to determine the size of polymorphic alleles at known chromosomal locations distributed throughout the entire genome. Polymorphic alleles that are shared among affected family members are linked to the disease (Fig. 2–6). However, alleles may be shared due to random clustering because each offspring of an affected carrier has a 50% chance of coinheritance of breast cancer susceptibility along with one of any two alleles throughout the 22 autosomal chromosomes. As the size of the family under study increases, the likelihood that polymorphic alleles are linked to disease and are not merely chance clusterings increases as well. This approach led to the identification of polymorphic markers on chromosome 17q21 and on chromosome 13q12 that were highly linked to breast cancer in

specific families.^{68,69} A search for genes within these regions uncovered *BRCA1* and *BRCA2* on chromosomes 17 and 13, respectively.^{38,39} These two genes were definitively identified as the causative lesions within these families by virtue of the mutations found in their DNA sequence that segregated with affected family members. Mutations of both of these genes usually disrupt the open reading frame, leading to a truncated protein product. Moreover, in the tumors of these patients, the remaining functional allele of the gene is also mutated somatically in most cases.

Who is at risk for inheriting mutations of *BRCA1* and *BRCA2*?

Individuals at risk are obviously those with a family history of breast cancer. In families with an identified mutation, the risk for being a carrier is 50%. In addition, about 10% of women without a family history but with a breast cancer diagnosis before 35 years of age are born with a mutation of *BRCA1*.⁷⁰ Perhaps the largest population of women at risk for harboring germline mutations can be found among Ashkenazi Jews of Eastern European descent. The combined frequency of germline mutation of *BRCA1* and *BRCA2* among these women is about 2%.^{71,72} Patients with these mutations frequently lack a family history of breast cancer.⁷³

How does the *BRCA1* gene function in the body to prevent breast cancer?

A clue to identifying the regions of the gene that are functionally important may be gained from analyzing the *BRCA1* gene in other species. A homologue of *BRCA1* is present in the mouse, and only two domains show significant areas of conservation of the amino acid code.⁷⁴ One of these is a ring-finger domain near the amino terminus of the protein.³⁸ Ring fingers are zinc-binding protein motifs. The other conserved domain is at the carboxyl terminus of the protein (Fig. 2–7). This domain has been shown to activate transcription when fused to the DNA-binding domain of *GAL4*, a yeast transcription factor.⁷⁵ These data suggest that *BRCA1* may be involved in the regulation of transcription. Interestingly, point mutations (mutations that change only a single amino acid) of *BRCA1* that disrupt the zinc-binding amino acids or disrupt the activation of transcription are found in breast cancer families.^{75,76} Mutation of the mouse *BRCA1* gene in mammary tissue predisposes these animals to a high rate of mammary tumors.⁷⁷ Other early studies of *BRCA1* indicate that it is capable of slowing cellular proliferation and inhibits tumor growth in vitro.⁷⁸ The gene may be exerting its effects during G₁ and S phases of the cell cycle when *BRCA1* is most expressed.⁷⁹

Several genetic and biochemical facts have emerged that are leading to a better understanding of the function of *BRCA1*. After DNA damage, *BRCA1* is recruited to sites of double-strand DNA breaks.⁸⁰ Recruitment appears to be important because mutation of *BRCA1* in cells leads to increased susceptibility to DNA damage.⁸¹ *BRCA1* is an integral part of the *ATM* pathway because it is phosphorylated by *ATM* after DNA damage at the site of DNA breaks.⁶⁶ Moreover, disruption of

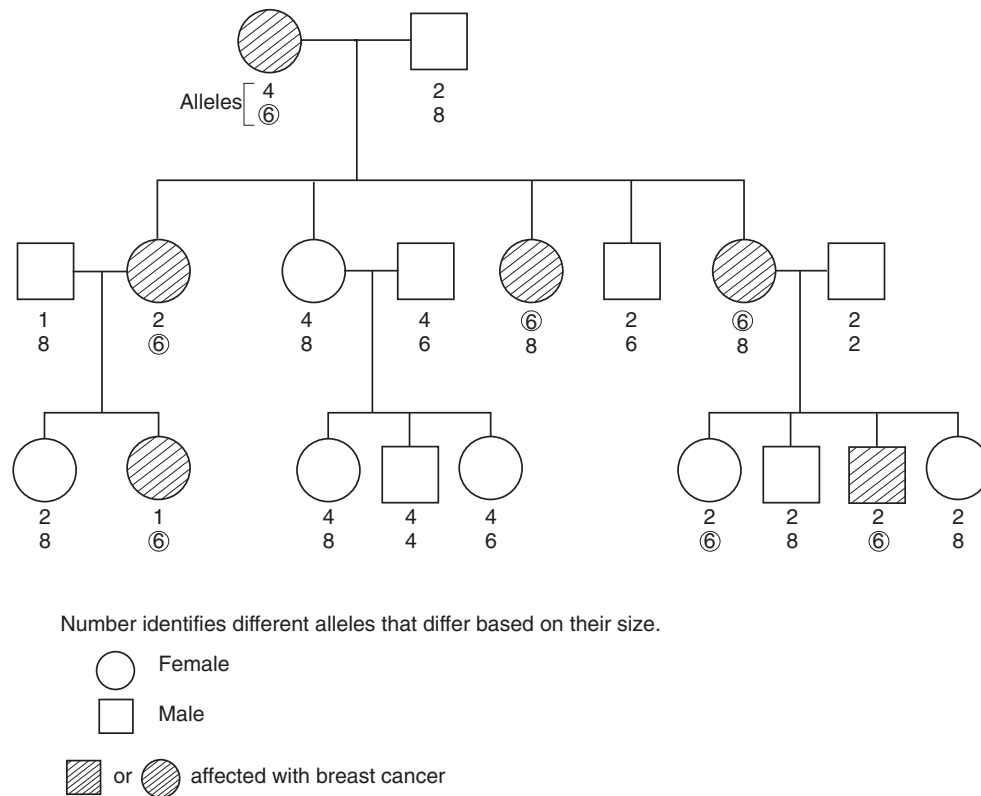

Figure 2-6 Segregation of a polymorphic marker in a family with hereditary breast cancer. A family affected by six cases of breast cancer over three generations is depicted. The numbers below each individual indicate the alleles that each has inherited for a specific marker located very close to the *BRCA1* gene. The numbers refer to the size of the allele, with 1 being the smallest and 8 being the largest allele. This allele is highly polymorphic because nearly all cases have alleles of two different sizes. In cases with two alleles of differing size, the marker is said to be informative because one is able to trace the origin of the alleles in the parents. The circled allele 6 has the same pattern of inheritance as breast cancer and appears at first glance to be linked. In one case in the third generation, the disease has not become penetrant. To test this hypothesis, one must compare the observed results with the likelihood of a similar segregation pattern of a marker far from the diseased locus.

Figure 2-7 Functional domains of human *BRCA1*. The ring-finger domain is a putative zinc-binding domain that may be involved in ubiquitin ligation of proteins (minimally amino acids 25–64). The transcription transactivating domain is at the carboxyl terminus from amino acids 1528 to 1863. Arrows below the gene indicate amino acid point mutations that are associated with early-onset breast cancer. Mutations of the ring finger would disrupt zinc, whereas mutations of the transactivation domain are known to disrupt transactivation.

BRCA1 in cells interrupts DNA repair signals downstream of *ATM*. *BRCA1* exists in a heterodimer with another ring-finger protein, *BARD1*.⁸² Together, *BRCA1* and *BARD1* form a potent ubiquitin ligase enzyme complex that is able to conjugate chains of ubiquitin onto other proteins. The nature of these substrates is currently unknown. Presumably, *BRCA1* is involved in the regulation of repair proteins through ubiquitination.

How does the *BRCA2* gene function?

Like *BRCA1*, mutation of mouse *BRCA2* predisposed animals to mammary cancer.⁸³ Cells lacking *BRCA2* are highly sensitive to DNA damage and display marked genetic instability.⁸⁴ Analysis of Fanconi anemia patient samples, which are highly sensitive to DNA damage, has demonstrated that two of the

Fanconi anemia complementation groups are due to biallelic mutation of *BRCA2*.⁸⁵ Biochemical analysis of the *BRCA2* protein has demonstrated that it is part of the homologous recombination DNA repair complex that repairs double-strand breaks.⁸⁴

Are there other genes that cause a predisposition to breast cancer?

More than half of the families with early-onset breast cancer in the absence of ovarian cancer (breast site-specific families) have no identified mutation of either *BRCA1* or *BRCA2*.⁸⁶ This information suggests that an unidentified gene exists that also increases susceptibility to breast cancer. Two rare syndromes, Li-Fraumeni and Reifenshtein syndromes, occasionally lead to breast cancer as well. They are caused by genetic lesions in *p53* and the androgen receptor, respectively.^{46,87} In addition, heterozygote carriers of ataxia-telangiectasia, who harbor *ATM* mutations, as well as patients with Cowden syndrome who are born with *PTEN* mutations, are at increased risk for breast cancer.^{88,89}

What is the difference between sporadic breast cancer and familial breast cancer?

Sporadic breast cancer is defined as breast cancer that occurs without an identifiable inherited risk. The risk for breast cancer over a lifetime is about 13%.⁹⁰ In contrast, familial breast cancer is an autosomally dominant inherited predisposition to breast cancer. The lifetime risk for breast cancer for carriers in these families is about 80%. This increased risk is due to the inherited mutation of *BRCA1* or *BRCA2* or perhaps other genes.

How is the estrogen receptor altered in breast cancer?

The first gene product studied in detail for breast cancer was the estrogen receptor.⁹¹ This protein is not expressed in about 40% of both ductal carcinoma in situ (CIS) and invasive breast cancers.⁹¹⁻⁹³ Because the proportion of tumors lacking estrogen receptor does not change during the transition from CIS to invasive breast cancer, one interpretation is that loss of the receptor influences CIS development but not the transition to invasive cancer. Even though tumor progression appears to be influenced by the loss of estrogen receptor expression, this gene does not behave as a typical tumor suppressor. In particular, the lack of expression in tumors is not associated with mutation of the gene or loss of heterozygosity. Rather, loss of expression appears to be due to repression of transcription through hypermethylation of nearby CpG islands, which are found in the transcriptional control region (promoter) of a gene.⁹⁴ This form of down-regulation of gene expression inactivates tumor suppressors, such as *p16*, in a variety of tumors.⁹⁵

Which oncogenes are altered in breast cancer?

The early analysis of genetic alterations in sporadic breast cancer focused on oncogenes. The two oncogenes that are commonly altered are the *erbB-2/HER-2/neu* oncogene and *cyclin D* oncogenes.^{96,97} These genes are overexpressed in both CIS and invasive carcinoma of the breast.⁹⁸⁻¹⁰⁰ The basis for overexpression is often amplification of the gene; however, overexpression is often seen in the absence of gene amplification. Other oncogenes are also altered by amplification in invasive breast cancer. They include *EGFR*, *c-myc*, and *IGFIR*.

What tumor suppressors are altered in breast cancer?

The most commonly mutated tumor suppressor in breast cancer is *p53*.³¹ Although an inherited mutation of *p53* is a rare cause of cancer, *p53* is mutated in nearly half of all invasive breast tumors.^{31,46} Immunohistochemical analysis of *p53* in ductal CIS also indicates a similar proportion of altered tumors.^{101,102} Of course, *BRCA1* and *BRCA2* are mutated in tumors of patients who inherited a defective copy of one of these genes, but these two genes are not mutated in sporadic breast cancer.^{103,104} However, silencing of *BRCA1* transcription due to methylation of the *BRCA1* promoter is detected in about 10% of unselected cancers and is particularly prevalent in medullary and mucinous carcinomas.¹⁰⁵ E-cadherin is mutated in a high fraction of lobular carcinomas and is methylated and silenced in a large proportion of ductal carcinomas.^{106,107} *PTEN* protein expression is not detected in about one third of sporadic carcinomas.¹⁰⁸ In addition, the tumor suppressors *Rb* and *p16* are rarely mutated.^{109,110}

How do these oncogenes and tumor suppressors normally function in the cell?

The oncogenes that are altered in breast cancer and some of the tumor suppressors all share one major feature. They are key components of signal transduction pathways that regulate the cell cycle by controlling the entrance into S phase^{20,50} (Fig. 2-8). In particular, *erbB-2/HER-2/neu*, *EGFR*, *c-myc*, *cyclin D*, *Rb*, and *p16* are all part of a pathway that responds to EGF (as well as other growth factors), which stimulates the cell to divide. *PTEN* is a negative regulator of signals that emerge from cell surface receptors.

How does *p53* normally function?

The function of *p53* is quite distinct from the other oncogenes and tumor suppressors. Instead of regulating the cell cycle, this gene appears to monitor and preserve genomic integrity.⁶² Cells lacking *p53* become genomically unstable and quickly lose the ability to maintain the correct number of chromosomes.⁶³ The *p53* gene responds to genetic damage by stalling the cell in G₁, S, or G₂ phase of the cell cycle to prevent mitosis before repairs on the damaged DNA can be made⁵⁹ (see Fig. 2-5B). Alternatively, after sensing damage, *p53* can induce the cell to undergo apoptosis.²⁵

How do genetic changes correlate with breast cancer development?

Breast cancer evolves over many years and is likely to involve the mutation of many genes. The natural history of the disease is unclear but may occur as follows: a normal breast epithelial cell acquires genetic damage that leads to a clonal proliferation of cells that eventually evolves into a CIS. The in situ

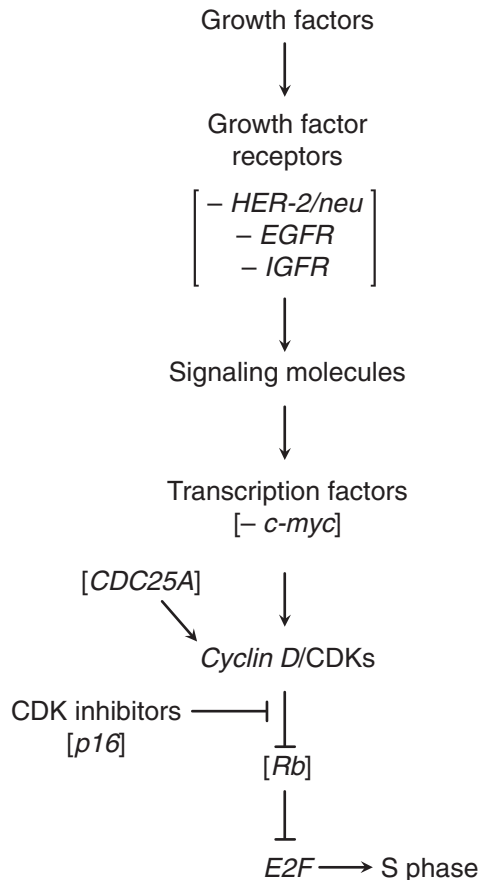

Figure 2-8 Mitogenic pathways and their relationship to breast cancer. Mitogenic pathways that stimulate cell division are affected in multiple ways in breast cancer.

lesion then matures to an invasive carcinoma, which in turn metastasizes to the lymph nodes and other organs¹¹¹ (Fig. 2–9). Current models of tumor progression for colon cancer correlate alterations of genes with the different phases of tumor development.¹¹² The simplistic model of breast tumor progression presented here (see Fig. 2–9) attempts to integrate much of the molecular information attained to date.

What is the earliest point in tumor development associated with genetic alterations?

The earliest genetic alterations have been observed in morphologically normal breast lobules and ducts near the site of a primary tumor¹¹³ (see Fig. 2–9). Similar structures distant from the tumor have no genetic changes. The alterations observed are large chromosomal deletions (LOH). These normal-appearing breast cells may be precursors of the nearby tumor because identical losses are seen in the more advanced lesion. These foci of histologically normal cells may have been the direct precursor of an invasive breast cancer or may have passed through the intermediate step of CIS. Nevertheless, no genes that are necessary for the early steps in tumor development have been identified.

What genetic changes are associated with carcinoma in situ?

Many genetic alterations have occurred by the time CIS has developed. These include alterations of the estrogen receptor, *p53*, *erb-2/HER-2/neu*, and *cyclin D*.³¹ In addition, CIS is usually genetically unstable, as evidenced by the high frequency of aneuploidy and alteration of both *p53* and *cyclin D*.^{100–102} These data have three important implications. First, the many mutations seen at this stage of development indicate that these lesions have gone through many rounds of clonal selection and are many steps away from their normal epithelial precursors. Second, the level of genetic instability seen in these lesions implies that selective pressure for the tumor to invade the basement membrane is likely to ultimately allow for the emergence of an invasive clone. Third, the frequency of alterations of estrogen receptor, *p53*, *erb-2/HER-2/neu*, and *cyclin*

Figure 2-9 Model of breast cancer progression from normal epithelium to metastatic tumor. A possible pathway of tumor progression is shown. A question mark indicates that at present no gene has been identified that is altered specifically at the indicated transition point. Although many alterations have been observed in invasive breast cancer, they are also shared by carcinoma in situ.

D apparently peaks with CIS, which implies that most of the genetic steps in the tumor's development occur before invasion. On the other hand, although CIS differs tremendously from normal breast epithelial cells, CIS apparently differs little from invasive breast cancer.

What are the genetic changes associated with invasive and metastatic breast cancer?

Little is known about what genetically distinguishes CIS from invasive breast cancer. One clue is that loss of *PTEN* expression appears to occur in carcinomas and is rarely seen in CIS. Similarly, no genetic lesions have been identified that mark the transition to metastasis. However, a distinct gene expression pattern is associated with tumors that are destined to become metastatic.¹¹⁴ This suggests that one or more programs of gene expression are altered in tumor to favor metastasis.

Are there other genes altered in breast cancer?

Our understanding of the genetic basis for the pathogenesis of breast cancer is incomplete. In the past 15 years, great strides have been made to delineate some of the pathways targeted for mutation. Most of these alterations seem to occur in pathways affecting proliferation and genomic stability. Nothing is known of the initiating events in sporadic breast cancer, nor has the actual chain of genetic events been determined for familial tumorigenesis involving *BRCA1* or *BRCA2*. Identification of a breast stem cell population should lead to a better understanding of breast epithelial development. Aberrant expansion of breast stem cells may provide the basis for tumor initiation and expansion.^{115,116} Furthermore, no genes that are responsible for the transition from CIS to invasive carcinoma have been identified, although one locus has been implicated in this transition. Finally, the transition from locally invasive to metastatic disease is also likely to be associated with specific genetic alterations. Characterization of these genetic events will define the pathogenesis of breast cancer and hopefully produce the rational targets for drug therapy that are needed to improve patient care.

Molecular, Cellular, and Developmental Biology of Breast Cancer

Sarah Hatsell, Minoti Hiremath, Peter Shamamian, and Pamela Cowin

Breast is a dynamic gland that undergoes considerable post-natal development and dramatic, cyclic morphologic changes throughout a woman's reproductive life. The temporal and spatial synchronization of these events requires endocrine and paracrine signals as well as a host of self-regulatory constraints. The chain of command begins with temporal signals from globally dispersed hormones. These are sensed by cells, discretely positioned throughout the breast, expressing hormone receptors. Hormone receptor-positive cells respond to hormones by producing highly localized growth factors that activate their receptors on neighboring cells. This in turn generates intracellular signals that produce the expression of cytoskeletal, adhesion, and extracellular matrix proteins as well as protein involved in tissue remodeling, cell cycle, and apoptosis.

Cancer research has approached breast biology with two major goals: to identify proteins that could serve as prognostic indicators or tumor cell markers and to curb breast cell proliferative pathways. Yet breast tumors grow slowly, developing with long latency, and mortality from breast cancer relates principally to metastatic spread and high rates of tumor recurrence. Cancers arise from inherited or acquired mutations. An increasing number of genetic mouse models, which provide powerful and incisive tools to dissect the consequences of such mutations, have suggested links between normal development and pathology of mammary gland. Moreover, a recent focus on stem cell biology has highlighted potential connections between normal breast stem-progenitor cells and cancer stem cells that are thought to be responsible for tumor recurrence. This chapter focuses on a selection of proteins and processes implicated in breast cancer viewed through the lens of their normal role in breast development and function.

Does the evolution of mammary glands suggest a mechanism for breast cancer metastases to bone?

Mammary glands are epidermal appendages that likely evolved from hair-associated apocrine glands.¹ Evidence for

this may be found in a number of living species. For example, duck-billed platypuses have mammo-pilo-sebaceous units, which secrete milk that is lapped by their hatchlings from the ends of specialized hairs; koala bears form vestigial mammary hairs that regress as nipples form; and squirrels show bilateral development of sensory hairs and nipples from the same original epidermal anlage.¹ Molecular evidence suggests that lactation evolved from cutaneous secretions serving as antimicrobial protectants and as egg supplements.¹ Prolactin, the hormone that stimulates milk protein expression, belongs to the inflammatory cytokine gene family, and the α -lactalbumin subunit of the lactose synthetase enzyme resembles lysozyme, an antimicrobial component of egg yolk.

The ability of the mammary gland to promote bone resorption is thought to have evolved from ancient mechanisms involving estrogenic mobilization and transfer of maternal skeletal calcium reserves to eggshell in birds and to egg vitellogenin in freshwater fish.² Mammary glands mobilize bone calcium by secreting parathyroid hormone-related protein (PTHrP). This protein was discovered as a tumor product that induced humoral hypercalcemia of malignancy (HHM), a metabolic complication of many cancers. Expression of PTHrP within primary breast tumors is predictive of bone metastases. PTHrP is proposed to promote osteotropism by enabling breast cancer metastases to carve a foothold and simultaneously release growth factors from bone. Thus, bone tropism of breast cancer metastases may be considered an unintended consequence of a physiologic mechanism that evolved to trigger bone resorption for the purpose of lactation.²

How do mammary glands develop in the embryo?

PTHrP is essential for the earliest stages of embryonic mammary development. Mammary glands form during early embryonic development as bilateral epidermal placodes that coalesce and invaginate to form mammary buds (Fig. 3-1). Epithelial cells within the mammary buds secrete PTHrP,

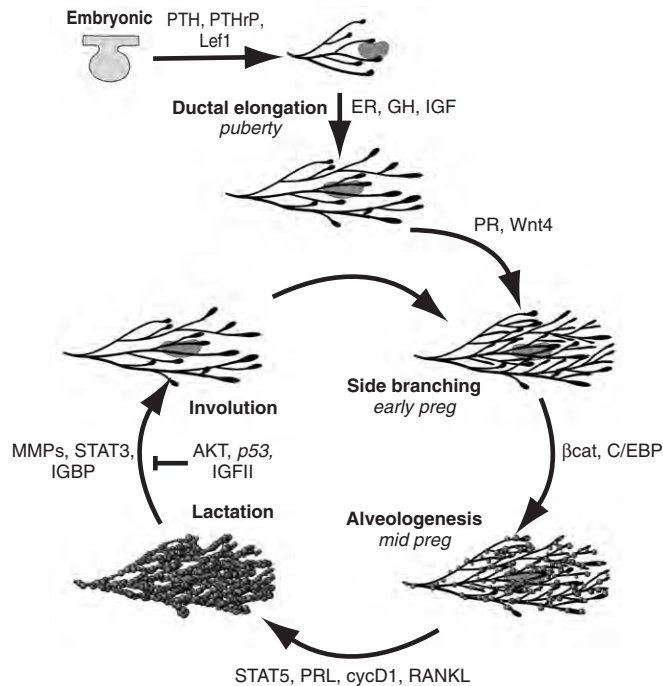

Figure 3–1 Diagram of the development of the mammary gland during puberty and pregnancy indicating some of the major signaling proteins involved. The mammary bud forms on about embryonic day 13 when epithelium, under the control of parathyroid hormone-related protein (PTHrP) and lymphoid-enhancer binder factor 1 (Lef1), grows down into the mammary mesenchyme and branches to form the small ductal structure present at birth. The gland stays quiescent until puberty, when estrogen receptor (ER), growth hormone (GH), and insulin-like growth factor (IGF) induce ductal elongation. In early pregnancy, progesterone receptor (PR) and Wnt4 stimulate side branching. Alveologenesis occurs in mid to late pregnancy and is controlled by β -catenin (β cat), CCAAT-enhancer binding protein beta (C/EBP), STAT5 (Signal transducer and activator of transcription), prolactin (PRL), cyclin D1 (cycD1), and receptor activator of NF-Kappa B ligand (RANKL). At the cessation of lactation, involution is mediated by matrix metalloproteinases (MMPs), STAT3, and IGF-binding protein (IGBP), where the gland undergoes remodeling to resemble a virgin gland.

which induces underlying stromal cells to become mammary mesenchyme.³ Mammary mesenchymal cells signal back, inducing the epidermis to form nipple skin and suppress hair follicle formation.³ PTHrP induces mesenchymal expression of androgen receptor (AR) and the transcription factor Lef-1, which is critical for elongation and formation of the rudimentary mammary tree.³ Male fetal androgens stimulate mammary mesenchymal cells to constrict around the mammary bud, leading to its degeneration. PTHrP^{-/-} and Lef-1^{-/-} mice fail to specify the mammary mesenchyme, extend the mammary ductal tree, or show sexual dimorphism.^{3,4} This phenotype is seen in Blomstrand chondroplasia, a form of human dwarfism resulting from mutations in the *PTHrP* gene.⁵ During embryogenesis in females, the mammary bud elongates and branches to form a rudimentary mammary tree that remains quiescent until puberty.

What are the normal roles of estrogen, growth hormone, and insulin-like growth factor in pubertal mammary development?

Pituitary and ovarian hormones produced during puberty induce proliferation of cap cells occupying multilayered club-shaped structures known as terminal end buds (TEBs) (Fig. 3–2). This results in rapid ductal elongation and progressive branching⁶ (see Fig. 3–1). Both estrogen and growth hormone (GH) are required for this to occur.⁷ These hormones act synergistically on stromal cells to induce insulin-like growth factor-1 (IGF-1).⁸ This protein appears to be the critical paracrine effector because ductal extension does not proceed in the absence of IGF-1, even when estrogens and GH are present.⁷ At the end of puberty, TEBs disappear, and the gland again becomes dormant.

What are the contributions of estrogen to breast cancer?

Alveola-like eruptions appear transiently in response to hormonal surges in estrogen and progesterone accompanying estrus or ovulation. The number of ovulatory cycles is a significant risk factor in breast cancer, suggesting that such transient hyperplasia could be important in the etiology of breast tumors. However, because epithelial estrogen receptor (ER) is required for progesterone receptor (PR) expression, it is presently unclear whether ovulation-induced hyperplasia is stimulated by estrogen or progesterone.⁹ Estrogen's role in breast cancer was first noted when oophorectomy in premenopausal women resulted in tumor regression.¹⁰ The role of estrogen in breast cancer was further supported by the observation of enhanced risk for breast cancer associated with early menarche, late first full-term pregnancy, late menopause, or oral contraception use. This has been interpreted as resulting from increased lifetime exposure to estrogen. However, the finding of the Women's Health Initiative Trial that estrogen-only hormone replacement therapy does not increase the risk for breast cancer suggests that these earlier epidemiologic data need re-evaluation regarding the potential detrimental role of progesterone in these processes.¹¹

Estrogen's biologic activities are mediated through ER, which occurs in α and β isoforms. In normal breast, ER-positive cells are seldom associated with markers of proliferation. Estrogen is thought to exercise its mitogenic effects by stimulating further paracrine signals.¹² In breast cancer, ER expression and proliferative markers overlap. About 70% of breast cancers express ER, and ER-positive breast tumors proliferate in response to estrogen when implanted into athymic nude mice.¹² The acquisition of proliferative capacity by ER-positive cells occurs at the earliest stages of tumorigenesis and therefore appears to contribute to breast tumor formation.¹²

In the absence of estrogen, ER is complexed with chaperone proteins (Hsp90, p23, Cyp-40, and FKBP52) that modulate ER DNA binding abilities. In the presence of estrogen, ER dissociates from chaperone proteins that bind to estrogen response elements (EREs) in the 5'-flanking regions of estrogen-responsive genes and initiates transcription in conjunction with coactivators (SRC-1, GRIP1, AIB1). ER

Figure 3–2 Diagram of a terminal end bud showing the major pathways involved in ductal extension during puberty. Estrogen and growth hormone (GH) promote ductal extension by stimulating estrogen receptor (ER)- and growth hormone receptor (GHR)-positive stromal cells surrounding the terminal end bud to produce insulin-like growth factor-1 (IGF1). IGF1 induces the proliferation of the cap cells, which differentiate and move to the more proximal part of the duct to become myoepithelial cells. The body cells divide and differentiate into luminal cells. Macrophages stimulated by colony-stimulating factor-1 (CSF1) are required for ductal elongation. EGF, epidermal growth factor; TGF α , transforming growth factor- α .

coactivators function by recruiting a histone acetyltransferase (CBP/p300) and basal transcription machinery (RNA polymerase, TBP, TFIIB). EREs are found in many promoters, and a large number of estrogen-responsive genes have been described (<http://research.i2r.a-star.edu.sg/promoter/Ergdb-v11/index.htm>). Genes encoding growth factors, such as IGF-1, and cell cycle regulators *cyclin D1* and *c-myc* are important transcriptional targets in the mitogenic response of breast to estrogen. In addition to its transcriptional targets, ER may also affect growth through “nongenomic activity.” An alternative plasma membrane-associated ER is proposed to stimulate growth through activation of the mitogen-activated protein kinase (MAPK) pathway by forming complexes with the MNAR scaffold protein and *src*, or with *shc*.¹³ Despite the demonstrated mitogenic effects of estrogen, ER-positive tumors are associated with better clinical outcome than ER-negative tumors, likely because ER also stimulates breast differentiation and contributes to epithelial stability and architecture by indirectly regulating expression of the E-cadherin breast tumor suppressor gene (discussed subsequently).

ER expression predicts tumor responsiveness to selective estrogen receptor modifiers (SERMs) such as tamoxifen and a related drug, raloxifene. SERMs have been used successfully as anti-cancer adjuvant therapies against hormone-responsive breast cancer.¹⁰ They compete with estrogen for ER binding and act in a tissue-specific manner as estrogen agonists or antagonists. ER crystal structures indicate that the receptor adopts different conformations when bound to specific ligands (estrogen, tamoxifen, and raloxifene).^{14,15} The type of steroid receptor coregulator in the tissue determines the effects of the ligand. For example, in the breast cancer cell line MCF7, both tamoxifen and raloxifene recruit corepressors and histone deacetylases (HDACs) to inhibit transcription of estrogen-stimulated genes, such as *c-myc* and *IGF-1*. However, in the uterus, tamoxifen, but not raloxifene, recruits the *SRC-1* coactivator and promotes transcription of these genes.¹⁶ This explains the observations of the STAR (Study of Tamoxifen and Raloxifene) trial in which tamoxifen, but not raloxifene, increased the risk for uterine cancer in breast cancer patients treated with these drugs. Although SERMs are

effective adjuvant therapies, reducing the incidence of ER-positive breast cancer and significantly prolonging survival, the benefits of these drugs are complicated by significant increases in gynecologic cancer and in cardiovascular deaths. In addition, most patients who show an initial response to SERMs eventually develop resistance to the treatment. Alternatively, aromatase inhibitors, such as anastrozole, which inhibits estrogen production rather than selectively modulating ER activity, have been effective. The ATAC (Arimidex, Tamoxifen, Alone or in Combination) trial has shown that anastrozole is superior to tamoxifen in reducing the incidence of contralateral invasive breast cancers. Anastrozole is better tolerated and induces fewer cardiovascular events and endometrial carcinomas. Side effects include bone loss from estrogen deprivation.¹⁷

What are the connections between cell–cell adhesion proteins and breast cancer?

Mammary ductal and alveolar epithelia are arranged in two layers (Fig. 3–3). Epithelial cells (expressing keratins 8, 18, and 19) line the central lumen and are surrounded by myoepithelial cells (expressing keratins 5 and 14) that directly contact the basal lamina. Cells in both layers are connected by cadherins (calcium-dependent cell–cell adhesion proteins). These proteins are essential for cell adhesion and exert profound effects on cell polarity, growth factor–mediated cell survival, and cell migration. Luminal cells adhere to one another by E-cadherin, and myoepithelial cell adhesion is mediated by P-

cadherin.^{18,19} Luminal and myoepithelial layers interconnect through the desmosomal cadherins, desmogleins (Dsg 2/3), and desmocollins (Dsc 2/3). Each of these proteins has a documented role in mammary development and breast cancer.

E-cadherin, the best characterized breast tumor suppressor protein, mediates luminal cell–cell adhesion.²⁰ It also stabilizes growth factor receptors, sustains survival signals, and is required for the formation of tight junctions, which maintain cell polarity and seal the alveolar lumen during lactation.²¹ Loss of E-cadherin^{-/-} in the mouse mammary gland causes precocious apoptosis and involution during late pregnancy.²² Germline mutations in the E-cadherin gene, *CDH1*, mildly predispose individuals to breast cancer. Loss of heterozygosity (LOH) of 16q22.1, which contains *CDH1*, is the second most frequent somatic genetic event in sporadic breast cancer, occurring in both lobular breast cancer and ductal carcinoma in situ (DCIS).²³ LOH with subsequent inactivating mutations in *CDH1* occurs in 50% of lobular breast cancers and is used as a diagnostic indicator of this type of tumor. LOH also occurs early in the more common grade 1 DCIS and preinvasive lobular carcinoma in situ (LCIS) but is not accompanied by further *CDH1* inactivating mutation.^{23–28}

Abundant evidence links poor E-cadherin expression with tumor invasion and metastasis, which has been correlated with metastasis and poor prognosis.²³ Increasing E-cadherin expression reduces the invasive capacities of cells in vitro by restoring cell–cell adhesion, sequestering the β -catenin proto-oncogene, and elevating expression of the *p27* cell cycle inhibitor. However, several studies of human breast cancer cell lines have shown that decreased E-cadherin

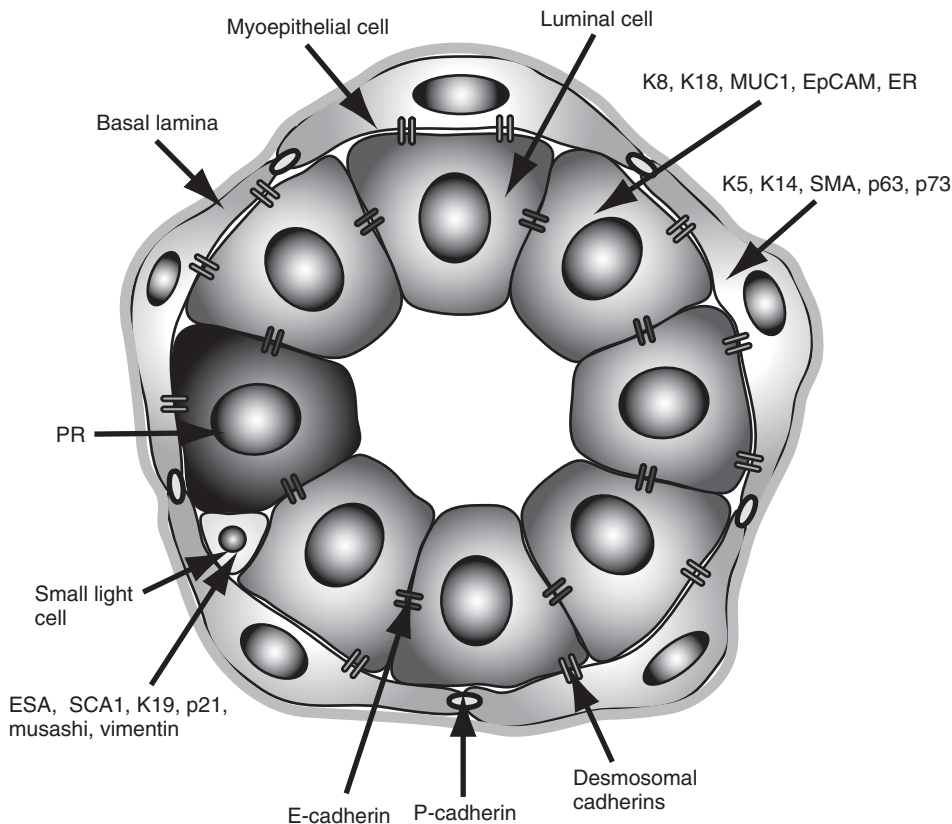

Figure 3–3 Diagram of a cross-section through mammary duct showing expression of markers commonly used to distinguish myoepithelial and luminal cell populations. Adherens junctions contain P-cadherin between myoepithelial cells and E-cadherin between luminal epithelial cells. Desmosomal cadherins link the two cell types. Progesterone receptor (PR) is expressed nonuniformly along the duct in mature virgins, where it is involved through the paracrine action of Wnt4 in side branching. The small light cell population is thought to comprise the stem and progenitor cells of the mammary gland. This cell population shows expression of several putative stem cell markers, including epithelium-specific antigen (ESA), K19, p21, stem cell antigen-1 (SCA1), and musashi. EpCAM, epithelial cell adhesion molecule; ER, estrogen receptor; SMA, smooth muscle actin.

expression level is not an absolute predictor of tumor invasive and metastatic behavior and that derivative metastases frequently show strong E-cadherin expression.^{29–31} In contrast, increased expression of other cadherins, N-, P-, and OB- (osteoblast cadherin 11), correlates with experimental parameters of invasion and metastasis. Little is known about expression patterns of these cadherins in normal breast, but they have been noted in several invasive breast cancer cell lines.^{29–32} P-cadherin^{-/-} mice show precocious mammary development, suggesting that loosening of myoepithelial cell junctions may be a key event precipitating alveologenesis.¹⁸ P-cadherin expression is associated with high histologic grade of ER-negative DCIS and invasive carcinomas.¹⁹ N-cadherin is proposed to enhance motility and epithelial-to-mesenchymal transition (EMT) by stabilizing the surface expression of the fibroblast growth factor receptor-1 (FGFR-1), enhancing its responsiveness to fibroblast growth factor-2 (FGF-2), and sustaining activation of the MAPK pathway.³³ This, in turn, increases expression of matrix remodeling agents, such as matrix metalloproteinase-9 (MMP-9).³³

The intracellular domain of cadherins associates with catenins.²⁶ α -Catenin, which connects the adhesion complex to the actin cytoskeleton, is down-regulated in breast cancer.³¹ β -Catenin, which forms a modulatable link between cadherins and α -catenin, shows aberrant expression and phosphorylation in human breast cancer and induces mouse mammary adenocarcinomas.^{34–37} Reduction in cell adhesion due to down-regulation of the desmosomal cadherin, Dsc 3, or the desmosomal plaque proteins desmoplakin and plakoglobin has been reported in poorly differentiated and invasive ductal carcinomas.^{36,38}

What do slug and snail transcription factors have to do with metastasis? Is estrogen good or bad?

Studies have suggested that estrogen regulates epithelial architecture through modulating E-cadherin.^{39,40} Estrogen-activated ER indirectly stimulates expression of *MTA3*, a component of Mi-2/NuRD, nucleosome-remodeling complex.³⁹ This represses expression of snail, a transcription factor and master regulator of epithelial-to-mesenchymal transition. Snail, like its related transcription factors slug and SIP, represses transcription from the E-cadherin promoter.⁴¹ Snail expression correlates with infiltration by ductal carcinomas and down-regulation of the aromatase gene.⁴² Slug expression correlates with lack of E-cadherin transcripts in breast cancer cell lines.^{43,44} Estrogen is hypothesized to maintain epithelial architecture by constraining these transcriptional repressors of E-cadherin expression.^{39,40} Studies in *Drosophila* species have also identified genetic connections between *taiman*, the homologue of the estrogen coactivator amplified in breast cancer (*AIB1*), cadherin expression, and cell migration.^{45–47} Thus, evidence is accumulating that estrogens, ER, and estrogen coactivators function to regulate cell morphology and migration in addition to proliferation. Each of these factors likely functions in the continual remodeling that is required of normal breast throughout the mammary cycle, but when dysregulated, each promotes invasion and metastasis, which lie at the root of breast cancer mortality.

What are the contributions of growth hormone and insulin-like growth factor to breast cancer?

IGF-1 is a potent mitogen that is essential during puberty for ductal proliferation and extension. Estrogens induce IGF-1, its receptor IGFR-1, and the downstream signaling molecules insulin receptor substrate-1 (IRS-1) and IRS-2, leading to enhanced epithelial survival in response to IGF-1.⁴⁸ IGF-1 is also a key survival factor for the breast epithelium during lactation.⁴⁹ Involution, following cessation of lactation, is triggered by STAT3-induced expression of an IGF-binding protein (IGF-BP), which provokes breast epithelial apoptosis by sequestering the IGF survival factor.⁵⁰ High IGF-BP levels have been associated with both increased and decreased risk for premenopausal breast cancer.⁵¹ Increased levels of GH and IGF-1 are found in premenopausal breast cancer, and IGFRs are increased 40-fold.^{51,52} IGFR-1 represses apoptosis that would result from the unbridled activity of other oncoproteins.⁵³ Its antiapoptotic effects may also negatively affect therapies dependent on radiation-induced cell death and underlie resistance to *HER-2* inhibitors, such as trastuzumab (Herceptin), that develop under selective pressure of breast cancer treatment.⁵²

What is the role of the *HER* family in mammary development and breast cancer?

All four members (*HER-1–4*) of the *HER/erbB/EGFR* gene family are expressed in breast.⁵⁴ The *HER* genes encode transmembrane receptors that bind growth factors and initiate internal mitogenic signal transduction pathways through their tyrosine-kinase domains. Although they are potent breast mitogens, they can also stimulate apoptosis when overexpressed.⁵⁵ *HER-1* binds epidermal growth factor (EGF), transforming growth factor- α (TGF- α), and amphiregulin. *HER-1* and *HER-4* bind betacellulin, epiregulin, and HBEGF. *HER-3* and *HER-4* bind neuregulins 1 to 4.⁵⁵ Many of these ligands are lipid bound in precursor form to the surface of the cells that produce them. Their polarized expression, cleavage, binding to heparin sulphate proteoglycans, and subsequent receptor internalization are important points of regulation that affect the initiation and duration of their signals. *HER-2* and *HER-3* are unusual in that so far no *HER-2* ligand has been identified and *HER-3* lacks intrinsic kinase activity.⁵⁴

On binding to ligand, members of the *HER* receptor family dimerize and phosphorylate specific tyrosine residues within their cytoplasmic domains. Each receptor contains specific phosphorylation sites that form binding sites for different downstream signaling molecules. Phosphorylation can lead to the association of Src-homology 2 proteins (SH2) and phosphotyrosine-binding domain proteins (PTBs), such as Src, PLC γ , and PI3K, and to adaptor proteins, such as Shc, Grb2, Grb7, and Nck.⁵⁴ These proteins link to intracellular signaling pathways, including the MAPK/ERK1. Downstream mediators also provide ample opportunity for integration with TGF- β and BMP2 signaling through MAPK-mediated phosphorylation of the Smad pathway.

The complexities introduced by receptor dimerization, ligand redundancy, and multiple levels of signal regulation make

defining the roles of individual HER proteins in breast biology challenging. This remains a work in progress. However, the following generalizations may be made. Epithelial amphiregulin and stromal HER-1/2 heterodimers play significant roles in ductal extension and maintain the survival of periductal stromal cells. During pregnancy, HER-1 TGF- α heterodimers affect side branching and alveologenesis. The naturally occurring HER-1 hypomorph, *waved-2* mouse, shows impaired lactation. HER-3 and the neuregulins play a major role in proliferation and differentiation, and HER-4 is critical for lactation.⁵⁵

Deregulated expression of *HER-1* and *HER-2* occurs frequently in breast cancer and may provide routes to estrogen-independent growth. *HER-2* is amplified in 30% of breast cancers, and this overexpression results in ligand-independent activation of its kinase domain.⁵⁶ Expression of activated or wild-type *HER-2* under the control of the MMTV promoter in mice causes tumors, supporting the hypothesis that *HER-2* is important in tumorigenesis.^{57,58} MMTV-*HER-2* tumors form with long latency, resemble human comedocarcinomas, and can develop metastasis to the lung.⁵⁸

HER-2 is the preferred dimerization partner for other family members and is required for activating downstream signaling of the kinase-dead *HER-3* receptor. High levels of phosphorylated *HER-3* are frequently found in tumors overexpressing *HER-2*, and this particular heterodimer appears to be the most potent.⁵⁸ Activation of *HER-2/3* recruits PI3K, which promotes the antiapoptotic AKT/PKB survival pathway and stimulates proliferation through effects on *cyclin D3* and *p27* elements of the cell cycle machinery. These observations have led to the use of antibodies directed against *HER-1* (C225), *HER-2* (Herceptin), and the *HER-2/3* heterodimer (2C4) and to the development of small molecule inhibitors of *HER-1* ZD1839 (Iressa) and OSI774.⁵⁹

Overexpression of *HER-2* also promotes invasion and metastasis. It may achieve this either by inhibiting E-cadherin transcription or by sequestering β -catenin.^{25,60} *HER-2* may also increase invasiveness by associating with ASGP2, the transmembrane component of MUC4, a protein that sterically hinders cadherin-mediated cell adhesion.⁶¹ *HER-2* has been proposed to increase cell motility by stimulating expression of MMP-9, uPA, and uPAR through MAPK pathways.

What changes take place in mammary glands during pregnancy? What are the roles of progesterone receptor and its paracrine pathways in breast cancer?

During pregnancy, mammary glands undergo extensive ductal side branching followed by alveolar development. These morphologic changes are accompanied by sequential expression of the milk proteins: WDNM1, casein, whey acid protein (WAP), and α -lactalbumin. Genetically engineered mice have provided definitive evidence of signaling pathways regulating these proliferative and differentiating processes as well as increased risk of cancer. Mice lacking progesterone receptor (PR^{-/-}) or Wnt-4^{-/-} show impaired ductal side branching, whereas those overexpressing Wnt-1 show increased branching.^{62,63} This form of increased branching is a premalignant condition. P-cadherin^{-/-} mice or those overexpressing β -catenin, cyclin D1, or one of several MMPs show precocious

alveolar development, again a premalignant condition.^{18,35,64-66} In contrast, mice expressing β -catenin suppressors or lacking cyclin D1, RANKL/osteoprotegerin (OPGL), or the transcription factor C/EBP- β are impaired in alveologenesis.⁶⁷⁻⁷¹ Mice lacking prolactin receptor (PrLR^{-/-}) or STAT5a^{-/-} show impaired development and milk synthesis.⁷²⁻⁷⁴ The fact that several of these mice develop tumors suggests links between activation of developmental pathways and breast cancer.^{35,65,66,75,76}

Hormone receptors (ER, PR, and PrLR) are expressed uniformly in virgin epithelial cells but adopt an intermittent expression pattern in adults.⁷⁷ This change is critical for proliferation and further development and is dependent on the transcription factor C/EBP- β .^{71,78,79} Proliferative cells lack steroid hormone receptors but reside near hormone-responsive cells.^{12,80,81} Thus, steroid receptor-positive cells may represent a stem-progenitor cell or a niche that acts as a sensor to influence the activity of nearby steroid receptor-negative stem or progenitor division-competent cells.⁸² An increased incidence of breast cancer in postmenopausal women receiving combined hormone replacement therapy (estrogen plus progesterone), compared with those receiving estrogen only, suggests that prolonged stimulation of PR may predispose to breast cancer.¹¹ Tumors that are positive for PR, however, have a better prognosis because they must also express ER and are therefore likely to respond to SERMs. In the current model of breast development, receipt of progesterone by PR-positive cells stimulates release of paracrine growth factor survival signals, including IGF-II, RANKL, and Wnt-4.^{83,84} These factors are prime candidates to mediate hormone-independent proliferation of tumors. IGF-II expression is responsive to hormone stimulation and is constitutively expressed in estrogen-independent MDA-MB-231 breast cancer cells. RANKL, a key osteoclast differentiation or activation factor that is essential for bone remodeling, is secreted by breast during pregnancy.⁷⁰ RANKL interaction with its receptor RANK results in activation of NF κ -B and up-regulation of cyclin D1, both of which are highly expressed in many breast tumors.⁸⁴ Ectopic expression of Wnt-1, which is presumed to mimic the endogenous *Wnt-4* gene, rescues the PR^{-/-} block in side-branching and induces mammary adenocarcinomas.^{63,85}

What is the evidence that cancer stem cells are central to breast cancer development and progression?

The long time lag (up to 30 years) in breast cancer incidence following radiation exposure in atomic bomb victims has strongly suggested that long-lived and possibly immortal stem-progenitor cells are targets for transformation. Further circumstantial evidence in support of this concept comes from high rates of breast cancer in women exposed to radiation during adolescence, a time when stem cells reside close to the surface of the epidermis and hence are more exposed to damage. The concept that breast tumors arise from transformation of stem cells, or from transformation of differentiated cells that revert to stem cell-like behavior, is of paramount importance for the design of therapeutic strategies.^{86,87} Current radiotherapy and chemotherapies target rapidly dividing cells, and their effectiveness is measured by their ability to reduce tumor mass and induce tumor regression by

apoptosis. As such, they effectively kill the differentiated and harmless progeny of stem cells, which form the tumor bulk, and quickly become limited in their effectiveness by the emergence of therapy-resistant cancer cells. Similarly, adjuvant therapies such as tamoxifen are directed at the ER-positive or *HER-2*-positive differentiated cells. They are not tailored to target stem cells, which by their nature are slowly dividing and resistant to apoptosis owing to higher levels of expression of the antiapoptotic factor *BCL-2* and of multidrug resistance channels, such as breast cancer-related protein-1 (BCRP1), which efficiently export chemotherapeutic agents.^{86–91} Stem cells therefore remain, causing tumor recurrence. Tumors contain heterogenous mixtures of different cell types. However, studies in mouse models of breast cancer have shown that all cells within a tumor contain the same genetic mutational fingerprint, supporting their origin from a common precursor.⁹² Nevertheless, very few of these cells are capable of reforming tumors.^{93,94} Such a subset of cells may be considered “tumor stem cells” that produce heterogenous progeny, of limited tumorigenic capacity, that form the tumor bulk.^{86,87,93,94} Studies have shown that epithelial-specific antigen (ESA-positive, CD44-positive, CD24-negative, lineage marker-negative) cells, isolated from nine different human breast tumors, are enriched 50-fold in their ability to form xenografted tumors compared with unsorted cells. Significantly, these cells are perpetuated within serial transplants and reproduce the heterogenous complexity of the original tumor, suggesting that they possess the twin stem cell capabilities of self-renewal and the ability to generate differentiated progeny.⁹⁴

Where are mammary stem cells and their cancer-prone progenitors?

The relationship between tumor stem cells and normal stem cells is implied but not proven. Identification of mammary stem cells has been approached from many angles. Transplantation studies established that stem cells, dispersed throughout the mammary epithelial tree, are capable of regenerating an entire gland.^{95,96} The presence of “small light cells” (SLCs), which occupy a niche intermediate between luminal and myoepithelial cell layers (see Fig. 3–3), correlates with regenerative capacity of such serial transplants.⁹⁷ These cells are capable of mitosis but are generally quiescent and display other stem cell-like features, including undifferentiated ultrastructural characteristics; an ability to retain BrdU label (indicating a low proliferative rate); expression of putative stem cell markers, such as Sca-1, p21, $\alpha 6$ -integrin, ESA, cytokeratin 19, telomerase, and musashi; and lack of differentiation markers.^{98,99} Recent work has applied the Hoechst dye-effluxing technique to the mammary gland. This approach led to isolation of hematopoietic stem cells by fluorescence-activated cell sorting into a side population (SP). Mammary SP overlaps with SLCs and label-retaining cells.^{99,100} A further approach has been to analyze cells capable of perpetuating three-dimensional mammosphere cultures, a technique that is proposed to select for stem cells. Gene expression profiles of such cells have revealed the presence of many proteins common to hemopoietic, neural, and embryonic stem cells.¹⁰¹

It is currently a matter of debate as to whether mammary stem cells are ER positive or ER negative.^{12,80,81} In addition to

stem cells, the mammary gland appears to regenerate itself through a hierarchy of progenitors, which may also be targets for oncogenic transformation. Mammary gland contains three types of lineage-limited progenitor cells. In serial transplantation studies, these give rise to outgrowths composed of ducts, alveoli, or both, the latter case indicating the presence of a common bipotent progenitor for ductal and alveolar structures.⁹⁶ In each case, outgrowths contain both luminal and myoepithelial cells. Wnts and their downstream signal transducer β -catenin play key roles in expanding specific mammary stem-progenitor populations.^{26,35,82,92,102} β -catenin expands an alveolar progenitor population and induces tumors when ectopically expressed in mammary gland.^{35,82} Inactivating mutations or down-regulation of Wnt and β -catenin suppressors, such as FRP, AXIN, and APC, and high levels of expression of β -catenin target genes, such as *cyclin D1* and *c-myc*, have been reported in a significant proportion of human breast tumors.²⁶ These studies suggest a connection between mammary stem-progenitor cell expansion and cancer susceptibility.

What is the involvement of cell cycle proteins in breast cancer?

An alternative view is that breast cancer is a disease of abnormal or uncontrolled proliferation resulting from deregulated growth factor signaling or aberrations in cell cycle control machinery. Thus, a great deal of interest has focused on the potential role of cell cycle elements in breast cancer. The cell cycle (Fig. 3–4) comprises four phases: G_1 (gap 1), S (DNA

Figure 3–4 Schematic diagram of activation of the cell cycle. Mitogenic stimuli cause the sequestration of p27 from its complex with cyclin-dependent kinase-2 (cdk2) and cyclin E (cycE) into a complex with cyclin D (cycD) and cyclin-dependent kinase-4 (cdk4). This activates both cyclin-dependent kinases to phosphorylate Rb, resulting in the dissociation of E2F, which activates expression of S-phase genes.

synthesis), G₂, and M (mitosis), in which cells duplicate their chromosomes and divide in two. Progression through this cycle is promoted by cyclin-dependent kinases (CDKs), which are positively regulated by cyclins and negatively regulated by CDK inhibitors. Cyclins are synthesized at different times in the cell cycle and are rapidly degraded by protein complexes that target them for proteasomal destruction. D-type cyclins provide a fundamental link between mitogens such as *erbB-2* and *ras*, which activates the MAPK cascade, and the cell cycle machinery. D-type cyclins interact with CDK4 and CDK6 to drive the progression of a cell through early and mid G₁ phase. They promote the activity of cyclin E–CDK2, which forms an active complex in late G₁ and directs entry into S phase, by sequestering the p21 and p27 inhibitors. Both cyclin D–CDK4 and cyclin E–CDK2 phosphorylate Rb, leading to the dissociation of E2F transcription factor from the pRb–E2F complex. E2F activates genes necessary for further cell cycle progression. S-phase progression to G₂ is directed by the cyclin A–CDK2 and cyclin A–CDK1 complexes. Lastly, cyclin B–CDK1 complex is necessary for the entry into mitosis.

Cyclin D1 is the most studied cell cycle protein in breast cancer. Cyclin D1 serves an essential role in alveologenesis, as demonstrated by the failure of alveoli to expand during late pregnancy in *cyclin D1*^{-/-} mice.^{69,103} The *cyclin D1* gene is amplified in 10% of breast cancers, and cyclin D1 protein is elevated in a further 40%.¹⁰⁴ The significance of these correlative findings in humans is bolstered by the observation that MMTV–cyclin D1 mice develop tumors, albeit with long latency and at low frequency.⁶⁴ Mammary glands of *cyclin D1*^{-/-} mice are resistant to transformation by oncogenic *ras* and *HER-2/neu*.¹⁰⁵ Thus, *ras* and *HER-2* signal exclusively through cyclin D1 to provoke hyperplasia and tumors. In contrast, although cyclin D1 is up-regulated in human tumors displaying nuclear β-catenin and in MMTV–Wnt-1 and β-catenin mouse tumors, the latter form tumors in the absence of cyclin D1 and indeed are suppressed to some extent by its presence.^{82,105} The involvement of cyclin D1 in tumor formation or promotion is currently a matter of debate. The partial rescue of the cyclin D1^{-/-} phenotype by placing the *cyclin E* gene under the control of the *cyclin D1* promoter or by loss of the *p27* cell cycle inhibitor gene has suggested that cyclin D1 functions solely to advance the cell cycle. However, recent data have shown that cyclin D1 has additional roles in differentiation.^{106,107} Indeed, patients with tumors expressing high levels of cyclin D1 generally have a better outcome. Cyclin D1 can act as a transcriptional coactivator of estrogen receptor and associate with and antagonize the transcriptional functions of C/EBP-β.¹⁰⁶ Statistical investigation of a large panel of human tumors shows a tight association of cyclin D1 up-regulation with a set of C/EBP-β-regulated genes, suggesting that this function contributes significantly to tumor progression.¹⁰⁶ C/EBP-β has several different isoforms. Cyclin D1 antagonizes the full-length form, LAP, which acts as a constitutive repressor of *cyclin D1* target genes. A shorter dominant negative isoform of C/EBP-β, LIP, mimics the effects of cyclin D1 on these transcriptional targets. The LAP/LIP ratio is tightly regulated and increases during terminal differentiation. This ratio is decreased markedly in breast tumors owing to increased levels of LIP.¹⁰⁸

Cell cycle inhibitors, such as *p27* and *p21*, have also received attention as potential prognostic indicators. Their expression has been correlated with proliferation and differentiation.

Thus, *p27* and *p21* inhibit cyclin E–CDK-2 and arrest the cell cycle by halting G₁ progression. However, they facilitate the formation and action of cyclin D1–CDK-4, promoting differentiation. The *p27*^{-/-} mice show multiorgan hyperplasia. In addition, *p27* is rarely mutated in breast cancer, but the cell cycle inhibitory action of this protein is often impaired through accelerated degradation, sequestration by cyclin D–CDK complexes and mislocalization. Reduction of *p27* does not alone cause cancer but accelerates tumor formation by tumor promoters. Many studies have suggested that loss of *p27*, or cytoplasmic *p27*, is a strong independent predictor of decreased disease-free survival and correlates with ER-positive status and high cyclin D1 expression.¹⁰⁹ However, others have suggested that *p27* has no prognostic value.¹⁰⁹ Increased cytosolic *p21* is associated with poor prognosis and is an early event in many neoplasias.¹¹⁰ It is highly expressed in stem cells and is responsible for maintaining them quiescent.⁹⁸ Furthermore, *p21* arrests growth after DNA damage to allow repair. Thus, *p21*-deficient tumors are sensitive to radiation. Attenuating *p21* in tumor cells can lead to an increased susceptibility to currently used DNA-damaging therapeutic agents, suggesting this may be a viable target for cancer therapy.

What role do apoptotic and survival pathways play in involution and breast cancer?

After weaning, the mammary alveolar epithelium undergoes apoptosis, causing the mammary gland to involute, resuming an appearance similar to that of the pubertal ductal tree.⁶ Studies in mice have shown that proteins that play a normal physiologic role as survival signals for the breast epithelium during lactation or as apoptotic or adipogenic signals during involution play significant roles in human breast cancer.

The *p53*^{-/-} mice fail to induce *p21* at the end of lactation, resulting in a reduced apoptotic response and delayed involution.¹¹¹ Sixty percent of *p53*^{-/+} mice produce significant numbers of mammary tumors after about 50 weeks, and mammary epithelial cells derived from *p53*^{-/-} mice produce mammary tumors when transplanted into wild-type fatpads.¹¹¹ The long latency with which these tumors develop indicates the need for other genetic events. Inactivating mutations in *p53* are the most common mutation of sporadic breast cancer, being present in about 60% of tumors.¹¹² Germline mutation of *p53* is found in less than 1% of breast cancers and is not accompanied by LOH.¹¹² Thus, *p53* deficiency promotes mammary tumors in mice and humans, and loss of one allele is sufficient to increase risk. Germline mutations in *p53* are present in Li-Fraumeni syndrome, which is characterized by an increased risk for many cancers, including an 18-fold higher risk for developing breast cancer before the age of 45 years.¹¹³

In addition, *p53* forms a tetrameric transcription factor that plays important tumor suppressor roles guarding the integrity of the genome. Its levels are tightly regulated by a complex feedback mechanism involving its transcriptional target *mdm2*, which binds to *p53* and facilitates its ubiquitination and hence proteolysis (Fig. 3–5). Although *p53* levels are kept low by this mechanism, *p53* is stabilized and activated in response to stressful stimuli such as DNA damage or hypoxia. It induces cell cycle arrest and apoptosis in response

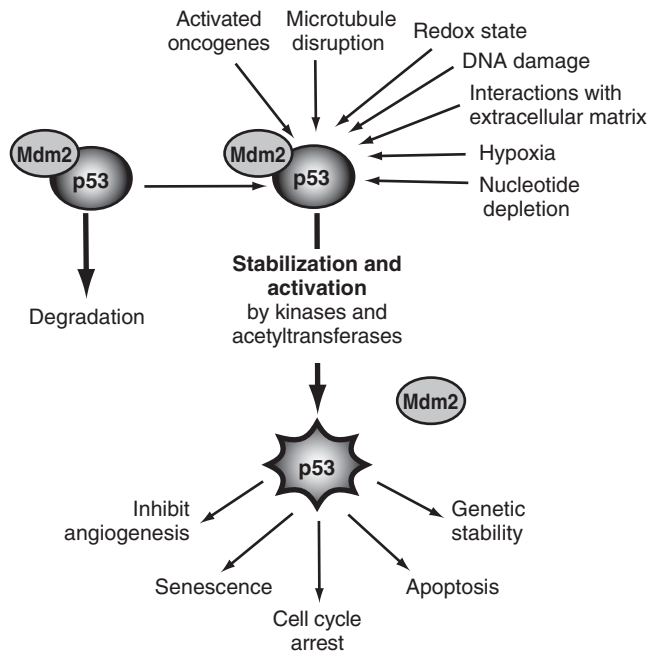

Figure 3–5 In unstimulated cells, p53 levels are kept low by rapid degradation by Mdm2. Large numbers of signals lead to the modification of p53 by various kinases and acetyltransferases, resulting in the detachment of Mdm2, stabilization, and activation, causing a number of downstream effects.

to these stresses by regulating expression of *p21* and *Bax*, respectively. In addition, p53 has 3', 5' exonuclease activity that contributes to fidelity of DNA replication. Thus, in the absence of functional p53, cells are retained that are genetically damaged and genomically unstable.¹¹²

The observation that *p53*^{+/-} mice replicate Li-Fraumeni syndrome only when bred onto a BALB/c background indicates the importance of modifier genes that cooperate in tumor progression. Cooperativity between *p53* and *BRCA1* and *BRCA2* in the rate of tumor incidence has been demonstrated by crossing mice deficient for these genes. Inactivation of *p53* is seen in less than 90% of *BRCA*-mediated breast cancers. Crosses between mice depleted in *p53* and those overexpressing *HER-2/neu*, *ras*, and *Wnt-1* show accelerated tumor incidence.¹¹¹

Mice with targeted deletion of *STAT3* within the mammary gland show reduced expression of IGF-binding proteins, reduced apoptosis, and delayed involution.¹¹⁴ Thus, the physiologic role of *STAT3* within the mammary gland is to regulate the early apoptotic stage of involution through inhibition of IGF-1 survival signals. *STAT3* transcriptionally regulates genes involved in both apoptosis and the cell cycle and therefore can function as an oncogene or tumor suppressor depending on the cellular context. Cytoplasmic expression of *STAT3* and phosphorylated (Tyr705) *STAT3* is seen in a large number of breast cancers but does not correlate with survival. However, activated nuclear *STAT3* (23% of tumors) and phospho-*STAT3* (45% of tumors) predicts significantly improved survival.¹¹⁵ These observations support the possibility that *STAT3* acts as a tumor suppressor in breast, consistent with its physiologic role in the gland in promoting apoptosis and involution.

Mice expressing constitutively activated *AKT* under the *MMTV* promoter show delayed involution and apoptosis. *AKT* lies downstream of *PTEN* and *HER* signaling through the *PI3K* survival pathway and therefore is activated in many breast cancers. Activated *AKT* phosphorylates *p27*, preventing nuclear import and cyclin-CDK complex formation, thereby leading to tumor progression.¹¹⁶

What is the involvement of DNA repair genes in breast cancer?

Germline mutations in several DNA repair genes have been linked to inherited predisposition to breast cancer. The *BRCA1* gene (17q21), isolated in 1994, accounts for almost 95% of familial breast and ovarian cancer but for less than 5% of all breast cancers. Somatic mutations are rare, but promoter hypermethylation is thought to occur in a significant proportion of sporadic breast cancers, and loss of the *BRCA1* protein is reported in high-grade ductal carcinomas. *BRCA1* serves multiple roles as a tumor suppressor in breast cancer tumorigenesis by coordinating multiple processes required for the maintenance of genomic integrity during DNA replication. It interacts directly and indirectly with many proteins, including DNA repair components (*RAD50* and *RAD51*, *BRCA2*, *p53*, *ATR* and *ATM*, and *BRCA1*-associated surveillance complex [*BASC*]) and a large number of cell cycle and checkpoint control proteins (*Rb*, *Esf1*, *E2F*, *c-Myc*, and *p53*).¹¹⁷ Loss of *BRCA1* function is associated with defects in S-phase checkpoint and G₂-to-M transition. *BRCA1*-deficient cells are radiation sensitive and defective in the rate of homologous recombination.¹¹⁸ In addition, *BRCA1* forms complexes with transcriptional activators and repressors, participates in chromatin remodeling (*RNA* polymerase II, *RHA*, *HDAC* complex, and *CtIP*), and may function in ubiquitination.^{119,120} *BRCA2* (13q12-13), discovered in 1995, bears no resemblance to *BRCA1*.¹²¹ It functions exclusively in DNA repair by homologous recombination through interaction with *RAD51*, a key component of the double-strand break repair pathway. *BRCA2* is proposed to sequester *RAD51* in an inactive state and to facilitate *RAD51* binding to single-stranded DNA at double-strand breaks. In the absence of *BRCA2*, critical events in the initiation of homologous recombination are impaired, and repair and replication errors accrue with each cell cycle. *BRCA1*^{-/-} mice die embryonically (~E8) with severe growth deficit and elevation of *p21*. Mice with conditional knockout of the *BRCA1* or *BRCA2* gene in mammary gland fail to differentiate properly and develop tumors with long latency (1.6 years).^{122,123}

What other genes and gene expression profiles are associated with breast cancer?

In addition to *BRCA1* and *BRCA2*, other breast cancer susceptibility genes are proposed to exist on 8p11-21 and 13q21.¹²⁴ Several rare genetic syndromes account for about 1% of familial breast cancer. The *PTEN* gene is mutated in 80% of patients with Cowden syndrome, and truncating mutations confer a 25% to 50% increased lifetime breast cancer risk. Germline and somatic mutations in *PTEN* are rare in the general population, but LOH occurs in 11% to 40% of

sporadic breast cancers. Truncating mutations in the *LKB1* gene, found in Peutz-Jeghers syndrome, confer increased breast cancer risk on patients with this syndrome. Mutations in the *APC* gene confer increased risk for developing breast cancer in patients with familial adenomatous polyposis coli, in the *Min* mouse model of this disease, and are found in a small percentage of sporadic breast tumors. A number of polymorphisms increase breast cancer susceptibility. These include polymorphisms in the *p53* and *mdm2* genes that increase and decrease susceptibility and rare alleles of *HRAS*: cytochrome P-450 genes *CYP1A1*, *CYP2D6*, and *CYP1B1*; vitamin D receptor; and glutathione-S-transferase genes *GSTM1* and *GSTP1*.¹²⁵ These low penetrance genes add incrementally to breast cancer risk.

Microarray technology has been deployed to classify breast cancer into subtypes with specific gene expression profiles.^{126–131} Botstein and colleagues have classified breast tumors into five subsets based on a marker profile indicative of a predominant cell type: luminal type A, luminal type B, basal epithelial, HER-2–positive, and “normal.”¹²⁷ Their findings support the concept that tumors arise from different breast cell types. The luminal group had improved survival rates, whereas the basal and HER-2–positive subtypes had the worst survival rates. Basal cells have been proposed to represent bipotent stem-progenitor cells that give rise to both luminal and myoepithelial lineages. *BRCA1* tumors display basal cell phenotypes. HER-2–positive cells are usually ER negative, a known indicator of poor survival.^{130,131} This report also noted that gene expression patterns do not change substantially between early DCIS and later stages, indicating that the various molecular events in breast tumor progression occur before metastasis.¹²⁹ A second study by van’t Veer and colleagues identified a set of 70 genes that together form a “poor prognosis signature.”¹²⁸ These include cell cycle, invasion, metastatic, and angiogenic markers. Patients with the poor prognosis signature had almost half the likelihood of remaining free of metastases or of surviving 10 years compared with those of the “good prognosis” category. This gene expression signature predicts disease outcome with 83% accuracy, performing better than St. Gallen’s and National Institutes of Health’s (NIH) standards, which use histologic and clinical criteria.¹³² However, the false-negative rate with this profile would result in undertreatment for 9% of patients and therefore requires further refinement before it can be used within a clinical setting. Several studies have evaluated the prognostic and predictive value of gene expression profiles found within early-stage breast cancer. Currently, issues of lack of validation of gene sets across platforms point to the need for further investigation and refinement of this otherwise promising approach.

What other cells promote tumorigenesis?

Although 90% of tumors are epithelial in origin, communication between different cell types within breast can contribute to tumor progression and metastasis. Myoepithelial cells modify the behavior and organization of epithelial cells.¹³³ For example, mammary epithelial cells plated onto plastic fail to differentiate. Addition of myoepithelial cells to the culture leads to correct apical polarization, tight junction formation, and differentiation.^{134–136} Myoepithelial cells are thought to

achieve this by secreting basement lamina components, such as laminin, and by regulating the access of luminal cells to these proteins. Normal myoepithelial cells have been proposed to act as natural tumor suppressors. Myoepithelial cells from human breast tumors fail to interact with epithelial cells and induce epithelial organization and show impaired laminin production capabilities.¹³⁷ Cells attach to proteins of the basal lamina, including collagens, fibronectin, and laminins, through members of the integrin family of cell surface receptors that are composed of α and β subunits. Integrin engagement by the ECM conveys critical survival and differentiating signals to epithelial cells.¹³⁸ They achieve these effects by synergizing with growth factors to cause sustained elevation of signaling pathways, including MAPK, GSK-3 β , and PI3-K. The repertoire of integrins changes when cells become invasive. The importance of integrin-mediated survival signals has been vividly demonstrated in mice expressing MMTV-polyoma middle-T antigen. Inactivation of β_1 -integrin induced apoptosis and inhibited metastasis.

Stromal cells surrounding the epithelial ducts and macrophages clustered in front of growing terminal end buds promote proliferation of epithelial cells by secreting growth factors, such as IGF-1, FGF-7, and CSF-1.¹³⁹ In addition, stromal cells can secrete proteins, such as scatter factor and hepatocyte growth factor, which induce changes in cell shape and motility, referred to as epithelial-to-mesenchymal transitions (EMTs), which induce migration.¹⁴⁰ Stromal cells further facilitate the processes of cell migration, extravasation, and metastasis by secreting proteases that degrade and compromise the basement membrane, remodel the extracellular matrix, and release and activate ECM-bound growth factors. Epithelial tumor cells stimulate stromal cells to secrete MMPs, a large family of ECM-degrading proteins that include collagenases, stromelysins, membrane-type MMPs, and gelatinases.¹⁴¹ Many are secreted in latent precursor forms that are activated in a cascade fashion by other members of the family. MMP-3 and MMP-7 give rise to preneoplastic and malignant mammary tumors, respectively, in mice, and MMP-3^{-/-} mice show decreased incidence of chemically induced tumorigenesis.^{66,142,143} MMP-2, MMP-9, and MMP-11 are more highly expressed in invasive breast cancer than in premalignant and normal breast, and a higher ratio of activated to latent forms is present in breast cancer samples.¹⁴⁴ MT-MMP, MMP-2, and MMP-11 are secreted in the stromal compartment around tumors. MMP activity is regulated by a family of three tissue inhibitors of metalloproteinase (TIMPs), and the balance between MMPs and TIMPs likely regulates many aspects of invasive and metastatic phenotype. Paradoxically, high levels of TIMP-1 and TIMP-2 in breast tumors predict adverse outcome for patients.¹⁴⁴ The extracellular matrix surrounding tumors is remodeled by the action of MMPs in a unique fashion that exposes “tumor-specific” collagen epitopes.¹⁴⁵ The exposure of such cryptic epitopes assists migration and metastasis and promotes the formation of new blood vessels, a process known as angiogenesis.

What is the role of angiogenesis in breast cancer development and metastasis?

For tumors to grow to more than a few millimeters, an extensive neovasculature must develop to supply the tumor with

oxygen and nutrients. A consistent body of experimental and clinical evidence has demonstrated the necessity of angiogenesis for the growth of solid tumors, including breast carcinoma.^{146,147} Angiogenesis is observed in all phases of breast cancer from benign hyperplastic breast lesions to DCIS and invasive ductal cancers.^{148,149} Tumor-associated angiogenesis is a complex process dependent on a variety of growth factors that are also associated with non-neoplastic vascularization seen in wound healing, ischemic tissue, reproduction, and development.^{150,151} Non-neoplastic vascularization is a tightly regulated process balanced by angiogenesis activators (vascular endothelial growth factor [VEGF], FGF-2, platelet-derived growth factor [PDGF]) and inhibitors (thrombospondin-1, angiostatin, endostatin). In the developing tumor bed, angiogenesis occurs when the balance of regulators favors angiogenesis activators, which allows tumors to grow and metastasize to the detriment of the host.¹⁵² The tumor vascular network is derived from two sources: sprouting of capillaries from preexisting blood vessels and endothelial progenitor cells (EPCs) that are mobilized from the bone marrow (BM).¹⁵³ Successful metastasis of a tumor is dependent on angiogenesis at both primary and metastatic sites. In order for a tumor cell to metastasize, it must gain access to the vasculature. In highly angiogenic tumors, multiple contact points between tumor cells and endothelial cells facilitates tumor cell entry into the circulation.¹⁵⁴

What initiates angiogenesis?

There have been several proangiogenic factors described, the most potent of which is VEGF. Up-regulation of VEGF by a tumor will result in stimulation of local endothelial ingrowth into the tumor bed and recruitment of EPC to traffic from the BM to the tumor bed. There are several potential mechanisms for VEGF up-regulation in breast cancer. In the developing tumor bed as the mass of rapidly dividing cells enlarges, oxygen diffusion is limited, resulting in local hypoxia. Hypoxia is a potent angiogenic stimulus that triggers vessel growth through hypoxia-inducible transcription factor (HIF). HIF induces expression of the potent proangiogenic growth factor VEGF and its receptor VEGF receptor-1 (VEGFR-1). Higher levels of HIF are associated with more advanced pathologic stage in breast cancer and are higher in poorly differentiated tumors. Increased levels of HIF-1 are also associated with increased expression of VEGF, suggesting that increased levels of HIF-1 are potentially associated with more aggressive breast cancers.¹⁵⁵ HER-2/neu contributes to angiogenesis by up-regulating VEGF expression.¹⁵⁶ Breast cancer overexpression of MMP-9 promotes the release of sequestered VEGF from the extracellular matrix.¹⁵⁷ The net result of these early local factors is up-regulation of VEGF production, which can be found even in noninvasive high-grade DCIS.¹⁵⁸

What factors are required for angiogenesis to progress?

The previous section should not be taken to suggest that VEGF is the lone growth factor responsible for angiogenesis; it merely outlines the most convincing data on the initiation of angiogenesis in breast cancer. Once angiogenesis is initiated

and the tumor begins rapid growth, a host of additional factors, including FGF-2, Ang1, and placenta growth factor (PlGF), act in concert to maintain the developing vascular network. It is not clear why the balance favors proangiogenic factors over angiogenesis inhibitors such as angiostatin, endostatin, or thrombospondin-1. The new developing vascular channels are leaky in response to VEGF and allow extravasation of plasma proteins to provide a new matrix for endothelial cell migration. EPCs are recruited from the bone marrow by a complex sequence of events, whereby MMP-9 releases membrane-bound Kit ligand (mKitL), allowing soluble Kit ligand (sKitL) to induce trafficking of cKit-positive EPCs from the BM to the tumor.^{159,160}

What is the effect of neovascularization on prognosis?

Several methods have been proposed to measure tumor angiogenesis.^{161,162} Microvessel density has been accepted as the standard to evaluate the angiogenic potential of a tumor.¹⁶³ Using this technique, several studies have demonstrated an inverse relationship between survival of patients with breast cancer and angiogenesis measured by microvessel density.^{147,164,165} The recognition that the level of tumor angiogenesis may predict a poor outcome in invasive cancer is valid for several solid malignancies. A unique finding in noninvasive breast cancer was that high-grade DCIS with increased vascularity, measured by microvascular density, was more likely to recur following resection.¹⁴⁹ In another series, inflammatory breast cancers expressed higher levels of proangiogenic mRNA (VEGF, flt-1, Ang1/2, Tie2) than noninflammatory breast cancers.¹⁶⁶

An alternative measure of tumor angiogenic potential is the number of circulating endothelial progenitors (CEPs) in the peripheral circulation. CEPs are bone marrow-derived EPCs that are found in the peripheral circulation, in transit from the bone marrow as they traffic to the neovasculature of the tumor bed.^{167,168} Resting and activated CEPs were found to be significantly increased in the peripheral blood of patients with breast cancer. CEPs decreased to healthy control levels following curative surgical resection.¹⁶⁷ Breast cancer patients have been found to have a fivefold increase in these cells when compared with non-tumor-bearing individuals. This observation was confirmed in another study that found CEPs to be increased in cancer patients, including breast cancer patients, with progressive disease when compared with patients with stable disease.¹⁶⁹ These data would suggest that breast cancer is angiogenesis dependent even at the earliest stage and that the switch to an angiogenic phenotype is associated with more aggressive tumors.

What are the therapeutic implications of angiogenesis in breast cancer?

The ability to develop antiangiogenic strategies would be an important new weapon to treat breast cancer. Agents that inhibit angiogenesis have been shown to block tumor growth and promote tumor regression in animal models.^{170,171} The translation of laboratory observations that inhibition of angiogenesis can block tumor growth and metastasis is now

clinically applicable because angiogenesis inhibitors are being used to treat cancer patients.¹⁷² One approach to breast cancer treatment is to target the potent proangiogenic growth factor VEGF. High tumor levels of VEGF have been associated with recurrence of node-negative breast cancer and resistance to radiation and systemic chemotherapy.^{173–175}

Clinical trials of bevacizumab, a humanized monoclonal anti-VEGF antibody (Avastin), suggest that inhibition of angiogenesis is beneficial to patients with breast, renal cell, and colorectal cancer, although this agent is presently only approved for patients with colorectal cancer.^{176–178} As the clinical experience with angiogenesis inhibitors grows, synergy between angiogenesis inhibitors and conventional chemotherapy may be exploited.¹⁷⁸ This is certainly one of the more exciting areas in anticancer therapy and will likely affect treatment in the near future.

Hormonal Influences on Oncogenesis and Growth of Breast Cancer

Allan Lipton

The specific cause of breast cancer remains unknown, as it does for many human cancers. Physicians looked to normal breast development for clues as to what would make a breast cancer grow and spread. It has long been recognized that some human breast cancers are “hormone dependent.” The growth of such tumors is influenced by fluctuations in the level of steroid sex hormones, and the tumors undergo regression after surgical removal of sex hormone-producing glands. As early as 1836, Cooper¹ observed a relationship between breast tumor growth and the menstrual cycle. This relationship between estrogens and breast cancer was strengthened by the report in 1896 by Beatson² that regression of metastatic lesions followed oophorectomy in premenopausal women. For postmenopausal women, Huggins and Bergenstal³ demonstrated in 1952 that excision of the adrenal glands can result in striking remissions of metastatic disease. Similar results were obtained by Pearson and Ray⁴ following hypophysectomy. In recent years, regression of metastatic disease has been obtained using drugs that prevent production of estrogens by the ovaries or adrenal glands.^{5,6}

The adult female breast is composed of epithelial lactiferous ducts that terminate in secretory alveoli embedded in a fibrous tissue framework and fat. Breast growth and development are regulated by the interactions of many hormones and growth factors, the most important of which is estrogen. In fact, estrogens influence many organs in the body. These include tissues of the reproductive system such as the breast and uterus; cells in the pituitary, hypothalamus, and brain; bone, where estrogens play an important role in maintenance; the liver; and the heart, where estrogens exert a cardioprotective effect.

What is the estrogen receptor?

Investigations during the 1960s elucidated the mechanisms of interaction of steroid hormones with their target tissues. Female reproductive tissues were shown to contain a characteristic estrogen-binding component, the estrogen receptor (ER). These tissues took up and retained tritiated estrogens, either after the administration of physiologic doses *in vivo* or on exposure of excised tissues to the hormone *in vitro*.^{7,8} Most

mammalian tissues contain small amounts of ER. The unique characteristic of the hormone-dependent tissues is the magnitude of their ER content.

The ER is a member of a large nuclear hormone receptor superfamily, of which more than 20 members have now been identified; all bind steroid or nonsteroid ligands (retinoic acid, vitamin D₃). Steroid hormone receptors are located in the interior of the cell, whereas polypeptide hormone receptors are located on the cell surface. Receptors for estrogen, progesterone, and androgens are probably located in the nucleus. Thyroid hormone receptors also reside in the cell nucleus. Steroid receptors have a common domain structure with two highly conserved regions: one in about the middle of the protein (known as domain C), which is involved in interaction with DNA; and a C-terminal region (known as domain E/F), which binds hormone. The ER carries out four functions: (1) ligand binding (estrogen and antiestrogen), (2) dimerization, (3) DNA binding, and (4) transcription activation. These four functions have been localized to distinct domains in the protein^{9–13} (Fig. 4–1).

Upon binding estrogen, the ER is believed to bind as a dimer to estrogen response element DNA, a 13-nucleotide palindromic sequence, usually located in the 5′-flanking region of estrogen-responsive genes. The estrogen-occupied receptor is then thought to interact with transcription factors to modulate gene transcription^{14–16} (Fig. 4–2). The actions of estrogens on the breast and uterus are antagonized by antiestrogens (e.g., tamoxifen), which bind to the ER in a manner that is competitive with estrogen, but, unlike estrogens, do not effectively activate gene transcription.^{17,18}

What are the clinical uses of estrogen receptor levels?

ER levels are used to identify hormone-dependent breast cancers. This developed from the early observation that female reproductive tissues take up and bind tritiated estrogens and by the subsequent recognition that estrogens exert their biologic effect in combination with a receptor protein of intracellular origin. An early study demonstrated that patients with breast cancer who responded favorably to adrenalectomy

ESTROGEN RECEPTOR ACTION

Figure 4-1 Four functions of the estrogen receptor: ligand binding, dimerization, DNA binding, and transcription activation. (From Katzenellenbogen BS, Fang H, Ince BA, et al. Estrogen receptors: Ligand discrimination and antiestrogen action. *Breast Cancer Research and Treatment* 1993;27:17-26.)

Figure 4-2 Biochemical mechanism of estrogen action in human breast cancer cells. E, estrogen; ER, estrogen receptor; PgR, progesterone receptor. (From Osborne CK. Receptors. In Harris JR, Lippman ME, Murrow M, Hellman S [eds]. *Breast Diseases*. Philadelphia, JB Lippincott, 1996, p 301.)

incorporated more radioactivity into their tumors when the patients were injected with tritiated hexestrol than those who did not respond.¹⁹ Subsequent studies have confirmed that ER-positive breast cancer patients with metastatic disease are more likely to respond to hormone treatment than are ER-negative breast cancer patients.

A second use for ER is as a prognostic marker in patients with primary breast cancer. Breast cancer patients with operable lesions can be segregated into two prognostic subgroups by ER status. An analysis of patients who had receptor assays on their primary tumor showed that patients with ER-negative tumors had recurrences at twice the rate of those with tumors containing ER and were dying at a faster rate than those with ER-positive tumors (Fig. 4-3). Furthermore, this difference was independent of other potential prognostic factors, including age or menopausal status, size of the primary tumor, axillary lymph node status, or treatment delivered after surgery.^{20,21}

Figure 4-3 Overall survival of patients with stage I or II breast cancer (calculated together) according to estrogen receptor (ER) status. (Data from Osborne CK. Estrogen receptor and prognosis in breast cancer. In McGuire WI [ed]. *Breast Cancer*, vol 4, *Advances in Research and Treatment*. New York, Plenum, 1981, p 33.)

What other receptors are found in breast cancer?

Androgen receptors, glucocorticoid receptors, and progesterone receptors (PgRs) are found in many breast cancers. They are thought to play a role in normal breast growth and development. Their precise role in breast cancer development is not known. Presumably, the effects of endocrine therapy with pharmacologic doses of these agents are mediated through their respective specific receptors. The presence of PgR, along with ER, is more predictive of an endocrine-responsive tumor than the presence of ER alone.²² Androgen receptor has been found in 35% to 50% and glucocorticoid receptor in up to 77% of breast cancers. Both are associated with the presence of ER and PgR and are thought to be biochemical markers of tumor differentiation.²³⁻²⁵ There is some evidence that androgen receptors, glucocorticoid receptors, GR, or both may correlate with response to endocrine therapy and with patient survival. At present, determination of levels of these receptors does not improve on the predictive value of ER and PgR and is thus not employed in routine clinical practice.

Normal breast development is also influenced by thyroid hormone. Specific nuclear thyroid receptors have been identified in cultured human breast cancer cell lines. The proliferation of several human breast cancer cell lines is stimulated by triiodothyronine. These findings have not resulted in clinically significant observations.

How do hormones influence breast cancer development?

Hormonal factors are thought to play a major role in the cause of breast cancer. In 1962, Bulbrook and colleagues²⁶ suggested that low excretion of androgen metabolites in the urine may precede the onset of clinical breast cancer. More recently, it was observed that bilateral oophorectomy before the age of 40 years reduced the breast cancer risk by at least 50%.²⁷

Alterations in hormone levels are thought to influence breast carcinogenesis through several mechanisms. One hypothesis is that the total number of ovulatory cycles, and thus exposure to higher estrogen levels, is the principal factor contributing to the risk for breast cancer.^{28,29} Estrogen exposure may contribute to carcinogenesis by increasing the rate of cell division and proliferation, thereby allowing for an increase in the accumulation of random genetic errors.^{29,30} Another hypothesis is that the continued cell division and proliferation resulting from multiple ovulatory cycles, principally between menarche and first birth, increases the susceptibility of breast tissue to carcinogenic environmental insults.³¹ The duration of exposure to both endogenous and exogenous estrogens is directly related to the risk for developing breast cancer. The role of prolactin in breast cancer development has been clearly established in the rat, but no clearcut role for prolactin has yet been established in humans.

What menstrual and reproductive factors influence breast cancer risks?

1. *Age at menarche.* One of the most significant associations established to date is age at menarche and subsequent development of breast cancer. Early age at menarche has been demonstrated as a risk factor for breast cancer in most case-control studies. Each earlier year of onset of menarche appears to add about 4% to 5% to the risk for breast cancer.^{28,32} Women with early menarche (≤ 12 years of age) and rapid establishment of regular cycles have an almost fourfold greater risk for breast cancer than women with late menarche (≥ 13 years of age) and long duration of irregular cycles.^{33,34}
2. *Age at menopause.* Age at menopause is another factor in breast cancer risk. Premenopausal women who undergo oophorectomy dramatically lower their risk for breast cancer. As mentioned earlier, bilateral oophorectomy before the age of 40 years reduces breast cancer risk by at least 50%.²⁷ In similar fashion, women who experience natural menopause (defined as cessation of periods) before age 45 years have only half the breast cancer risk of those in whom

menopause occurs after age 55 years.³⁵ Each additional year until menopause adds a risk of about 4%.³⁵ The influences of menarcheal and menopausal age may partly explain some of the geographic variance in breast cancer incidence around the world.³⁶ For example, in Asian countries, the age at menarche is later and menopause occurs earlier than in the United States. The expected lower breast cancer incidence is observed in Asian women.

3. *Age at first term pregnancy.* Parity and age at first birth are other endogenous hormonal factors that influence breast cancer risk. Nulliparous women are at greater risk for the development of breast cancer than parous women, with a relative risk of 1.4.³⁷ The age at first birth is extremely important for subsequent development of breast cancer. Age younger than 20 years at first childbirth can reduce breast cancer risk by about 50%, compared with first birth beyond age 35 years.³⁷⁻³⁹ Abortion, whether spontaneous or induced, before full-term pregnancy has no protective effect and has been shown to increase breast cancer risk.⁴⁰ Breast-feeding, once thought to decrease the risk for breast cancer and then abandoned as a factor in decreasing breast cancer risk, has been restudied and does appear to have a small protective effect.⁴¹

Does the use of oral contraceptives predispose to the development of breast cancer?

Oral contraceptives were introduced in the 1960s and each year are taken by millions of women. On the basis of proposed hypotheses of breast carcinogenesis, a role for exogenous hormones, such as oral contraceptives and hormone replacement therapy, might be expected. Numerous studies examining the association between exogenous hormones and the risk for breast cancer have been published. The results are conflicting and difficult to interpret because of changes in dose of hormones over time and in methods of delivery (e.g., sequential versus combination).

When the overall risk for breast cancer in birth control pill users has been studied in large populations, no increased risk has been seen (Fig. 4-4). Despite this, there is continuing

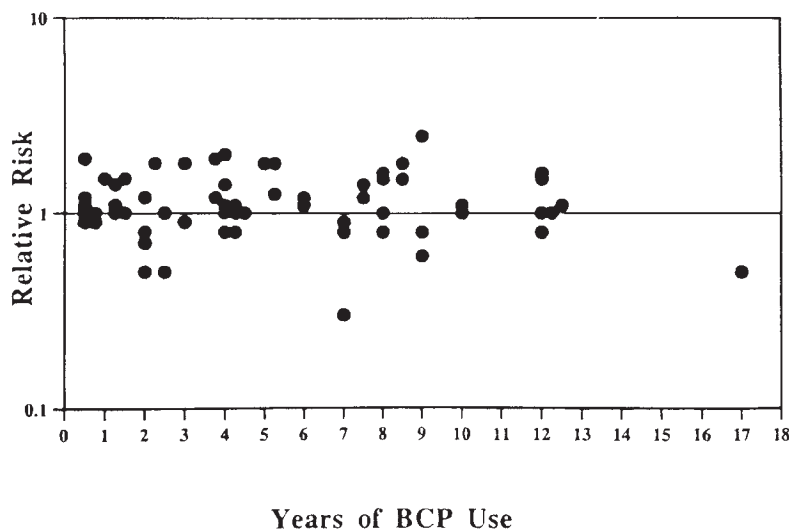

Figure 4-4 The relative risk for being diagnosed with breast cancer as a function of years of birth control pill (BCP) usage (summary of 17 studies). Almost all studies cluster around a relative risk of 1, indicating no influence of birth control pills on the occurrence of breast cancer. (Data from Abeloff MD, Lichter AS, Niederhuber JE, et al. *Breast*. In Abeloff MD, Armitage JO, Lichter AS, et al. [eds]. *Clinical Oncology*. New York, Churchill Livingstone, 1995, p 1626; adapted from Schlesselman JJ. *Cancer of the breast and reproductive tract in relation to use of oral contraceptives*. *Contraception* 1989;40:1-39.)

concern about the potential risks in several subgroups. Several studies have demonstrated an increased risk for breast cancer in long-term users of oral contraceptives. Risk estimates range from 1.7 for use longer than 8 years to 4.1 for use for 10 or more years.^{42–46} One of the largest case-control studies, the Cancer and Steroid Hormone Study,⁴⁷ found no association between breast cancer and oral contraceptive use for women up to the age of 54 years. A risk was again found only among a subgroup of women, that is, those who experienced menarche before age 13 years and who had used oral contraceptives for at least 10 years before the birth of their first child.⁴⁸ At present, oral contraceptive use appears to be safe and beneficial to women, especially women older than 25 years and women who have already had their first pregnancy.

Are replacement estrogens safe for postmenopausal women?

Many studies and meta-analyses have examined the possible relation between estrogen replacement therapy and breast cancer. Most studies have found no association between breast cancer and short-term use of replacement estrogens (5 years or less).^{49–52} Several meta-analyses have discovered an increase in relative risk for development of breast cancer for each year after 5 years of estrogen use.^{53–55} The highest risk calculated was 1.3 (95% confidence interval, 1.2–1.6) for more than 15 years of use.⁵¹

Hormone use has dropped sharply since July 2002, when a large study in the United States called the Women's Health Initiative was stopped ahead of schedule because it detected an increased risk for breast cancer in women who took Prempro, a widely used hormone combination.⁵⁶ The Women's Health Initiative included 16,608 postmenopausal women aged 50 to 79 years with an intact uterus at baseline recruited by 40 U.S. clinical centers from 1993 to 1998. Participants received conjugated equine estrogens, 0.625 mg/day, plus medroxyprogesterone acetate, 2.5 mg/day in one tablet ($n = 8506$) or placebo ($n = 8102$). On May 31, 2002, after a mean of 5.2 years of follow-up, the Data and Safety monitoring board recommended stopping the trial because the test statistic for invasive breast cancer exceeded the stopping boundary. The hazard ratio for breast cancer in the patients who received hormone replacement therapy was 1.26 (166 invasive cancers on Prempro versus 124 on placebo). The 26% excess of breast cancer is consistent with estimates from pooled epidemiologic data, which reported a 15% increase for estrogen plus progestin use for less than 5 years and a 53% increase for use for more than 5 years. In summary, overall health risks exceeded benefit from use of combined estrogen plus progestin for an average 5.2-year follow-up among healthy postmenopausal U.S. women.

Does a family history of breast cancer affect other risk factors for this disease?

Older studies suggest that the use of estrogen replacement therapy by postmenopausal women with a positive family history of breast cancer has been associated with an elevated risk for breast cancer.^{57–60} In similar fashion, estrogen use in

women with benign breast disease has been associated with an increased risk for the development of breast cancer.^{61,62}

Recently, a large prospective study was performed to determine the effect of a family history of breast cancer on other risk factors for this disease. A cohort of 89,132 women aged 30 to 55 years was followed for 14 years (1.1 million person-years of follow-up). Reproductive factors were associated with different degrees of risk in women with and without a family history of breast cancer.⁶³ In women with a family history of breast cancer, there was little protection from later age at menarche; no protection from multiple births when compared with nulliparity; and no protection from early, as compared with later, age at first birth. The most significant finding was a consistent increase in risk for breast cancer among women with a mother or sister with a history of the disease that was exacerbated by first pregnancy. This adverse effect of pregnancy persisted to age 70 years. In contrast, among women with no family history of breast cancer, first pregnancy was associated with a smaller risk. The greater magnitude of the adverse effect of first pregnancy among women with a positive family history of breast cancer is consistent with the hypothesis that a subset of these women inherit genetic changes that are multiplied during cell proliferation of first pregnancy. History of benign breast disease, past use of oral contraceptives, and use of postmenopausal hormones showed relative risks that did not differ between women with a family history and those without a family history of the disease. In summary, among women with a family history of breast cancer, many of the traditional reproductive risk factors should not be used to predict risk for breast cancer.

Should women with a personal history of breast cancer receive hormone replacement therapy after menopause?

With more widespread use of mammography over the past decade, more women are being diagnosed with very-early-stage breast cancer. In addition, as adjuvant chemotherapy and hormone therapy are employed more commonly in premenopausal women, increasing numbers of young women will undergo premature menopause. These women will live longer and be at greater risk for the complications of menopause. Should they receive estrogen replacement therapy?

Relatively few studies have been performed examining the risk for administration of estrogen replacement therapy to women with a history of breast cancer. Most studies are nonrandomized and of small size and have a short duration of follow-up.^{64–69} A large study of breast cancer survivors in Sweden was conducted.⁷⁰ Patients were randomized to hormone therapy for menopausal symptoms or placebo. The study was halted when an increase in recurrent breast cancer was detected in the women receiving hormone therapy. Thus, women who have had breast cancer should avoid hormones and find other ways to treat menopause. Bisphosphonate treatment is one such alternative therapy. Bisphosphonates such as Actonel and Fosamax can retard the rate of bone loss and development of fractures in postmenopausal women.

Is pregnancy advisable after a diagnosis of breast cancer?

This question is frequently asked by patients because adjuvant oophorectomy in the surgical management of breast cancer is not common, and women are bearing children in later years. About 7% of women who are fertile after mastectomy have one or more pregnancies, and 70% of these pregnancies occur within the first 5 years.⁷¹

Several studies have examined the influence of pregnancy before, during, or after a diagnosis of breast cancer, but in each study, the number of women was relatively small. In these studies, there was no adverse effect on relapse rate or survival associated with subsequent pregnancy.⁷²⁻⁷⁷ In fact, in one recent study, there is a suggestion of a decreased incidence of distant metastases in women who became pregnant after their breast cancer.⁷⁸

When counseling women about becoming pregnant after breast cancer, the clinician needs to consider that the reports of the effect of pregnancy on breast cancer prognosis are of limited sample size and include select populations. We cannot, at this time, be certain about the effect of pregnancy. Most women are advised to wait 2 to 3 years before becoming pregnant to allow aggressive disease to become manifest. Despite these limitations, the consistent lack of an adverse influence of pregnancy on breast cancer prognosis should reassure young women with breast cancer who want to have children.

What effect do growth factors have on breast cancer?

About two thirds of breast malignancies are dependent on estrogens for growth, but not all breast cancers that express the ER respond to hormone manipulation. Furthermore, many breast cancers that initially express ER gradually become hormone independent and capable of sustaining themselves without the need for estrogenic stimulation. What, then, promotes the growth of the estrogen-independent breast cancer cell?

Growth factors are polypeptides that regulate cell growth by binding to specific receptor molecules in the plasma membrane and stimulating receptor-mediated activation of intracellular signal transduction pathways. More than 60 growth factors have been described. The main group of non-hematopoietic growth factors mediate their effects by means of receptors containing an intrinsic protein, tyrosine kinase. Growth factor receptors are transmembrane glycoproteins. They have an extracellular ligand-binding domain, a transmembrane portion, and an intracellular tyrosine kinase domain; these domains mediate signal transduction into growth regulatory pathways. The binding of ligand alters the state of the receptor (monomeric to oligomeric), and this stimulates the internal tyrosine kinase domain to carry out transphosphorylation of other cell proteins. This results in activation of a cascade of biochemical reactions collectively referred to as the *signal transduction pathways*. These pathways initiate cell cycle traversal and differentiation (Fig. 4-5).

Growth factors are found in all tissues of the body. Simultaneous production of a growth factor and expression of

Figure 4-5 Model depicting protein kinase and estrogen receptor transcriptional synergism. (From Katzenellenbogen BS, Montano MM, LeGoff P, et al. Antiestrogens: Mechanisms and actions in target cells. *J Steroid Biochem Mol Biol* 1995;53:390.)

its specific receptor by the same cell is called *autocrine growth*. When the growth factor for a particular cell is produced by a neighboring cell, this is called *paracrine growth*. This latter type of interaction can be between cells of the same or different histologic type. For example, breast cancer cell lines can be stimulated by insulin-like growth factor-2 (IGF-2), which is produced by fibroblasts in adjacent normal tissues. Platelet-derived growth factor (PDGF) produced by breast cancer cells can in turn activate the fibroblasts, which bear PDGF receptors, but not breast cancer cells, because they do not express PDGF receptors.

Many primary human tumors and human tumor cell lines express high levels of growth factor receptors and are capable of producing the relevant growth factors, thus establishing conditions necessary for autocrine or paracrine growth stimulation. Membrane receptors for prolactin, insulin, IGF-1, epidermal growth factor (EGF), and transforming growth factor- β (TGF- β) have been identified in cultured human breast cancer cell lines and also in human breast cancer biopsy specimens. Expression of high levels of growth factor receptors in primary human tumor specimens correlates with a poor clinical outcome for these patients. For example, high epidermal growth factor receptor (EGFR) levels predict a poor prognosis in adenocarcinoma of the breast, transitional bladder cancer, and squamous cell lung carcinoma.⁷⁹⁻⁸² In similar fashion, increased expression of *HER-2/neu/c-erbB-2* (a shortened molecule similar to EGFR) is associated with a worse prognosis in breast and ovarian cancer.⁸³⁻⁸⁵

What is the significance of *HER-2/neu* in breast cancer?

About one fourth of primary or metastatic breast cancers overexpress *HER-2/neu*. As a result, some breast cancers that are ER positive also are *HER-2/neu* positive. They have an intact mechanism to be stimulated by either an estrogen or a growth factor pathway. Recent observations have

demonstrated that ER-positive, *HER-2/neu*-positive metastatic human breast cancers are less likely to respond to hormone therapy than are cancers that are only ER positive.^{86,87} This is consistent with the *in vitro* observation that MCF-7 cells (ER positive) become resistant to tamoxifen after they are transfected with the *HER-2/neu* oncogene.⁸⁸ Recent biochemical evidence suggests that *HER-2/neu* activation can result in an alteration of the ER. Treatment of cells that overexpress *HER-2/neu* with estrogen decreases *HER-2/neu* mRNA, as well as down-regulating the *HER-2/neu* product.⁸⁹ Conversely, treatment of ER-positive cells with *HER-2/neu* ligand leads to decreased ER expression.^{90,91} This crosstalk between a polypeptide growth factor receptor-activated pathway and a hormone receptor pathway appears to be a mechanism by which the cell can become hormone independent. Preliminary experiments suggest that blocking both pathways may result in an enhanced antiproliferative effect.⁹²

Risk Factors for Development of Breast Cancer

Darcy V. Spicer and Malcolm C. Pike

Epidemiologic research has clearly identified important reproductive risk factors for breast cancer, including age at menarche, age at menopause, and age at first-term pregnancy (Table 5–1). These provide important clues to the hormonal origin of this disease. The widespread use of exogenous sex steroids as contraceptive agents by premenopausal women and as hormone replacement therapy (HRT) by postmenopausal women has provided a unique opportunity for epidemiologists to further understand the role of sex steroids in the genesis of breast cancer, and recent randomized clinical trials testing the impact of HRT have provided important insights into their effects on breast cancer (and other diseases). As we will show, the effects of sex steroids on the normal breast in women are increasingly well understood—estrogen induces some breast epithelial cell proliferation, but estrogen plus progesterone produces much greater cell proliferation.¹ Proliferating cell populations are more susceptible to carcinogenic effects, and the rise in cancer risk associated with cell proliferation is secondary to an increased chance of mutation.^{2–6} Thus, breast cancer risk would be predicted to increase to the greatest extent during periods of exposure to both estrogen and progesterone, as in the premenopausal period or in women receiving oral contraceptives; to be less during periods of estrogen-only exposure, as in postmenopausal women receiving estrogen replacement therapy (ERT) or in obese postmenopausal women; and to be least during periods of exposure to neither hormone, as in slender postmenopausal Asian women. These predictions fit very well with epidemiologic observations. The more complex effects of term pregnancy on breast cancer risk are discussed below.

Is age a risk factor for breast cancer?

It is essential to understand the relationship of breast cancer incidence to age (i.e., the risk for breast cancer diagnosis during a 1-year period at different ages). Although breast cancer risk rises throughout life in almost all populations (although not after menopause in some “traditional” Asian populations),⁷ the rate at which risk rises declines significantly around age 50 years. Most common non-hormone-dependent adult cancers increase in incidence with advancing

age; when age and incidence are plotted logarithmically, a straight line is seen, as in Figure 5–1 for colorectal cancer in white U.S. women.⁸ The incidence of these common non-hormone-dependent cancers rises continuously and increasingly rapidly with age. The incidence at age t , $I(t)$, of such a cancer rises as the k power of age and can be written as $I(t) = \text{constant} \times t^k$.⁹ This pattern is consistent with such cancers arising from a multistage process in which the stochastic rate of change from stage to stage is relatively independent of age,¹⁰ consistent with modern molecular biology concepts of cancer as a multistep process.

A similar logarithmic plot of age and breast cancer incidence is shown in Figure 5–2⁸; in contrast to non-hormone-dependent cancers, this curve is best described as two straight lines—a steeply sloped line until about age 50 years, followed by a second line with a more gentle slope after this age. The implication of this observation is that elements important in the genesis of breast cancer decline at about 50 years of age. Ovarian and endometrial cancers have the same complex relationship between age and incidence.¹¹

Is age at menopause a risk factor for breast cancer?

Early natural menopause substantially reduces breast cancer risk.^{12,13} Similarly, early bilateral oophorectomy reduces breast cancer risk, an observation that effectively proves a cause-and-effect relationship between ovarian function and breast cancer risk. Menopause is the proximate cause of the complex relationship between age and breast cancer risk. If menopause did not occur, then the age-incidence curve for breast cancer would in all likelihood be similar to that for other adult malignancies.

The data from the large case-control study of Trichopoulos and colleagues¹⁴ are given in Table 5–2, whereby artificial menopause before age 35 years is associated with a breast cancer relative risk of 0.36 (a 64% reduction). Feinleib¹⁵ noted in his large cohort study that among 1278 women with artificial menopause before age 40 years, 6 had breast cancer, as compared with an expected incidence of 24.0—a 75% reduction. The epidemiologic study of breast cancer by Hirayama

Table 5-1 Factors That Influence Breast Cancer Risk

Factor	Effect on Risk
<i>BRCA1</i> or <i>BRCA2</i> or <i>chk2</i> mutations	↑
Family history of early-onset or bilateral disease or multiple first-degree affected members	↑
Increasing age	↑
Early menarche	↑
Irregular menses, with long interval between menses	↓
Physical activity (exercise)	↓
Late menopause	↑
Early bilateral oophorectomy	↓
Proliferative breast disease	↑
Late first term pregnancy or nulliparity	↑
Increasing parity	↓
Breast-feeding	↓
Premenopausal obesity	↓
Postmenopausal obesity	↑
Current or recent oral contraceptive use	↑
Postmenopausal estrogen-progestin replacement therapy	↑
Greater mammographic density	↑
Ionizing radiation exposure	↑

**Figure 5-1** Age-specific incidence rates for colorectal cancer in U.S. white women (1969–1971).**Table 5-2** Effect of Natural and Artificial Menopause on Breast Cancer Risk

No. of Patients	Type of Menopause	Age at Menopause (yr)	RR(c)
2578 breast cancer patients and 2682 controls	Natural	<45	0.73
		45–49	0.93
		50–54	1.07
		55+	1.48
524 breast cancer patients and 754 controls	Artificial	<35	0.36
		35–39	0.68
		40–44	0.65
		45–49	0.73
		50+	0.98

RR (c), relative risk expressed relative to a natural menopause at age 50 years.

**Figure 5-2** Age-specific incidence rates for breast cancer in U.S. white women (1969–1971).

and Wynder¹⁶ found that the relative risk for breast cancer was 0.56 for women with bilateral oophorectomy; for women who had oophorectomy before age 37 years, the relative risk was 0.41 (i.e., a 59% reduction). What is of key importance is the consistency of these findings and the magnitude of the risk reduction. Menopause before age 35 years is associated with a 60% to 75% reduction in breast cancer risk. This effect of early menopause on the age-incidence curve of breast cancer is depicted in Figure 5-2. Age at menopause determines the transition point from the steeply rising premenopausal curve to the slower rising postmenopausal curve. Thus, the factors involved in the genesis of breast cancer are sharply reduced with cessation of ovarian function. This indicates that the hormonal pattern of premenopausal women with cyclic production of relatively large amounts of estradiol and progesterone

causes a greater rate of increase in risk for breast cancer than the hormonal pattern of postmenopausal women (constant low estradiol and very low progesterone). Age at menopause provides no information concerning the relative importance of either ovarian hormone in determining breast cancer risk.

How do sex steroids affect breast cell proliferation?

To properly interpret the age-incidence curve for breast cancer and other epidemiologic studies of breast cancer risk, an understanding of the specific effects of sex steroids on rates of epithelial cell proliferation in the normal breast is critical. With few exceptions, sex steroids are not genotoxic, but they do influence cell division rates, and their effects on the genesis of breast cancer are thus most likely to be through their effects on cell proliferation. Evidence from studies of chemical carcinogenesis, molecular genetics, and epidemiology suggests that repetitive cell proliferation is central to the risk for many common human cancers.²⁻⁶ Factors that increase cell proliferation in a tissue can result in malignant transformation by increasing the probability of conversion of DNA damage, however caused, into stable mutations.

Because the effects of hormones on cell proliferation are dependent on dose and duration, the effects of endogenous and exogenous hormones are relevant only within the context of dose and duration. Considerations of ever-never use of a particular exogenous hormone are of little value.

How does premenopausal status affect breast cell proliferation?

In the premenopausal period, 14% to 20% of the volume of the breast consists of epithelial cells, decreasing to about 2% to 5% by age 60 years.¹⁷ The growth of the normal breast epithelium is under the endocrine control of the ovarian hormones

estrogen and progesterone. Most breast cancers undoubtedly arise from the epithelial cells of the terminal duct lobular unit (TDLU), and an understanding of the cell proliferation kinetics in the TDLU is thus critical to our understanding of breast cancer. Cell proliferation kinetics of normal breast epithelial cells has been studied in benign surgical specimens, in normal tissue removed at reductive mammoplasty, and at autopsy. Cell proliferation rates have been assessed both by mitotic counts and ³H-thymidine labeling index (TLI).

In nonpregnant premenopausal women, the breast epithelium undergoes repetitive periods of cell proliferation and cell loss secondary to cyclic ovarian activity. During the follicular phase of the menstrual cycle, the ovary produces substantial amounts of estrogen but very little progesterone. After ovulation, in the luteal phase, the corpus luteum produces progesterone. Cell proliferation is low during the follicular phase of the menstrual cycle but increases about twofold in the luteal phase.^{1,18-22} Table 5-3 shows the TLI and mitotic rates by week of the menstrual cycle, and in Figure 5-3, the rates (weighted mean) are shown with normal cyclical estradiol and progesterone levels.

These results suggest that the estrogen levels of the follicular phase induce some breast cell proliferation. However, the combined effect of estrogen and progesterone together produces greater breast cell proliferation; that is, both estrogen and progesterone are mitogens in the normal human breast TDLU epithelium. The correlative morphologic study of Longacre and Bartow²⁰ defined the cyclic morphologic changes in the premenopausal breast, and consistent with the breast cell proliferative rates, the size and number of terminal ductules peak during the late-luteal phase. If fertilization and pregnancy do not ensue, progesterone levels fall, breast cell division decreases, and a wave of cell death by apoptosis follows the peak in cell proliferation.¹⁹

Recent studies in the mouse mammary gland are generally in agreement with what has been observed in humans and provide a deeper insight into the effects of sex steroids and growth factors and the interrelationship between epithelium

and stroma. Similar to its effects in the human breast, progesterone is an important mitogen in the adult mouse mammary gland and produces increased ductal side branching and lobuloalveolar development.^{23,24} Epidermal growth factor and its receptor influence ductal cell growth,²⁵⁻²⁷ and the effects of ovarian hormones in the mouse mammary epithelium may be mediated, in part, through epidermal growth factor receptor levels.²⁸ Transforming growth factor 1, sequestered within the periductal extracellular matrix, locally inhibits ductal growth and side branching, as a mechanism for local regulation of morphogenesis.²⁹ Undoubtedly, local growth factors regulate morphogenesis in the normal human breast as well.

How does postmenopausal status affect breast cell proliferation?

Only one study has determined the rate of cell proliferation in the postmenopausal breast.³⁰ The mean TLI in the normal lobule of the postmenopausal breast was only 25% of that found in the follicular phase in the premenopausal breast. This finding is consistent with the morphologic studies demonstrating a reduction in the epithelial component of the postmenopausal breast.¹⁷ The very low breast cell proliferative rate of postmenopausal women undoubtedly accounts for the sharp slowing down of the rate of increase in breast cancer risk seen after menopause.

Does age at menarche affect breast cancer risk?

Age at menarche determines the time of exposure to the mitogenic effect of ovarian hormones. It is thus understandable that later menarche decreases breast cancer risk. The effect is substantial: there is an approximately 15% decrease in breast cancer risk with each year that menarche is delayed.⁷ The pattern of menses following menarche also influences breast

cancer risk. The sooner regular menstruation is established, the greater the subsequent risk for breast cancer.³¹

Do parity and age at first-term pregnancy affect breast cancer risk?

Most epidemiologic studies have found a clear association between age at first-full-term pregnancy (FFTP) and risk for breast cancer. Women with an FFTP under the age of 20 years have about half the breast cancer risk of nulliparous women. Additional babies after the first provide additional long-term protection of approximately 7.0% per birth.³² The protection from FFTP decreases with increasing age at FFTP, and women who have an FFTP after about age 32 years have a greater breast cancer risk than nulliparous women.¹² Each birth, particularly the first birth, is followed by a transient increase in breast cancer incidence.¹³ We have previously shown that this is likely to be the same phenomenon as a late age at FFTP increasing breast cancer risk past that of a nulliparous woman,⁷ but the mechanisms of these effects are poorly understood. Several possible explanations exist: (1) it has been suggested that pregnancy alters the susceptibility of breast tissue to carcinogenic exposure³³; and (2) hormone levels are decreased permanently after FFTP.^{34,35} The sparse available information suggests that breast cell proliferation increases during the first half of pregnancy and then decreases during the second half of pregnancy, when cell differentiation occurs.³⁶ The increased cell proliferation during the first half of the pregnancy provides an explanation of the transient increase in risk after each birth. Pregnancy also provides protection against chemical-induced breast cancer in rodents, and there has been considerable progress in elucidating the differences between nulliparous and parous breast tissue in rodents and the mechanism by which these differences arise.³⁷⁻³⁹ Further research correlating this rodent work with similar work in human breast tissue could be most informative.

Does breast-feeding affect breast cancer risk?

Patterns of breast-feeding have undergone substantial change over time and differ considerably in different countries. The results of epidemiologic studies relating breast cancer risk to breast-feeding patterns have been quite variable. For example, in a recent U.S. prospective assessment of breast-feeding, no association was found between history of breast-feeding and subsequent risk for breast cancer except for women who had given birth only once.⁴⁰ However, protective associations between breast-feeding and breast cancer risk have been consistently found in studies from Asian countries, where the duration of breast-feeding has been substantially greater than in the United States.⁴¹ The Collaborative Group on Hormonal Factors in Breast Cancer recently analyzed almost all epidemiologic studies of this issue and found from this analysis of 47 studies that the risk for breast cancer was statistically significantly but that the effect is quite small.³² This analysis estimated the effect to be a decrease of 4.3% in risk for every 12 months of breast-feeding, so that the protective effect becomes clearly evident only after many years of breast-feeding. In the single study of the breast cell mitotic activity during breast-feeding in the first 3 months after delivery, the mitotic activity was extremely low.³⁶

Does postmenopausal weight affect breast cancer risk?

Obesity during the postmenopausal years increases breast cancer risk, but obesity during the premenopausal years actually reduces risk.⁴² This inverse relationship can be explained in terms of the differential effects of premenopausal and postmenopausal obesity on endogenous hormone levels. Although premenopausal obesity decreases sex hormone-binding globulin and may minimally increase exposure to estrogen,⁴³ it is associated with increased anovulation and *decreases* breast exposure to progesterone.⁴⁴ Postmenopausally, what appears to happen is that the decrease in risk associated with premenopausal obesity is gradually eliminated, and eventually, the increased bioavailable estrogen levels associated with postmenopausal obesity produce an increased risk for breast cancer. There is, however, no evidence that postmenopausal weight is positively correlated with estrogen levels *in the breast*, a gap in our knowledge that needs to be filled if we are to fully explain how the effect of increasing weight on breast cancer comes about.⁴⁵

Does exercise affect breast cancer risk?

Physical activity (exercise) has been consistently found to be associated with a decreased risk for breast cancer, with a greater amount of exercise being associated with a greater decrease in risk.⁴⁶ There is good evidence that exercise before menarche and as a premenopausal woman decreases risk,⁴⁷ and some evidence that exercise in the postmenopausal period is also protective.⁴⁸ Moderate exercise of about 4 hours per week is associated with a reduction in risk of about 30%. This is a measure of the effect of a long-term exercise pattern; it

does not represent what can be achieved in the short term. Exercise delays the onset of menarche and in teenage girls increases the frequency of anovulatory cycles.⁴⁹ Intense exercise clearly decreases estrogen and progesterone, and moderate exercise may also reduce sex steroids, although the evidence for this is not compelling. Exercise in the postmenopausal period may be protective through a change in body composition.

Do race or ethnicity affect the risk for breast cancer?

There is substantial international variation in the age-adjusted incidence of breast cancer. Until about 1970, some of the lowest rates were seen in Asia; of particular interest to epidemiologists and endocrinologists, the incidence in Japanese women living in the United States was five to six times higher than that in Japanese women living in Japan. About half of this difference could be explained by the 2- to 3-years-later average age at menarche in Japan and the low average postmenopausal weight of Japanese women (45 kg).⁷ The rest of the difference is probably due to lower sex steroid levels in these “traditional” Japanese women.^{50–53} Why their estradiol levels, in particular, were lower than in U.S. and U.K. women is not understood. The incidence of breast cancer has now increased significantly in Japan,⁵⁴ and Japanese Americans in Hawaii now have the same breast cancer incidence as do whites.^{55,56}

Does family history affect breast cancer risk?

Familial clustering of breast cancer has long been recognized. Epidemiologic studies have shown the risk for breast cancer to be greatest in women with a first-degree relative with early-onset bilateral breast cancer and in those with early-onset breast cancer affecting two first-degree relatives.

Highly penetrant mutant forms of the *BRCA1* and *BRCA2* genes account for not more than 20% of the excess familial risk for breast cancer.⁵⁷ Other genetic abnormalities associated with an increased risk for breast cancer are *p53*, *chk2*, and *ATM*, but they account for very few familial cases of the disease. There is an intense ongoing search for other highly penetrant genetic abnormalities as well as for genes that have low penetrance but when acting together could give rise to familial aggregation of cases. The mechanism by which these genetic abnormalities confer the increase in cancer risk remains to be elucidated.⁵⁸

Does benign breast disease affect breast cancer risk?

Women with a history of prior breast biopsy for benign breast disease have an increased risk for breast cancer. This increase in risk is associated with specific epithelial abnormalities, and those without proliferative breast disease do not have an increase in risk. Biopsy-proven atypical hyperplasia is associated with an approximately fivefold increase in breast cancer risk, and proliferative lesions without atypia are associated with a twofold increase in risk.⁵⁹ Identification of atypical

hyperplasia by cytologic examination of periareolar fine-needle aspirates and nipple aspiration fluid is also associated with increased breast cancer risk.^{60,61}

Can mammographic parenchymal pattern affect breast cancer risk?

Most of the breast consists of adipose and fibrous tissue. In premenopausal women, less than 15% of the volume of the breast consists of epithelial cells, and this decreases to less than 5% by age 60 years.¹⁷ Fibrous tissue is radiopaque, and adipose tissue is radiolucent; the relative amounts of fibrous and adipose tissue are what determine the appearance of the mammographic image. Increased fibrous tissue equates to increased mammographic densities. Classification of mammograms into different breast cancer risk patterns, essentially based on radiographic densities, has been done in a number of ways. Epidemiologic studies have consistently found that these classification schemes are strongly associated with breast cancer risk, independent of other breast cancer risk factors, with increased densities being associated with greater risk, and the variation in risk is greater than that seen with almost all other breast cancer risk factors.⁶² Mammographic patterns with substantial densities are also associated with proliferative breast disease and carcinoma in situ.⁶³

Densities vary enormously between different women. This variability has a strong genetic component⁶⁴ and is also associated with a woman's hormonal status. Densities decrease after menopause or oophorectomy, and the decrease after treatment with a gonadotropin-releasing hormone analogue that blocks ovarian function is reversed when the treatment is stopped.⁶⁵⁻⁶⁷ An important point to note is that, while breast cancer risk increases with age, mammographic densities decrease: the association of increased densities with greater breast cancer risk is for women of the same age.

Is the use of oral contraceptives a risk factor for breast cancer?

Oral contraceptives (OCs) inhibit gonadotropin secretion, thus reducing ovarian steroidogenesis, but the ovarian steroid loss is compensated for by the synthetic estrogen and progestin in the OC. The combined estrogen and progestin of the OC is present for three fourths of the 28-day OC cycle, whereas in the natural cycle, progesterone is effectively present only for less than half the cycle. Common OCs also contain the synthetic estrogen ethinylestradiol combined with one of a number of synthetic progestins. Given the evidence that progestins do not oppose estrogen in breast cells (i.e., breast cell proliferation is not decreased during the luteal phase of the natural menstrual cycle) and that the progestin potency of the progestin component of OCs is higher than normal luteal phase progesterone,^{68,69} it is unlikely that OCs will reduce normal breast cell proliferation, and available data show that the level of sex steroids necessary to provide acceptable contraception from OCs appears to produce breast cell proliferation to about the same extent as a normal ovulatory cycle.¹

The effect of OCs on breast cancer risk has been the subject of a large number of epidemiologic studies. In the Collaborative Group analysis of 54 such studies, current OC

users showed a 40% increase in the risk for breast cancer,⁷⁰ but the risk declined after stopping use, and by 10 years after stopping use, there was no excess risk. A large U.S. population-based case-control study completed more recently to determine the risk for breast cancer later in life among OC users found no evidence for an increased risk in current or prior users, including in women with a family history.⁷¹

Is the contraceptive use of depot medroxyprogesterone acetate a risk factor for breast cancer?

Depot medroxyprogesterone acetate (DMPA) is a long-lasting (90-day), injectable progestin releasing medroxyprogesterone acetate (MPA), now approved as a contraceptive in the United States. DMPA suppresses ovulation, and estradiol levels average slightly below those of the normal early follicular phase level, without a preovulatory or mid-luteal phase peak.^{72,73} Although endogenous progesterone is completely suppressed, substantial amounts of the synthetic progestin MPA are present. Epidemiologic studies of the effect of DMPA on breast cancer risk have found no evidence for a reduction in breast cancer risk,^{74,75} despite the reduction in estradiol levels, consistent with the belief that progestins are important in the genesis of breast cancer. An analysis of the case-control studies conducted by the World Health Organization (WHO) and in New Zealand showed a slight increased breast cancer risk in current users but not in past users.⁷⁵

Is postmenopausal hormone replacement a risk factor for breast cancer?

The effect of postmenopausal HRT on breast cancer risk has been the subject of numerous epidemiologic studies. Compared with the pronounced effect of postmenopausal unopposed ERT on the risk for endometrial cancer, the effects of HRT on breast cancer risk are of much smaller magnitude. However, given the high incidence of breast cancer, even small relative risks are important. HRT has been prescribed for control of menopausal symptoms and for long-term use for the prevention of osteoporosis and cardiovascular disease (although the latter claim for HRT is now in serious dispute). In women with prior hysterectomy, ERT is prescribed; in women with an intact uterus, estrogen combined with various regimens of progestin (estrogen-progestin replacement therapy; EPRT) designed to protect the endometrium is used.

The likely effect of HRT on breast cancer risk can be predicted on the basis of the effects of ovarian hormones on breast cancer risk. After menopause, breast cancer incidence increases about 2% per year; this compares to an approximately 10% per year increase that one would predict if the incidence curve for breast cancer in the premenopausal period continued.⁷ The effect of OCs on breast cell proliferation is about the same as normal menstrual cycling,¹ and HRT given as EPRT is administered at lower total estrogen and progestin doses than OCs (at least in the United States), so that EPRT should at most increase the postmenopausal breast cancer rate to what it would have been if the woman had continued to cycle regularly. This implies that EPRT should increase breast cancer risk by at most 10% per year of use, and

the single study of breast cell proliferation in women on EPRT, which showed proliferation levels comparable to those seen over the menstrual cycle in cycling women, suggests that it will be close to this value.⁷⁶ The effects of ERT would be predicted to be much less.

Relative risks of this magnitude are difficult to detect because of confounding effects. Most notably is the effect of age at menopause, which is difficult to establish when HRT is initiated before menopause has clearly occurred. Further, it is not possible to correctly adjust for age at menopause in women who underwent hysterectomy, and such women need to be excluded from consideration in studying the effects of HRT on breast cancer risk.⁷⁷ Failure to correctly deal with age at menopause and the inclusion of hysterectomized women will tend to nullify the measured effects of HRT on breast cancer risk.

The results of epidemiologic studies suggest that ERT causes an approximately 10% increase in breast cancer risk after 5 years of use—that is, a 10% increase in risk at the 5-year point after 5 years of use, or a cumulative increase in risk for 5 years of use of about half this amount, or a relative risk of 1.02 per year of use.⁷⁸ This increase in breast cancer risk is in agreement with the relative increase in effective estrogen levels with ERT.⁷⁹ The increased risk diminishes with time after stopping use, and there is little residual effect 10 years after stopping use. In the Women's Health Initiative (WHI) randomized trial of ERT, women with prior hysterectomy were treated with conjugated estrogens (CE) alone at a dose of 0.625 mg/day or placebo.⁸⁰ The study was designed to evaluate the effects on cardiovascular events and was stopped early because of a lack of cardiovascular disease benefit and an increased risk for stroke in the ERT arm. In this study, the incidence of breast cancer was actually lower in the ERT arm, but the difference was not statistically significant, and chance must be considered as the likely explanation for the decreased risk. This study does suggest, however, that the 2% per year of use increase estimated from observational studies is an overestimate of effect.

Epidemiologic studies of menopausal EPRT have found a considerably greater increased risk in the range of 25% to 40% after 5 years of use—that is, a 25% to 40% increase in risk at the 5-year point after 5 years of use or a cumulative increase in risk for 5 years of use of about half this amount.^{78,81–83} Two randomized studies have tested EPRT compared with a placebo. The Heart and Estrogen/Progestin Replacement Study (HERS) tested EPRT (0.625 of CE and 2.5 mg of MPA per day) in women with prior coronary disease and found a 30% increased breast cancer risk after an average of 4.1 years of follow-up.⁸⁴ The WHI study compared the same EPRT regimen and was terminated early after an average of 5.2 years of follow-up because of a 26% excess risk for breast cancer,⁸⁵ and the breast cancers were diagnosed at a more advanced stage in the women in the EPRT arm than in the placebo arm.⁸⁶ The EPRT also increased the percentage of women with abnormal mammograms, in line with the known effect of EPRT to increase mammographic breast density.⁸⁷

Our meta-analysis of these studies and studies published since shows an approximately 40% increased risk after 5 years of use (relative risk of 1.07 per year of use).⁸⁸ At the progestin doses given in the United States (MPA at 5–10 mg/day for 10–12 days with sequential therapy or 2.5 mg/day with continuous-combined therapy), there is little difference in the

breast cancer risk from these regimens. At the doses commonly given in Scandinavia, the continuous-combined regimen has two to three times the progestin dose of the sequential regimen, and the relative risk is much greater with the continuous regimen, showing again that it is the progestin component of EPRT that conveys most of the risk.

Prevention of Breast Cancer

Polly R. Etkind and Joseph A. Sparano

The potential benefits of a disease prevention strategy depend on the incidence of the disease in the population and the associated morbidity and mortality. Breast cancer is very common in North America and Western Europe. For the average white American woman, there is a 1 in 8 lifetime risk of developing breast cancer, and a nearly 1 in 28 chance of dying of breast cancer.¹ Furthermore, breast cancer results in substantial cost and morbidity because of the need for screening, surgery, adjuvant local or systemic therapy, and follow-up. It is clearly reasonable, therefore, to consider breast cancer prevention in healthy populations, particularly in those that have a high incidence of the disease.

PREVENTION STRATEGIES

What populations should be targeted for prevention?

The likelihood of benefit from prevention is increased by targeting high-risk populations for prevention, although this assumes that the intervention strategy is equally effective in such targeted populations. A germline mutation in the tumor suppressor gene *BRCA1* or *BRCA2* is the most reliable predictive factor because it is associated with up to an 80% lifetime risk for developing breast cancer as well as about a 20% to 40% lifetime risk for ovarian cancer.² However, it is estimated that *BRCA1* gene mutations account for only 5% of all breast cancers.² Age is perhaps the next most important factor: the incidence of the disease increases with each decade of life.³ Other factors are outlined in Table 6–1 and include family history,⁴ reproductive factors, and exogenous hormone use (as reviewed in Chapter 4). Although there are many risk factors, nearly one half of patients with the disease have no identifiable risk factor.⁵

What factors should be considered in selecting a prevention strategy?

The characteristics of a sound prevention strategy include a substantial reduction in risk, a reasonable likelihood of deriving benefit, absence of any short-term or long-term deleterious effects, feasibility of implementation, and reasonable cost. The appeal of a prevention strategy would be greatly strengthened by secondary benefits in reducing other major

causes of morbidity or mortality, such as other malignancies and cardiovascular disease.

What prevention strategies are available or under investigation?

Potential strategies for breast cancer prevention include modification of reproductive factors and hormone use (e.g., early pregnancy, lactation, prophylactic oophorectomy), modification of lifestyle (e.g., diet, exercise), chemoprevention (e.g., tamoxifen), and removal of the target organ (e.g., prophylactic mastectomy).

MODIFICATION OF REPRODUCTIVE FACTORS AND EXOGENOUS HORMONE USE

What role do steroid hormones play in the pathogenesis of breast cancer?

Although the pathogenesis of breast cancer is not completely understood, a popular theory is that mutagenesis and mitogenesis are important factors.⁶ Sex steroid hormones have potent mitogenic effects and also increase the susceptibility of breast epithelia to mutagens. Breast epithelial cells undergo cycles of cell proliferation and cell loss in response to ovarian production of estrogen and luteal production of progesterone. The cells of the terminal duct lobular units increase in number in response to progesterone during the luteal phase and stop dividing and enter apoptosis when progesterone production wanes. Such proliferating cells are more susceptible to mutagens and are more likely to develop somatic mutations. Numerous clinical observations support the importance of hormones in the pathogenesis of breast cancer; they have been reviewed in Chapter 4. The role of hormones is believed to be manifested in a protective effect of early menopause,⁷ the steeper age-related increase in breast cancer incidence that occurs in premenopausal compared with postmenopausal women,¹ the multifactorial effects of pregnancy on breast cancer risk,⁸ the association between more prolonged ovarian cycling (i.e., early menarche, late menopause) and increased breast cancer risk,⁹ and the association between relatively high circulating estrogen levels and breast cancer in postmenopausal women.¹⁰ Factors supporting a mutagenic role for hormones include the increased incidence of oxidative

Table 6-1 Classification of Breast Cancer Risk

Group	Lifetime Risk for Breast Cancer (%)	Risk Factors
Average risk	11–12	No family history or reproductive factors*
Increased risk	10–20	No family history but at least two reproductive factors Atypical hyperplasia without a family history Weak family history (no more than two second-degree or more distant relatives with breast cancer)
High risk	>20	Atypical hyperplasia with a family history Lobular carcinoma in situ Strong family history (any first-degree relative, any second-degree relative with onset <40 yr, or 3 or more family members with breast cancer)
Very high risk	Up to 85	Breast cancer susceptibility gene (<i>BRCA1</i> , <i>BRCA2</i> , or other cancer susceptibility syndromes)

*Reproductive factors include (1) menarche ≤ 11 years of age, (2) menopause ≥ 55 years of age, (3) nulliparity, (4) first pregnancy after age 30 years, (5) current use of hormone replacement therapy.

DNA damage in the peripheral blood and breast tissue of women with breast cancer.^{11,12}

What is the relationship between pregnancy and breast cancer?

Pregnancy is associated with a short-term increase in breast cancer risk followed by a long-term protective effect. Lambe and colleagues⁸ reported a case-control study involving 12,666 patients with breast cancer and 62,121 age-matched residents of Sweden. Uniparous women had a higher risk for breast cancer than nulliparous women for up to 15 years following delivery. For women aged 25 to 35 years at the time of delivery, the risk steadily declined over 10 to 15 years following delivery until a protective effect began to be evident. For women aged 20 years at first delivery, long-term reduction in breast cancer occurred without a short-term increase. Having a second delivery at 30 years old or younger also had a protective effect without a short-term increase. This study provides explanations of why nulliparous women have reduced breast cancer risk during the childbearing years despite having a higher lifetime breast cancer risk, why the average age at diagnosis of breast cancer is younger in parous compared with nulliparous women, and why previous studies that did not consider the potential interaction among age at delivery, age at breast cancer diagnosis, and parity demonstrated conflicting results.¹³ A plausible biologic interpretation is that pregnancy increases the short-term risk for breast cancer by stimulating the growth of cells that have undergone the early stages of malignant transformation, but confers long-term protection by inducing the differentiation of normal mammary stem cells, which, when undifferentiated, have a greater potential for neoplastic change.

The Russos and their colleagues¹⁴ have proposed a biologic model that provides an explanation for these clinical observations. They have shown that in rats, pregnancy results in complete differentiation of terminal end buds to lobules and renders the mammary gland relatively resistant to malignant transformation. In humans, the Russos¹⁵ have identified four distinct lobular structures in the breast, each representing sequential developmental stages in mammary development. Type 1 lobules are the most undifferentiated and are

most prevalent in the immature female breast before menarche. Type 2 lobules arise from type 1 and have a more complex morphology. Type 3 lobules are seen during pregnancy. Type 4 lobules are present only during the lactation period and are considered the most differentiated lobules. Type 1 lobules are postulated to give rise to invasive and noninvasive ductal carcinomas. Pregnancy between the ages of 14 and 20 years results in an increase in type 3 lobules that persists until the age of 40 years, when the lobules involute. It has been postulated that the artificial induction of a pregnancy-like state in the late teens could theoretically reduce breast cancer incidence by about one third.¹⁵ Although the timing of such an intervention and the optimal hormonal differentiation-producing combination are under intense investigation, there are considerable research and ethical hurdles to clear before any clinical applications of this idea are possible.

What is the relationship between lactation and breast cancer?

Most epidemiologic studies demonstrate that lactation is associated with a small but significant reduction in breast cancer risk, although its protective effect is observed only in premenopausal women and only after relatively long periods of lactation.^{16,17} Newcomb and colleagues¹⁶ studied 5878 women who had nursed their offspring and 8216 parous women who had not nursed offspring. All of these women were homemakers whose duration or extent of lactation was not limited by a return to employment. The relative risk for developing breast cancer in women who had ever nursed a child was 0.72 for premenopausal women and 1.04 for postmenopausal women. Increasing duration of lactation was associated with significantly more protection for premenopausal women, with a significant protective effect observed for women who lactated for at least 4 months after one pregnancy. Younger age at first lactation was associated with significantly lower breast cancer risk, although protection was observed for patients who initiated lactation up to 29 years of age. In contrast to previous data suggesting that insufficient milk production was associated with increased breast cancer risk, the authors found no difference in breast cancer risk whether insufficient milk

production or other reasons were the cause of a short (less than 4 months) period of lactation. The use of hormones to discontinue milk flow was reported by an equal proportion in the case-control group and had no effect on breast cancer risk. A similar, more recent study involving 110,604 premenopausal Korean women provided additional empirical evidence that lactation decreases the risk for breast cancer among premenopausal women.¹⁸ Lactation may be protective against breast cancer by modifying pituitary and ovarian hormone production, thereby resulting in more anovulatory cycles.¹⁹ In mice, lactation also results in relative resistance to chemical carcinogens, lowers the rate of epithelial proliferation, and allows the elimination of carcinogen through the mammary gland.²⁰

Can modification of endogenous steroid hormone production protect against breast cancer?

For women seeking contraception, Spicer and Pike⁶ have proposed that a combination of a gonadotropin-releasing hormone agonist (to suppress ovarian function) and low-dose hormone replacement therapy (with exogenous synthetic estrogen and progestogen) can produce effective contraception and reduce breast cancer risk. This treatment results in hormone levels that are insufficient to promote ovulation or stimulation of breast epithelium but sufficient to prevent vasomotor symptoms, urogenital atrophy, atherosclerosis, and osteoporosis. It has been estimated that this method can reduce lifetime breast cancer risk by 50% if used for 10 years and by as much as 70% if used for 15 years. This strategy also results in a significant reduction in mammographic density at 1 year in premenopausal women.²¹ Increased mammographic density is associated with increased breast cancer risk for both premenopausal and postmenopausal women and is independent of other recognized variables.²² This strategy has not been tested in large-scale trials.

Therefore, for women seeking to have children, pregnancy at a young age, multiple pregnancies, and lactation at an early age can all have a substantial protective effect. On the other hand, education, employment, and other societal factors may make this approach impractical for many women.

What is the role of prophylactic oophorectomy in reducing breast cancer risk?

Observational studies have suggested that bilateral oophorectomy performed before menopause is associated with a reduced breast cancer risk.^{23,24} Although prophylactic oophorectomy may be impractical to consider in average-risk women, it may be a reasonable option for women with a heritable predisposition to breast cancer. Because mutations in the *BRCA1* and *BRCA2* genes are associated with an increased risk for not only breast cancer but also ovarian cancer, it is logical to consider this procedure for women with mutations in these genes. Kauff and colleagues enrolled 170 premenopausal women at least 35 years of age who had *BRCA1* or *BRCA2* mutations and had not yet developed breast or ovarian cancer.²⁵ All were offered risk-reducing salpingo-oophorectomy, of whom 98 chose surgery and 72 chose surveillance. After a

mean follow-up of 2 years, there were 3 cases of breast cancer and 1 case of peritoneal cancer among the 98 women in a surgery group, compared with 8 cases of breast cancer, 4 cases of ovarian cancer, and 1 case of peritoneal cancer among the 72 patients in the surveillance group. The hazard rate for a breast or gynecologic cancer among patients who chose risk-reducing salpingo-oophorectomy was significantly reduced (hazard ratio, 0.25%; 95% confidence interval [CI], 0.08%–0.74%). Risk-reducing salpingo-oophorectomy may therefore be a reasonable option for premenopausal women known to have *BRCA1* or *BRCA2* mutations and who have completed childbearing. The procedure may also have a role in postmenopausal women, although when used in that setting it would not likely have a protective effect in reducing breast cancer risk.

Would avoidance of oral contraceptives help in breast cancer prevention?

In the past, some studies have suggested increased risk for breast cancer with the use of oral contraceptives (OCs),^{26–29} whereas others have shown no association.^{30,31} Most studies do not show a consistent effect of various OC formulations and risk, although some studies have found a higher breast cancer risk among patients who took OCs containing high-risk progestins,³² perhaps owing to progestin-related increases in breast epithelial replication.³³ Recent studies suggest that newer low-potency/low-estrogen-dose contraceptives may impart a lower risk for breast cancer than those associated with earlier high-potency/high-dose preparations.³⁴ An exhaustive analysis representing about 90% of all worldwide epidemiologic evidence on breast cancer risk and birth control pills has concluded that there is no evidence of an increase in risk for having breast cancer diagnosed 10 or more years after cessation of use.³⁵ This meta-analysis did report that women who are currently using combined OCs or have used them in the past 10 years are at a slightly increased risk for having breast cancer diagnosed, although the cancers diagnosed in these women tend to be localized to the breast.

Is hormone replacement therapy associated with an increase in breast cancer risk?

Hormone replacement therapy (HRT) became a popular treatment for postmenopausal women because it effectively relieves vasomotor symptoms and urogenital atrophy and was thought to protect against bone fractures and cardiovascular disease based on case-control retrospective studies. The Women's Health Initiative^{36,37} prospectively evaluated the health effects of conjugated equine estrogens (0.625 mg daily) plus medroxyprogesterone acetate (2.5 mg daily) in 16,608 postmenopausal women who had a uterus, and estrogen alone in those who had prior hysterectomy. The trial was halted by the data and safety monitoring board when it was determined that HRT increased the risk for cardiovascular disease (non-fatal myocardial infarction or death due to coronary heart disease), which was the primary efficacy outcome; after a mean follow-up of 5.2 years (planned duration, 8.5 years), HRT was associated with about a 25% increase in this end point. The incidence of breast cancer was also increased in the HRT

group compared with placebo (hazard ratio, 1.24%; $P < .001$). The invasive breast cancers diagnosed in the HRT group were at a more advanced stage (regional/metastatic 25.4% vs. 16.0%, respectively; $P = .04$), although they did not differ in histology or grade. The percentage of women with abnormal mammograms was significantly higher at 1 year in the HRT group (9.4% vs. 5.4%; $P < .001$). The study also included women without a uterus receiving estrogen alone, and that part of the study remains in blinded follow-up with no evidence of increased risk for cardiovascular disease or breast cancer for estrogen alone.

LIFESTYLE MODIFICATION

Is there a role for exercise in breast cancer prevention?

Recreational physical activity appears to be inversely related to risk for breast cancer,^{38,39} yet some results remain inconsistent.^{40,41} Bernstein and associates³⁸ reported a case-control study involving personal interviews with a total of 545 women (aged 40 years and younger at diagnosis) who had been newly diagnosed with invasive or in situ carcinoma and 545 control subjects matched for age, race, parity, and neighborhood of residence. Lifetime histories of participants in physical exercise activities on a regular basis were obtained during the interview. After adjustment for potential confounding factors, the average number of hours spent in physical exercise activities per week from menarche to 1 year before diagnosis was a significant predictor of reduced breast cancer risk during the reproductive years. More recently, Dirx and colleagues³⁹ reported on their findings from the Netherlands Cohort Study on diet and breast cancer in which exercise information was collected by questionnaire from 62,537 women aged 55 to 69 years at baseline. After 7.3 years of follow-up, 1208 incident breast carcinoma cases were available for case-cohort analysis. A summed total of baseline exercise showed an inverse association between exercise and breast carcinoma for postmenopausal women.

Although physical activity in untrained women results in acute increases in estradiol and progesterone levels,⁴² with continued physical activity performed on a regular basis, there is a reduction in the length of the luteal phase and in luteal phase progesterone levels.⁴³ Strenuous activity may even result in secondary amenorrhea during adolescence.⁴⁴ This may explain why menarche is delayed in premenarcheal girls who engage in regular exercise and why physical activity may result in anovulatory cycles in adolescent girls.⁴⁵ It is unclear whether the protective effect of exercise, however, is due to reduction in ovulatory cycles, later menarche, earlier menopause, or other factors that tend to be associated with exercise, such as leaner body weight, reduced fat consumption, or other unrecognized factors. The etiologic window in a woman's life for a protective effect of physical activity on breast cancer prevention has not been determined. Given the other known benefits of regular exercise, however, including its effects in reducing the risk for atherosclerotic heart disease, diabetes mellitus, osteoporosis, and colon and endometrial carcinoma, it seems justified to advise regular exercise

beginning early in life, specifically during puberty, and continuing into adulthood.⁴⁶⁻⁴⁸

Is there a role for dietary modification in breast cancer prevention?

Epidemiologic studies have consistently noted a lower risk for breast cancer, gastrointestinal cancers, and cardiovascular disease among persons whose diets include relatively large amounts of fruits and vegetables.^{49,50} Ecologic studies have also noted a positive correlation between national per capita fat consumption and breast cancer⁵¹ and an inverse correlation between soy consumption and both breast cancer and cardiovascular disease.⁵²⁻⁵⁴

Does dietary fat have any effect on breast cancer development?

Dietary experiments in rats and mice demonstrate a mammary tumor-promoting effect of diets high in total fat (approximately 35% to 40% fat in calories, which is similar to the typical American diet) as compared with diets low in total fat (approximately 10% fat in calories, which is similar to the Japanese diet). Moreover, diets with a greater proportion of unsaturated fats (specifically corn oil) were more effective than diets rich in saturated fats in increasing the mammary tumor incidence or reducing the latent period of mammary tumor appearance.⁵⁵⁻⁵⁹ Monounsaturated fat (e.g., olive oil), on the other hand, appears either to act as a poor promoter or to have a protective effect.⁵⁹ In humans, ingestion of a low-fat diet reduces endogenous estradiol and estrone levels without affecting ovulation.⁶⁰

Hunter and colleagues⁶¹ reported a meta-analysis of seven prospective cohort studies that included 4980 breast cancer cases among 337,819 women in four countries: the United States, Canada, Sweden, and the Netherlands. When women in the highest quartile of energy-adjusted total fat intake were compared with women in the lowest quartile, there was no significant difference in breast cancer risk when adjusted for other factors. There was also no association when intakes of cholesterol, saturated fat, monounsaturated fat, and polyunsaturated fat were considered individually. In contrast, Howe and colleagues,⁶² in a meta-analysis of 12 case-control studies that included 4427 breast cancer cases and 6095 controls, revealed a highly significant positive association between saturated fat intake and breast cancer risk in postmenopausal women. The relative risk for the highest to lowest quintile was 1.46. Cho and associates reported a slight increased risk for dietary fat and breast cancer for premenopausal women.⁶³ In this study, dietary fat and breast cancer risk were assessed among 90,655 premenopausal women in the Nurses' Health Study II. During the 8 years of follow-up, 714 women developed incident breast cancer. The relative risk for the highest to lowest quintile was 1.25. The increase was associated with intake of animal fat but not of vegetable fat. Among food groups contributing to animal fat, red meat and high-fat dairy foods each was associated with an increased risk for breast cancer.

Changing one's dietary habits to protect against breast cancer may mean lowering fat levels far below what the average American woman consumes. In addition, the times of

consumption of dietary fat such as during childhood and adolescence may play an important role in prevention.

Do dietary monounsaturated fats protect against breast cancer?

Some evidence suggests a protective effect from monounsaturated fats. Although corn oil, a polyunsaturated fat, promotes mammary cancer in animal models, olive oil, a monounsaturated fat, either acts as a poor promoter or has a protective effect.⁵⁹ Furthermore, Greek women have a substantially lower breast cancer mortality than American women despite their higher relative energy intake from fat.⁶⁴ Three case-control studies have evaluated the effect of monounsaturated fats in the form of olive oil consumption on breast cancer risk in Greece, Italy, and Spain, all of which have high per capita consumption of olive oil.⁶⁵⁻⁶⁷ Two of the studies (performed in Greece and Spain) demonstrated a protective effect for relatively high olive oil consumption. A protective effect for monounsaturated fat was not found in the pooled analysis of cohort studies reported by Hunter and colleagues,⁶¹ although none of the cohort studies included in this analysis were performed in countries with high consumption of olive oil. Cho and associates reported that both saturated and monounsaturated fat were related to modestly elevated breast cancer risk.⁶³

Is there a role for soy or soy derivatives in breast cancer prevention?

Soybeans and soy-based products and derivatives of soy-based products, such as genistein and daidzein, contain isoflavonoids, which are naturally occurring phytoestrogens that inhibit carcinogen-induced mammary tumors in animals.⁶⁸ The isoflavonoids are weak estrogen agonists and may interfere with the promoting effects of physiologic concentrations of estrogens. Soy-based products are also rich in protease inhibitors, which also inhibit carcinogen-induced mammary tumors. Although there are epidemiologic data that demonstrate an inverse correlation between soy consumption and breast cancer risk,⁶⁹ other studies have not been consistent in this correlation.^{70,71} Also, there is no evidence that supplementation of a typical Western diet with soy-based products modifies breast cancer risk.

Does obesity control play a role in breast cancer prevention?

Obesity is associated with an increased risk for breast cancer, specifically in postmenopausal women.^{72,73} Obesity is also associated with a higher recurrence rate and poorer survival in women with breast cancer.⁷⁴ In a prospectively studied population of more than 900,000 U.S. adults who were free of cancer at enrollment and followed for up to 16 years, there was a positive association between high body mass index (BMI—weight in kilograms divided by the square of the height in meters) and breast cancer mortality. In addition, there was a linear association between increasing BMI and breast cancer mortality; the relative risk (RR) was 1.34% for a BMI between 25 and 29.9, 1.63% for a BMI between 30 and

34.9, 1.70% for a BMI between 35 and 39.9, and 2.12% (1.41%–3.19%) for a BMI of 40 or more ($P < .001$ for trend).⁷⁵ Avoidance of weight gain during adulthood has many benefits that are likely to include reduction in risk for postmenopausal breast cancer.⁷⁶

What role does fiber play in breast cancer prevention?

Fiber ingestion inhibits the intestinal resorption of estrogens in humans and reduces mammary cancer incidence in animals.^{60,77} Asian women eating a traditional low-fat, high-fiber diet have lower estrogen levels before and after menopause and have a lower breast cancer risk compared with Western populations.⁷⁸ Ingestion of a low-fat (less than 10% of calories), high-fiber (35 to 45 g/day) diet by white women significantly reduces serum estrone and estradiol levels during the early follicular and late luteal phases of the menstrual cycle without affecting ovulation.⁷⁹ In another study, however, ingestion of pure fiber (20 g of α -cellulose daily) without modification of fat intake had no effect on estrogen metabolism.⁸⁰

Despite a strong biologic rationale, epidemiologic data do not demonstrate a consistent benefit for fiber. Howe⁵¹ reported a meta-analysis of 12 case-control studies in which the relative risk for breast cancer was 0.85 for subjects who consumed more fiber. Other studies employing prospective cohort methodology observed no effect or a marginally significant effect of fiber ingestion.⁸¹⁻⁸³

What role do vitamins play in breast cancer prevention?

There has been increasing scientific and public interest in supplemental vitamin ingestion to reduce cancer risk, including breast cancer risk. Observational studies had suggested that people who consume more fruits and vegetables containing the antioxidant vitamins A, C, and E have somewhat lower risks for cancer.^{49,50,84} Vitamin A reduces the proliferative capacity and promotes the differentiation of primary human mammary epithelial cells.⁸⁵ The antioxidant vitamins may prevent cancer-causing DNA damage and inhibit atherogenesis by their ability to scavenge free radicals, the byproducts of normal metabolism.^{86,87} In order to assess the impact of vitamin ingestion on cancer risk, Hunter and colleagues⁸⁸ prospectively studied 89,494 women aged 34 to 59 years in 1980 who did not have cancer, assessing their intakes of vitamins C, E, and A at baseline and 4 years later with a validated semiquantitative food frequency questionnaire. During the 8-year follow-up period, large intakes of vitamins C and E were not protective against breast cancer. A low intake of vitamin A from food was associated with increased breast cancer risk; this was reduced by ingestion of vitamin A supplements. Similar results were recently published by Michels and coworkers⁸⁹ based on a large population-based prospective cohort study in Sweden. This study comprised 59,036 women, 40 to 76 years of age, who were free of breast cancer at baseline and 1271 of these women who later developed breast cancer. Trials are underway to determine whether the retinoids, which include vitamin A and its synthetic analogues (i.e., fenretidine), may play a role in breast cancer prevention.

There has also been interest in a possible relationship between calcium and vitamin D intake and breast cancer. There is an inverse correlation between sunlight exposure (as a source of vitamin D) and breast cancer.⁹⁰ The promoting activity of high dietary fat in animals is enhanced by low intake of calcium and vitamin D and can be inhibited by increased calcium (and probably vitamin D) supplementation.⁹¹ Vitamin D and its synthetic analogues have been shown to promote the death of breast cancer cells grown in the laboratory.⁹² Vitamin D and calcium intake is well below the recommended daily allowance in American women in all age groups, but especially in elderly people.⁹³ Breast cancer prevention, and simultaneous prevention of osteoporosis, might be achieved by increasing dietary intake of calcium and vitamin D to recommended dietary allowance (RDA) levels. This may be particularly applicable to females during puberty and adolescence. There is currently no proof, however, that calcium or vitamin D supplements are protective against breast cancer development.

Can consumption of no alcohol or decreased consumption of alcohol be associated with breast cancer prevention?

The available evidence from more than 50 epidemiologic studies, as well as numerous meta-analyses involving cohort and case control studies, indicates that alcohol consumption (i.e., beer, wine, and spirits) is associated with a moderate increase in breast cancer risk.^{94,95} Data indicate a modest positive association between alcohol and breast cancer (an approximately 25% increase in risk with daily intake of the equivalent of two drinks) and a dose-response relation.⁹⁴ The biologic basis for the effect of alcohol is unclear, although some data suggest that alcohol may augment gonadotropin-induced increases in serum estradiol levels.⁹⁶ The alcohol-breast cancer hypothesis is important because alcohol consumption is common and drinking is a potentially modifiable behavior for a motivated individual. In one survey, 61% of women reported being “current drinkers” (at least 12 drinks yearly). Of the current drinkers, 39% were light drinkers (up to 3 drinks weekly), 27% were moderate drinkers (4 to 13 drinks weekly), and 9% were heavy drinkers (14 or more drinks weekly).⁹⁴

MODIFICATION OF EXPOSURE TO ENVIRONMENTAL FACTORS

What role does radiation exposure play in breast cancer development?

The risk for breast cancer is increased in women exposed to relatively high doses of ionizing irradiation, such as in therapeutic use (for postpartum mastitis, thymic enlargement, and Hodgkin’s disease) and after inadvertent or accidental exposure (fluoroscopy for tuberculosis or nuclear fallout from an atomic bomb).^{97–100} Exposure during puberty or earlier is associated with a substantially greater risk for breast cancer than comparable exposure at an older age, and thus the

benefit of using diagnostic radiation, particularly in women younger than 20 years, should be considered carefully. The low irradiation dose employed in a routine mammogram (0.15 cGy to each breast) and chest film (0.002 cGy to each breast) and the relatively advanced age during which these modalities are employed make it extremely unlikely that they in any way contribute to breast cancer risk. Furthermore, annual screening mammography clearly reduces breast cancer mortality in women 50 years or older, indicating that the benefits far outweigh any risks that may be involved.¹⁰¹

Exposure to diagnostic radiation may be associated with increased breast cancer risk, however, in patients who are heterozygotes for the ataxia-telangiectasia (*AT*) gene, a group that makes up about 1.4% of the general population.¹⁰² *AT* heterozygotes are healthy persons, whereas homozygotes have a characteristic disorder including cerebellar ataxia, oculocutaneous telangiectases, endocrine disorders, and humoral and cellular immune defects. The homozygotes have a markedly increased risk for developing lymphoid and epithelial neoplasms, and they exhibit tissue necrosis after exposure to therapeutic irradiation, effects that are due to an inherent deficiency in repairing damaged DNA.¹⁰³ Evidence suggests that *AT* heterozygotes have a fivefold increased risk for breast cancer and that exposure to diagnostic irradiation (in the form of fluoroscopic examination of the chest, back, or abdomen) contributes to this increased risk.^{104,105} Although screening of the general population for the *AT* gene is not yet practical, it may be prudent to screen relatives of *AT* homozygotes. It appears that special measures involving low-dose radiation exposure could help prevent breast cancer development in these persons and others who are heterozygous for familial and chromosomal breakage syndromes.

Is electromagnetic radiation exposure associated with breast cancer?

Increased breast cancer risk has been reported in female and male electrical workers.^{106,107} In contrast, others have found no association between low-frequency field exposure in the workplace and breast cancer risk.^{108–110} A recent study of the effect of exposure of magnetic fields to female residents of Los Angeles county, California (743 breast cancer cases and 699 controls) suggest that residential magnetic field exposure did not influence risk for breast cancer.¹¹¹ Similarly, a case-control study of the relationship between electromagnetic fields and breast cancer on Long Island (the Electromagnetic Field Breast Cancer Long Island Study, or EBCLIS) reported no association between breast cancer and residential electromagnetic field exposures.¹¹²

CHEMOPREVENTION

What is the rationale for chemoprevention with tamoxifen and other selective estrogen modulators?

The selective estrogen receptor modulators (SERMs) are chemically diverse compounds that lack the steroid structure

of estrogen yet bind to the estrogen receptor (ER) and mediate antagonist or agonist effects, depending on the conformation of the SERM, differing level of ER expression in the target tissue, and differing expression and binding of coregulatory proteins.¹¹³ Both tamoxifen and raloxifene are SERMs that have many attributes of a good chemoprevention agent. Both are taken once daily, are commonly prescribed for other conditions, and are generally safe and well tolerated. Furthermore, substantial preclinical and clinical evidence has demonstrated potential chemopreventive effects for these agents. Tamoxifen has been approved for many years for the treatment of early-stage and advanced breast cancer in both premenopausal and postmenopausal women, whereas raloxifene is approved for the treatment and prevention of osteoporosis in postmenopausal women.¹¹⁴ Tamoxifen significantly reduces the risk for contralateral breast cancer in patients with a prior history of breast cancer. In the meta-analysis performed by the Early Breast Cancer Trialists' Collaborative Group, tamoxifen reduced the rate of contralateral breast cancer by 47%.¹¹⁵ Raloxifene has likewise been associated with a reduced breast cancer risk in patients with osteopenia or osteoporosis. The Multiple Outcomes of Raloxifene Evaluation (MORE) Trial included 7704 healthy postmenopausal subjects with osteoporosis up to 80 years of age who were randomized to receive either raloxifene (60 or 120 mg daily) or a placebo.¹¹⁶ Although raloxifene was also associated with an increased risk for thromboembolic disease comparable to tamoxifen, it was not associated with an increased risk for endometrial cancer. Although these studies would seem to indicate that these drugs have equivalent chemopreventive effects, there were important differences between the study populations. Tamoxifen was evaluated in both premenopausal and postmenopausal patients with a previous diagnosis of breast cancer, a condition known to be associated with an increased risk for breast cancer. Raloxifene was evaluated only in postmenopausal patients with osteoporosis, a condition known to be associated with reduced breast cancer risk.¹¹⁷ These findings have prompted the evaluation of SERMs as chemopreventive agents.

Does tamoxifen reduce the risk for developing breast cancer?

The National Surgical Adjuvant Breast and Bowel Project (NSABP) performed a trial that included 13,388 healthy female subjects who had an elevated risk for developing breast cancer (P-1 trial). Selection criteria included prior diagnosis of lobular carcinoma in situ of any age, age of at least 60 years, or age between 35 and 59 years with a 5-year risk for developing breast cancer as estimated by the Gail model to be at least equivalent to that of a 60-year-old woman (at least 1.66%).¹¹⁸ Seventy-seven percent had at least one first-degree relative with breast cancer, and the age distribution was fairly evenly balanced between older women (30% older than 60 years), middle-aged women (31% between 50 and 60 years), and younger women (39% between 35 and 49 years). All women were followed with annual physical examination and mammography. After a median follow-up of 3.5 years, the Data Monitoring Committee recommended unblinding the treatment arms because of a 49% reduction in the risk for developing breast cancer (both invasive and noninvasive cancer) in

the tamoxifen arm compared with the placebo arm. Other noteworthy findings included the following: (1) about 4% of women in the placebo arm developed invasive breast cancer during the course of the study, indicating that the eligibility criteria used were successful in selecting a group at elevated risk for developing breast cancer; (2) tamoxifen reduced the risk for estrogen receptor (ER)-positive breast cancers but had no effect on the development of ER-negative breast cancers; (3) there was a reduction in the risk for both invasive and in situ carcinoma; and (4) tamoxifen reduced the risk for breast cancer in all age groups, in patients with a family history, and in patients with lobular carcinoma in situ (LCIS) or atypical hyperplasia. Tamoxifen had no effect on survival, although a beneficial effect on survival was not expected.

On the basis of these findings, the U.S. Food and Drug Administration approved tamoxifen for reducing the risk for breast cancer in women at high risk for developing the disease. Three other trials evaluating tamoxifen were ongoing at the time that these findings were initially reported, prompting early reporting of the trials. The results of these trials are contrasted with the P-1 trial in Table 6-2.¹¹⁹⁻¹²¹ The trials varied in their sample size, selection criteria, and other factors, including the use of concurrent hormone replacement therapy in 20% to 40% of patients in these trials. Only IBIS-I trial demonstrated that tamoxifen significantly reduced the risk for breast cancer by 33%. A meta-analysis that included these four trials confirmed a significant reduction in breast cancer risk of 38% (95% CI, 28%–46%; $P < .0001$) for tamoxifen, with no significant reduction in the risk of ER-negative breast cancer but a 48% reduction (95% CI, 36%–58%; $P < .0001$) in the risk for ER-positive breast cancer.¹²² It also confirmed that tamoxifen was associated with an increased risk for endometrial cancer (RR 2.4%; 95% CI, 1.5%–4.0%; $P = .0005$), an effect that was not seen with raloxifene. Both tamoxifen and raloxifene were associated with an increased risk for thromboembolic events (RR, 1.9%; 95% CI, 1.4%–2.6%; $P < .0001$). The American Society of Clinical Oncology Technology Assessment Panel¹²³ concluded, “For women with a defined five year projected breast cancer risk of $> 1.66\%$, tamoxifen (at 20 mg/day for 5 years) may be offered to reduce their risk.” The panel did not recommend against the use of raloxifene, aromatase inhibitors, or retinoids for prevention. Other expert panels, including the Canadian Task Force on Preventive Health Care¹²⁴ and the National Comprehensive Cancer Network,¹²⁵ came to similar conclusions.

How should subjects be selected for tamoxifen prevention therapy?

Healthy subjects were selected for participation in the P-1 trial. Ideally, an individual should not have a significant comorbid condition or history of or known predisposition to thromboembolic disease. Individuals were selected by the Gail model, which includes the following factors in estimating risk: (1) current age, (2) age at menarche, (3) age at first live birth [nulliparous, <20 , $20-24$, $25-29$, >29 , unknown], (4) number of first-degree relatives with breast cancer [0, 1, 2 or more, unknown], (5) number of prior breast biopsies [0, 1, 2 or more, unknown], (6) did any prior biopsy show atypical hyperplasia [yes, no, unknown], and (7) race [white, black, Hispanic].¹²⁶⁻¹²⁸ The model calculates a 5-year risk and a

lifetime risk for the individual, and a comparison risk of a woman having the same current age but with average risk factors. Individuals were required to have an estimated 5-year risk of at least 1.66% to be eligible for the P-1 trial. The Gail model is appropriate for women without prior breast cancer and those who are not known to have or to be at increased risk for having a *BRCA1* or *BRCA2* mutation. In addition, for women who have family members with breast cancer diagnosed before the age of 50 years, the Claus model may be preferable.¹²⁹

A version of the Gail Model may be found on the National Cancer Institute website (<http://bcra.nci.nih.gov/brc>).

What are the side effects of tamoxifen therapy when used for risk reduction?

The NSABP trial demonstrated that tamoxifen has a 2.5-fold elevation in the risk for uterine carcinoma and a nearly 2-fold elevation in the risk for thromboembolic disease in women 50 years of age or older, but not in younger women. Women taking tamoxifen were also slightly more likely to be diagnosed with cataracts and to require cataract surgery. There was no significant difference in the risk for bone fracture, and there was no difference in mortality between the tamoxifen and placebo groups. There was an increased prevalence of bothersome symptoms (described as extremely bothersome or quite a bit bothersome), including hot flashes (46% vs. 29%) and vaginal discharge (13% vs. 3%).¹¹⁸ There was no difference found in the health-related quality-of-life measures (including depression and physical well-being). Patients taking tamoxifen reported problems with sexual function at a definite or serious level, although the overall rates of sexual activity in the two groups were not different.¹³⁰

Does the risk-to-benefit ratio favor taking tamoxifen?

A key question for an individual considering tamoxifen for risk reduction is whether the benefits of tamoxifen outweigh

the risk. The risk-to-benefit ratio is therefore dependent not only on the subject's underlying risk for developing breast cancer but also on the subject's likelihood of developing serious problems such as thromboembolic disease or uterine carcinoma. Gail and colleagues¹³¹ have developed models for estimating risk-to-benefit ratio for individuals considering tamoxifen for risk reduction. The models are based on assumptions regarding underlying risks for uterine cancer, thromboembolic disease, fractures, and cataracts in the general population, factors that vary by race. In general, women who are younger, who have a higher risk for breast cancer, and who have had a prior hysterectomy are more likely to have a favorable risk-to-benefit ratio. For example, the risk-to-benefit ratio using this model does not favor use of tamoxifen for any white or black women with a uterus who is 60 years of age or older. For women between the ages of 50 and 59 years, the risk-to-benefit ratio is favorable only for white women who have a 5-year breast cancer risk exceeding 4%, or black women who have a 5-year risk exceeding 6.5%. For women 49 years or younger, the risk-to-benefit ratio is favorable for both black and white women of all risk groups. For women who have had a prior hysterectomy, the risk-to-benefit ratio becomes favorable for white women between 50 and 59 years, and between 60 and 69 years if their risk exceeds 3.5%, but is generally not favorable for black women of the same age. Subjects considering tamoxifen prophylaxis should be routinely counseled regarding their risk-to-benefit ratio.

Is tamoxifen beneficial in women with hereditary breast cancer?

Tamoxifen is clearly effective in reducing the risk for breast cancer in women who have at least one first-degree relative with the disease. There is less information regarding its effectiveness in subjects with known heritable mutations predisposing to breast cancer, such as *BRCA1* or *BRCA2*. Because about 80% of breast cancers in women with *BRCA1* mutations are ER negative, there is concern that tamoxifen may not be effective in such women; on the other hand, risk-reducing

salpingo-oophorectomy seems to reduce breast cancer risk in this setting. King and associates reported on a subset of 288 women participating in the P-1 trial who developed breast cancer, of whom only 8 had *BRCA1* mutations and 11 had *BRCA2* mutations.¹³² Because of the relatively small sample size and relative wide confidence intervals, firm conclusions could not be drawn. However, a case-control study demonstrated a protective effect of tamoxifen against contralateral breast cancer for women with *BRCA1* mutations but not *BRCA2* mutations.¹³³ There is currently a need for additional information concerning the use of tamoxifen in women with *BRCA1* or *BRCA2* mutations.

Are there alternatives to tamoxifen?

No drug other than tamoxifen has been proven to reduce the risk for breast cancer in women at elevated risk for developing the disease, but other agents are currently being evaluated in ongoing clinical trials, including retinoids, other SERMs, and aromatase inhibitors. Raloxifene is being evaluated as an alternative to tamoxifen because it does not seem to be associated with an increased risk for uterine cancer. Aromatase inhibitors offer a promising route of chemoprevention through suppression of estrogen formation within the breast tissue. Aromatase converts androgens to estrogen and is expressed at a higher level in breast tissue than in the surrounding tissue. Aromatase inhibitors (e.g., anastrozole, letrozole, exemestane) are being evaluated based on sound preclinical and clinical rationale,¹³⁴ a position that is supported by several recently reported trials in women with early-stage breast cancer. For example, the risk for contralateral breast cancer was reduced by about 60% in women treated with anastrozole compared with tamoxifen in the ATAC trial.¹³⁵ In addition, letrozole reduced the risk for contralateral breast cancer by approximately 45% when used following 5 years of tamoxifen therapy.¹³⁶ Ongoing trials evaluating these agents are summarized in Table 6–3.^{136–140}

The studies evaluating SERMs and aromatase inhibitors outlined above are generally being performed in patients with either natural or induced menopause, either because of the lack of safety information in premenopausal women (i.e., raloxifene) or because the drug requires a menopausal state to

be effective (i.e., aromatase inhibitors). Veronesi evaluated the synthetic retinoid fenretinide (200 mg daily) compared with a placebo for 5 years in 2972 women with early-stage breast carcinoma. Although there was no effect in reducing contralateral breast cancer in the entire study population, there was a significant reduction in contralateral breast cancer in premenopausal women.¹⁴¹ There is insufficient evidence, however, to recommend retinoids for this indication. Recently, grapes and red wine have been shown to contain the compound resveratrol that inhibits aromatase. Resveratrol has been shown to inhibit the development of preneoplastic lesions in mouse mammary tumor cells and human cancer cells grown in the laboratory.¹⁴²

What other candidate chemopreventive agents may be considered in the future?

There are numerous additional agents that are currently under active evaluation as potential chemopreventive agents. In addition, recent studies suggest that protocols based on combinations of chemopreventive agents should be the focus of future investigations. A few of the more promising compounds under evaluation are reviewed here.

Nonsteroidal anti-inflammatory agents (NSAIDs), including inhibitors of cyclo-oxygenase-2 (COX-2), have received much attention as potential chemopreventive agents.¹⁴³ For example, regular NSAID use (2 or more tablets/week) for 10 or more years was associated with a 28% reduction in the incidence of breast cancer (RR, 0.72%; 95% CI, 0.56%–0.91%) in the Women's Health Initiative, and there was a statistically significant inverse linear trend of breast cancer incidence with the duration of NSAID use ($P < .01$).¹⁴⁴ Regular use of acetaminophen (an analgesic agent with little or no anti-inflammatory activity) or low-dose aspirin (<100 mg) was unrelated to the incidence of breast cancer. The inducible prostaglandin synthetase COX-2 is normally expressed predominantly in kidney and brain. COX-2 overexpression has been described in numerous human cancers, and recently COX-2 has been shown to be present in approximately 40% of invasive breast cancers, particularly those that overexpress *HER-2/neu*. There is an increasing body of evidence supporting a role for COX-2 in breast cancer development and pro-

gression through effects on angiogenesis and apoptosis as well as through effects on intramural aromatase.¹⁴³ A large clinical trial is currently evaluating the role of the COX-2 inhibitor celecoxib when used as secondary prevention in conjunction with aromatase inhibitors in women with early-stage breast cancer.¹³⁶

The peroxisome proliferator-activated receptor (PPAR) gamma, whose inactivation occurs during mammary gland carcinogenesis, is a nuclear receptor that is activated by polyunsaturated fatty acids (PUFAs), eicosanoids, and anti-diabetic agents. Such activation, which is enhanced by ligands of the retinoic receptor (RAR) and the retinoid X receptor (RXR), suppresses breast carcinogenesis in experimental models and induces differentiation of human liposarcoma cells. Selective PPAR ligands or modulators (SPARMs) are currently being designed to have desired effects on specific genes relevant to breast cancer development. Recent evidence for a synergistic interaction between RAR as well as RXR with PPAR gamma suggests that appropriate selective ligands from these two groups of receptors might be combined in breast cancer chemoprevention studies.^{145,146}

Histone deacetylation inhibitors, combined with demethylating agents, are promising as a means of rehabilitating silenced tumor suppressor genes. Inhibitors of activated tyrosine kinases (receptor tyrosine kinase inhibitors) offer a means of inhibiting increased growth factors and growth factor receptor expression and activation.¹⁴⁷

The statins atorvastatin, fluvastatin, lovastatin, and simvastatin were shown to inhibit proliferation of MCF-7, a human breast cancer cell line, by up to 90%. These data have led to studies to determine whether statins, in addition to their cholesterol-lowering effect, may have clinical significance in chemoprevention of human breast cancer.¹⁴⁸

The monoterpenes, including limonene and perillyl alcohol, prevent carcinogen-induced and spontaneous rodent mammary tumors during the initiation phase as well as the promotion/progression phase. Limonene, a monocyclic monoterpene that is the major component of the peels of oranges and lemons, has little or no toxicity. Both D-limonene and perillyl alcohol, a more potent analogue of limonene, are in phase I and II prevention trials.^{149,150}

The isothiocyanates, thiocyanates, and other sulfur-containing compounds (disulfiram and allyl sulfides) are effective chemopreventive agents in animal models in which they have been utilized as anti-initiators against carcinogen-induced mammary tumors.¹⁵¹ They inhibit cytochrome P-450 phase I hepatic enzymes or induce phase II detoxification enzymes.¹⁵² Increased consumption of cruciferous vegetables (e.g., cabbage, broccoli, cauliflower, Brussels sprouts), which are rich sources of isothiocyanates, are associated with a reduced incidence of intestinal cancers in humans.¹⁵³ Cruciferous vegetables are also rich in indole-3-carbinol, an effective chemopreventive agent in animals.¹⁵⁴ Ingestion of indole-3-carbinol by humans (400 mg/day) produces a significant increase in 2-hydroxyestrone, resulting in decreased production of 16- α -hydroxyestrone.⁷⁸ 16- α -Hydroxyestrone is genotoxic to mammary cells, and its production correlates closely with the development of mammary tumors in animals.¹⁵⁵ Women with breast cancer often have a low urinary ratio of 2-hydroxyestrone to 16- α -hydroxyestrone compared with age-matched controls, suggesting that endogenous differences in estrogen metabolism may account for increased

breast cancer risk.¹⁵⁶ Preliminary human trials have demonstrated that indole-3-carbinol is well tolerated and has a sustained estrogen-modifying effect.¹⁵⁷ Therefore, the evidence suggests that indole-3-carbinol, by modulating estrogen metabolism, may be chemopreventive.

Lycopene, a carotenoid present in tomatoes, processed tomato products, and other fruits, is one of the most potent antioxidants among dietary carotenoids. Although some recent studies have suggested that lycopene and other plasma carotenoids may reduce the risk for developing breast cancer, others have not seen an association.¹⁵⁸⁻¹⁶⁰

Calcium glucarate, which is normally synthesized in human liver cells and is also present in vegetables and fruits, has been shown to inhibit chemically induced mammary tumors in the rat. Oral supplementation of calcium-D-glucarate has been shown to inhibit β -glucuronidase, an enzyme whose elevated expression is associated with an increased risk for breast cancer. The chemopreventive ability of this nontoxic agent may be twofold in that it may act as a regulator of estrogen metabolism and also as a detoxifying agent of carcinogens responsible for breast cancer.¹⁶¹

Organic and inorganic selenium inhibits both chemically induced and spontaneous mammary tumors in animal models.¹⁶² Although selenium inhibits the initiation and postinitiation phases of carcinogenesis at both the cellular and molecular levels, its toxicity has been of concern. Recently, however, synthetic organoselenium compounds, such as Se-methylselenocysteine, that have optimal chemopreventive potency and low toxicity in animals have been developed and should allow for the adequate investigation of selenium as a chemopreventive agent in human breast cancer.¹⁶³

Dihydroepiandrosterone (DHEA) is an adrenocortical steroid that prevents carcinogen-induced mammary tumors in animal models. DHEA appears to affect the promotion stage of tumorigenesis, suggesting that this agent may be useful in inhibiting the transition from human ductal carcinoma in situ (DCIS) to invasive carcinoma.¹⁶⁴

REMOVAL OF THE TARGET ORGAN (PROPHYLACTIC BILATERAL MASTECTOMY)

What is the rationale for prophylactic bilateral mastectomy?

Prophylactic bilateral mastectomy (PBM) is a logical, although extreme, measure for the prevention of breast cancer. Indeed, occult cancer has been detected in up to 5% of prophylactic mastectomy specimens in untargeted populations that included low-risk and high-risk patients.¹⁶⁵ On the other hand, occult cancer has been reported to be found incidentally at autopsy in 20% of young and middle-aged women who died of causes other than breast cancer.¹⁶⁶ Mammary tumors can occur in animals, however, despite prophylactic removal of mammary tissue, and risk reduction is not proportional to the percentage of mammary tissue removed.^{167,168} In humans treated with mastectomy for breast cancer, residual mammary tissue is often left behind in the axilla and pectoralis fascia.¹⁶⁹

What are the results of prophylactic bilateral mastectomy?

Hartmann and colleagues retrospectively evaluated all women with a family history of breast cancer who underwent PBM at the Mayo Clinic over a 33-year period.¹⁷⁰ Of the 1065 women who underwent the procedure, 214 met their criteria for “high-risk” family history and 425 met their criteria for “moderate-risk” family history. High-risk family history was defined as established criteria suggestive of a heritable breast cancer predisposition, whereas moderate risk included those who had a family history in first-degree or more distant relatives but who did not meet the high-risk criteria.¹⁷¹ The median age at mastectomy was 42 years, and the median length of follow-up was 14 years. Using the Gail model to estimate the expected incidence in the moderate-risk group, there was a 90% reduction in the observed-to-expected incidence of breast cancer (0.9% vs. 8.8%). When comparing the 214 high-risk probands with their 403 sisters who had not undergone a mastectomy, there was a significant reduction in the incidence of breast cancer in the probands compared with their sisters (1.4% vs. 38.7%). Recurrent cancers most often were diagnosed only on the chest wall and occurred after a median of 6 years (range, 2–25 years). PBM also resulted in about a 90% reduction in the risk for death from breast cancer. A subsequent report from this same group retrospectively identified 26 women with an alteration in *BRCA1* or *BRCA2*, 18 of which were known to be deleterious.¹⁷² None of the 26 women who had PBM developed breast cancer after a median of 13.4 years of follow-up (range, 5.8–28.5 years), suggesting a beneficial effect in mutation carriers.

Meijers-Heijboer prospectively evaluated the effectiveness of PBM in 139 healthy women known to have *BRCA1* or *BRCA2* mutations but no prior history of breast cancer, of whom 76 chose PBM and 63 chose surveillance.¹⁷³ After a mean follow-up of about 3 years, there were no cases of breast cancer in the PBM group compared with 8 cases in the surveillance group. The annual incidence of breast cancer in the surveillance group was 2.5% and was consistent with the number of cases expected for this population.

Although these studies seem to indicate a clear protective effect for PBM, some experts have pointed out that it is difficult to accept the notion that prevention of the disease by PBM is not too extreme a procedure as a cure of established disease, which can often be managed with breast-conserving surgery.¹⁷⁴ In addition, most women with established disease are cured, and up to 50% of women with heritable mutations may never develop breast cancer. Furthermore, the PBM is not protective against ovarian cancer, which is less common among mutation carriers than breast cancer but much more lethal. Finally, risk-reducing salpingo-oophorectomy is protective against both ovarian and breast cancer (when performed in premenopausal women) and does not induce the physical and psychosocial consequences of breast loss, nor does it result in the need for additional reconstructive breast surgery. For individuals who are more fearful of a breast cancer diagnosis than the surgery required to prevent it, however, PBM may be an appropriate choice.

Is there a role for prophylactic mastectomy in women with a prior history of breast cancer?

McDonnell and coworkers¹⁷⁵ followed 745 women with a first breast cancer and a family history of breast or ovarian cancer who underwent contralateral prophylactic mastectomy (CPM) at the Mayo Clinic over a 33-year period. There was about a 95% reduction in the risk for contralateral breast cancer, a result similar to that obtained for PBM in high-risk women with no prior breast cancer history.

What is the optimal procedure for patients who undergo prophylactic bilateral mastectomy?

Bilimoria and Morrow¹⁷⁶ have recommended that preventive surgery should be simple mastectomy, which encompasses removal of the entire breast, including the nipple, the areola, and the breast tissue that extends into the axilla. Axillary lymph node dissection is not appropriate in these prophylactic procedures. Simple mastectomy may be followed by immediate reconstruction using implant or myocutaneous flaps. Subcutaneous mastectomy may not be adequate because substantially more glandular tissue remains beneath the nipple–areolar complex, beneath the skin flaps, and in the axilla than after simple mastectomy.

What are the physical and psychological consequences of prophylactic bilateral mastectomy and breast reconstruction?

Prophylactic mastectomy and reconstruction are associated with sensate loss, particularly of the nipple–areolar complex. Another important consideration is the need for additional surgery in those individuals who choose breast reconstruction.¹⁷⁷ In the Mayo Clinic experience, approximately one half of those women who had reconstruction with implants required at least one unanticipated reoperation during a median follow-up of 14 years. Implant-related issues were the most common cause for reoperation.

One report indicated that approximately 60% of women indicated negative impact of the surgery on their sex lives, and 20% of women were not satisfied with the cosmetic result.¹⁷⁸ On the other hand, Frost and colleagues reported that among women who chose PBM at the Mayo Clinic, about 70% were satisfied with the procedure, compared with 30% who were either dissatisfied (19%) or neutral (11%).¹⁷⁹ Importantly, 74% reported a diminished level of emotional concern about developing breast cancer. Most women reported no change/favorable effects in levels of emotional stability (68%/23%), level of stress (58%/28%), self-esteem (69%/13%), sexual relationships (73%/4%), and feelings of femininity (67%/8%). In addition, 48% reported no change in their level of satisfaction with body appearance, and 16% reported favorable effects. These findings indicate that most women who choose PBM are satisfied with their decision, although a substantial minority may be dissatisfied.

Who should be offered prophylactic bilateral mastectomy? What are the alternatives to the procedure? How should a woman be counseled?

There are no absolute indications for prophylactic bilateral mastectomy. Close clinical observation and mammographic surveillance are a reasonable alternative for high-risk patients and offer the advantage of sparing the procedure in a substantial proportion of them. On the other hand, advanced disease may still occur in patients who undergo close surveillance, and even patients with early-stage invasive carcinoma are at risk for cancer-related mortality. Furthermore, routine screening mammography in patients younger than 50 years, the age at which close follow-up begins for the high-risk patient, is not associated with reduced breast cancer mortality.¹⁰¹ In addition, there is no information regarding the efficacy of clinical and mammographic surveillance in high-risk populations. On the other hand, the finding that the 60% to 90% of premenopausal women with breast cancer have mammographically detectable cancers suggests that this approach is reasonable and likely to be efficacious in this population.¹⁷⁶

It is well known that most women with a family history of breast cancer substantially overestimate their risk for developing the disease, which in turn results not only in unnecessary

anxiety but also in diminished compliance with screening recommendations for some women and unnecessary requests for genetic testing or prophylactic mastectomy by others.^{180–182} A limited period of regular counseling and education significantly reduces risk perception and enhances compliance with screening.¹⁸³ Other investigators have demonstrated, however, that breast cancer risk continues to be overestimated by most patients despite formal, standardized counseling sessions.¹⁸⁴

CONCLUSION

Is there any effective strategy for a woman to prevent breast cancer at the present time?

The measures that a woman may wish to consider to prevent breast cancer are dependent on her underlying risks for developing the disease (see Table 6–1; see also Chapter 5). Measures that might be taken and previously discussed in detail in this chapter are summarized in Table 6–4 and have also been reviewed by experts in the field.¹⁸⁵ Early or multiple pregnancies, lactation, regular exercise, ingestion of adequate amounts of fruits and vegetables, limiting alcohol consumption,

Table 6–4 Modifiable Factors in Breast Cancer Prevention

Factors	Effect	Comments
Reproductive or Hormonal		
Term pregnancy before age 30 yr	Up to 30% decrease in risk	Increased risk for up to 15 yr after delivery followed by reduced risk
Multiple pregnancies	Up to 20% decrease in risk	
Lactation	Small but significant decrease in risk	Protection for premenopausal women who initiate lactation before age 29 yr and continue for at least 4 mo
Oral contraceptives, ever use	No increased risk \geq 10 yr after cessation of use	
Oral contraceptives, current use or in past 10 yr	Slight increased risk for having breast cancer diagnosed	
Hormone replacement therapy, ever use	No risk effect	
Hormone replacement therapy, current use for >15 yr	Increases risk up to 50%	Greatest relative risk is for those with a family history
Contraceptive to suppress ovarian function through use of gonadotropin-releasing hormone agonist	May decrease risk by 50% (10-yr use); by 70% (15-yr use)	Not yet tested in large trials
Lifestyle		
Ingestion of adequate amounts of fruits and vegetables, olive oil, and soy products	Decreased risk	
Alcohol consumption	Increased risk	Proportionate to amount consumed
Exercise	Decreased risk	Proportionate to amount
Obesity	Increased risk	Applies to postmenopausal women
Tamoxifen	Decreases risk about 40%	Applies to contralateral breast cancer in women with prior breast cancer history

avoidance of obesity in postmenopausal women, and perhaps the use of olive oil and soy products may all have a protective effect and should be considered sufficient by women at average risk. Preventive measures that include diet, exercise, and avoidance of alcohol may be especially important during adolescence. For high-risk women, all of the aforementioned measures may also afford some protection, although the risk may be sufficiently high to warrant consideration of a chemoprevention trial or screening by those older than 50 years. Close observation and mammographic surveillance are clearly indicated for this group. For very-high-risk women, such as those who have a *BRCA1* or *BRCA2* gene mutation, participation in a chemoprevention trial, close observation, and prophylactic oophorectomy or bilateral mastectomy are reasonable considerations. Screening average-risk individuals with mammography and selected high-risk individuals with magnetic resonance imaging is always an option, not to prevent the disease but rather to detect it at an earlier time. Chemoprevention is not a substitute for screening, and screening should continue in those who elect chemoprevention. In addition, chemoprevention or prophylactic bilateral mastectomy should always be discussed in the context of screening as a possible alternative.

Pathologic Evolution of Preinvasive Breast Cancer: The Atypical Hyperplasias

David L. Page

The precursors of breast cancer are unknown, but there are histologic patterns associated with an increased risk for developing breast cancer. The associations are of differing magnitude for different anatomic lesions and are potentially useful for determining prevention strategies. They also provide current guidelines for clinical management and patient counseling.

How do the atypical hyperplastic lesions differ in clinical significance from ductal carcinoma in situ?

The major thrust of this chapter is to differentiate the atypical hyperplastic lesions from ductal carcinoma in situ (DCIS), which is discussed in detail in Chapter 8. When minimal examples of DCIS are identified and these samples are incompletely removed, the invasive cancer that may develop later is regularly in the same breast at the same site.^{1,2} This differs from the later cancers developing after identification of atypical hyperplasia (AH) of the lobular or ductal type, which are largely and evenly distributed within each breast at any site.³⁻⁵ Thus, it has become well established (Table 7-1) that the AHs, including lobular carcinoma in situ (LCIS), are markers of increased risk for cancer development anywhere within either breast over the next 10 to 15 years at least. This is very different from the obviously local progression to malignant behavior of the DCIS lesions, although there is a regional implication for the lesions of atypical lobular hyperplasia (ALH) that is strongly supported by the fact that 70% of the later-developing invasive carcinomas are in the ipsilateral breast, with the biopsy showing ALH. This tendency toward favoring one breast rather than having the even and bilateral distribution found with atypical ductal hyperplasia (ADH) has been recognized since the 1970s, when contralateral biopsies for lobular neoplasia (ALH) and LCIS frequently demonstrated no disease in the contralateral breast. However, there are differences of risk magnitude and site of later cancers, as discussed elsewhere.

What is the magnitude and location of risk for later invasive breast cancer after atypias?

Prediction of later untoward events, specifically the development of invasive breast carcinoma, is the important practical and biologic association of the specifically defined AHs. Although there are some characteristics that are especially relevant to either the *lobular* or *ductal* pattern of AH, the practical consequences of the AHs may be discussed as a cohesive group because in the important age group of 35 to 55 years, the consequences and presentations are similar.^{6,7}

A major part of this discussion is the difference between AHs (see Table 7-1) and the conceptual “parent” carcinoma in situ (CIS) lesions.⁸⁻¹⁰ Before the 1980s, a woman with benign breast disease was understood to have had a history of a benign breast biopsy. It was accepted as common knowledge that these women had a threefold increased risk for breast cancer.¹¹ Since the late 1980s, we have widely accepted the fact that most women undergoing breast biopsy for a benign lesion have no increased risk for subsequent breast cancer, and that a subset of these women may be identified as being at some risk of later breast cancer on the basis of histologic patterns of disease^{4,5,10,12,13} (see Table 7-1).

Figures 7-1 and 7-2 present data from follow-up studies of women with hyperplastic lesions of various types and the philosophic underpinnings of these and analogous observations. Only three other cohort studies^{12,14,15} similar to the one presented in Figure 7-1 have been performed using the same criteria for stratification of hyperplastic lesions. These have been essentially confirmatory, with small differences discussed elsewhere.^{6,7,15,16} Other studies using analogous criteria or criteria derived from different pathologists without using criteria-driven terminology are essentially supportive in that the more complex (or “atypical”) the hyperplastic lesions, the more elevated the risk.^{17,18} However, the cancer risk of the atypical hyperplastic lesions is highest when strict criteria are used for their evaluation. Considering that none of these predictions is absolute, there may actually be little practical difference between a patient with extensive usual-pattern hyperplasia and a patient with a small amount of AH. These risk implications may also vary somewhat with age and are

Table 7-1 Characterization of Breast Histopathology, from Benign through Carcinoma In Situ

Definition	Clinical Implications	Diagnoses
Benign	No increased risk for later invasive cancer compared with similar women (age most important)	Cysts, fibrosis, apocrine change, most fibroadenomas
Benign; similar to above group in practical terms	Slightly increased cancer risk, reliably approaching double that of comparable women	Well-developed patterns of usual hyperplasia; sclerosing adenosis; subsets of fibroadenoma; possibly, many larger and recurring cysts
Benign; elevated cancer concern in some age groups	Moderate magnitude, and generalized (anywhere in breasts) increased risk	Specific patterns of atypia; cytologic and histologic criteria of ADH and ALH/LCIS
CIS, low-grade DCIS	Prolonged, local evolution into invasive carcinoma	Low-grade DCIS, <1 cm
CIS, high-grade DCIS	Shorter and more certain local evolution into invasion, about 50% in 3 yr for larger lesions incompletely removed	High-grade CIS, ductal pattern, regional disease, regularly >1 cm in greatest extent; can be large

ADH, atypical ductal hyperplasia; ALH, atypical lobular hyperplasia; LCIS, lobular carcinoma in situ; CIS, carcinoma in situ; DCIS, ductal carcinoma in situ.

Figure 7-1 This Kaplan-Meier life table presents the experience of women after benign breast biopsy and records the incidence of later development of invasive breast cancer. Patients were excluded when lost to follow-up and if they died of other conditions, which accelerates the apparent incidence after 15 years; thus, the absolute risk indicated by the findings on breast biopsy should properly be cut off at 10 to 15 years. Note that this represents an average experience of women of average age (mid- to late mid-40s) in the initial Nashville series. Thus, a woman of that age with atypical hyperplasia experiences a risk for invasive carcinoma in the next 10 to 15 years of 10%. This risk might be slightly higher for older women, certainly for those into their 50s at the time of biopsy, but other causes of death after that age (certainly in the late 60s) would not increase this incidence. The incidence in women without proliferative disease may be extrapolated from the incidence in the general population, with an error rate of about 10%. In this series from the premammographic era, women developing invasive breast carcinoma had a death rate of only 28% at 10 years after mastectomy.

certainly of less importance in older women, who are more likely to develop cancers of increasingly lower malignant capacity and whose mortality is increasingly likely to result from cardiovascular causes.

The occurrence of fibroadenomas has also been studied, with attempts made to stratify the 1.4 to 1.7 times increased risk found for all fibroadenomas. One large study has found that some elements occurring with fibroadenomas identify

women as being at a slightly increased risk for breast cancer, and about 70% of women with fibroadenomas and without the added risk elements are left without an increased risk (Table 7-2).¹⁹

Figure 7-1 presents percentages of women developing invasive breast cancer and indicates that the most relevant and practical information is obtained in the first 15 or so years after diagnosis. The information more than 15 years after

Figure 7-2 This graph indicates levels of likelihood of developing true malignancy over time as measured by anatomic lesions at benign biopsy. The implication is that women who developed proliferative disease (PD) or atypical hyperplasia (AH) are more likely to proceed to the next step, carcinoma in situ (CIS). This is certainly not a guaranteed progression but must be viewed as one that is likely; for that reason, the connections between the different levels are in *dotted lines*, indicating a more tenuous link. The *arrows* pointing up and down indicate that lesions may recede or progress; the *dashed lines* indicate that they may maintain stability over a long period of time. It is believed that as one progresses, certainly to and past the level of atypical hyperplasia, recession of lesions is less likely. However, there is good indication that even low-grade ductal carcinoma in situ may remain stable or regress about 50% of the time.

Table 7-2 Features Associated with Fibroadenoma* That Elevate Breast Cancer Risk

<p>Complex histology: any combination of apocrine change, cysts, sclerosing adenosis, or calcification (epithelium related)</p> <p>Usual patterns of hyperplasia; moderate and florid in surrounding parenchyma (similar to women without fibroadenoma)</p> <p>History of breast cancer in first-degree relative (slightly higher than the history of cancer in a relative alone)</p>

*Most of the risk is operative 10 to 15 years after diagnosis.

biopsy is fragmentary and related to a small number of women. It also should be recognized that those women are now on average almost 20 years older than when their risk was evaluated initially. Because this is a cumulative risk statement, women who have developed cancer in the early years are also included in the statement. Basically, the relative risk for these older women (15 to 20 years after biopsy) may change to be more like that of comparable women of the same age at that period of time. Because of this somewhat confusing aspect, we believe that for practical reasons, predictiveness should be truncated at 10 to 15 years.^{6,20} The relationship of relative risk (a comparison with similar women in magnitude of risk) to absolute risk (an indication of the specific risk in percentage likelihood applying to the woman being counseled) is presented by Dupont and Plummer.²¹ One of the most important aspects of risk assessment is that breast disease and its treatment are constantly changing. Any decision based on what might happen to a woman more than 15 or 16 years in the

future would seem best made at that time, rather than at a time 10 to 20 years earlier that does not integrate the other events that may occur in that time.

Figure 7-2 presents a stochastic model proposing that cancer development takes place through a series of steps whose recognition determines the likelihood or probability of development of carcinoma. The individual lesions cannot be identified as specific precursors. This model must take into consideration the fact that any lesion that is viewed under the microscope and categorized has been removed from the breast. Presumably, then, lesions remaining within the breast or nonanatomically defined factors are the causative or provoking agents for later cancer development. Thus, the DCIS lesions that proved to be local precursors may be so because even the smallest lesions usually have dimensions in the 5- to 10-mm range^{1,21} and are more likely to remain after biopsy than after planned wide excision (see Chapter 8).

What is the histologic definition of atypical ductal hyperplasia and its special features?

Atypical ductal hyperplasia (ADH) is most often a solitary lesion on biopsy and confined within a single lobular unit, seldom larger than about 3 mm overall. Figure 7-3 presents a theoretical progression of lesions to invasion through levels of hyperplasia, although in reality very few lesions progress. Some of the particulars of histologic diagnosis were discussed earlier, but Figure 7-4 indicates more precisely the criteria used to arrive at a specifically defined lesion of ADH.²² Three

Figure 7-3 The hypothetical progression of lesions to invasion through levels of hyperplasia is presented. Note that each of these units is a space bounded by a basement membrane. These are usually acini or terminal ducts within the breast, but they could be major ducts as well. *A*, Normally, there is a single luminal layer of cells and a single outer layer of basal or myoepithelial cells. *B*, A slight increase in cell number, three to four cells above the basement membrane, is not associated with a measurable increase in likelihood of breast cancer incidence in the next 10 to 15 years. *C*, The usual hyperplasia, with irregularity in placement of cells and irregularity of intercellular spaces. *D*, More regular arches are present, similar to those seen in low-grade ductal carcinoma in situ (DCIS), with maintenance of normally polarized cells around the outside. *E*, Patterns of atypical ductal hyperplasia or DCIS of very low grade are indicated, with the arches and bars formed by a uniform population of cells. *F*, It is suggested that microinvasion into stroma occurs from the in situ lesions, with the protrusion of cells in the lower portion indicating loss of basement membrane materials and invasion. However, an in situ component is often absent, and invasive lesions can form basement membrane components, a further example of the heterogeneity of these processes.

criteria are important: cytology, histologic pattern, and extent (or size) of lesion.²³ Agreement among pathologists is usually obtained when consistent criteria are used.²⁴

Recognizing that these specifically defined, atypical lesions are clinically important indicators of increased risk will also lead to the recognition of anatomic patterns that mimic and may be confused with these lesions. An excellent example is that of “collagenous spherulosis,” originally described by Clement and colleagues.²⁶ Further studies have confirmed that this hyaline element is usually related to basement membrane materials.²⁷ The importance of collagenous spherulosis lies in the fact that with its sharply defined, round spaces it strongly mimics the histologic pattern of ADH. However, the lack of a uniform population of neoplastic-appearing cells makes its recognition as an AH (identifying moderate risk) inappropriate. Both the cytologic features of an appropriate population of cells and the histologic pattern criteria are necessary for a diagnosis of AH, which is indicative of a moderately increased cancer risk (four to five times that of comparable women; see Table 7-1). The risk implications of ADH are slightly smaller in the studies from the Nurses’ Health Study at Harvard. This may relate to the selection of cases during the mammographic era.

The incidence of ADH probably continues to rise for 10 to 20 years after menopause, a major differential feature

from ALH, which tends to decrease in incidence after menopause.^{4,6,9}

What is the histologic definition of atypical lobular hyperplasia and its special features?

Special considerations of ALH relate to its regular multicentricity. Although usually complete lobular units are involved, many units may be involved without involvement of intervening ducts. This multicentricity has been thought to be the reason for dispersion of sites of later-developing carcinomas, although the breast with identified ALH is twice as likely to be the site of later invasive cancer.²⁸

Of special note is the terminology related to ALH and LCIS. The histologic criteria demand alteration of lobular units as well as a characteristic and uniform cytology. The diagnosis is less difficult than with ADH, but problems with the use of the term LCIS remain. These problems may be considered resolved when one recognizes the slightly different criteria used to describe the same spectrum of change from “fully developed” (LCIS) to “minor deformity of lobular units” (just a few atypical cells without distention). When pathologists agree on criteria, they usually agree on diagnostic assessment.²⁵ Basically, this is a problem in terminology only

DCIS vs. ADH vs. FHWA
cytology & histology

Figure 7-4 The specific histologic features in the sequence of ductal pattern lesions. Florid hyperplasia without atypia (FHWA) is shown with irregular spaces between the cells. The *insert* above FHWA shows the irregularity of cell placement and nuclear features. These irregularities may indicate atypia in another organ but within the breast usually indicate the variation of ordinary hyperplasia, unless advanced nuclear atypia, as seen in comedocarcinoma in situ, is present. The anatomically intermediate lesion of atypical ductal hyperplasia (ADH) has specific features of ductal carcinoma in situ (DCIS) in less than completely developed form, usually best measured by the extent of the lesion (see text). Note that the even placement of similar-appearing cells is seen in both low-grade DCIS and ADH but that remaining areas within the same basement membrane–bounded space of normally polarized cells (*insert* below ADH) and also intermixtures of the varied cell population of usual hyperplasia are present. In DCIS, the uniform population of cells is present throughout the space without another cell population (although myoepithelial cells can be present). Usually, at least two spaces are completely involved, and the area of discernible atypia is greater than approximately 3 mm in overall size.

because recently performed studies in fairly large groups of patients^{4,29–32} have shown that lesser changes within the lobular units indicate a lesser risk than the more fully developed lesions that may be identified as LCIS.^{27,29–33} In this way, use of the term ALH is understood to mean an implication of increased risk only, without an implication of “carcinoma attached with LCIS.” Others accept *lobular neoplasia* as a clinically useful term,^{31,32,34} although the term ALH for most of these cases is appropriate and clinically useful. The term LCIS, which has historical precedent and wide clinical acceptance, is then reserved for the most fully developed lesions, which probably have a greater associated cancer risk.^{9,29,31} Also, dense local disease, approaching 1 cm in size, may have lobular cytology. Fisher and coworkers have presented a group of such patients with excellent follow-up after excision.²⁹

In 1996, Bodian and associates³⁰ stated that all of the changes should be called “lobular neoplasia,”³⁴ while documenting that lesser examples of this phenomenon, called “ALH” by others, are associated with a significantly lower risk. It would seem immaterial whether one calls these “lobular neoplasia types 1 and 2” rather than “ALH” or whether one

calls the fully developed examples of LCIS by that name or by “lobular neoplasia number 3.”

Fisher and coworkers²⁹ document the cases of LCIS presenting within the National Surgical Adjuvant Breast Project (NSABP). These cases are particularly valuable because they document a subset of LCIS that is quite advanced and that mimicked DCIS in the view of the original pathologist. These cases have a significant risk for later cancer development, which is not as high if the changes are not as advanced.

What are the nonclassic forms of atypical hyperplasia?

In addition to the relatively common and verified lobular and ductal series of AHs, other lesions presenting in the breast may also be considered “atypical” in the sense that they are close in their characteristics to those recognized as CIS. Such lesions include the hypersecretory atypias and the apocrine atypias.^{35,36} Basically, the available literature has not proceeded beyond the stage of recognizing these as a potential

problem. Some lesions with these cytoplasmic characteristics³⁷⁻⁴⁰ may appropriately be considered CIS because of their extent and seemingly neoplastic population of cells. Basically, each of these types of CIS presents as DCIS, with extensive areas of the breast involved in continuity through the branching system of ducts. O'Malley and associates³⁹ considered the criteria for minimal DCIS of the apocrine type and primarily used the clustering size and cytology. They recommended that lesions larger than 8 mm and involving multiple lobular units and ducts in continuity be considered apocrine DCIS. With lesions of this extent, the implication of local recurrence is evident. This approach was used because the pattern criteria so useful in classic forms of DCIS are often lacking. The hypersecretory atypias present an even greater problem because of their variety of presentations.⁴⁰

Lobular units may present quite remarkable alterations, including enlargement and cellular change, the latter of which may include extreme nuclear atypia. The confinement of these changes to solitary lobules indicates that these changes have little clinical significance, except that adjacent lobular units and tissue may contain similar or more advanced changes.⁴¹⁻⁴⁵ The enlargement of these other adjacent lobular units involves unfolding and occasionally some cystic alteration; hence, these units have been called "unfolded lobules." These changes associated with prominent snouts and secretions have been associated with contiguous changes of AH or DCIS in the setting of limited biopsy by core needle. Various studies have focused on the enlarged unit or the cytologic changes. We have taken the approach of using the background of the enlarged lobular unit as a descriptor⁴⁶ and follow with an explanation of the remarkable cytologic and hyperplastic changes that may be present within the unit.

These altered lobular units are about 3 to 8 mm and are usually enlarged compared with other lobular units. Their abundance is usually due to the active nature of the involved stroma. The enlarged involved cells are frequently apocrine or apocrine-like and may involve a range of other nuclear and cytoplasmic changes. Most often, the cells are columnar with apocrine-like cytoplasm and frequent apical cytoplasmic blebs or snouts. Such lesions may be termed *enlarged lobular units with columnar alteration* (ELUCA). Nuclei are usually enlarged and occasionally very atypical, but cytologically normal cells are almost always intermixed unless there are specifically defined features of ADH or ALH. The secretory activity of the cells is important because it is the calcification of the secretions that renders these lesions detectable by mammography. Sometimes, individual lobular units will appear as completely normal lactational units with secreted foamy material within the lumen as well as a similar foamy appearance of the cytoplasm. There are quite a few variations of this alteration between the secretory change and apocrine change.

Although clinical implications are not completely known, the mere local association of ELUCA with invasive cancer (often, the low-grade tubular lesions^{47,48}) does not provide malevolent implications when ELUCA is found alone. The predictive implication for later or associated cancer is minimal without further hyperplastic changes. This assertion was first supported in the mid-1970s in the important subgross studies of Wellings and colleagues,⁴⁹ who ascertained the abnormality of lobular units by viewing specimens at slight magnification; indeed, most of the specimens' changes were classified on the basis of the altered and enlarged lobular unit

for assignment to at least the first two or three major categories in Wellings and Jensen's system. The enlarged lobular unit with columnar and apocrine alteration that did not also have hyperplasia they termed ALA-1. The subsequent categories in the ductal series 2, 3, and 4 included various aspects of hyperplasia within the enlarged lobular units, recognizing that these are favored foci for the presentation of hyperplasias. Wellings and colleagues⁴⁹ found that these enlarged lobular units had a small association with concurrent carcinoma. Follow-up studies sought to separate the enlarged lobular units, as identified by the subgross evaluation⁴⁸ from the hyperplastic changes. When the enlarged, distorted lobular units and the hyperplasias were evaluated, there was a slight tendency for the larger lesions to have an increased risk for later invasive cancer, at 1.9. When the specifically defined AHs were removed from the analysis, the levels of risk were not significant statistically.⁵⁰ This does not clarify the meaning of these lesions when identified mammographically because there is a selectivity for calcifications and because ELUCA indicates possible associations with other lesions of greater neoplastic significance.⁵¹

Can fine-needle aspiration cytology and core needle biopsy allow an accurate diagnosis of atypical hyperplasia?

There have been some attempts to recognize different forms of hyperplasia, atypical and otherwise, by cytologic examination of fine-needle aspirates.⁵²⁻⁵⁴ Most investigators have maintained that these attempts are extremely difficult and the results from cytology alone cannot relate directly to the findings from specifically defined AHS that are recognized by histologic and extent criteria in addition to cytologic criteria. This has been supported by the studies of Stanley and associates⁵⁵ and Sneige and Staerkel.⁵⁶ Thus, it is currently impossible to maintain that one detects the same AH lesions in fine-needle aspirations by cytologic criteria alone. However, rarely, clustering of cells may be appreciated in cytologic preparations, which with proper cytology may suggest ADH or ALH.^{56,57}

The recent emergence of core needle biopsy techniques under stereotactic or ultrasound guidance has introduced a need to understand the role of the special aspects of AH in this setting. Most researchers have held that the presence of AH on a biopsy of this type should lead to an open biopsy.⁵⁸⁻⁶⁰ This appears to be appropriate and accepts the fact that more extensive lesions of similar morphology may be diagnostic of CIS. This is more important in the ductal than in the lobular series of lesions. Also, if a larger specimen is removed with many core samples and with use of larger needles, then further biopsy may not be necessary if the atypia is proved to be of limited extent. Both Ely and coworkers⁶¹ and Sneige and colleagues⁶² have stated that if only one or two lobulocentric foci of ADH are present in a specimen of multiple cores, re-excision will be regularly negative for atypia and CIS.⁶³

What are the clinical implications of a diagnosis of atypical hyperplasia?

The most important consideration in the area of histopathology and its interface with clinical management is the

difference between ADH and minimal examples of DCIS.^{7,22,25} This concept demands the separation and stratification of different forms of DCIS, a fact now widely established (see Chapter 8).

A diagnosis of AH recorded in the clinical record indicates an increased risk for breast cancer in the next 15 years. This increased risk applies to either breast and is of a magnitude greater than double that of the general population of similar women. This risk is not as great as that associated with the most minor DCIS left untreated or with fully developed LCIS. It is notable that this risk implication of AH is largely confined to women between the ages of 35 and 55 years. AHs are uncommon in women younger than 35 years, and the association of risk in women older than 55 years is complicated by the fact that the risk probably becomes less for the lobular series of lesions in women older than 60 years. Also, with regard to women older than 60 to 65 years, risk for death from other causes makes the increased risk for breast cancer less important. There is certainly no direct clinical implication of these diagnoses in an individual woman except for the acceptance of some increase in later breast cancer risk. This clinical situation is currently answered by mandating frequent mammographic surveillance.

It should be recalled that lesions now widely recognized as ALH and ADH were frequently diagnosed as lobular or ductal CIS in the 1970s and early 1980s. Thus, one of the important features of the AHs is that they avoid overdiagnosis of CIS and provide clinical implications that are clearly much less than those associated with CIS.

The specific, criteria-driven definition of ADH is widely accepted in the Americas as well as in Australia and much of Europe. The definition of ADH includes criteria of cytology as well as histologic pattern and some indication of size or extent. Basically, ADH-like lesions of uniform cytology and even placement found in areas greater than 5 to 8 mm are accepted as examples of minimal DCIS. The problem with this definition is that sometimes individual spaces are not completely involved; hence, others have used a “two-space rule,” which demands that two basement membrane-bound spaces (usually acini or ductules within lobular units) be completely involved by the same population of cells. Both approaches (extent vs. number of spaces completely involved) recognize essentially the same cases. There are a small number of cases that may be most fruitfully recognized as the borderline between ADH and DCIS. Most of these may be viewed as large examples of ADH.

The clinically practical important difference between these diagnoses is that a portion of an area with a lesion recognized as low-grade DCIS, left untreated, will eventuate in invasive carcinoma in the same site in the same breast in at least 30% of cases within 15 years.¹

Pathology of In Situ Breast Cancer

Michael D. Lagios

In situ carcinoma of the breast refers to two disparate types of lesions, with very different biologies, risks for invasive carcinoma, and treatment approaches. It is in fact a semantic anachronism that joins *lobular carcinoma in situ* (LCIS) with *ductal carcinoma in situ* (DCIS) and *Paget's disease of the nipple*, a form of DCIS involving the nipple epidermis, as a single entity.

LCIS and atypical lobular hyperplasia (ALH; generically, lobular neoplasia) are not obligate precursor lesions to invasive growth and are usually incidental microscopic features that are neither palpable nor mammographically visible. LCIS and ALH signify a variable level of risk equally distributed to either breast. In contrast, both DCIS and Paget's disease are usually obligate precursor lesions to invasive growth; are usually detected by mammography, palpation, or visual examination; and indicate a variable but substantially larger risk than LCIS as a whole, but limited to the ipsilateral breast.

What is lobular neoplasia?

The term *lobular carcinoma in situ*, coined by Foote and Stewart in 1941,¹ was meant to describe a definitive precursor lesion to invasive lobular carcinoma and to document a separate anatomic origin for lobular as opposed to all other types of invasive breast carcinoma. The original paper does not cite a specific number of cases of LCIS but suggests that the authors noted three or four, only one of which was followed prospectively. The others were examples of invasive carcinomas concurrently associated with LCIS.

Subsequent studies have shed considerable light on the biology of LCIS. The blinded retrospective follow-up studies of Rosen and colleagues,² the prospective follow-up studies of Haagensen and associates,³ and the disturbing study of Wheeler and coworkers,⁴ along with an update of Haagensen's data,⁵ challenged the concept, as set forth in 1941, that LCIS was a direct precursor of invasive lobular carcinoma. Rather, LCIS was seen to be associated with a cumulative risk for subsequent invasive carcinoma of about 1% per annum. Most important, in these early studies the risk for subsequent invasion to either breast was nearly equally distributed, a biology incompatible with a direct precursor status. Wellings and colleagues,⁶ in a three-dimensional study of cleared mastectomy specimens, put an end to speculation about a special site of origin for lobular carcinoma by demonstrating that the

terminal floret of small ductules, the lobule-acinus—or as Wellings referred to it, the terminal ductolobular unit (TDLU)—was the site of origin of most of the distinctive metaplastic, hyperplastic, and neoplastic lesions of the breast, including both *ductal* and lobular carcinoma in situ.

The current clinical paradigm synthesized from these studies regards lobular neoplasia (LCIS and ALH) as a risk marker (a morphologic lesion that indicates a patient at greater risk for subsequent invasive carcinoma) but not as a precursor lesion. The paradigm dictates that risk is equally distributed to either breast and bears no relationship to the prior biopsy site or involved margins. As a result, surgical intervention to prevent an invasive event following a diagnosis of lobular neoplasia requires bilateral mastectomy; there is no rationale for a re-excision to achieve free margins because they have no bearing on local control because subsequent invasive events have no relationship to either the biopsy site or involved quadrant. Lobular neoplasia was seen as a multicentric process, and cumulative risk for a subsequent invasive event was relatively low, about 18% at 20 years of follow-up. This paradigm for surgical and oncologic practice for lobular neoplasia has become the most prevalent but is now in flux.

Lobular Neoplasia as a Precursor Lesion

The clinical paradigm of lobular neoplasia as a marker lesion has been challenged by two more recent studies showing that most subsequent events occur in the ipsilateral breast; in one of the studies, they usually occurred within the same quadrant and were predominantly of the same histologic type (i.e., invasive lobular carcinoma).

Fisher and colleagues⁷ provide a prospective outcome for patients with lobular neoplasia—the majority ALH—entered into the National Surgical Adjuvant Breast Project (NSABP) protocol B-17 DCIS trial. After 5 years, there were six subsequent invasive breast cancers among 182 patients with lobular neoplasia: four ipsilateral and two contralateral. Five of six of these subsequent invasive carcinomas were of lobular subtype; all subsequent invasive events occurred in the same quadrant. There were also five subsequently diagnosed cases of DCIS among this group: four ipsilateral and one contralateral. In a recent update with a 12-year follow-up,⁸ 19 patients developed a subsequent invasive event; these were equally distributed to the ipsilateral⁹ and contralateral breasts.¹⁰ Fifteen of 17 invasive events were lobular or lobulotubular subtypes. Lobular neoplasia equivalent to minimal ALH exhibited a

mean annual rate of subsequent events less than one third that of more significant ALH and frank LCIS (0.55 per 100 patient-years vs. 1.84 per 100 patient-years).

Fisher noted that only 10.5% of the 181 patients with lobular neoplasia developed a subsequent invasive carcinoma within the 12-year follow-up, whereas Page and associates,⁹ in a retrospective cohort study, noted that 21% of all lobular neoplasia patients (predominantly with ALH) developed an invasive event after a mean 17.2 years of follow-up.

Page and associates,⁹ in a separate database and analyzing ALH as opposed to LCIS, noted an even greater preponderance of ipsilateral subsequent events: 70% were purely ipsilateral, 25% contralateral, and the remainder bilateral.

Impact of Lobular Neoplasia on Local Control in Programs of Breast Conservation for Invasive Disease

Regarding lobular neoplasia as a risk marker, there would be no rationale for its re-excision; in contrast, regarding it as a precursor for an ipsilateral invasive event, there would be a potential role for such re-excision. Sasson and colleagues¹⁰ identified 65 women with an LCIS component in their resections for stage I or II breast carcinoma. Subsequent follow-up revealed a threefold increase in risk for an in-breast local recurrence, as compared with non-LCIS patients (15% vs. 5%), although numbers were small. A first-order family history of breast cancer increased the 10-year cumulative incidence dramatically to 47% for patients with LCIS, as compared with 3% for those patients whose resections did not disclose this lesion. Ninety percent of in-breast recurrences were invasive in the LCIS group, and of these, 44% were of lobular or mixed lobular subtypes (4 of 9), compared with 8.3% (4 of 48) in the non-LCIS cohort. Mean interval to recurrence for true misses at the excision site was 6.9 years for the LCIS subset, compared with 3.6 years for the non-LCIS subset. Recurrence was not related to margin involvement by lobular neoplasia.

On the other hand, Abner and associates,¹¹ in a larger study of the impact of LCIS on local control in breast conservation therapy (BCT) for invasive disease, noted no increase in local recurrence at 8 years for either the presence or the extent of LCIS in surrounding tissue. Goldstein and coworkers,¹² in a compulsive analysis of factors affecting local control in BCT, also noted no impact for the presence of LCIS.

Does lobular carcinoma in situ or atypical lobular hyperplasia in a core biopsy require open excision?

The finding of either atypical ductal hyperplasia (ADH) or DCIS within a core biopsy is generally regarded as an indication for a subsequent open biopsy because of the frequency of diagnostic upgrades at excision to either DCIS or invasion. In studies of ADH, the gauge of the biopsy needle, the number of cores, the number of TDLUs with ADH, and the completeness of sampling of the mammographic target microcalcification affect the frequency of upgrades. Lobular neoplasia (LCIS or ALH) is much less frequently encountered than either ADH or DCIS in biopsies (about 1.5% or less), and the management of the patient with such a diagnosis has not been completely resolved.

A common feature of studies that have failed to document a significant number of upgrades with an initial core diagnosis of lobular neoplasia, however, is a more extensive and thorough examination of the core biopsy specimen and careful mammographic pathologic correlation. Renshaw and associates¹³ limited the number of cores per cassette to improve processing and then cut through the entire block with 10 levels for 14- and 11-gauge ultrasound and stereotactic core biopsy material. Liberman and colleagues¹⁴ noted upgrades at open excision with initial core diagnoses of LCIS in certain specific situations: when the lesion could not be definitively classified as LCIS as opposed to cancerization of lobules; when another marker lesion was present (e.g., ADH); and when the diagnosis was discordant with the mammographic target. There were no upgrades when LCIS occurred alone and when the diagnosis was concordant with imaging. Similarly, Berg and coworkers¹⁵ recommended open excision for lobular neoplasia associated with microcalcification only when the mammographic microcalcific target remained, and Bauer and colleagues¹⁶ recommended open excision only when carcinoma or another marker lesion was present. Berg and coworkers¹⁵ reported on 25 cases of lobular neoplasia (15 ALH and 10 LCIS) detected in a core biopsy (40% vacuum assisted), 16 of which went on to open excision. Only one of the excisions revealed DCIS, six showed ADH with microcalcification, and another showed DCIS but in a patient with known ipsilateral disease.

In contrast, studies that fail to adequately examine the pathology specimen, or by correlation fail to confirm that the mammography target had been sampled, indicate that open biopsy is necessary for cores with lobular neoplasia.^{17,18}

Histopathology

Morphologically, LCIS represents a solid proliferation of small cells within a TDLU and in a “pagetoid” fashion, that is, beneath the luminal epithelium of extralobular ducts. Classically, LCIS exhibits nuclear grade I (NG I) morphology (Table 8–1) and a discohesive pattern of growth. These lesions have been shown to be diploid with a low S-phase fraction (Fig. 8–1).

Distinguishing between LCIS and solid, ductal-type proliferations within a TDLU in a pattern of cancerization of lobules can be difficult, particularly when the DCIS also exhibits

Table 8–1 Ductal Carcinoma In Situ: Grading

Grade	Diameter	Nuclear Morphology		
		Chromatin; Nucleoli	Mitotic Index*	Necrosis
High	2+	Vesicular; ≥1	2+	+++
Intermediate	1–2	Coarse; infrequent	1–2	+
Low	1.0–1.5	Diffuse; none	1	0

Diameter, nuclear diameter in red blood cell diameters; chromatin and nucleoli, chromatin pattern and nucleolar development; mitotic index, number of mitoses per 10 high-power fields—numbers refer to the usual case.

*The mitotic index can be quite variable. Some high-grade lesions have rare mitoses; others exceed indexes of 20 or more.

Data from Bloom HJG, Richardson WW. Histological grading and prognosis in breast cancer. A study of 1409 cases of which 359 have been followed for 15 years. *Br J Cancer* 1957;9:359–377.

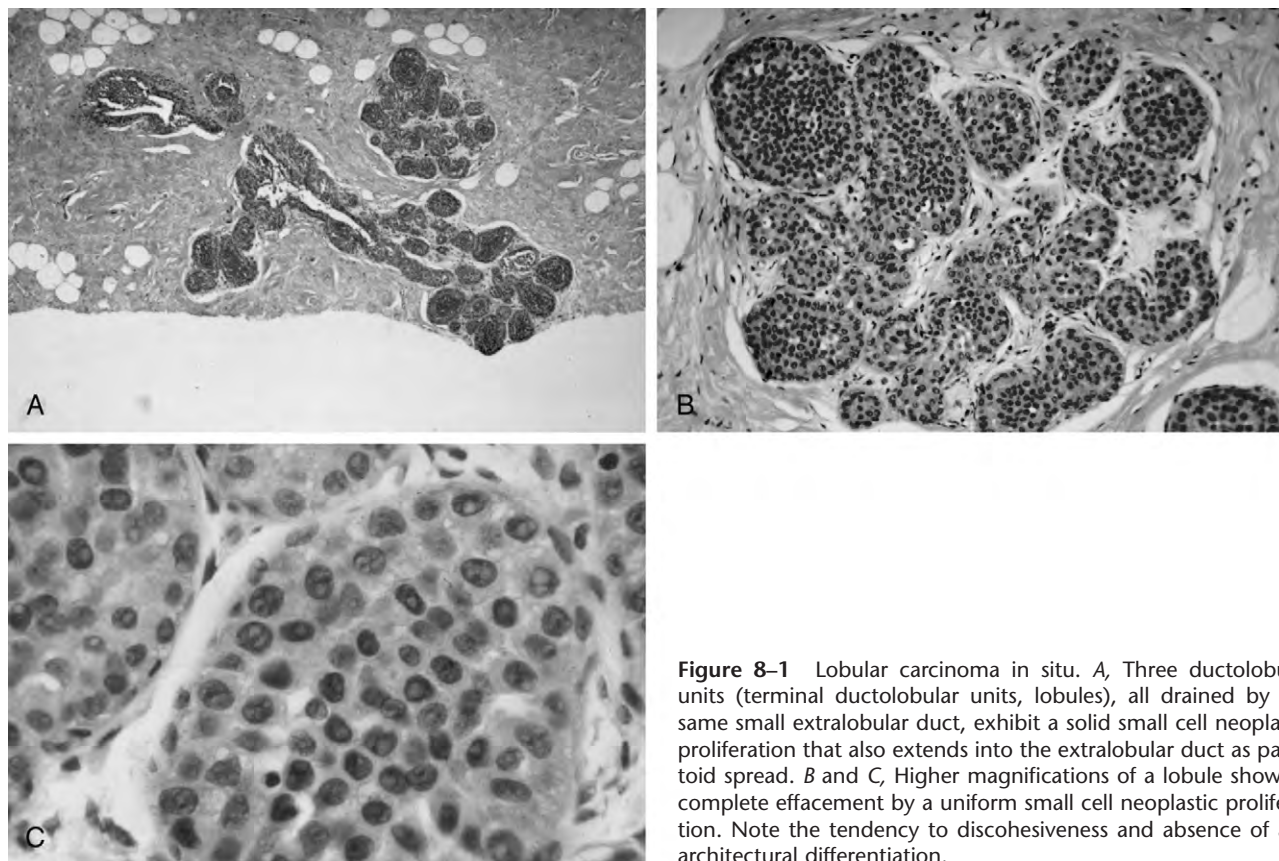

Figure 8-1 Lobular carcinoma in situ. *A*, Three ductolobular units (terminal ductolobular units, lobules), all drained by the same small extralobular duct, exhibit a solid small cell neoplastic proliferation that also extends into the extralobular duct as pagetoid spread. *B* and *C*, Higher magnifications of a lobule showing complete effacement by a uniform small cell neoplastic proliferation. Note the tendency to discohesiveness and absence of any architectural differentiation.

NG I morphology. Ductal-type lesions tend to exhibit a greater degree of cohesiveness and often demonstrate some architectural organization (e.g., subtle microacinar or cribriform structures). The recent introduction of E-cadherin immunohistochemistry has permitted the distinction of most such lesions on the basis of the presence or absence of an adhesion protein located on the cell membranes. Ductal-type lesions exhibit a pronounced membranous reaction product, whereas lobular lesions are usually negative, except for myoepithelial and residual luminal epithelial elements.¹⁹

Pleomorphic Lobular Carcinoma In Situ and Its Significance

Although lobular neoplasia characteristically exhibits small, very uniform nuclear morphology, variants that exhibit more significant nuclear pleomorphism have been long recognized. Haagensen and associates³ described *lobular neoplasia type B* as exhibiting larger and more pleomorphic nuclei but found no differences in outcome for this variant in the subsequent risk for an invasive carcinoma. Similarly, Bodian and colleagues,⁵ in an update of this database, were unable to demonstrate a significant difference in risk related to the nuclear morphology and cytology of the process.

A small fraction of such cases exhibit zonal necrosis (comedonecrosis) and dystrophic microcalcification, and are detected by mammographic surveillance, as is DCIS. In the recent past, many of these lesions were likely to be classified as DCIS with comedonecrosis and so treated (Fig. 8-2). Only since the recent introduction of E-cadherin immunohistochemistry has the identification of such variant lobular

Figure 8-2 Interval development of pleomorphic microcalcification in the left breast in a 51-year-old patient.

neoplasias become feasible (Fig. 8-3). Several studies have now shown that lobular neoplasia characteristically loses an adhesion molecule (E-cadherin), which ductal lesions exhibit uniformly. New studies have shown some differences in biomarkers between typical examples of lobular neoplasia and pleomorphic variants. Sneige and associates²⁰ noted that patients with pleomorphic LCIS exhibit a much higher percentage of Ki-67 (47% of patients with Ki-67 greater than 20%) and p53 (30% of patients) than typical lobular neoplasia. They reported a short (mean, 17-month) follow-up of seven patients with pleomorphic lobular neoplasia, five of

Figure 8-3 E-cadherin immunohistochemistry. Three duct spaces on the right represent columnar alteration with prominent apocrine snouts. Note the uniform cell membrane reaction product with E-cadherin antiserum characteristic of ductal proliferations. On the left, pleomorphic lobular carcinoma in situ shows no such reaction product, except for myoepithelial elements at the duct periphery and surrounding the pseudocribiform spaces, which are invaginations of the ductal wall.

whom had undergone needle-localized excision and had a breast at risk. Only one of these five had a recurrence; this patient had an initial margin smaller than 1 mm that was additional pleomorphic lobular neoplasia. Georgian-Smith and Lawton²¹ reported that two of five patients with pleomorphic lobular neoplasia undergoing excision exhibited invasive lobular carcinoma but provided no follow-up data on cases with pleomorphic lobular neoplasia alone after excision. Fisher and colleagues⁷ relegated all comparable cases of pleomorphic lobular neoplasia (*ductolobular carcinoma in situ*, in their terminology) to treatment as DCIS in the NSABP B-17 protocol.

Because knowledge of the biology of pleomorphic lobular neoplasia, particularly of the type detected by microcalcification, is presently so limited, treatment will necessarily represent speculative projections based on the significance of more pleomorphic nuclear morphology, higher proliferative index, or p53, but not on outcome studies. Although it would appear reasonable to excise pleomorphic lobular neoplasia in cases in which the mammographic target has only been sampled, re-excision for the presence of the histologic finding alone near or at a margin may be over-reaching.

How does lobular carcinoma in situ differ from atypical lobular hyperplasia?

LCIS differs from ALH only by degree morphologically and biologically; both are risk markers. Current criteria for LCIS established by Page and Anderson²² require uniform effacement of the ductular architecture and uniform involvement of the entire lobule with significant distention of each terminal ductule. In practice, this generally requires distention of the affected ductule equivalent to the sum of the diameters of six to seven neoplastic cells or more. Lesser degrees of involvement are classified as ALH. Biologically, ALH is associated with a lesser relative risk for breast cancer; women with ALH have about four or five times the risk of the general population, and their risk is also influenced by a first-order

family history (mother, sister, daughter) and menopausal status. The presence of a first-order family history in a premenopausal patient essentially doubles the relative risk for ALH.^{23,24} Such a patient experiences a risk similar to that associated with LCIS itself. In patients with ALH who are postmenopausal, in contrast, the relative risk is lower than that associated with proliferative breast disease in a premenopausal patient (relative risk [RR] of 2.6).²⁴

From the therapeutic point of view, patients with LCIS and ALH, both of which generically are lobular neoplasia, receive no benefit for local control from attempts at re-excision—the risk remains the same. Lobular neoplasia tends to be diffuse in the ipsilateral breast, in contrast to the segmental distribution of DCIS, and may occur in the contralateral breast in some 30% to 35% of cases. There is no medical rationale for the ipsilateral treatment of lobular neoplasia, and the cumulative risk even at 20 years of follow-up does not warrant the treatment popular 20 years ago, which was bilateral total mastectomy. Well-documented cases of invasive carcinoma occurring after mastectomy for LCIS exist²⁵ and emphasize the limitations of a surgical approach to a diffuse disease in a nonencapsulated organ system.

What is ductal carcinoma in situ?

DCIS and Paget's disease of the nipple, by contrast with lobular neoplasia, are variably obligate precursors to invasive growth with risk limited to the ipsilateral breast. Unlike LCIS, DCIS and Paget's disease are infrequently bilateral at their discovery, and in follow-up series of treated DCIS, the risk for contralateral disease remains low, comparable to that seen for invasive carcinoma.

In contrast to LCIS, DCIS exhibits an exceedingly heterogeneous appearance in regard to both nuclear morphology or grade and histologic (i.e., architectural) pattern. Moreover, a significant number of DCIS cases exhibit a spectrum of nuclear grades and architectural patterns within a single lesion.²⁶

How is ductal carcinoma in situ detected?

DCIS has only recently been clearly separated from invasive carcinoma and had been considered the same disease in actual practice.²⁷ In the early 1970s, DCIS constituted 2% to 5% of all new breast cancer diagnoses. Mammographic technology increased this rate 7- to 10-fold within a few years of its introduction.^{28,29} Before mammography became available, DCIS was generally an extensive or diffuse disease that presented as a clinical mass, nipple discharge, or concurrent Paget's disease. DCIS was frequently associated with occult areas of invasive growth detected at mastectomy (the only available treatment at the time) but was rarely associated with axillary metastases. Mammographically detected DCIS, in contrast, had generally progressed to a far more limited extent, was less frequently associated with invasive growth, and never exhibited axillary metastases. The small size at which DCIS was detected with mammography led to attempts at BCT, and this shift in approach formed the basis for the explosive interest in the disease that followed. These studies have demonstrated that DCIS comprises numerous entities, all with distinctive

Figure 8-4 Specimen radiograph of 11-gauge cores. Note that most of the microcalcification is spherical.

Figure 8-5 Uniform proliferation with pseudocribriform spaces in pleomorphic lobular carcinoma in situ. Note the large psammomatous microcalcification (arrow).

biologies and risks for progression. Clearly, DCIS is biologically as well as morphologically very heterogeneous, like invasive breast carcinoma itself. It became clear from studies of BCT that not all DCIS progresses to invasive growth within a given follow-up period; rather, it is possible to provide for local control of this disease without a mastectomy. Moreover, there is a relationship between the morphology of the DCIS and the risk for local recurrence and invasion,^{30–34} as well as a relationship between extent of disease and the risk for invasion.^{29,35} More recently, the impact of the size and margin status of DCIS on local recurrence rate has become clear.^{33,36}

What are the pathologic determinants of clinical outcome for ductal carcinoma in situ with breast conservation?

Three features largely determine clinical outcome for attempts at BCT in DCIS: (1) the *grade* of the DCIS; (2) the *extent* or size in the carcinoma; and (3) the *width* and adequacy of the resection margins.

The grade or subtype of the DCIS is currently based on the nuclear grade and the presence of comedonecrosis. This system has begun to supersede an older, conventional classification based largely on the architectural features of DCIS (e.g., solid, cribriform). The older system provides little prognostic separation for DCIS patients and has been largely abandoned. Nuclear grading for DCIS follows the Bloom Richardson System (see Table 8-1). For purposes of clinical classification, patients with NG III lesions and comedonecrosis of any extent are classified as having high-grade lesions (Fig. 8-4). A small group of NG III DCIS cases in which comedonecrosis is not detected are also included in the high-grade subset. Intermediate-grade lesions are variously defined as NG II with or without necrosis or NG I and II with necrosis^{28,30,33}; low-grade DCIS is variously defined as NG I without necrosis or NG I and II without necrosis (Fig. 8-5). Analyses of outcome by grade, whether by the criteria of Lagios and associates^{32,37} or Silverstein and colleagues,^{30,33} are comparable (Table 8-2).

High-grade DCIS as defined here has been shown to have the highest frequency of local recurrence and invasive

Table 8-2 Van Nuys Prognostic Index Scores in Ductal Carcinoma In Situ*

transformation of the three subtypes.^{32–34,38} Comparably defined high-grade DCIS^{39,40} shows similar high frequencies of local failure.

Outcomes of BCT for high-grade DCIS depend a great deal on the extent of the DCIS in the breast and the adequacy of the resection margins. For example, high-grade DCIS of small size (<15 mm) and with margins of 10 mm or more has an 8% local recurrence rate at 7 years of follow-up without irradiation and a 0% recurrence rate with irradiation. Patients with high-grade DCIS with more extensive disease in the breast or narrower margins are at greater risk for local recurrence, but the risk can be somewhat reduced with successful attempts at re-excision to produce more adequate margins.^{33,38}

The Van Nuys Prognostic Index (VNPI) provides a method for weighing these three prognostic features (grade, extent, and width) that is most useful for high-grade DCIS (Table 8-3).

In the VNPI system, scores of 3 and 4 are associated with excellent local recurrence-free survival at 8 years without irradiation. Patients with scores of 5, 6, and 7 have an intermediate local recurrence-free survival and benefit from radiation therapy, but the actual benefit is only 14% over those who do

not receive radiation. Patients with scores of 8 and 9 have very poor local recurrence-free survival with BCT and are candidates for mastectomy. For high-grade DCIS, two thirds of the nine prognostic subtypes are amenable to breast conservation (with or without irradiation), and the remaining three may be candidates if their margins were reduced by re-excision (see Table 8-3).

In intermediate-grade DCIS (group II, NG I and II with necrosis), all VNPI scores are compatible with BCT except for a single prognostic subset with the largest extent of disease (>41 mm) and with inadequate margins (Table 8-4).

Among low-grade DCIS (NG I and II without necrosis), all nine subsets are amenable to BCT. One third would expect no benefit from irradiation, and two thirds could achieve a lower score after a successful re-excision with wider margins (Table 8-5).

Conventional pathologic classification of DCIS has been based predominantly on architectural pattern. Papillary, cribriform, micropapillary, and solid growth patterns were recognized as specific types of DCIS. Central coagulative or comedonecrosis within DCIS was often interpreted as a

specific type of DCIS with the term *comedo-type DCIS*. A solid growth pattern and central necrosis would define most cases of comedo-type DCIS, although it was the only conventionally defined DCIS for which a specific nuclear morphology (i.e., high grade or NG III) was included as a characteristic if not requisite diagnostic feature. The remainder of conventionally classified DCIS cases were defined on the basis of predominant architectural patterns regardless of nuclear grade (Figs. 8-6, 8-7, 8-8, and 8-9).

Follow-up studies have shown that such features are not significant as prognostic indicators. A, Solid growth pattern; B, cribriform growth pattern; C, micropapillary growth pattern; D, contrasting micropapillary DCIS with low nuclear grade (NG I) at the same magnification.

How does age affect local recurrence rate in ductal carcinoma in situ?

Age at diagnosis is frequently cited as one of the significant, nonpathologic prognostic variables for local control in programs of breast conservation with irradiation for DCIS. Vicini and colleagues^{41,42} noted a greater than threefold increase in local failure among patients younger than 45 years (26.1% vs. 8.6%) in their series of DCIS patients. However, the high rate of local failure in these patients was associated with smaller excision volumes. Among patients who underwent re-excision, the actuarial rate of true recurrence-to-marginal miss was significantly greater only in those patients with excision volumes of less than 40 mL. This variable had the highest *P* value (*P* = .005) for ipsilateral breast failure at 10 years in their study.

Silverstein³⁸ has shown a significant increase in local in-breast failures for DCIS patients younger than 40 years—a relative risk 2.5 times that of women 60 years of age and older. However, if this small subset of patients (7% of the patient database) is stratified by margin width 10 mm or greater or negative re-excision, the added risk of younger age disappears for low- and intermediate-grade DCIS patients and is markedly reduced for younger patients even with high-grade lesions.

These observations suggest that much of the adverse impact of younger age on local recurrence reflects a bias toward breast

cosmesis resulting in smaller excision volumes with a greater likelihood of inadequate surgical resection. An extensive intraductal component (EIC) previously had been shown in analogous fashion to affect local control only when the margins of resection were inadequate or the entire extent of the component was not included in the resection.

What is the importance of pathology practice in determining treatment of ductal carcinoma in situ?

All discussions of DCIS must take into consideration the variations in tissue sampling and capabilities of identifying margins that are encountered in pathology practice. These limitations, not obvious in a statistical analysis of a population, come into sharp focus in a second-opinion practice for individual patients. A recent example illustrates this point: A 49-year-old grammar school teacher sought a consultation for a palpable and mammographically evident focus of DCIS. Formal request for the slide materials resulted in receipt of 2 of 4 slides prepared of a biopsy described as 5 × 4 × 3 cm. The 2 slides demonstrated intermediate-grade DCIS extending to the margins and no microinvasion. An inquiry to the reference laboratory obtained the release of the remaining slides and also revealed that sufficient unsampled wet tissue

Figure 8-8 Necrosis and microcalcification. *A*, Central zones of necrosis in this high-grade ductal carcinoma in situ (DCIS) have a linear distribution following the anatomy of the extralobular ducts and terminal ductolobular units. Dystrophic microcalcification deposited in the necrotic debris results in a linear and branching mammographic pattern characteristic of DCIS with comedonecrosis. *B*, High-grade DCIS with central comedo-type necrosis (*top right*). Note karyorrhectic fragments with the debris. *C* and *D*, Psammomatous microcalcifications tend to be rounded both mammographically and microscopically. They can be seen as laminated in favorable preparations. They are characteristic of DCIS, exhibiting a papillary and cribriform architecture, and are generally associated with lower-nuclear-grade DCIS. Psammomatous microcalcifications do not require necrotic debris but represent calcification within proteinaceous secretions of the neoplastic epithelium.

remained to require 9 additional blocks. One of the 9 additional slides, 1 of the total of 13 now prepared, contained a T1a invasive carcinoma. Such foci of microinvasion and minimal invasion profoundly affect local recurrence rates in the ipsilateral breast, particularly in situations in which radiation therapy is not offered.

Some would argue that because of current practice standards in pathology, all presumptive DCIS patients would benefit (statistically) from radiation therapy, given that pathology practice is “immutable.” This is a costly presumption given the expense, time, and in some cases morbidity that radiation therapy entails. In addition, it is important to remember that radiation therapy can be utilized only once, and its use in a prophylactic setting will obviate its more effective use for a future invasive recurrence. In this specific example, the cost saved by not processing the additional 9 blocks is about \$56.70 (at \$6.30 total cost per slide for processing). In contrast, the expense, on average, of radiation therapy is \$15,000 (80% Medicare reimbursement for whole breast exclusive of node bearing tissues = \$7000).

Data on local recurrence-free survival from my prior work^{29,32,43} was obtained with thorough pathologic evaluation of the biopsy and the re-excision. This type of examination

mandates that all of the biopsy sample be processed and in sequence, that all margins be inked and evaluated, and that microinvasion or greater areas of invasion be excluded. This requirement is now generally recognized.^{35,44,45} Treatment options for DCIS that exclude radiation therapy in programs of BCT will not be successful without the requisite thorough pathologic examination.

Although this discussion focuses on the pathologic aspects of noninvasive carcinoma, some mention must be made of the controversy surrounding radiation therapy for DCIS. Our work on DCIS antedates the first of the more recent publications on radiation therapy for DCIS by 9 years,⁴⁶ at which time we had a growing experience with BCT for DCIS without irradiation.²⁹ Most of the studies on radiation for DCIS have been conducted by single institutions without a comparison arm.

Three published randomized trials of radiation therapy in programs of breast conservation for DCIS have all shown a 50% significant benefit in reducing ipsilateral local recurrences. However, the outcome data from these trials are limited by the now historic, suboptimal pathologic practice employed at the time. Both NSABP B-17 and EORTC 10853^{40,47-51} entered patients without prospective mammographic pathologic correlation and with incomplete sampling

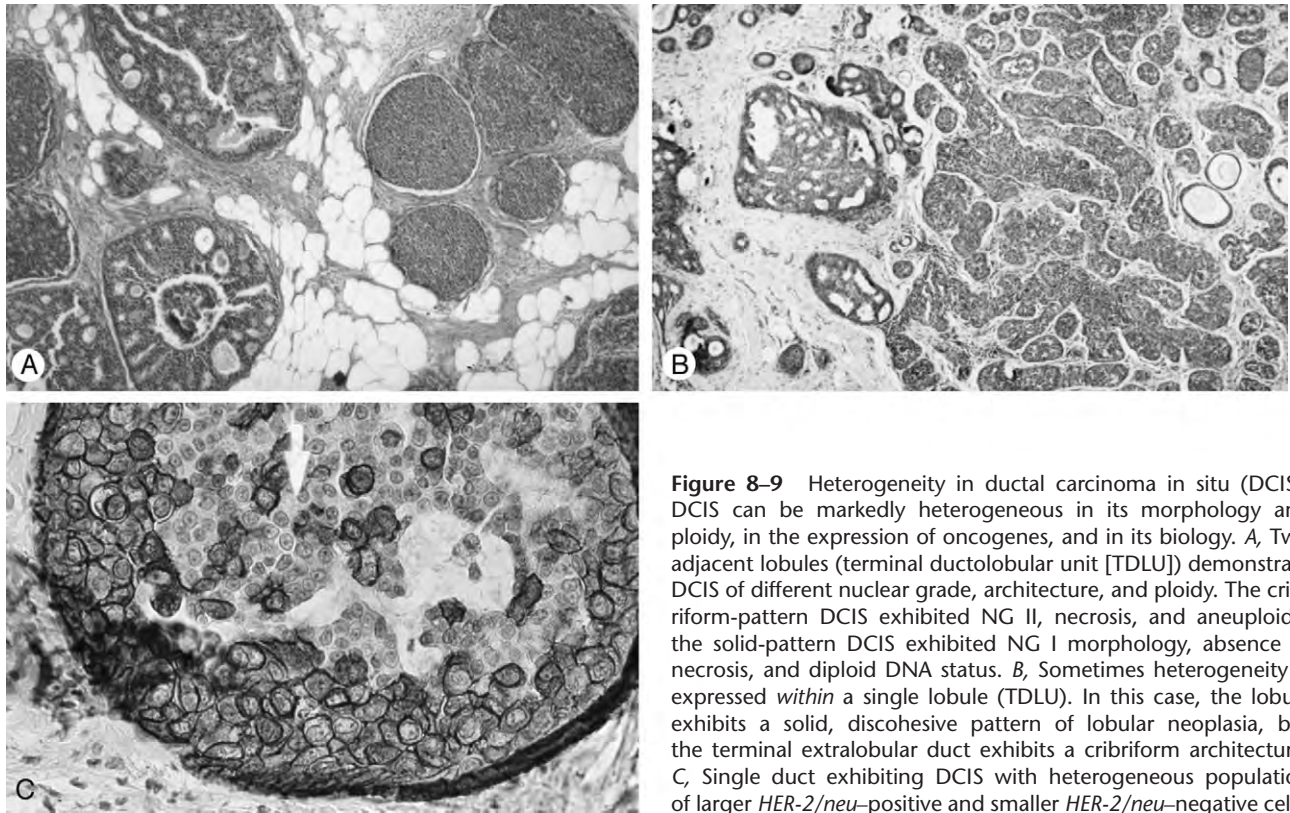

Figure 8-9 Heterogeneity in ductal carcinoma in situ (DCIS). DCIS can be markedly heterogeneous in its morphology and ploidy, in the expression of oncogenes, and in its biology. *A*, Two adjacent lobules (terminal ductalobular unit [TDLU]) demonstrate DCIS of different nuclear grade, architecture, and ploidy. The cribriform-pattern DCIS exhibited NG II, necrosis, and aneuploidy; the solid-pattern DCIS exhibited NG I morphology, absence of necrosis, and diploid DNA status. *B*, Sometimes heterogeneity is expressed *within* a single lobule (TDLU). In this case, the lobule exhibits a solid, discohesive pattern of lobular neoplasia, but the terminal extralobular duct exhibits a cribriform architecture. *C*, Single duct exhibiting DCIS with heterogeneous population of larger *HER-2/neu*-positive and smaller *HER-2/neu*-negative cells.

of the resected tissue and therefore with an inherent inability to define margin status accurately and exclude invasion. Inking of margins was not required in B-17 or the UK/ANZ trial, and margins were defined as positive only when transected in all three trials.^{40,48,52-54} The local control rate achieved with radiation therapy in these circumstances was suboptimal. In B-17, a local recurrence rate of 7% at 43 months was reported, with 16% at 12 years in the irradiated arm. In EORTC 10853, the local recurrence rate was 11% at 8 years. The UK/ANZ trial achieved a superior local control rate of 4.8% (vs. 9% EORTC and 10% B-17) at 5 years of follow-up.

Because the age of the patients was comparable in the EORTC 10853 trial and the UK/ANZ trial, this difference probably reflects a well-developed pathologic protocol that requires determination of disease extent and mammographic pathologic correlation, with extensive excision of margins and with inking of margins advised in the UK/ANZ trial. However, 3% of patients had “microinvasion,” and breast cancer mortality at 52 months’ median follow-up was 2.6%, comparable to the rates in the EORTC and B-17 trials. A similar overall breast cancer mortality rate is seen in the VNPI database only at 12 years, but this largely reflects progressive disease in patients whose previous radiation therapy obscured and delayed discovery of local invasive recurrences.⁵⁵

In summary, all of the published randomized trials are limited by a type of pathology practice that was current at their inception in 1985 and 1986. The quality of mammography, localization procedures, and need for correlation and pathologic techniques today are quite different from those that existed at that time. The conclusions of these trials cannot be projected into contemporary practice, for which they were not designed and for which they are largely noninformative. This

is particularly true regarding their inability to define low-risk subsets, for which irradiation provides little if any benefit.

Previous studies of radiation therapy in DCIS had shown that local recurrences increase substantially after 5 years, and in all studies with 5- and 8-year comparisons, the local recurrence rate at least doubled by 8 years.^{56,57} These studies had shown that radiation therapy is very effective for local control within the first 5 years, but as noted by Solin and coworkers, the in-breast local recurrence rate is 16% by 86 months (i.e., 7 years) and 19% at 15 years.^{31,57} Fisher and colleagues,⁵⁰ in a further update of B-17, noted a local recurrence rate of 16% in the irradiated arm at 12 years. Although these local recurrence rates are roughly half of the rate in the nonirradiated arm in B-17 and EORTC 10853, they are very high relative to control rates for invasive breast cancer with radiation therapy. An actuarial analysis of our initial 79 patients,³² none of whom received irradiation or tamoxifen, demonstrates a 19% local recurrence rate at 15 years of follow-up.³⁷ Although these patients were carefully selected for size and margin status, this recurrence rate is comparable to that reported by Solin and coworkers⁵⁸ and Fisher and colleagues⁵⁰ in studies that included irradiation.

The conclusions of Silverstein and associates^{33,36,38} provide a marked contrast. These studies were all based on complete tissue processing, evaluation of margins, and a consistent analysis of pathologic subtype. All cases reported were complete with regard to grade size and margin analysis. There was no difference in local recurrence-free survival with or without irradiation in patients with low- and intermediate-grade DCIS at 82 months, and there was only a modest benefit of radiation therapy (14%) in patients whose sum prognostic index score was 5, 6, or 7. Because low- and

intermediate-grade DCIS cases constitute more than 50% of all DCIS cases, a substantial portion of the 25% to 30% of newly diagnosed DCIS cases will not require irradiation for local control.

What is Paget's disease of the nipple?

Paget's disease of the nipple represents in situ carcinoma within the nipple epidermis, where it commonly simulates an eczematoid inflammatory response (Fig. 8–10). Most cases of Paget's disease of the nipple, in contrast to the same disease in the anogenital area, are associated with underlying demonstrable breast carcinoma, either DCIS or invasion.

Historically, Paget's disease was thought of as an epidermotropic carcinoma (i.e., cancer cells originating in the ducts) that migrated to the nipple epidermis either through the duct system or by direct invasion or lymphatic permeation. In most cases, the pathologic findings at mastectomy were at least consistent with this hypothesis, with frequently demonstrated

Figure 8–10 Paget's disease limited to the nipple epidermis. Note the distribution of the Paget cells from the basal portion of the epidermis into the stratum corneum. Paget cells are carried by the growth of the epidermis to its surface, like melanoma, but many Paget cells tend to exhibit maturation with nuclear and cytoplasmic changes similar to that of the adjacent non-neoplastic keratinocytes.

contiguous DCIS involving one or more distal lactiferous duct profiles or invasive carcinoma underlying the epidermis itself.

Where does Paget's disease originate?

Paget's cells are usually large with pleomorphic nuclei and exhibit immunohistochemical markers similar to DCIS (e.g., *HER-2/neu*, estrogen and progesterone receptors, AE1 cytokeratin, casein, carcinoembryonic antigen, and lactalbumin).⁵⁹ The prevalent association of Paget's disease with underlying breast cancer and its distinctive immunohistochemistry supported the concept of epidermotropism. As a consequence, BCT was not considered for patients with Paget's disease.

There are, however, a number of discrepancies in the epidermotropic concept of Paget's disease. Ashikari and associates⁶⁰ reported that in 2.8% of patients undergoing radical mastectomy for Paget's disease, no underlying carcinoma could be found. Excluding patients with palpable abnormalities raised this frequency to 6%.

It was clear even before the availability of mammography that in some patients, Paget's disease of the nipple is limited to the epidermis, the predominant pattern seen in anogenital Paget's disease. If Paget's disease can exist without underlying carcinoma in 6% of patients without a palpable mass, then underlying carcinoma with epidermotropic tendencies will not account for this distribution. Where do Paget's cells originate?

Some older, as well as more recent, studies of Paget's disease would suggest an intraepidermal origin. Darier in 1889⁶¹ described what he interpreted as parasites in the stratum corneum of Paget's but what we would now interpret as corps ronds, that is, abnormal nuclei exhibiting a kind of parakeratosis as they mature into the more superficial epidermis. They can be detected in exfoliative cytologic analyses with an appearance reminiscent of cervical intraepithelial neoplasia. More recent morphologic evidence demonstrates complex tripartite desmosomal attachments with abundant tonofibrils between Paget cells and keratinocytes,^{62–64} similar to those developed between keratinocytes in the stratum malpighii, and the presence of specific types of cytokeratins within Paget cells that are shared with epidermal basal epithelium.⁶⁵ These findings support a neoplastic origin of Paget cells within the epidermis of the nipple itself, rather than some mysterious traverse of an in situ carcinomatous cell through an intact benign ductal epithelium and epidermis. Recent studies comparing the clonality of Paget cells and underlying carcinoma support separate origins in at least some cases.⁶⁶ One can then think of Paget's disease and underlying breast cancer as separate events. When DCIS involves underlying distal lactiferous ducts, it can be regarded as multifocal in distribution. When, as not infrequently occurs, the underlying carcinoma is separated by 8 cm or more of uninvolved breast, it can be regarded as multicentric.

How might pathologic assessment of Paget's disease affect treatment?

With greater surveillance for breast cancer in recent decades, a larger proportion of Paget's cases can be identified without either palpable or mammographic findings. In a select few

patients, an initial alternative to mastectomy is complete nipple-areolar resection. Based on a methodical analysis of the nipple-areolar resection, patients can be categorized as having either (1) limited or more extensive noninvasive disease or (2) invasive disease. Patients with limited noninvasive disease have either Paget's disease alone (epidermal involvement) or Paget's disease and DCIS. If the ductal and epidermal margins were free, we had proposed⁶⁴ follow-up alone as a treatment option. It should be understood that this option can be offered only when meticulous and complete pathologic examination and correlative preoperative imaging are available. Eleven patients who had elected the breast conservation option without irradiation and who were previously reported⁶⁴ were updated through 1992. Two of these patients developed ipsilateral recurrences at 128 and 65 months. Two other patients died without recurrences, one of congestive heart failure after 49 months and the other of a cerebrovascular accident after 60 months.

Of the 11 patients not receiving radiation therapy, 1 patient had recurrence after 128 months after initial treatment with an axillary tail de novo breast cancer, a T1b node-negative mucinous carcinoma of low grade. She was treated with re-excision and radiation therapy and remains without evidence of disease at last follow-up. The second patient, who was the youngest in the series (38 years old) at the time of the initial diagnosis, developed a T1c N1 duct carcinoma recurrence at 65 months of follow-up. She underwent modified radical mastectomy but developed a chest wall recurrence and concurrent distant metastases 18 months later and died of brain and liver metastases after 98 months of follow-up. More recent discussions on conservative management for Paget's disease have adopted similar approaches but have advocated radiation therapy.^{67,68}

Breast conservation for Paget's disease is a practical option only when the underlying disease in the breast is limited and can be resected with some semblance of adequate margin. Kothari and colleagues,⁶⁹ in a retrospective study, concluded that breast conservation is not an acceptable option for patients presenting with clinical Paget's disease based on a pathologic analysis of the extent of disease in mastectomy specimens, but their accrual period (1977 to 1999) would suggest patients with more extensive disease than seen currently. In their analyses, however, 25% of their patients had disease limited to the central quadrant, and 41% exhibited central quadrant and less than one additional quadrant of involvement. Twenty-nine percent of cases exhibited only DCIS, with a 96% overall survival rate at 20 years of follow-up; 17 cases were node negative and exhibited a 68% overall survival rate at 20 years of follow-up.

A recent study and subsequent update of BCT in patients presenting with Paget's disease without underlying palpable mass or mammographic density have concluded that breast conservation provides excellent local control. Pierce and coworkers⁷⁰ note 5- and 8-year actuarial estimates of local failure rate as the only site of failure of 9% and 16%, respectively, among 30 cases in a collaborative multi-institutional study. Only one of the 30 cases exhibited microinvasion; the remainder were entirely noninvasive in an examination of the nipple-areolar resection. In an update of this database, Marshall and associates⁷¹ noted a 97% cause-specific survival rate and a 13% breast-only local recurrence rate as first failure rate at 15 years of follow-up.

SUMMARY

In situ carcinomas of the breast represent a morphologically and biologically diverse assemblage of noninvasive lesions whose clinical significance has only been partially clarified in the past 20 years. Therefore, treatment options for these lesions are still evolving and often result in contradictory recommendations for management.

LCIS (lobular neoplasia of Haagensen) is presently understood to represent a marker for increased risk rather than a precursor lesion. LCIS has a predominantly multicentric distribution in the ipsilateral breast, is significantly bilateral, and is associated with a modest but cumulative risk for subsequent invasive breast cancer of about 1% per annum, equally distributed to either breast. Some recent studies describe a predominantly ipsilateral risk for subsequent invasion, but not at the level associated with DCIS. LCIS differs only quantitatively from ALH. ALH is affected by both first-order family history and menopausal status. LCIS and ALH are not surgically resectable diseases, except by bilateral total mastectomy. Education, reassurance, and appropriate follow-up examination are the most rational approaches to these diseases.

DCIS, in contrast, is a segmental disease in the ipsilateral breast and can be an obligate precursor to invasive growth. The grade, extent of the lesion, and status of the margins all determine the risk for local recurrence after attempts at BCT. Young age variously defined as younger than 40 or 45 years also has a significant impact on local recurrence rates in programs of breast conservation, but not when corrected for the adequacy of the resection. Surgical intervention with adequate margins is the most rational treatment option for this disease. Radiation therapy has provided limited benefit to certain subsets of patients, but its use in this setting is not as successful as when used for invasive carcinoma.

Paget's disease of the nipple based on all the available evidence most likely represents a separate intraepidermal manifestation of DCIS. It is usually, but not invariably, associated with underlying duct carcinoma, either in situ or invasive.

Pathology of Invasive Breast Cancer

Ira J. Bleiweiss and Shabnam Jaffer

Invasive carcinoma of the breast is truly the *raison d'être* for all modern methods aimed at prevention, early diagnosis, and treatment of breast cancer. Even the diagnosis and treatment of intraductal carcinoma (ductal carcinoma in situ [DCIS]) is, in effect, aimed at the prevention of invasive carcinoma, largely because breast cancer has no lethal potential unless it is invasive. It is clear that one of the major contributions of high-quality mammography has been the detection of breast carcinoma before it has become invasive, thereby saving lives.

Invasive carcinoma is pathologically defined as malignant cells that have gained access to the stroma of the breast, no longer being delimited by the natural boundary of the basement membrane, the wall that surrounds the entire ductolobular system of the breast. By doing so, the tumor cells also, at least theoretically, may gain access to the lymphatic or vascular system, potentially giving rise to distant metastases, often with lethal consequences. The likelihood of this occurrence is directly proportional to the size of the invasive component, as will be discussed later; thus, the second great advance made possible by modern breast imaging is the detection of non-palpable invasive carcinomas small enough to have not yet metastasized at the time of their diagnosis.

This chapter describes the two main histologic types of invasive carcinoma of the breast: invasive duct carcinoma and invasive lobular carcinoma. Together they constitute the vast majority of infiltrative malignancies that will be encountered in routine practice. Also discussed is invasive tubulolobular carcinoma, a variant that has combined features of the two but is probably more closely related to the lobular phenotype. Issues regarding histologic prognostic factors, margins, and pathologic specimen handling are also addressed.

What is invasive duct carcinoma?

Invasive duct carcinoma is the most common form of infiltrative malignancy of the breast. It is something of a misnomer because the name implies ductal origin, yet most carcinomas of the breast are thought to originate at the level of the terminal ductolobular unit (TDLU). It is typically a unifocal lesion, but it encompasses a wide spectrum of histologic appearances ranging from gland-forming to solid undifferentiated proliferations and is something of a catch-all term for invasive tumors showing no specific histology but composed of larger cells. Thus, the terms *carcinoma, not otherwise specified* and

carcinoma, no special type have been applied. Standard methods of histologic grading account for these varying microscopic patterns and are discussed later.

What are the pathologic features of invasive duct carcinoma?

Invasive duct carcinoma is composed of accumulations of large cells that have broken free of the restraints of the ductolobular system to infiltrate the fibrous and fatty stroma of the breast, usually in a haphazard manner (Fig. 9-1). This perturbation of the normal milieu is detected by the body, and dense fibrosis is produced in reaction to it, the so-called desmoplastic response, frequently accompanied by variable degrees of chronic inflammatory cells. The desmoplastic response can be extremely intense, as in scirrhous carcinoma (Fig. 9-2), or it may be minimal. The irregular patterns in which the tumor cells invade are a model on which the fibrous response is laid down, and thus the usual invasive duct carcinoma is a mass with ill-defined, irregular borders (see Fig. 9-1) correlating with a stellate radiodensity mammographically, a solid lesion sonographically, and, often, a palpable tumor. In the current era of breast imaging, it is not uncommon for such lesions to be detected well under 1 cm in size, below the generally accepted threshold for clinical palpability; however, invasive tumors of all sizes from microinvasive (<1 mm) to those replacing the breast may also be encountered.

Grossly, a typical invasive duct carcinoma is a hard mass, distinct from its surrounding tissue, tan-white with ill-defined, irregular borders, although some, usually higher grade, tumors are well circumscribed. The low-power microscopic findings mirror the gross appearance in that the advancing edge of the tumor shows an irregular but usually definable interface with the adjacent benign breast tissue (see Fig. 9-1). These findings are generally due to the tendency for invasive duct carcinoma to provoke fibrosis in its path. Thus, the gross and imaging (especially sonographic) measurements of the tumor tend to correlate with the microscopic size of the lesion fairly accurately, especially when the immediately surrounding breast tissue is fatty rather than fibrous. Microscopically, most invasive duct carcinomas are characterized by large tumor cells with abundant, typically lightly eosinophilic cytoplasm; the cells usually infiltrate in groups, retaining intercellular adhesion, often either forming small,

Figure 9-1 Invasive carcinoma. Nests of gland-forming tumor cells infiltrate surrounding fatty breast tissue in a haphazard fashion (arrows), forming the leading edge of the tumor. An incidental benign cyst is present on the right (arrowhead).

occasionally back-to-back (cribriform) glands or aggregating in nests. They have increased nuclear-to-cytoplasmic ratios with varying degrees of nuclear pleomorphism and mitotic activity. A nearly infinite variety of invasive growth patterns are possible either in isolation or in combination. A central part of the histologic evaluation of invasive duct carcinoma is

Table 9-1 Histologic Grading of Invasive Duct Carcinoma

Histologic Parameter	Score

Data from Elston CW, Ellis IO. Pathological prognostic factors in breast cancer. I. The value of histologic grade in breast cancer: Experience from a large study with long-term follow-up. *Histopathology* 1991;19:403–410.

its classification as well, moderately, or poorly differentiated, that is, determination of histologic grade.

What is the value of histologic grading and how is it performed?

Histologic grading is an essential aspect of routine microscopic examination of invasive duct carcinoma. The prognostic value of grading has been amply and repeatedly demonstrated.¹ As might be expected, well-differentiated invasive duct carcinomas (Fig. 9-3) confer a better prognosis than those that are moderately differentiated (Fig. 9-4), which, in turn, confer a better prognosis than those classified as poorly differentiated. In a similar vein, a patient with a poorly differentiated invasive duct carcinoma (Fig. 9-5) will be far more likely to have axillary lymph node metastasis than one with a well-differentiated tumor, given invasive tumors of the same size; a tumor considered moderately differentiated will have an intermediate risk. The grading schemes commonly in use today are largely based on the findings of Bloom and Richardson² and include the assessment of three parameters: amount of gland or tubule formation, degree of nuclear atypia or pleomorphism, and mitotic rate. Although their evaluation is fraught with greater or lesser degrees of subjectivity, reasonable consistency can be obtained,³ especially using the Nottingham modification of the Bloom-Richardson criteria. This scheme is the one in most frequent use today and is recommended by most authorities because of its consistent success in prognostication.⁴ It provides specific guidelines in order to assign scores to each of the three criteria. The individual scores are totaled to reach an overall point total that determines the assigned tumor grade (Table 9-1). The system is easily applicable to most invasive duct carcinomas; however, difficulty will be encountered in smaller lesions, especially with regard to mitotic rate, because some cancers are too small to allow assessment of adequate numbers of microscopic fields. In such instances, we assign grade based largely on nuclear features and gland formation.

A

Figure 9-3 Infiltrating duct carcinoma, well differentiated. *A*, Nearly all the tumor is composed of glands invading stroma in a disorganized fashion. Normal terminal ducts and lobules are present in the upper third of the photograph. *B*, Higher power of the infiltrating glands reveals uniform nuclei in terms of size and shape and minimal mitotic activity (*arrow*).

Figure 9-4 Infiltrating duct carcinoma, moderately differentiated. Whereas parts of this invasive tumor are forming glands, other areas are not. Higher power (not shown) would reveal an intermediate degree of nuclear atypia and occasional mitoses.

Figure 9-5 Infiltrating duct carcinoma, poorly differentiated. Only a minority of this invasive tumor is gland forming (*arrow*), and there is severe nuclear pleomorphism with frequent mitoses.

What is invasive lobular carcinoma?

Invasive lobular carcinoma is the second most commonly encountered type of invasive carcinoma of the breast and was first described in 1946 by Foote and Stewart,⁵ who deemed it the invasive counterpart to lobular carcinoma in situ (LCIS), previously described by the same authors. Modern thinking does not, however, classify LCIS as an obligate precursor lesion to invasion but rather as a risk factor for its development. In fact, most invasive carcinomas that develop in patients with LCIS are ductal in type, and it is not uncommon to encounter an invasive lobular carcinoma accompanied by an intraductal component (DCIS).

In contrast to infiltrating duct carcinoma, most invasive lobular carcinomas either provoke no desmoplastic reaction

at all or do so to a far lesser degree. Rather, the cells grow around or in between normal glandular structures of the breast and may even invade adipose tissue without inducing a fibrous reaction. The result is that the radiologic, clinical, and even gross estimation of size of invasive lobular carcinoma may be inaccurate or misleading. Yet, invasive lobular carcinomas typically are as irregular in shape as most invasive duct carcinomas and, in our experience, do not form well-circumscribed lesions. Grossly, the tumor may consist of a firm tan-white area, but it may merge imperceptibly with the surrounding breast tissue. There is also a distinct tendency for invasive lobular carcinoma to be multifocal (i.e., multiple, often tiny, areas of invasion separated from each other by benign tissue or intraductal carcinoma), complicating the assessment of both size and margins (discussed later).

Figure 9-6 Invasive lobular carcinoma, classic form. Tumor cells surround a benign ductal structure, creating a targetoid pattern. The cells invade in a linear fashion (single file) and have relatively uniform nuclei without mitoses.

What is the classic form of invasive lobular carcinoma?

Invasive lobular carcinoma, in its classic, originally described form, is composed of a uniform population of cells that infiltrate the breast parenchyma in so-called single file, following each other in a linear fashion to surround both benign ductal or lobular structures and those containing in situ carcinoma. This centripetal array is the basis of the designation “targetoid” for this pattern (Fig. 9-6). The cytology, however, truly defines the classic form of invasive lobular carcinoma and consists of relatively small cells with minimal cytoplasm, large but nonpleomorphic nuclei, and few if any mitoses (see Fig. 9-6). Desmoplastic reaction is minimal and sometimes nonexistent, particularly at the periphery of lesions (Fig. 9-7). It is extremely unusual to identify lymphatic invasion in such cases, and lymph node metastases may be difficult to identify without the aid of immunohistochemical stains.

What are the histologic variants of invasive lobular carcinoma?

Several forms of invasive lobular carcinoma have been characterized since the initial description of the classic type. These variants are only rarely seen in isolation because they nearly always coexist with at least some areas of the classic type. As a group, the variants tend to exhibit more aggressive histologic characteristics and a greater tendency for lymph node metastasis. Although the variant classifications are based on either cytologic or growth pattern characteristics, in practice, mixtures of each are frequently encountered. The cytologically based designators are pleomorphic, histiocytoid, and signet-ring cell; the pattern-based classifications are alveolar, solid, and tubulolobular (considered by some authors to be a variant of invasive duct carcinoma). The common thread among all the variants, in our experience, is that they share the same clinical and radiologic characteristics described earlier for the classic invasive lobular carcinoma in general.

Figure 9-7 Invasive lobular carcinoma, classic form. At the periphery of a mass tumor cells invade adipose tissue (clear areas) without provoking a desmoplastic reaction.

Pleomorphic invasive lobular carcinoma was first described by Weidner and Semple⁶ and is characterized by larger cells with pleomorphic nuclei and mitotic activity but maintenance of the growth pattern of the classic form (Fig. 9-8). The criteria for such a designation are somewhat arbitrary and overlapping with other designations such as alveolar. Furthermore, the distinction of pleomorphic lobular carcinoma from invasive poorly differentiated duct carcinoma may be difficult or arbitrary, particularly if the classic pattern of invasion is completely lacking. The signet-ring cell variant^{7,8} similarly is rarely pure, and it is debatable what percentage of such cells is necessary for the designation; however, the cells contain nuclei that are indented or pushed peripherally by mucinous cytoplasm (Fig. 9-9). The cells of histiocytoid invasive lobular carcinoma⁹ are so designated because they have abundant, lightly eosinophilic foamy or granular cytoplasm and resemble histiocytes (Fig. 9-10) to such an extent that the diagnosis may be difficult, necessitating the use of immunohistochemical stains for cytokeratins for confirmation.

Alveolar invasive lobular carcinoma¹⁰ is composed of cells forming small, well-circumscribed nests devoid of a fibrous wall around them (Fig. 9-11). Because the nuclei of these nests are frequently pleomorphic, the designation of this as an entity separate from the pleomorphic type is an unsettled issue. The appellation “solid”¹¹ is applied when the invasive tumor cells form large sheets without a dominant pattern, except at the periphery, where a single-file pattern of invasion is typically seen (Fig. 9-12).

What is the prognostic significance of classic and variant forms of invasive lobular carcinoma?

As a group, invasive lobular carcinomas are prognostically not different from tumors of ductal type.¹² Because of methodologic differences and variation in inclusion criteria, it is difficult to compare studies; however, some authors have reported slightly better survival rates for invasive lobular carcinoma, at least at 5 and 10 years,¹³ whereas survival curves may merge with longer term (>15 year) follow-up.^{10,13} Others

report a statistically significant improved 10-year survival for invasive lobular carcinoma (with inclusion of tubulolobular).¹⁴ When considered separately, the classic invasive lobular phenotype conferred a small but significant survival advantage.¹⁴ When allowing for variant lobular forms, the literature becomes difficult to interpret because of overlapping inclusion and classification criteria, differences in treatment protocols, and relatively small numbers of patients. In general, the classic pattern seems to have a relatively better prognosis when compared with the solid and alveolar patterns^{10,14,15}; however, in practice, these patterns are rarely pure. It is also possible that the poorer prognosis may actually be due to the pattern variants' frequent admixture with the cytologic variant pleomorphic lobular carcinoma. Weidner and Semple showed a markedly increased recurrence rate and nonstatistically significant decreased survival for pleomorphic lobular carcinoma.⁶ In Eusebi and colleagues' small series, 9 of 10 patients with

invasive pleomorphic lobular carcinoma either developed recurrence or metastasis very rapidly or died within 42 months.¹⁶ Prognostically, the difference may be due to the higher rate of lymph node positivity for this variant (9 of 10 of Eusebi's patients exhibited positive axillary lymph nodes). The signet-ring cell variant is generally thought to have a relatively poor prognosis,¹⁷ whereas the histiocytoid type may mirror the classic form in outcome.¹⁸ In our experience, pure populations are rare, and the variants do not vary in prognosis, stage for stage; however, the poorer prognosis associated with some variants (i.e., pleomorphic) may be ascribed to their higher rate of lymph node positivity. Thus, pleomorphic lobular carcinoma may represent an innately more aggressive phenotype in that lymph node metastasis may be occurring more frequently in smaller lesions with nuclear atypia and mitoses than in those without. This might explain the lack of prognostic difference between invasive lobular carcinoma as a whole relative to invasive duct carcinoma.

What is invasive tubulolobular carcinoma?

Invasive tubulolobular carcinoma was first described by Fisher and colleagues as part of the early National Surgical Adjuvant Breast Project (NSABP) studies.¹⁹ Although historically it has constituted only a small percentage of invasive carcinoma, our experience is that this is due to its infrequent recognition by pathologists. As its name implies, it is histologically a combination of tubular carcinoma and invasive lobular carcinoma in which well-formed glands or tubules merge directly into a linear single-cell pattern of invasion surrounding normal structures (Fig. 9-13). Both patterns contain identical tumor cells and are contiguous with each other. Calcifications may also be seen in the invasive tumor. Although some authors have classified this lesion as a variant form of invasive duct carcinoma, we believe it is more accurate to consider it a form of invasive lobular carcinoma because it has a propensity for multifocality, has the same clinical and radiographic characteristics as lobular type, and provokes less desmoplastic reaction than a routine invasive duct carcinoma. In our experience, it is not infrequent to encounter cases in which areas separate from an invasive tubulolobular carcinoma are histologically composed purely of tubular carcinoma or invasive lobular carcinoma.

Are mixed duct and lobular invasive tumors possible?

Although most invasive carcinomas are easily classified as ductal or lobular, a significant subset of tumors has growth or cytologic features of both. The different forms may be in separate areas of the same mass or intimately admixed. In either case, the lesion is probably best treated with respect to the dominant type of tumor present. In practice, such cases are frequently designated as invasive carcinoma with mixed ductal and lobular features.

What features distinguish metastatic lobular from metastatic duct carcinoma?

The growth pattern of metastatic breast carcinoma typically recapitulates that of the primary lesion. Thus, the classic

Figure 9-13 Invasive tubulolobular carcinoma. *A*, At low power, this invasive tumor grows in a lobular targetoid fashion (*center*) and is largely composed of small angulated glands with uniform nuclei (tubular component). *B*, The glands (*arrows*) merge almost imperceptibly with the linear growth pattern (*arrowhead*) of classic invasive lobular carcinoma.

Figure 9-14 Lymph node with metastatic lobular carcinoma. Immunohistochemical stains for cytokeratin reveal tumor cells spreading into the nodal parenchyma from the peripheral sinuses (*A*) and as individual cells (*B*).

single-file pattern of lobular carcinoma is often seen in distant metastases. Deposits of lobular carcinoma in lymph nodes, however, may consist of nests of cells, more diffuse involvement of the sinuses, or scattered individual cells usually found in the peripheral sinuses. Metastatic lobular carcinoma in lymph nodes is often very subtle and may be difficult to distinguish from histiocytes, especially in classic and histiocytoid forms. In such cases, immunohistochemical stains for cytokeratins are extremely helpful and often reveal far more tumor cells than were evident on examination with routine stains (Fig. 9-14). Metastatic duct carcinoma grows in cohesive clusters, occasionally provoking a fibrous reaction (Fig. 9-15).

Several studies have documented a different spread pattern for distant metastasis of lobular carcinoma as opposed to duct carcinoma.^{20,21} Ductal carcinomas favor bony sites, followed by lung, liver, and brain. Lobular metastases tend to occur after a longer lag period, sometimes up to 15 to 20 years, and

its metastatic sites are far more variable, including peritoneum, retroperitoneum, ovaries, gastrointestinal tract, and meninges, in addition to those sites typical of ductal spread. Patients with metastatic lobular carcinoma may present in unusual ways, such as with gastric outlet or ureteral obstruction. There may be diffuse involvement of pelvic and peritoneal structures, and involvement of the stomach can closely mimic a primary gastric signet-ring cell carcinoma. Immunohistochemical stains are invaluable in the resultant differential diagnosis.

Are patients with invasive lobular carcinoma candidates for breast conservation?

Given the predilection for invasive lobular carcinoma to form multiple separate tumors apart from the main mass, often

Figure 9–15 Lymph node with metastatic duct carcinoma. A large area of the lymph node parenchyma is replaced by metastatic tumor cells arranged in large cohesive, irregular groups with extensive fibrosis.

clinically and radiographically undetectable because of their small size and lack of desmoplastic reaction, it would be logical to assume that lumpectomy margins in such patients may be falsely negative owing to the presence of tiny areas of invasion retained in the breast. In fact, a lobular phenotype has been used as a rationale for mastectomy as opposed to lumpectomy. Yeatman and associates²² reported a higher rate of mastectomy in patients with lobular tumors than in those with ductal carcinomas. In more than half of patients in whom breast conservation was unsuccessful because of persistently positive margins, the tumor was lobular.

One therefore would expect that such patients would have an increased local recurrence rate when compared with identically treated patients with invasive duct carcinoma. Recent studies of large numbers of patients, however, have not confirmed this and in fact show no difference in 5-year recurrence rates between such groups of patients treated with lumpectomy and radiation.²³ Schnitt and colleagues²⁴ showed similar results, with 5-year local recurrence rates of 12% for lobular and 11% for ductal carcinoma. Kurtz and coworkers²⁵ showed a slightly higher 5-year recurrence rate for lobular (13.5%) than ductal (9%) carcinoma, but the result was not statistically significant. These authors noted, however, that lobular recurrences tended to be multifocal and multicentric. Thus, the available data would appear to indicate that breast conservation with radiation is feasible in patients with invasive lobular carcinoma.

What pathologic factors are of particular significance in breast conservation specimens?

Breast conservation specimens are commonly termed *lumpectomy*, but the synonymous terms *partial mastectomy*, *quadrantectomy*, and *tumorectomy* have also been applied. However labeled, these specimens demand attention to several factors that are less relevant in mastectomies. In most current practices, a diagnosis of invasive breast carcinoma is initially made upon examination of a mammographically or sonographi-

cally directed core biopsy. It is crucial that the pathologist histologically identify the site of this biopsy in the subsequent lumpectomy specimen, regardless of whether there is residual tumor. This ensures that the correct, originally targeted area of the breast has been removed. Occasionally, core biopsies remove the entire invasive tumor, typically when the target lesion consists of mammographic calcifications, and a small or microinvasive carcinoma is found incidental to the imaging findings. Complete removal can be confirmed only by identification and examination of the biopsy site in the lumpectomy specimen. Finding the biopsy site in a mastectomy specimen of such a patient is to be strongly encouraged; however, it is not nearly as important as in breast conservation therapy.

Margins of resection are also of particular importance in the pathologic examination of a lumpectomy specimen and are known to affect the likelihood of local recurrence, although the subsequent impact of local recurrence on disease-free and overall survival is controversial. Several pathologic factors are important in assessing the surgical adequacy of a lumpectomy specimen: status of the margins, closest distance of tumor to a margin, presence or absence of an extensive intraductal component, and lymphatic and blood vessel invasion.

How are breast conservation specimens evaluated by pathologists?

Proper pathologic evaluation of lumpectomy specimens actually begins with their proper handling by the surgeon. Ideally, such specimens should be removed intact, with surgeons resisting the temptation to incise them to have a gross peek at the tumor. At least two margins (or one if a segment of skin is attached) should be designated, usually with sutures. This, along with the specimen's laterality, allows the pathologist to orient any lumpectomy specimen in six planes. The external surface of the specimen is then painted, usually with India ink, and sections are typically taken perpendicular to the inked surfaces or as pieces of tissue shaved from the surfaces. Many color inks are available so that each individual margin (e.g., superior, lateral) can be assigned a color, keeping in mind that the borders between these planes cannot be delineated and are subjective at best. These inks are visible under the microscope and thus histologically represent the surgical margins. Seepage of these inks into folds and crevices presents a significant problem, particularly in fatty breast tissue, and methods are available that fix the ink to the external surface, decreasing its tendency to run. Only after the inks are applied to the intact specimen's surface does the pathologist slice into the specimen and grossly evaluate the internal aspect of the lumpectomy. The macroscopic tumor or biopsy site is identified and measured in three dimensions, and its apparent distance from the margins is noted, particularly with respect to its closest approach to a margin. Often, the latter assessment is made during the surgical procedure so that the surgeon can immediately re-excise that specific margin. Frozen section can be performed and is reasonably accurate in assessing invasive tumor margins, especially in invasive duct carcinoma; however, it is inadequate in ruling out intraductal carcinoma at margins because of a combination of sampling issues and technical difficulties inherent in freezing of fatty tissue. Frozen sections should be discouraged because they can hamper

Figure 9-16 Invasive tumor involving a margin. The tumor cells of this invasive lobular carcinoma are present at the inked surface of this tissue (arrows), representing a positive margin.

permanent histologic assessment, especially in small mammographically detected lesions; thus, they are usually performed only in the currently unusual circumstance in which the diagnosis of invasive carcinoma has not already been established by prior core biopsy. Sections of the tumor are taken so that its largest grossly measured size as well as its relation to the inked margins may be confirmed microscopically.

The India or multiple-colored inks are visible under the microscope, and thus slides are examined such that if the cells of intraductal or invasive carcinoma touch an inked surface, that margin is considered positive (Fig. 9-16). The closest proximity of tumor to individual margins can also be assessed and reported. The use of cautery also produces specific histologic effects and can be used as an adjunct to ink (or in lieu of ink if the specimen is received in fragments or if ink is unavailable). It should be kept in mind, however, that margin evaluation is by no means precise. Microscopic examination is a two-dimensional representation of a three-dimensional process, and thus deeper sections of tissue in a paraffin block may reveal a positive margin where the original was read as close or even negative. Nowhere is this more apparent than in the situation of intraductal carcinoma or invasive carcinoma with extensive intraductal component (discussed later). The actual protocols and methods of sampling such specimens are beyond the scope of this chapter but are highly variable and dependent on institutional and individual practice.

What is the significance of margins?

The evaluation of margins in carcinoma of the breast builds on the pivotal work of Holland and colleagues,²⁶ who used a mapping technique to document areas of malignancy separate from a known “index” invasive tumor in mastectomy specimens. These investigators found that the incidence of additional intraductal or invasive carcinoma decreased in direct proportion to the distance of the margin from the index lesion. Furthermore, intraductal carcinoma was found to be a lesion of contiguous spread through the ductolobular tree rather than one of multiple widely separated foci. Thus, such

tumors are generally unicentric even if large, and pathologic assessment of margins should therefore theoretically be predictive of complete excision of the tumor. In practice, however, positive margins do not absolutely predict the presence of residual tumor on re-excision, nor do negative margins necessarily dictate its absence. This can be attributed to several issues of sampling, including those described previously, and the fact that it is impossible to examine histologically every area of the margin even if all of the tissue of a lumpectomy is embedded in paraffin blocks (not the typical situation). In general, however, the more tumor found at or close to the margins and the shorter the distance to the margins, the more likely it is that residual tumor will be found. Put another way, the likelihood of complete excision of a tumor is inversely related to the amount of tumor at the margins and its proximity to them.²⁷⁻²⁹

Numerous studies have addressed the importance of margins in terms of assigning risk for local recurrence, but a few deserve special mention. Although radiation is currently included for most lumpectomy patients, an early test of the importance of margins alone was provided by Lagios and associates,³⁰ who reported relatively short follow-up time (mean, 24 months) of a group of such patients in whom radiation therapy was not given. The local recurrence rate was 45% in those patients with positive margins versus 9% when the margins were clear. The short interval until recurrence and the corresponding margin status indicate that local recurrence is probably a phenomenon of progression of persistent disease rather than the development of true de novo tumor. The addition of radiation therapy decreases the local recurrence rate, but most studies indicate that it does not substitute for negative margins, with local recurrence rates ranging from 0% to 9% with negative margins, compared with 10% to 21% in patients with positive margins.^{29,31,32} Other authors have expanded this idea, showing that risk for local recurrence is directly proportional to the amount of tumor at the margins and its proximity to them.^{33,34} For example, Schnitt and colleagues³³ reported 5-year recurrence rates of 0%, 4%, 6%, and 21% for groups of irradiated lumpectomy patients with negative (no tumor within 1 mm), close (tumor within 1 mm), focally positive, or positive margins, respectively. Similar findings have been derived from studies of relatively larger surgical procedures, that is, quadrantectomy versus tumorectomy.³⁵

The extreme variations of technique, evaluation criteria, and treatment in such studies makes direct comparison difficult; however, it seems clear from all the accumulated data that (1) the goal of breast-conserving surgery should be to achieve negative margins; (2) the closer a tumor is histologically to the margin, the greater the likelihood that the margin is, in fact, occultly positive; (3) the greater the amount of tumor at or close to the margins, the higher the risk for local recurrence; and (4) more extensive surgery decreases the risk for local recurrence by increasing the likelihood of attaining truly negative surgical margins.

What is meant by “extensive intraductal component” and what is its significance?

Extensive intraductal component (EIC) is a term that was first introduced by Schnitt and colleagues.³⁶ It applies only to invasive carcinomas and refers to cases in which either (1) at least

Figure 9-17 Invasive duct carcinoma with extensive intraductal carcinoma (EIC). *A*, The majority of this tumor mass is composed of invasive carcinoma, especially on the left side of the picture; however, more than 25% of the lesion is histologically intraductal carcinoma, the rounded structures containing central necrosis (*arrows*) on the right side. *B*, Areas of intraductal carcinoma are also present in fatty breast tissue outside of the mass. The two together fulfill criteria for the first definition of EIC.

Figure 9-18 Microinvasive duct carcinoma. An area of invasive, poorly differentiated duct carcinoma measuring just below 1 mm is present between the *arrows*. Four duct spaces containing intraductal carcinoma surround it. This fulfills the criteria for the second definition of extensive intraductal carcinoma (EIC).

25% of the mass of invasive tumor is histologically composed of intraductal carcinoma, and the intraductal component is also present in breast tissue clearly outside the tumor mass (Fig. 9-17), or (2) there is microinvasive carcinoma (measuring <1 mm) accompanying intraductal carcinoma (Fig. 9-18). Cases classified as EIC positive were more likely to have residual DCIS in their respective re-excision specimens than cases designated EIC negative.³⁷ In irradiated patients, regardless of whether margins were actually evaluated, EIC-positive cases had higher local recurrence rates than those deemed to be EIC negative.³⁶ Furthermore, when margins were categorized as negative, close, focally positive, or positive, the recurrence rate for EIC-negative patients was half that of EIC-positive cases, arguing for the importance of attaining negative margins for local control.³³

Because, at least theoretically, local recurrence risk should be entirely attributable to the DCIS outside the invasive mass, we additionally categorize tumors as EIC negative but DCIS in surrounding breast tissue for those cases in which the amount of DCIS within the invasive tumor is minimal or below 25%. In our care, such cases have local recurrence rates identical to those designated EIC positive. Other studies have cited no difference or a nonsignificant difference in local recurrence rates between EIC-positive and EIC-negative groups of patients with clear margins and radiation.³⁸ Thus, achieving negative margins is of paramount importance. Some clinicians have used the designation EIC positive as a justification for mastectomy as opposed to lumpectomy. Whereas the extent and location of the tumor relative to the size of the individual patient's breast may necessitate mastectomy, the appellation EIC positive can be applied to both large and small tumors and should be interpreted to signify that a larger excision will be necessary to achieve negative margins than in an EIC-negative case. EIC positive is not an absolute contraindication to breast conservation.^{33,37-39}

What is the significance of lymphatic and vascular invasion?

The terms *lymphatic invasion*, *vascular invasion*, and *lympho-vascular invasion* are commonly invoked by pathologists but are applied somewhat loosely to what nearly always represents lymphatic invasion. Strictly speaking, the term *vascular invasion* should be reserved for the histologic finding of tumor cells within a vessel containing a muscular wall; the presence of red blood cells in its lumen is helpful but not specific. Defined in this way, true vascular invasion in the breast is identified exceedingly rarely. Lymphatic invasion, conversely, is not infrequent and depends on the identification of intraluminal groups of tumor cells usually conforming to the shape of the endothelial-lined space. The space may or may not contain red blood cells, but usually small arterial or venous

Figure 9-19 Lymphatic invasion. Cohesive clusters of tumor cells are present in a dilated endothelial-lined (arrow) space adjacent to a muscular vein (arrowhead). The tumor cells conform to the shape of the lymphatic space but appear to float in it.

structures will be immediately adjacent to the lymphatic channel (Fig. 9-19). In practice, lymphatic invasion can be difficult to differentiate from retraction artifacts because of tissue processing (in invasive carcinoma) or from DCIS. Thus, the diagnosis should only be considered in breast tissue outside the invasive carcinoma. There is considerable disagreement in the literature about the reproducibility of this diagnosis even with careful adherence to diagnostic criteria.^{40,41} The use of immunohistochemical markers has been attempted but not universally accepted,⁴² in part because of the lack, until recently, of antibodies able to differentiate lymphatic channels from other endothelial lined vessels.⁴³

All studies have shown a greater than 50% predictive value of lymphatic invasion for the presence of axillary lymph node metastasis.^{44,45} Curiously, the amount of lymphatic invasion (extensive areas may be termed *lymphatic permeation*) does not imply the extent of lymph node involvement. The presence of any lymphatic invasion simply correlates with axillary disease in a qualitative, not quantitative, sense. Most studies have indicated a decrease in disease-free survival for patients with lymphatic invasion or lymphatic and vascular invasion as a group, mostly in lymph node–negative patients;^{41,42,44–47} however, these were carried out before the current era of identifying microscopic metastases in sentinel lymph nodes, and it is possible that lymphatic invasion may not contribute additional prognostic information in terms of survival. Although there are far fewer data available, it does appear that lymphatic invasion is a risk factor for local recurrence in patients treated with lumpectomy and radiation, especially when the lymphatic invasion is present at or close to a surgical margin.⁴⁷ Most studies have shown blood vessel invasion alone to be a negative indicator of disease-free and overall survival.^{27,41,48,49}

What is the importance of the size of the invasive tumor and how is it determined?

Size of the invasive tumor is arguably the most important factor determined by the pathologic evaluation of breast

carcinoma.⁵⁰ A classic study by Rosen and coworkers⁵¹ showed that node-negative patients with invasive tumors greater than 1 cm had a significantly decreased survival compared with those who had tumors smaller than 1 cm. Decisions regarding the use or withholding of systemic therapy are often made on the basis of tumor size regardless of lymph node status. Thus, it is crucial to assess size accurately. Generally, the size of a breast cancer is the measurement of the largest pathologically identifiable area of contiguous invasive carcinoma. Although, in our experience, tumor measurement using modern sonographic equipment is often quite accurate, pathologic size may or may not correspond to the clinical or radiographically determined size. Clinically and radiographically determined sizes should be regarded as estimates because they cannot account for the possible contribution of adjacent benign fibrous tissue or other masses (e.g., fibroadenoma, intraductal papilloma) to their size assessment. In fact, this holds true, although to a lesser degree, even for the examiner of the gross specimen, particularly in cases of invasive lobular carcinoma (discussed earlier). In practice, therefore, the grossly suspicious mass is measured in three dimensions, and at least one section is taken of the largest gross diameter to confirm the largest size microscopically. In the case of multiple invasive tumors, as is frequent in infiltrating lobular carcinoma, the largest microscopic area of contiguous invasive tumor is used for purposes of staging and systemic therapy decisions, while noting the presence of the other invasive areas and their relationship to margins. This situation is created iatrogenically by the use of preoperative chemotherapy when a large invasive tumor is shrunken into multiple tiny dispersed areas of invasion separated by fibrous tissue, often making postchemotherapy pathologic size determination a futile exercise.

The current era of imaging-directed core biopsy followed by sometimes multiple surgical specimens has added a layer of complexity to the evaluation of tumor size. Substantial amounts of invasive tumor may be removed by core biopsy, sometimes leading to the situation in which the largest area of invasive tumor is present in the core biopsy specimens rather than in the lumpectomy. More commonly, however, the bulk of the invasive tumor is present in the lumpectomy and, despite the granulation tissue that forms in the interval between core biopsy and surgery, the microscopic size of tumor in the surgical specimen closely mirrors that measured by imaging,⁵² with sonography being especially accurate. It is incorrect to add the size of the invasive tumor seen on core to that seen on excision, and it is similarly misleading to add the size of any residual invasive tumor on re-excision of a positive lumpectomy margin to the original size. Thus, it is important that the same pathologist review the slides of each diagnostic procedure in order to assign the proper size and therefore provide accurate information for staging purposes.

What other additional histologic factors are prognostic?

Numerous other histopathologic characteristics have been evaluated as possible indicators of favorable or unfavorable prognostic factors, among them inflammatory infiltrate, stromal fibrosis, circumscribed versus irregular tumor border, necrosis of invasive tumor, and perineural invasion.^{27,41,49} Most of these have not consistently yielded additional

Figure 9–20 Necrosis in invasive duct carcinoma. This infiltrating duct carcinoma is poorly differentiated. *A*, Only minimal gland formation is evident, there is extreme nuclear pleomorphism, and there is extensive necrosis (arrows). Such tumors are often well circumscribed (top left corner) and exhibit very rapid growth. *B*, This is histologically seen as numerous mitoses (arrows) adjacent to areas of necrosis (lower left corner).

prognostic information in the literature; however, necrosis of the invasive component may impart additional poor prognosis,⁵³ probably because it is associated with rapid tumor growth (Fig. 9–20). Perineural invasion does not, by itself, impart a worse prognosis, but it is associated with lymphatic invasion and therefore, by extension, with positive axillary lymph nodes.

What additional prognostic and predictive actors should be tested for in invasive carcinoma?

A vast number of additional immunohistochemical and other markers have been studied over the years with varying success, and it is beyond the scope of this chapter to describe all of them. Currently, testing for estrogen receptor protein, progesterone receptor protein, and HER-2/neu oncoprotein is standard for any newly diagnosed invasive carcinoma.⁵⁴ Although other methods are available, all of these parameters are most commonly evaluated by direct immunohistochemistry, allowing the pathologist to visually evaluate the number of tumor cells staining and the intensity of the reaction (Fig. 9–21). Most important, direct immunohistochemistry permits the confirmation that it is truly the invasive tumor contributing to the test result, as opposed to normal tissue or in situ carcinoma. Immunohistochemical testing for HER-2/neu is often inconclusive and may be supplanted by fluorescence in situ hybridization if clinically necessary. Other, less frequently performed tests include flow cytometry and immunohistochemical evaluation for p53 protein and proliferation markers such as Ki-67, but conflicting data can be found in the literature as to the prognostic value of each.⁵⁴ Newer tests, including molecular characterization of invasive breast cancer by gene expression assays,⁵⁵ appear to hold great promise in separating invasive carcinomas into prognostically relevant groups irrespective of their histologic categorization.

Figure 9–21 Immunohistochemical stain for HER-2/neu oncoprotein. Each individual cell in this carcinoma shows intense cytoplasmic membrane staining, creating a mosaic pattern.

Pathology of Special Forms of Breast Cancer

Shabnam Jaffer

Invasive carcinomas of the breast are ductal (65% to 80%), lobular (5% to 15%), or mixed (6%).^{1,2} Most invasive duct carcinomas (IDCs) are of the conventional type (see Chapter 9), also known as *ordinary*, *classic*, *usual*, and *not otherwise specified*. A smaller proportion of breast carcinomas (10% to 25%) constitute the *special* or *unusual* variants of infiltrating breast carcinoma owing to distinct cytoarchitecture and pattern of spread.¹ This chapter describes the pertinent clinical, morphologic, and biologic features of these special types of breast carcinomas.

How are the variants of breast cancer defined?

These distinct carcinoma variants are separated from IDC owing to unique features, such as specific cell types (e.g., apocrine), secretion (e.g., mucinous carcinoma), architectural features (e.g., papillary carcinoma), pattern of spread (e.g., micropapillary carcinoma), and biologic behavior (e.g., good prognosis—tubular carcinoma; poor prognosis—metaplastic carcinoma).

What is the implication of a diagnosis of a variant of invasive breast cancer when it coexists with ordinary invasive breast carcinoma?

For prognostic reasons, it is important to qualify whether a variant of IDC is present in pure or mixed form. In contrast to the mixed forms, the pure types are endowed with unique biologic behavior. Second, in most cases, the mixed form is more common than the pure form. Inaccurate distinction of the pure from the mixed forms leads to conflicting data in the literature regarding the behavior of these variants. For the purposes of this chapter, we will discuss only the salient features of the pure and not the mixed variants of IDC.

TUBULAR CARCINOMA

A well-differentiated invasive carcinoma, tubular carcinoma is characterized by the formation of neoplastic tubules that closely resemble breast ductules. It constitutes less than 2% of all breast carcinomas^{3–7} and 9% of carcinomas smaller than

1.0 cm.⁸ Tubular carcinoma may commonly be admixed with invasive lobular carcinoma, known as tubulolobular carcinoma.

What are the clinical features of tubular carcinoma?

Compared with IDC, tubular carcinoma is more likely to occur in older patients and to be multicentric (10% to 56%), bilateral (38%), and associated with a family history of breast carcinoma (40%).^{9,10} Most tubular carcinomas (80% to 87%) are less than 1 cm, suggestive of slow growth.^{11–13} They are usually not palpable and thus are detected primarily by mammography, presenting as spiculated densities or as trabecular distortion.

Tubular carcinoma is associated with a favorable prognosis owing to a combination of its small size at presentation, well-differentiated histology, and low rate of axillary lymph node metastases (0% to 29%).^{3,6,7,12–17} This favorable prognosis is maintained even when axillary lymph nodes are involved. Multifocal tumor with its associated greater tumor volume has a predisposition to lymph node metastases. Cumulative survival rates for tumors of all sizes were 97.3% at 5 years, 87.8% at 10 years, and 77.3% at 20 years, compared with 45.3%, 32.6%, and 19.8%, respectively, for IDC.³ The rate of recurrence over an interval of 2 to 22 years is reported to be about 3% to 4% and occurs more commonly in patients with axillary lymph node metastases.^{5,6,11,12,15,18}

A study comparing tubular carcinoma and tubulolobular carcinoma found a higher incidence of multifocality (20% versus 29%), axillary lymph node metastases (12% versus 43%), and recurrence rate (1% versus 12%) for the latter.¹⁸ However, analyses of these results failed to find any statistical significance.¹⁹ Thus, the prognosis of these tumors is thought to be intermediate between tubular carcinomas and invasive lobular carcinomas. Additional studies are indicated to further delineate the clinical features of these two tumors.

What are the pathologic features of tubular carcinoma?

Grossly and microscopically, tubular carcinomas recapitulate the mammographic appearance of a stellate mass (Fig. 10–1).

Figure 10-1 Gross appearance of tubular carcinoma showing a spiculated mass.

Figure 10-2 Histologic appearance of tubular carcinoma showing neoplastic glands with angulated contours infiltrating fat.

Morphologically, it is composed of a haphazard distribution of small open glands or tubules with irregular shapes and angular contours lined by a single layer of neoplastic columnar or cuboidal ductal cells infiltrating fat (Fig. 10-2). The nuclei are bland, basally oriented, hyperchromatic, and round to oval with inconspicuous nucleoli. The cytoplasm is usually amphophilic, rarely clear or eosinophilic. Apocrine-type cytoplasmic tufts or snouts may be present along the luminal border of the cells and are seen in one third of cases. Alternatively, the glands may have open lumina containing basophilic secretions or calcifications. Mitoses are rare to nil.

There is a lack of agreement with regard to the extent of tubular differentiation necessary to make a diagnosis of tubular carcinoma. Criteria range from being strict, requiring 100% tubular differentiation,^{3,4} to others ranging from 75% to 90%.^{6,12,20,21} Most authors agree with a cutoff at 90%, such that tumors with 50% to 90% tubular differentiation are labeled as mixed type.

The interglandular stroma may be composed of altered collagen that may contain myofibroblasts, myxoid matrix, calcifications, and/or elastin. Elastin may be seen in other IDC and radial scars, raising the differential diagnosis and possible

Figure 10-3 Histologic appearance of tubulolobular carcinoma showing features of both tubular carcinoma (arrows) and lobular carcinoma (arrowheads).

origin from radial scar. In fact, in some cases, tubular carcinoma has been found to arise from or to be associated with radial scars.^{20,22} Microscopically, the distinction from radial scar is made by the presence of glands lined by a single cell type, that is, devoid of myoepithelial cells and infiltrating adipose tissue (see Fig. 10-2). Associated low-grade intraductal carcinoma, micropapillary or cribriform types, may be present in 60% to 84% of tubular carcinomas.^{5,11,14,16}

As the name indicates, tubulolobular carcinoma is the morphologic sum of tubular carcinoma intimately admixed with invasive lobular carcinoma that is characterized by cords of small, uniform cells arranged in single linear file fashion (Fig. 10-3). It is more likely to be admixed with lobular carcinoma in situ.

Most tubular and tubulolobular carcinomas are estrogen and progesterone hormone receptor positive.²³

CRIBRIFORM CARCINOMA

As the name suggests, the morphology of this tumor is characterized by a cribriform pattern. It is a form of well-differentiated IDC whose incidence ranges from 0.3% to 4%.²⁴⁻²⁶

What are the clinical features of cribriform carcinoma?

As with IDC, cribriform carcinoma can present as a spiculated mass or calcifications. Multifocal tumors are present in 20% of cases.²⁵ The rate of axillary lymph node metastases (11%) is lower than in conventional IDC, portending a favorable prognosis.^{24,25}

However, studies on cribriform carcinoma are few in number, and the data are not standardized in terms of tumor size or surgical treatment. Nevertheless, postmastectomy disease-free survival approaches almost 100%, with follow-up times ranging from 5 to 21 years.²⁴⁻²⁶ The role of conservative surgery is currently unknown but worthy of future study.

Figure 10-4 Histologic appearance of cribriform carcinoma showing a fenestrated pattern with sharp cookie-cutter spaces in a desmoplastic stroma and associated focal tubular carcinoma.

Figure 10-5 Histologic appearance of cribriform intraductal carcinoma showing prominent basement membrane and absence of desmoplastic stroma.

What are the pathologic features of cribriform carcinoma?

A cribriform pattern is characterized by the presence of nests of tumor cells containing sharply outlined cookie-cutter type round to oval arched glandular spaces imparting a fenestrated or sievelike appearance with a desmoplastic stroma (Fig. 10-4). The cells within these nests have low-grade nuclei and rare mitoses. Cribriform carcinoma may also have tubular differentiation (see Fig. 10-4) and still qualify as cribriform carcinoma as long as the tubular differentiation is less than 50%.²⁴

A similar pattern is observed in cribriform intraductal carcinoma, distinguished by the presence of basement membrane around the cribriform nests, rare myoepithelial cells, and lack of stromal invasion (Fig. 10-5). Nevertheless, distinction of the in situ form from the invasive component may be difficult, particularly because the invasive form is usually associated with the in situ form. A cribriform growth pattern is also seen in adenoid cystic carcinoma (described later) and is differentiated by the absence of the cylindromatous basement membrane in cribriform carcinoma. All tumors express estrogen hormone receptor, and up to 70% also express progesterone receptor.²⁵

MEDULLARY CARCINOMA

The term *medullary carcinoma* was coined by Ewing in 1940²⁷ to describe a small group (1% to 7% of all IDC)^{6,28-33} of well-circumscribed, poorly differentiated tumors, paradoxically associated with good prognosis. It is for this reason that strict morphologic criteria must be met in order to diagnose medullary carcinoma. Alternatively, when most, but not all, diagnostic criteria are met, a diagnosis of atypical medullary carcinoma or IDC with medullary features is made, both of which are associated with a prognosis similar to that of IDC.

What are the clinical features of medullary carcinoma?

Medullary carcinoma affects younger women (range, 45 to 54 years).^{28,34-36} It occurs more frequently in native Japanese women^{37,38} and black women³⁹ in the United States. Of all *BRCA1* tumors analyzed, 19% were pure medullary carcinomas,^{40,41} a higher rate than that of IDC. Radiologically, the circumscription of these tumors leads them to be mistaken for fibroadenomas.⁴² Whereas in the past they were designated as bulky adenocarcinomas, today smaller tumors are detected (<3.0 cm).

The favorable prognosis associated with medullary carcinoma in older series, even with involved axillary lymph nodes (10%), has been confirmed in several newer series with post-mastectomy survival rates as follows: 5 years, 78% to 88.5%; 10 years, 64%; and 20 years, 95% (stage I) and 61% (stage II).^{31,33,34,43-46} In a few other series, patients have been treated with conservative surgery followed by radiotherapy, also with favorable results.^{47,48} Despite a higher reported rate of axillary lymph node metastases in some series (42% to 45%), the prognosis is still better than in IDC.^{31,43} Patients with medullary carcinoma typically experience reactive lymphadenopathy that is readily palpable and may lead to clinical upstaging. However, the actual number of involved nodes is usually less than three and limited to the lower axillary group. When metastases occur in medullary carcinoma, they do so within the first 5 years and are usually systemic, associated with poor survival.^{27,43}

What are the pathologic features of medullary carcinoma?

Grossly, these tumors differ from IDC by being brown, soft, lobulated, and bulging (Fig. 10-6). Foci of necrosis and cystic degeneration may also be present. Despite strict criteria for the diagnosis of medullary carcinoma, this entity is unfortunately overdiagnosed, as seen in previous series.^{49,50} As stressed before, the pathologist should diagnose medullary carcinoma

Figure 10-6 Gross appearance of medullary carcinoma showing a well-circumscribed brown soft tumor.

Figure 10-8 High-power histologic appearance of medullary carcinoma showing a syncytial growth pattern, admixed rich lymphoid reaction, high-grade nuclei, and frequent mitoses (arrows).

Figure 10-7 Low-power histologic appearance of medullary carcinoma showing a well-circumscribed tumor with central cystic necrosis (arrow).

only using strict histologic criteria to preserve its predictive favorable prognosis.

First, the carcinoma must be microscopically circumscribed, characterized by a smooth rounded pushing border (Fig. 10-7). Second, a lymphoplasmacytic reaction must be present both within and at the periphery of the tumor (see Fig. 10-7). Germinal centers may occasionally be present, such that distinguishing a true medullary carcinoma from an intramammary lymph node with metastatic carcinoma may be difficult, particularly on core biopsy. Thus, medullary carcinomas are rich in activated cytotoxic and HLA-DR–positive lymphocytes, both of which may be related to its favorable prognosis.^{51,52} In addition, the level of immunoglobulin G (IgG) can be high and may be inversely related to diminished expression of estrogen hormone receptor (<10%).^{53,54} Third, a syncytial growth pattern, a prognostically important finding,⁵⁵ is present, characterized by broad irregular sheets or islands of cells devoid of any glandular differentiation, such that the borders between the cells are indiscriminant. Finally, the

carcinoma must be poorly differentiated, consisting of cells with high nuclear grade and mitotic activity (Fig. 10-8). This correlates with an increased expression of *p53* and *Ki-67* but low *bcl-2*, consistent with rapid cell turnover and possibly related to a good prognosis. *HER-2/neu* expression is variable but usually negative.

Other microscopic features associated with, but not diagnostic for, medullary carcinoma may be present. The first is the presence of high-grade intraductal carcinoma, usually at the periphery of the tumor, also associated with a lymphoplasmacytic reaction. Second, metaplastic change, particularly of the squamous type, may be found in up to 16% of medullary carcinomas.³³ Finally, necrosis may be present, directly related to size, such that with increasing tumor size, cystic degeneration may occur.

The term *atypical medullary carcinoma* was introduced to classify carcinomas that differ from typical medullary carcinomas by one or more histologic features. One or more of the following may characterize them: invasive growth pattern, diminished lymphoplasmacytic reaction, well-differentiated carcinoma, and low mitotic count. The distinction is crucial so as to make clear the favorable prognosis of medullary carcinoma versus atypical medullary carcinoma, which has a prognosis equivalent to that of IDC.

MUCINOUS CARCINOMA

Initially recognized in 1826,⁵⁶ mucinous carcinoma constitutes 2% of all breast carcinomas. Also known as colloid or gelatinous carcinoma, these tumors, as their name implies, are composed of large amounts of extracellular mucus that is visible both grossly and microscopically.

What are the clinical features of mucinous carcinoma?

Mucinous carcinoma affects mostly elderly women (average age, 62 years), with the exception of Japanese women (average

Figure 10-9 Gross appearance of mucinous carcinoma showing a well-circumscribed tumor with a gelatinous or mucoid cut surface.

Figure 10-10 Low-power histologic appearance of mucinous carcinoma showing a predominantly well-circumscribed tumor with focal pushing borders (arrows).

age, 49 years)⁵⁷⁻⁵⁹ Clinical presentation is that of a soft to moderately firm lesion, which may rarely be crepitant (“swish sign”). The average time from onset of symptoms to biopsy and diagnosis may be 3 months or less.⁶⁰ Delay in seeking treatment, particularly in elderly women, may lead to larger tumor size at presentation.⁶¹ Although most mucinous carcinomas are mammographically occult, some may present as either a circumscribed, lobulated mass lesion, deceptively resembling a benign lesion, or rarely with calcifications.⁶²⁻⁶⁴ Based on serial mammograms, these carcinomas most likely have a slow growth rate. This is further supported by the low incidence of axillary lymph node metastases reported by several series, ranging from 0% to 29%.^{60,64,65} Second, the survival rate is also favorable, ranging from 79% to 90% at 10 to 20 years,^{59,61,66} with death from disease usually occurring after more than 10 years.⁶⁷ Thus, a small node-negative mucinous carcinoma can be appropriately treated without the need for systemic adjuvant therapy.^{61,68,69} However, postmastectomy chest wall recurrence has been reported in up to 15% of cases, and systemic recurrences have been described as long as 25 to 30 years after mastectomy.⁷⁰⁻⁷³ Rarely, cerebral metastases have been described that manifest as a mucin embolus, leading to fatal cerebral infarction.^{74,75}

What are the pathologic features of mucinous carcinoma?

In contrast to IDC, mucinous carcinomas are usually well-circumscribed, larger (range, 1 to 20 cm; mean, 2.8 cm) tumors, with a soft, currant-jelly gelatinous cut surface (Fig. 10-9). Larger tumors may also have cystic degeneration. Despite their gross circumscription, microscopically most tumors (70%) have pushing borders demonstrated by irregular knobby contours protruding into normal breast tissue⁶⁶ (Fig. 10-10). The key microscopic feature is the presence of well-differentiated tumor cells floating in a sea of extracellular mucin separated by fibrous septa (Fig. 10-11). Rarely, the carcinomas are poorly differentiated, probably representing admixed invasive micropapillary carcinoma (described later), the two being difficult to separate. The cells may be arranged

Figure 10-11 High-power histologic appearance of mucinous carcinoma showing well-differentiated tumor cells in a sea of mucin.

in strands, alveolar nests, macropapillae, or cribriform clusters, usually correlating with the intraductal pattern that is present in 20% to 75% of cases. The ratio of cells to mucin may vary from case to case but is usually consistent within a case. The mucin is composed of neutral and acidic mucopolysaccharides⁷⁶ and expresses MUC-5 and MUC-2 (gel-forming mucin),⁷⁷ the latter being highly specific for mucinous carcinoma. The typical indolent behavior of mucinous carcinoma is probably related to MUC-2, which not only confers tumor suppressor activity but also acts as a containing factor, hindering the spread of cells.⁷⁸

In contrast to mucin-rich tumors, hypercellular tumors with diminished mucin are associated with a worse prognosis.^{59,65,71} Occasionally, the entire tumor may consist of mucin and needs to be thoroughly sampled to identify the cells. Thus, the margin of a mucinous carcinoma may be deemed positive based on the presence of mucin with or without admixed cells. Based on ultrastructural studies, the extent of neuroendocrine differentiation ranges from 25% to 50%

but is not prognostically significant.^{57,79–81} Most mucinous carcinomas express estrogen (>90%) and progesterone (>50%) hormone receptors and only rarely (<5%) express *HER-2/neu*.^{59,65,71}

APOCRINE CARCINOMA

Apocrine carcinomas constitute less than 1% to 4% of all breast carcinomas.^{82,83} It is hypothesized that these carcinomas originate from ductal cells with apocrine differentiation because of their normal existence in the breast and their capacity to proliferate into atypical and eventually neoplastic lesions. In fact, this spectrum of lesions may be found adjacent to an invasive apocrine carcinoma.

What are the clinical features of apocrine carcinoma?

The clinical features of apocrine carcinoma are similar to those of IDC and thus will be excluded from discussion, with the exception of one report stating the frequent association of older age and or postmenopausal status with apocrine carcinoma.⁸⁴

What are the pathologic features of apocrine carcinoma?

Although the architectural features of apocrine carcinoma include the usual growth patterns found in IDC, it is the cytologic features that justify its distinction as a unique entity. The cells contain large pleomorphic nuclei with prominent eosinophilic nucleoli (Fig. 10–12). The cytoplasm contains abundant granular eosinophilia that is periodic acid–Schiff (PAS) stain positive after diastase digestion. Alternatively, the cytoplasm may contain fine empty vacuoles, such that the cells may resemble histiocytes. Immunohistochemically, gross cystic disease fluid protein (GCDFP-15) marks more than half of

Figure 10–12 Histologic appearance of apocrine carcinoma showing cells containing granular eosinophilic cytoplasm and pleomorphic nuclei with conspicuous nucleoli.

all apocrine carcinomas and is thus considered a putative marker of apocrine differentiation.^{83,85} These cytologic and immunohistochemical features are also seen and overlap with the histiocytoid variant of infiltrating lobular carcinoma, making the distinction difficult.⁸⁵

Studies on hormone receptor expression in apocrine carcinomas have been conflicting, with estrogen receptor positivity ranging from 0% to 50% of cases, whereas progesterone receptor expression is usually negative or low.^{82,83,86,87} Interestingly, some apocrine carcinomas express androgen receptors,⁸⁸ a finding of uncertain significance at present.

MICROPAPILLARY CARCINOMA

First recognized in 1979 and later described in 1993,^{89,90} this is the most recently described variant of IDC. It makes up less than 2% of all IDC and is characterized by a distinctive “exfoliative” morphology and lymphotropism.

What are the clinical features of micropapillary carcinoma?

Women with invasive micropapillary carcinoma tend to be older than those with other types of IDC. Patients may present with a palpable mass or radiologic abnormality. Mammographically, a spiculated, irregular, or round, high-density mass with or without calcifications may be present. Sonographically, a homogeneously hypoechoic irregular or microlobulated mass may be present.

The aggressive nature of these carcinomas is reflected in high rates of both lymphatic invasion (>50%)^{91,92} and axillary lymph node metastases (72% to 77%),⁹³ regardless of size or extent of differentiation.⁹⁴ Thus, they are best treated with mastectomy and axillary dissection^{93–98}; chemotherapy is advocated for tumors larger than 1.0 cm regardless of lymph node status. However, the treatment of smaller tumors is not clear. Despite studies indicating a shorter disease-free and overall survival, when cases are stratified by involved lymph nodes and other prognostic features, multivariate analysis failed to show any difference between invasive micropapillary carcinoma and IDC.^{95,96}

What are the pathologic features of micropapillary carcinoma?

The distinctive growth pattern of this carcinoma is characterized by solid morules or nests floating within punched-out spaces with a serrated border in the fibrous stroma (Fig. 10–13). On cross-section, the aggregates of malignant cells have a tubular appearance with minimal to no lumina formation. These artifactual spaces represent shrinkage owing to fixation, as proved by their absence on frozen sections. They deceptively resemble angiolymphatic spaces but lack an endothelial lining. Cytologically, the cells are cuboidal to columnar, containing finely granular or densely eosinophilic cytoplasm and intermediate- to high-grade nuclei. Apocrine and mucinous differentiation may be present. In fact, as mentioned previously, mucinous carcinomas with high-grade

Figure 10-13 Histologic appearance of micropapillary carcinoma showing morules of cells floating in punched-out spaces.

Figure 10-14 Histologic appearance of metaplastic squamous cell carcinoma showing a cystic tumor with spindled (*left*) and dyskeratotic cells with intercellular bridges and keratin pearl formation (*right*).

nuclear features may actually represent admixed invasive micropapillary carcinoma, and the distinction may not always be feasible. A high mitotic rate and calcifications in the form of psammoma bodies may be present. Intraductal carcinoma, micropapillary type, with intermediate- to high-nuclear-grade and associated necrosis may be present.

Ultrastructurally, microvilli have been observed on the peripheral cell surfaces, suggesting that the spaces around the clusters are glandular lumina with an inside-out growth pattern.⁹⁷ Furthermore, immunohistochemical staining with epithelial membrane antigen (EMA) demonstrates staining of these peripheral spaces, supporting this hypothesis. It is this reverse polarization that is hypothetically responsible for the lymphotropic behavior.

Invasive micropapillary carcinoma is usually estrogen positive (73% to 90%) and progesterone positive (45% to 70%) but paradoxically may also be *HER-2/neu* positive (36% to 100%).^{91,92,94,98}

METAPLASTIC CARCINOMA

Metaplasia is defined as the change from one cell type to another. In metaplastic breast carcinomas, it is the transformation of IDC into a nonglandular component (i.e., mesenchymal differentiation). Composed of a heterogeneous group of neoplasms, metaplastic carcinomas are characterized by an admixture of mammary carcinoma with spindle, squamous, chondroid, or osseous elements. The incidence of these neoplasms ranges from 1% to 5%. Low-grade adenosquamous carcinoma, a distinct variant of metaplastic carcinoma, has unique morphologic and clinical features, described next.

What are the clinical features of metaplastic carcinoma?

These tumors usually present clinically and radiologically as well-circumscribed, firm, palpable masses. They tend to be rapidly growing with a short duration before detection. They are larger than IDC, ranging in size from 1 to 21 cm (mean, 3

to 4 cm), with more than half greater than 5 cm. They may reach massive sizes (>20 cm) with consequent ulceration and displacement of the skin and nipple. Relative to their large size, the frequency of axillary lymph node metastases is low, ranging from 0% to 54%.⁹⁹⁻¹⁰⁵ Five-year mortality rates range from 25% to 86%.^{99-101,103,105} The higher end of these two incidences is true mostly for tumors with spindle and squamous differentiation.⁹⁸ Metastases are composed of ductal or metaplastic elements or both.

After adjusting for nodal status and tumor size, metaplastic carcinoma has a more favorable prognosis than IDC; however, this difference is not statistically significant.¹⁰⁶ In fact, with the exception of extensive spindle cell metaplasia in a squamous cell carcinoma, heterologous metaplasia does not negatively affect prognosis.¹⁰⁷ The above data are derived from treatment by mastectomy and axillary dissection; the roles of lumpectomy, chemotherapy, and radiotherapy are currently unknown.

What are the pathologic features of metaplastic carcinoma?

Grossly, these tumors are large, cystic, and necrotic, with pushing or infiltrative borders. Morphologically, they are usually poorly differentiated IDC that are further subdivided into two arbitrary categories: squamous and heterologous differentiation. Tumors with mixed components also occur.

Squamous Metaplasia

Given the identical histologic features of squamous cell carcinoma from other body sites (i.e., formation of intercellular bridges, dyskeratotic cells, and keratin pearl formation; Fig. 10-14), metastasis must be excluded. The most common manifestation of metaplastic squamous cell carcinoma is focal squamous metaplasia within a typical IDC, described in up to 3.7% of IDC.¹⁰⁸ The IDC can range from poorly to well differentiated, the latter known as *low-grade adenosquamous carcinoma*, described later. When squamous differentiation is

Figure 10-15 High-power histologic appearance of metaplastic squamous cell carcinoma (*arrow*) showing acantholytic areas with a pseudovascular stroma resembling angiosarcoma (*asterisk*).

predominant or diffuse, a spectrum of histologic patterns can emerge singly or in combination as follows: keratinizing, large cell, spindle cells, and acantholytic.

Tumors may be cystic, lined by bland-appearing cells that become focally spindled as they invade the stroma (see Fig. 10-14). The acantholytic variant of squamous cell carcinoma, associated with aggressive behavior, contains degenerated squamous cells embedded in a rich spindle cell and pseudovascular stroma and can be mistaken for angiosarcoma (Fig. 10-15). The distinction of pure spindle cell variants of squamous cell carcinoma from primary or metastatic sarcoma is difficult, if not impossible. Extensive sampling may be necessary to find areas of squamous differentiation; in situ and/or invasive duct carcinoma usually presents at the periphery. In the absence of any epithelial components, one can resort to immunohistochemistry (discussed later). These tumors are usually negative for hormone receptors.

Low-grade adenosquamous carcinomas, a distinct variant of squamous metaplastic carcinoma, are similar to adenosquamous carcinoma of the skin and are also known as syringomatous squamous tumors.¹⁰⁹ Smaller than other metaplastic carcinomas, they range in size from 0.5 to 3.4 cm. They are composed of varying proportions of three components of IDC: glands, solid nests, and stroma. The solid nests may be cystic or solid, the latter composed of squamous cells or keratin pearl formation. The stroma can also be variable, ranging from fibrotic to having osseous and chondroid metaplasia. Some low-grade adenosquamous carcinomas may be associated with radial sclerosing papillary lesions or sclerosing adenosis. Most of these carcinomas have an excellent prognosis, but some can be locally aggressive because of infiltrative borders.

Heterologous Metaplasia

Carcinomas with heterologous metaplasia are biphasic, composed of an epithelial component and a heterologous component. The latter can range from bland to malignant and more commonly consist of spindle cells, bone, and cartilage; less frequently, they consist of muscle, adipose, and vascular differentiation.¹¹¹ When both the epithelial and mesenchymal

Figure 10-16 Histologic appearance of metaplastic carcinoma with heterologous metaplasia showing an intermediate myxoid stroma (*asterisk*) bridging between the chondroid elements and invasive ductal carcinoma.

Figure 10-17 Histologic appearance of metaplastic carcinoma, "matrix-producing" type, showing an abrupt transition between the chondroid and ductal carcinoma.

elements are poorly differentiated, it is called *carcinosarcoma*. When the heterologous elements are osseous or chondroid, it is known as *matrix-producing carcinoma*. Although some metaplastic carcinomas have a transitional myxoid or spindle cell component bridging the two components (Fig. 10-16), in both carcinosarcoma and matrix-producing carcinomas, there is a sharp transition between these two elements without an intermediary¹¹⁰ (Fig. 10-17). Multinucleated osteoclast giant cells may accompany carcinomas with osseous, chondroid, and spindle cell differentiation.

Despite numerous immunohistochemical studies attempting to analyze the relation between the epithelial and mesenchymal components, the results are inconsistent.¹¹²⁻¹¹⁴ Typically, the epithelial elements express cytokeratin and EMA, and the mesenchymal elements express vimentin and actin, but these results can overlap. For instance, cytokeratin expression may be present in 63% of spindle cell carcinomas,¹¹⁵ and EMA reactivity has been observed in 31% of

heterologous carcinomas.¹⁰³ However, the sarcomatous elements in carcinosarcomas and matrix-producing carcinomas is usually negative for cytokeratin. The sarcomatous areas may also stain with 34 β E12, suggesting myoepithelial derivation. Estrogen and progesterone hormone receptor expression is usually negative, depending on the grade of the invasive component.

MAMMARY CARCINOMA WITH OSTEOCLAST-LIKE GIANT CELLS

As mentioned earlier, osteoclast giant cells may be admixed with chondroid and osseous elements in metaplastic carcinoma. However, mammary carcinoma with osteoclast-like giant cells is distinguished by the association with only IDC and no heterologous elements. They constitute 0.5% to 1.2% of all IDCs.^{116,117} The clinical features of this tumor are similar to IDC and will not be discussed.

What are the pathologic features of mammary carcinoma with osteoclast-like giant cells?

Grossly, these tumors are fleshy, firm, and well circumscribed, with a bulging, dark brown-red cut surface. The IDC component is moderately to poorly differentiated but can occasionally also be lobular. The osteoclast giant cells can be present in the periphery, center, or glandular lumina of the IDC (Fig. 10–18). The stroma may contain extravasated erythrocytes or hemosiderin, suggestive of recent or old hemorrhage. It is unknown what induces the presence of the osteoclast giant cells, but one in vitro study suggested a role played by interleukin-1 (IL-1).¹¹⁶ Both immunohistochemical and ultrastructural studies definitively show these cells to be of mesenchymal rather than epithelial origin. They are hypothesized to be a specific type of macrophage with osteoclastic functional ability. Interestingly, they have higher progesterone than estrogen hormone receptor expression.^{115,117–120}

Figure 10–18 Histologic appearance of mammary carcinoma with osteoclast giant cells (*arrows*) showing both components with associated hemorrhage.

LIPID-RICH CARCINOMA

As the name suggests, this variant of breast carcinoma is characterized by the predominant presence (>90%) of cells containing abundant cytoplasmic neutral lipids.¹²¹ The incidence ranges from 1% to 6% of all IDCs.^{122–124}

What are the clinical features of lipid-rich carcinoma?

Because of a limited number of series in the literature with short follow-up data, clinical data on these cases are also limited. These series indicate that these tumors are larger and more aggressive than IDC, with a higher incidence of axillary lymph node metastases.¹²³

What are the pathologic features of lipid-rich carcinoma?

These carcinomas are characterized by cells containing neutral lipids such that they contain clear, foamy to vacuolated cytoplasm as a result of lipid extraction during histologic processing. Morphologically, they are poorly differentiated tumors characterized by large pleomorphic cells arranged in an alveolar pattern with a hobnail appearance.

The differential diagnosis includes other IDCs containing similar-appearing vacuolated cells (Fig. 10–19) and includes apocrine carcinoma, glycogen-rich carcinoma, and secretory carcinoma (described later). Metastatic carcinomas with clear cells, such as renal cell carcinoma, should also be excluded. The presence of lipids can be confirmed by specialized tissue processing that preserves cytoplasmic lipids, electron microscopy, or histochemical analysis (oil red O stain) of fresh-frozen tissue for cytoplasmic lipid. When the latter is done, up to 75% of IDCs are reactive, but only 6% contain lipids in large enough amounts to qualify as lipid-rich carcinoma.¹¹⁹

Figure 10–19 Histologic appearance of an invasive duct carcinoma with clear cell features raising the differential diagnosis of lipid-rich, glycogen-rich, and secretory carcinoma.

The carcinomas are usually negative for estrogen and progesterone hormone receptors but may express α -lactalbumin and lactoferrin.

GLYCOGEN-RICH CLEAR CELL CARCINOMA

This is yet another carcinoma that contains cells with predominantly (>90%) clear cytoplasm, but it is composed of glycogen. It constitutes 1% to 3% of all breast carcinomas.^{125,126}

What are the clinical features of glycogen-rich clear cell carcinoma?

Based on limited number of series, these tumors appear to be more aggressive than conventional IDCs,¹²⁷ with a high rate (30%) of axillary lymph node metastases.¹²⁶ This is reflected in a low disease-free and overall survival rate, with up to 30% to 50% of patients reported dying from metastatic disease.^{125,128}

What are the pathologic features of glycogen-rich clear cell carcinoma?

This carcinoma is usually composed of architectural features of IDC but rarely may also be of lobular origin. The cells have sharply defined cell borders and polygonal contours. As with lipid-rich clear cell carcinomas, extraction of cytoplasmic substances during processing causes the cytoplasm to acquire a clear vacuolated to granular appearance, raising the same differential diagnoses. However, in up to 58% of cases, these carcinomas may have no significant clear cell change.¹²⁵ The cells stain with the diastase-labile PAS stain. About half of these tumors are estrogen hormone receptor positive, but they are never positive for progesterone.^{125,128}

SECRETORY CARCINOMA

Secretory carcinoma is a rare neoplasm with an incidence of 0.15% of all breast carcinomas. Because of its original description in children,¹²⁹ it was labeled “juvenile” carcinoma. Today, we know this carcinoma to occur over a wide age range (3 to 73 years),^{130,131} and it has thus been renamed *secretory carcinoma*. Most patients are younger than 30 years of age.¹³²

What are the clinical features of secretory carcinoma?

These tumors portend a good prognosis in children, but they are slightly more aggressive in adults.¹³³ Specifically, recurrences in children are rare. However, the incidence of axillary lymph node metastases (15% to 27%) is similar in both age groups.^{134,135} Recurrences can occur as late as 20 years, thus warranting long-term follow-up.¹³⁶ Although most patients are treated by mastectomy, local excision should be attempted in adolescents to maximize preservation of the breast bud.

The role of radiotherapy and chemotherapy is currently unknown.

What are the pathologic features of secretory carcinoma?

Grossly, these carcinomas are usually circumscribed and lobulated owing to the presence of fibrous septa within the tumor. Morphologically it is a compact tumor with solid, papillary, tubular, and microcystic areas (Fig. 10–20). Cytologically, the cells contain small, round, low-grade-appearing nuclei with inconspicuous nucleoli. Secretions can be extracellular or intracellular; the latter can be abundant and variable from small to large, fusing to impart a microcystic appearance (Fig. 10–21). Some of the cells may contain vacuolated, granular, or eosinophilic cytoplasm, making the distinction from apocrine carcinoma difficult. Few to rare mitoses may be present. Low-grade intraductal car-

Figure 10–20 Low-power histologic appearance of secretory carcinoma showing peripheral solid and central cystic and papillary areas.

Figure 10–21 High-power histologic appearance of secretory carcinoma showing cells with low-grade cytology associated with intraluminal (arrows) and extraluminal eosinophilic secretions.

cinoma may also be present. Histochemically, the secretory material stains with mucin and PAS, consistent with its mucopolysaccharide nature. Immunohistochemically, reaction with α -lactalbumin, S-100, and carcinoembryonic antigen (CEA) is present. Ultrastructurally, the secretions correspond to membrane-bound vacuoles. Most of the carcinomas are nonreactive with estrogen and progesterone hormone receptors.

NEUROENDOCRINE CARCINOMA

These neoplasms encompass a heterogeneous group of neoplasms defined by the presence of one or more of the following: most important, an endocrine growth pattern; argyrophilic granules (positive Grimelius silver stain); expression of neuroendocrine markers (>50%); or ultrastructural finding of neurosecretory granules. They make up 1% to 5% of breast carcinomas. Although many carcinomas (mucinous carcinoma, infiltrating lobular carcinoma) may exhibit some of these features, to qualify as a neuroendocrine carcinoma, these features must be predominant. The cell of origin is hypothesized to be neuroendocrine, located between the basal myoepithelial and luminal epithelial cell.^{137–140}

What are the clinical features of neuroendocrine carcinoma?

Neuroendocrine carcinomas tend to occur in elderly women in the sixth to seventh decade of life.¹³⁸ Rarely, they may present with systemic ectopic endocrine hormone-related syndromes such as adrenocorticotropic hormone (ACTH), parathyroid hormone (PTH), calcitonin, and epinephrine. Prognostic data on these carcinomas are limited owing to the lack of case-controlled studies.

What are the pathologic features of neuroendocrine carcinoma?

Histologic features typical of endocrine neoplasms as seen in other organs must be present and include cells with uniform, low-nuclear-grade cytology arranged in solid nests, trabeculae, rosettes, and alveolar arrangements (Figs. 10–22 and 10–23). A morphologic spectrum akin to neuroendocrine neoplasms in other organs, ranging from carcinoid tumors to small and large cell carcinomas, may be present. Although small and large cell carcinomas represent poorly differentiated carcinomas, most (85%) endocrine neoplasms in the breast are well to moderately differentiated.

Immunohistochemically, they stain with neuroendocrine markers such as neuron-specific enolase (NSE) (100%), and about half are positive for chromogranin and synaptophysin. Most of these carcinomas express estrogen and progesterone hormone receptors, including half of all small cell carcinomas.¹⁴¹

Finally, it is important to be aware that extramammary neuroendocrine metastases can rarely occur in the breast. The presence of intraductal carcinoma and hormone receptor positivity helps confirm the mammary origin of these tumors.

Figure 10–22 Low-power histologic appearance of neuroendocrine carcinoma showing cells arranged in nests, trabeculae, and rosettes.

Figure 10–23 High-power histologic appearance of neuroendocrine carcinoma showing uniform cells with low-grade cytology.

ADENOID CYSTIC CARCINOMA

These low-grade tumors predominantly arise in salivary glands and rarely occur in the breast (0.1%).¹⁴²

What are the clinical features of adenoid cystic carcinoma?

Adenoid cystic carcinoma usually forms a palpable discrete firm mass that may present later than conventional IDC (mean, 24 months).¹⁴³ About half occur in the subperiareolar region and can be painful, tender, or cystic. By mammography, adenoid cystic carcinoma appears as either a well-defined lobulated mass or an ill-defined lesion.

As in the salivary gland, these tumors are low grade and associated with a good prognosis, mastectomy being curative. Few cases of axillary lymph node metastases are described in

A

B

C

Figure 10–24 Histologic appearance of adenoid cystic carcinoma showing patterns of increasing aggressive potential. A, Cribriform. B, Tubular. C, Solid.

the literature.¹⁴⁴ Distant metastases occur in 10% of cases, usually to the lungs.¹⁴⁵

What are the pathologic features of adenoid cystic carcinoma?

Despite their circumscribed and nodular gross appearance, histologically, more than half of adenoid cystic adenomas demonstrate an invasive growth pattern. Cystic areas may be present in up to 25% of cases, particularly in larger tumors with cystic degeneration. Morphologically, they are characterized by a variable mixture of proliferating glands and stromal and basement membrane material (type IV collagen), creating much intratumoral heterogeneity. The glandular component may present in a myriad of patterns, including cribriform, tubular, trabecular, solid, basaloid, and scirrhous (Fig. 10–24).

The cribriform pattern is the most characteristic, formed by nests of cells perforated by a sieve or fenestrated pattern. The spaces contain small spherules or cylinders of hyaline material (Fig. 10–25), consistent with basal lamina, which stains immunohistochemically with laminin and collagen IV. The surrounding cells consist of predominantly

Figure 10–25 High-power histologic appearance of adenoid cystic carcinoma with cribriform pattern with associated basement membrane material.

Figure 10-26 Histologic appearance of collagenous spherulosis showing a benign glandular proliferation consisting of spherules of basement membrane material.

myoepithelial cells with basaloid features, followed by cells with more eosinophilic cytoplasm and thirdly by cells with sebaceous elements.

Cribriform carcinoma is differentiated from adenoid cystic carcinoma by the uniformity of its cells and absence of stromal component (see Fig. 10-4). Furthermore, whereas adenoid cystic carcinomas are hormone receptor negative, cribriform carcinomas are positive. Nevertheless, the distinction of cribriform carcinoma from adenoid cystic carcinoma may be challenging on limited core biopsy material. Another entity in the differential diagnosis is collagenous spherulosis (Fig. 10-26), a benign proliferation composed of ductal and myoepithelial cells associated with spherules of basement membrane material.

A grading system using morphologic features such as cytology, mitoses, and architecture is proposed.¹⁴⁶ Architecturally, adenoid cystic carcinoma is divided into a three-tiered system—cribriform, tubular, and solid, in order of increasing aggressive potential. These features are directly associated with large tumor size and increased rate of recurrence. In a minority of cases, an associated *in situ* carcinoma may be present. In fact, intraductal carcinoma is an important contributing factor for recurrence. Although perineural invasion and resultant pain is a common finding in salivary gland type tumors, it is rare in the breast. It has been suggested that adenoid cystic carcinoma probably develops in a background of and is continuous with microglandular adenosis, a benign proliferative lesion. Atypical microglandular adenosis, a more complex proliferative lesion both cytologically and architecturally, is found to have areas of transition with adenoid cystic carcinoma and is interpreted as adenoid cystic carcinoma *in situ* by some.¹⁴⁷

INFLAMMATORY CARCINOMA

Inflammatory carcinoma is not a true variant of IDC, but rather a specific mode of local spread of breast carcinoma. Clinically, it is defined by the distinct appearance of erythema of the skin of the breast. Morphologically, lymphatic

obstruction from an underlying IDC is almost always present. It is a misnomer because it lacks any inflammatory condition clinically or morphologically. It is an advanced form of breast cancer classified as T4d. The frequency of inflammatory carcinoma ranges from 1% to 10% of all IDCs, depending on the diagnostic criteria used and the nature of the institution (community versus tertiary medical center),¹⁴⁸⁻¹⁵⁰ and inflammatory carcinoma occurs more commonly in younger women. A strikingly high incidence of 28% has been reported from Tunisia.¹⁵¹

What are the clinical features of inflammatory carcinoma?

On physical examination, the cardinal signs of inflammation characterized by color, tumor, rubor, and dolor are present. The mammary skin is thickened 2 to 8 mm (mean, 4 mm),¹⁵² manifesting with a palpable ridge at the edge of the involved skin, and also has *peau d'orange* changes. Depending on the stage of the tumor, the breast may contain a central palpable tumor or may be diffusely indurated. The size of the tumor can be large, ranging from 2 to 12 cm (mean, 6 cm).¹⁵³ Most patients present with lymphadenopathy, affecting axillary lymph nodes more commonly than supraclavicular. Mammography confirms clinical findings of skin thickening, an underlying mass, stromal coarsening, and increased parenchymal density. Although magnetic resonance imaging (MRI) cannot distinguish between mastitis and inflammatory carcinoma, it shows more than 100% enhancement in the first minute after contrast administration.

Secondary inflammatory carcinoma occurs as a result of metastases in the skin of patients who initially present with axillary lymph node metastases and is clinically similar to primary inflammatory carcinoma. These patients can also present with palpable tumor infiltrates in the chest wall, at the site of prior mastectomy, within or outside of the radiated field. They are more likely to be IDC, particularly of the apocrine type.

The presence of morphologic changes in the absence of clinical findings of inflammatory carcinoma is known as occult inflammatory carcinoma. These patients have a large central or multicentric tumor and are prone to inflammatory recurrences. Although they have a less acute clinical course, survival is similar to that of conventional inflammatory carcinoma. Thus, irrespective of the clinical findings of inflammatory carcinoma, dermal lymphatic involvement portends a poor prognosis.

Before the advent of combined-modality intensive chemotherapy, the prognosis of inflammatory carcinoma was dismal. Although earlier studies indicated that patients with clinical but no morphologic evidence of inflammatory carcinoma did better than those with histologically proven inflammatory carcinoma,¹⁴⁸ additional later studies refuted these findings.¹⁵⁴⁻¹⁵⁶ Today, systemic chemotherapy, particularly preoperative anthracycline-based neoadjuvant chemotherapy followed by radiotherapy, provides better local control and an improved disease-free survival (5-year survival rate of 40% to 50%).¹⁵⁶⁻¹⁵⁸ Radiation and chemotherapy decrease or eliminate the skin erythema, edema, and tumor size. Clinical features associated with a poor prognosis include diffuse erythema, chest wall adhesions, and axillary lymph node metastases.

Figure 10–27 Histologic appearance of inflammatory carcinoma showing dermal lymphatics (arrows) containing tumor emboli.

What are the pathologic features of inflammatory carcinoma?

There are no specific histologic features of inflammatory carcinoma, and up to half of all skin biopsy samples may be negative.^{159,160} In fact, when the characteristic skin findings are clinically present, a skin biopsy may not be required for diagnosis. Histologic changes in skin may be variable and may not necessarily correlate with the clinical findings. The typical histologic finding includes tumor emboli in dermal lymphatics (Fig. 10–27). Other histologic changes in skin include a broad reticular dermal layer due to edema and collagen deposition, and dilated lymphocytes surrounded by a lymphoplasmacytic cell population. A widespread, poorly differentiated IDC with extensive carcinomatosis of lymphatics in the breast and skin is usually present. In secondary inflammatory carcinoma, in addition to tumor emboli in dermal lymphatics, dermal plaques and nodules of IDC are also present. Estrogen hormone receptor positivity ranges from 31% to 47%, whereas progesterone positivity ranges from 30% to 34%.^{161–163} *HER-2/neu* amplification has been observed in some tumors.¹⁶⁴

PHYLLODES TUMOR

First characterized in 1838,¹⁶⁵ this group of fibroepithelial tumors was named *cystosarcoma phyllodes* because of its leaflike and fleshy gross appearance. Although most phyllodes tumors (PTs) are benign, the biologic behavior, that is, the potential for recurrence and metastasis, cannot be reliably predicted. Thus, today, we more appropriately call them phyllodes tumors and histologically subclassify them as benign, low-grade (borderline), or malignant. PTs make up 0.3% to 1% of all breast tumors.

What are the clinical features of phyllodes tumor?

Patients present with a discrete, painless, palpable mass that is firm to hard, ranging in size from 1 to more than 20 cm

(range, 4 to 5 cm).^{166–169} Infrequently, PT may present as diffuse enlargement of the breast. The nipple may become flattened from the underlying PT, but skin changes are rare. PTs occur in women over a wide age range (10 to 86 years), with a mean and median of 45 years (at least 15 years later than the mean age for fibroadenomas), and are rare in adolescents.^{166–169} An unusual presentation with bloody nipple discharge due to spontaneous infarction has been described in a few adolescents.^{170,171} The age-adjusted incidence of PT is 2.1 per 1 million women per year.¹⁷² A threefold to fourfold higher incidence has been observed in foreign-born Latino women from Mexico or the Americas compared with those born in the United States.¹⁷³ A younger age of onset (average, 25 to 30 years) has been described in Asian and Latino patients.¹⁷⁴

There are no specific clinical or radiologic features that can reliably differentiate among the three histologic grades of PT. By mammography, PTs are rounded, lobulated, sharply defined opaque masses, occasionally with indistinct borders. On sonography, a circumscribed heterogeneous mass is present resulting from the presence of cysts and epithelial-lined clefts. Even though size is not a reliable indicator of clinical behavior, a diagnosis of PT is favored if the tumor is larger than 4 cm. History of rapid growth suggests malignant transformation of a benign PT or origin from a previous fibroadenoma. The latter has further been supported by clonal analysis of three fibroadenomas that recurred as PT.¹⁷⁵ Furthermore, in up to 40% of cases, coexistent fibroadenomas may be present histologically.¹⁷⁶

Based on histologic features, PTs are classified into benign, low-grade/borderline, and high-grade/malignant (described later) tumors. Although these features correlate with the frequency of recurrence, metastases, and mortality, the biologic behavior of PT cannot be reliably predicted, and there is much interseries variability. Benign PT almost never metastasizes and has a low probability (8% to 20%) of local recurrence.^{176–178} Low-grade PT has a low probability (<5%) of metastasis and a slightly higher risk (25%) for recurrence. High-grade PT metastasizes in about 22% to 25% of cases and has the highest risk for recurrence (27% to 71%). Time to recurrence was shortest in malignant PT, recurrence almost always happening within a year of diagnosis. In contrast, less than half of all benign PTs recurred within a year, the remainder from 3 to 17 years. Slightly more than half of low-grade malignant PTs recurred within a year, most within 10 years. Morphologically, the recurrences are usually of higher grade (75%),¹⁷⁵ may invade the chest wall, and are fibroepithelial or stromal; the amount of stroma increases with each recurrence.

In addition to histologic classification, factors predictive of recurrence include, most importantly, incomplete excision, invasive tumor border, and secondary peripheral tumor nodules. Higher recurrence rates were reported for low-grade/borderline PT (29% to 46%) and malignant PT (36% to 65%) when treated by lumpectomy,¹⁷⁹ the lower rates reflecting wider local excisions. Although smaller tumors may be treated by lumpectomy and still be cosmetically acceptable, mastectomy is indicated for larger tumors. Axillary dissection is not necessary because of infrequent involvement (10% to 15%).¹⁷⁸

Although metastases are more common in malignant PT, it may not always be preceded by recurrence. However, in benign and low-grade PT, metastases are rare and are usually

preceded by recurrence. They usually spread hematogenously to the lungs, bone, and heart and infrequently to the axillary lymph nodes. If the cancer is unresponsive to chemotherapy and radiotherapy, death from metastatic disease usually occurs in malignant PT (primary or recurrent) within 5 years of diagnosis.^{176,180} Whereas the 5-year overall survival rate for all PT is about 90%,¹⁷⁶ for malignant PT it decreases to 65%.^{169,181} By histologic grade, death from disease is estimated as follows: benign, 0.3%; low-grade/borderline, 6.6%; and malignant, 20%.

What are the pathologic features of phyllodes tumor?

Grossly, PTs are well-circumscribed, unencapsulated, firm, bulging, singular to multinodular masses, which are amenable to being shelled out surgically. Foci of degeneration, necrosis, and infarction may be present, suggestive of malignancy. An arborizing pattern can be grossly appreciated (Fig. 10–28), owing to the histologic presence of elongated epithelial clefts consisting of ductal and myoepithelial cells (Fig. 10–29). These cells may show hyperplasia or metaplasia (apocrine or squamous).

As members of the family of fibroepithelial tumors, PTs are distinguished from fibroadenomas by the expanded and increased cellularity of the stromal component, particularly along the periductal stroma, the favored site of origin of PT (Fig. 10–30). The distinction of fibroadenoma with cellular stroma from a benign PT is not always straightforward, particularly on limited core needle biopsies. Furthermore, the stroma in PT can be heterogeneous, with hypocellular, hyalinized (Fig. 10–31), and myxoid areas, as in fibroadenomas. These areas may be adjacent to more cellular areas typical of PT, creating diagnostic difficulties on core biopsies.

At a microscopic level, PTs are classified as benign, low-grade malignant/borderline and high-grade/malignant tumors based on the following histologic features: stromal cellularity, cytologic atypia, tumor borders, mitotic rate, and necrosis. Benign PTs (Fig. 10–32) are characterized by a uniform mild to moderate stromal cellular overgrowth, slight to moderate cytologic pleomorphism, well-defined tumor

Figure 10–28 Gross appearance of phyllodes tumor showing a fleshy tumor with leaflike growth pattern.

Figure 10–30 Histologic appearance of a phyllodes tumor showing cellular periductal stroma, the favored site of origin of a phyllodes tumor.

borders, and few mitoses (1 or 2 per 10 high-power fields [hpf]). Benign lipomatous (Fig. 10–33), chondroid, and osseous metaplasia may occur in the stroma. Borderline PTs have more aggressive histologic features that include greater stromal cellularity and atypia, microscopically invasive border, and moderate mitotic activity (2 to 5 per 10 hpf) (Fig. 10–34). Metaplastic areas are infrequently present. At the other end of the spectrum, malignant PT is characterized by

extensively invasive tumor border (Fig. 10-35) and hypercellular stromal overgrowth, with marked pleomorphism, high mitotic rate (>5 per 10 hpf) (Fig. 10-36), and necrosis. An important diagnostic criterion of malignancy is stromal overgrowth (Fig. 10-37), defined as stromal proliferation to the extent that the epithelial elements are not identifiable in at least one low-power field and may be seen only after extensive sampling.^{182,183} In rare cases, the stroma may exhibit heterologous stromal elements, such as angiosarcoma, liposarcoma (Fig. 10-38A), rhabdomyosarcoma, chondrosarcoma, and osteosarcoma (see Fig. 10-38B); the latter two more prone to systemic metastases.^{184,185} Proliferative immunohistochemical markers, such as Ki-67 and MIB-1, show a concordance with the classification of PT, such that such markers are lowest in benign PTs and highest in the malignant tumors. Progesterone receptor positivity has been described in the stromal component both biochemically and immunohistochemically.¹⁸⁶

SARCOMAS

This heterogeneous group of malignant mesenchymal neoplasms is thought to arise from the interlobular mesenchymal elements that constitute the supporting mammary stroma. Given the rarity of mammary sarcomas, the diagnosis should be made only after excluding metaplastic carcinoma and PT, both of which can have sarcomatoid elements, as discussed previously. Thus, sarcomas should be extensively sampled to detect *in situ* and invasive carcinoma or PT.

Histogenetically, sarcomas in the breast are identical to those from other body sites and include angiosarcoma, leiomyosarcoma, liposarcoma, osteosarcoma, chondrosarcoma, malignant fibrous histiocytoma, rhabdomyosarcoma, and fibrosarcoma, among others. Given that angiosarcoma is the only sarcoma that has a predilection for the breast, we will discuss only this sarcoma.

What are the clinical features of sarcomas?

Patients usually present with a rapidly enlarging mass. Grading is prognostically important, with 5- and 10-year survival rates as follows: low-grade, 75% and 63%, respectively; intermediate-grade, 55% and 40%, respectively; and high-grade, 29% and 19%, respectively.¹⁸⁷ Whereas low-grade lesions may be treated by local excision, higher grade sarcomas should be treated by mastectomy. As with PTs, axillary dissection is not indicated because sarcomas are blood borne. Death results from metastatic disease, especially to the lungs. The role of radiation and chemotherapy is still investigative.

Postradiation sarcomas can occur in soft tissue or bone after mastectomy and radiation to the chest wall and axilla and include almost always angiosarcoma (discussed later), fibrosarcoma, malignant fibrous histiocytoma, and osteosarcoma.

What are the pathologic features of sarcomas?

Grossly, sarcomas can range in size from 1 to 30 cm (mean, 3 to 4 cm). They are typically fleshy with areas of hemorrhage and necrosis. Despite their gross circumscription, they are usually microscopically infiltrative. Grading of sarcomas is three tiered (low, intermediate, high) based on the extent of cytologic atypia, necrosis, pushing borders, and mitoses. Immunohistochemically, all sarcomas express vimentin, a nonspecific mesenchymal marker. As mentioned previously, cytokeratin can serve as a useful marker to exclude metaplastic carcinoma. To determine further histogenetic differentiation, more specific connective tissue markers can be used.

ANGIOSARCOMA

Angiosarcomas of the chest wall, mammary skin, and parenchyma are rare (0.05%), described almost exclusively after radiation treatment. Although the incidence of primary angiosarcoma has remained constant, the rate of postradiation angiosarcoma (PRA) has risen. On the other hand, the incidence of Stewart-Treves syndrome, characterized by angiosarcoma in the skin and soft tissues of the arm after radical mastectomy, radiation, and lymphedema, has declined as a result of more frequent lumpectomies versus mastectomies.

All postradiation sarcomas in the breast are almost always angiosarcoma. The risk for developing PRA of the skin or breast after breast conservation and radiation ranges from 0.06% to 1.35% from 3 to 12 years (mean, 6 years) and is inversely related to age.^{188–192} No relationship has been found between PRA and radiation dose, tumor site, and lymphedema. Morphologically heterogeneous, the grading of these neoplasms is prognostically important.

What are the clinical features of angiosarcoma?

Patients with primary angiosarcoma range in age from 17 to 70 years (mean, 38 years). PRA usually occurs in older women (range, 61 to 78 years) and more frequently affects the skin rather than the breast. Mammary angiosarcomas usually also involve the skin, are multifocal, and are high grade. In PRA, age is inversely linked to tumor grade, with median ages as follows: low grade, 43 years; intermediate grade, 34 years; and high grade, 29 years. Pregnancy-associated PRA is usually high grade and portends a poor prognosis.

Skin changes may be subtle, with areas of blue or purple discoloration. Hemorrhagic discoloration in adjacent breast is indicative of tumor spread away from the primary lesion. Patients with high-grade lesions may present with multiple subcutaneous and dermal tumor nodules. Tumors may be avascular and present as skin thickening or induration. Patients with mammary lesions usually present with a painless mass and rarely with diffuse breast enlargement. By mammography, these neoplasms are noted to be ill-defined lobulated tumors, whereas sonography demonstrates high and low echogenicity, and MRI shows markedly enhancing lesions.

Initially angiosarcoma was regarded as a fatal disease; occasional cases with prolonged survival (up to 18 years) are

described today.¹⁹³ Stratified by grade, the disease-free and recurrence-free survival rates at 5 years are as follows, respectively: low-grade, 91% and 76%; intermediate-grade, 68% and 70%; and high-grade, 14% and 15%.¹⁹² All patients with high-grade tumors died of recurrent disease within 5 years.¹⁹³ Duration of disease-free survival was also directly related to grade as follows: low-grade, 15 years or longer; intermediate-grade, 12 years or longer; and high-grade, 15 months or longer.¹⁹² Metastases occur soon after primary diagnosis, most frequently to bone, lungs, liver, skin, and the contralateral breast. The latter may prove challenging to distinguish from a new primary. However, bilateral primary angiosarcomas are much rarer than metastases, particularly given the cutaneous tropism of these tumors.

As with PT, the recommended treatment is total mastectomy without axillary dissection. The efficacy of radiation and chemotherapy is presently investigative, even though studies, albeit not statistically significant, indicate that recurrences are consistently less frequent after treatment with radiation and chemotherapy.^{192–194}

What are the pathologic features of angiosarcoma?

Grossly, the tumors range in size from 1 to 20 cm (average, 5 cm). Smaller tumors (<2 cm) are rare and usually detected by mammography. The cut surface reveals a friable, firm, spongy, hemorrhagic tumor. Whereas well-differentiated tumors may have a rim of vascular engorgement, poorly differentiated tumors are ill-defined, indurated, fibrous lesions.

Morphologically, angiosarcomas consist of an infiltrative tumor composed of vascular channels. There are two similar proposed systems that divide angiosarcomas into three categories that directly correlate with prognosis: low grade (type I), intermediate grade (type II), and high grade (type III).^{193,195} Low-grade tumors contain large open anastomosing vascular channels with red blood cells that diffusely dissect the intralobular stroma, causing lobular atrophy. Atypical endothelial cells with prominent hyperchromatic nuclei line the vessels in a flat, single cell fashion (Fig. 10–39). Occasional papillary formation and few to rare mitoses may be present. The differential diagnosis of low-grade angiosarcoma includes atypical vascular lesions that may also occur after radiation and may be difficult to differentiate.

Low-grade components may be the predominant constituent in an intermediate- or high-grade lesion. In fact, intermediate-grade lesions may contain mostly (75%) low-grade elements, with scattered hypercellular areas, the transition between the two being sharp. Thus, limited material from a core biopsy may cause erroneous grading of a tumor. They are best graded on excision specimens and require extensive sampling to identify the minor but prognostically more important higher grade lesion. Intermediate-grade lesions (Fig. 10–40) are distinguished from low-grade lesions by higher cellularity and more frequent mitoses. They are composed of spindle and polygonal cells forming small papillae that bud into the vascular luminal spaces.

High-grade angiosarcomas (Fig. 10–41) have obviously malignant features consisting of interanastomosing vascular channels admixed with solid and spindle cell areas. The vessels show endothelial tufting and solid papillary formations

Figure 10-39 A, Histologic appearance of a low-grade angiosarcoma showing an open vascular channel lined by and surrounding atypical endothelial cells. B, High-power view of marked area in A.

Figure 10-40 Histologic appearance of an intermediate-grade angiosarcoma showing higher cellularity and atypia.

Figure 10-41 Histologic appearance of a high-grade angiosarcoma in skin (arrow) showing solid and spindle cell areas and a blood lake (asterisk).

composed of malignant endothelial cells (Figs. 10-42 and 10-43), frequent mitoses (>5 per 10 hpf), and necrosis. Grossly and microscopically, areas of hemorrhagic necrosis, also known as “blood lakes” (see Fig. 10-41), are only found in malignant angiosarcomas. In more than half of the high-grade tumors, the solid and spindle cell tumors are predominant without any vascular component, a finding that can be mistaken for a metaplastic spindle cell carcinoma. Immunohistochemically, as mentioned earlier, metaplastic carcinoma stains with cytokeratin but not with endothelial antigens (CD34, factor VIII-related antigen).

MALIGNANT LYMPHOMA

Another rare neoplasm of the breast, malignant lymphoma, occurs either as a primary (<5%) or, more commonly, as a secondary form; the two forms are morphologically indistinguishable. Criteria¹⁹⁶ established to diagnose primary

Figure 10-42 High-power histologic appearance of a high-grade angiosarcoma in skin showing malignant spindle cells lining vessels.

lymphoma stress that there should be no history of lymphoma in extramammary organs or lymph nodes, with the exception of axillary lymph nodes. Second, breast tissue should be involved by the lymphoma. To broaden these restrictive criteria, lymphoma that initially presents in the breast but that subsequently is found in extramammary lymph nodes, organs, and bone marrow during subsequent staging is also included.^{197,198}

What are the clinical features of malignant lymphoma?

Malignant lymphoma affects mostly women and has a bimodal age distribution in the mid 30s and 60s. As with breast carcinoma, patients usually present with a solitary mass ranging in size from 1 to 12 cm (mean, 2 cm) or multiple rapidly growing masses that may be painful, located in the upper outer quadrant. In contrast to IDC, mammary lymphoma affects the right breast more than the left. Alternatively, there may be diffuse infiltration of the breast. The skin and nipple may be involved, mimicking inflammatory breast cancer. Bilateral disease may occur in 10% of patients, particularly in postpartum or pregnant patients with Burkitt's lymphoma. Axillary lymph nodes may be involved in 30% to 50% of patients. Mammary lymphoma has been described occasionally in association with silicone breast implants,^{199,200} gynecomastia,²⁰¹ autoimmune disease,²⁰² and diabetic mastopathy.^{203,204}

By mammography, malignant lymphomas can range from being well circumscribed to irregular. Findings suggestive of malignant lymphomas include the presence of multiple ill-defined lesions and diffuse infiltration of the breast. By ultrasound, hypoechoic lesions are seen, and by MRI, rapid and strong enhancement of multicentric lesions is present.

The behavior of breast lymphomas is similar to that of lymphomas of identical grade and type in other sites. Although mastectomy used to be the standard treatment for malignant lymphomas, better local control may be achieved today with partial mastectomy followed by radiation, mastectomy being

indicated for bulky local disease or infected ulcerated lesions. Consequently, the disease-free survival rate has improved such that the 10-year survival rate is 47%.^{205–207} Although grade and stage affect prognosis, tumor size and bilateral disease are not prognostically relevant. Most recurrences are in the contralateral breast or are systemic.

What are the pathologic features of malignant lymphoma?

Grossly, malignant lymphomas are well-circumscribed, nodular, fleshy, grayish white tumors. Morphologically heterogeneous, most lymphomas are diffuse large B-cell type. Other less common lymphomas include Burkitt's, marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT), follicular lymphoma, lymphoblastic lymphoma, and T-cell lymphoma. Rare primary hematopoietic neoplasms of the breast include Hodgkin's disease, myelocytic leukemia, and plasmacytoma associated with serum monoclonal protein.

The discussion will begin with the general histologic features of mammary lymphomas and then cover the specific morphologic features of each subtype as seen in other organs and lymph nodes. In general, malignant lymphomas are characterized by a dense uniform lymphoid population that infiltrates and obliterates the ductulobular units (see Fig. 10–43). Immunohistochemical stains for cytokeratin may sometimes be necessary to delineate the atrophic ducts and lobules. Few reports describe estrogen and progesterone hormone receptor positivity in lymphomas, but others interpret this as expression by entrapped mammary epithelium.^{198,206} Malignant lymphoma is distinguished from IDC by the presence of discohesive lymphoid cells and the absence of an in situ component. Nevertheless, it may sometimes be mistaken for medullary carcinoma owing to the rich lymphoid infiltrate, particularly on core biopsies. Another differential is infiltrating lobular carcinoma with its targetoid and linear growth pattern, which may be focally present in lymphoma owing to entrapped malignant lymphoid cells in the background sclerotic stroma.

Diffuse Large B-Cell Lymphoma

As the name indicates, diffuse infiltration by large pleomorphic cells that are mitotically active in a background of smaller reactive lymphocytes is characteristic. The nuclei are oval, indented, or lobated with one or more conspicuous nucleoli, resembling centroblasts or immunoblasts. Immunohistochemically, the cells are reactive for B-cell markers that include CD20, CD79a, and CD45RB.

Burkitt's Lymphoma

The typical low-power picture is described as a “starry sky” because of the admixture of neoplastic lymphoid cells and tingible body macrophages (Fig. 10–44). The lymphoid cells are uniform, primitive-appearing cells with round nuclei, multiple nucleoli, coarse chromatin, thick nuclear membranes, cytoplasmic lipid vacuoles, and frequent mitoses. Immunohistochemically, the cells are reactive for pan B-cell markers. Epstein-Barr virus (EBV) may be found in the endemic African form.

Figure 10–44 Histologic appearance of a Burkitt's lymphoma showing a starry-sky appearance due to the admixture of malignant lymphocytes and tingible body macrophages.

Mucosa-Associated Lymphoid Tissue Lymphoma

The basis of the MALT lymphoma is founded on the tendency of malignant lymphoma to surround mammary ducts, interpreted by some as originating from the MALT.^{208,209} According to this theory, the breast is supposed to be one of the many components of the common mucosal immune process.^{209,210} A characteristic feature of MALT lymphoma is the lymphoepithelial lesion, characterized by the displacement and replacement of the ductal epithelium by lymphocytes. Initially thought to be a prerequisite for MALT lymphomas, it is now known to be present in from 0% to 75% of cases,^{206,207,211} weakening the theory of a common mucosal immune process.

Histologically, there is a diffuse proliferation of small lymphocytes, marginal zone, or monocytoid B cells and rare large blastic cells. Because of the mixed cell population, MALT lymphomas may be misdiagnosed as reactive inflammatory conditions. In fact, cases previously diagnosed as pseudolymphoma in the lung have been shown to progress and evolve into lymphomas over time. Immunohistochemically, the cells are reactive for pan B-cell markers and *bcl-2*.

Follicular Lymphoma

Follicular lymphoma is composed of neoplastic follicles with varying portions of centrocytes and centroblasts, the latter determining grade. Immunohistochemically, they are reactive for pan B-cell markers.

METASTATIC TUMORS TO THE BREAST

Metastases account for 0.5% to 6% of all malignancies in the breast.^{212,213} The breast may serve as the initial manifestation of a nonmammary malignant neoplasm in the breast of patients with metastatic tumor. They include most commonly lymphoma followed by melanoma. Metastatic melanoma may

be a challenging diagnosis, particularly if the primary is occult or if no history is provided. Metastatic carcinomas to the breast originate from the following sites: the opposite breast, lung, kidney, stomach, ovary, cervix, and thyroid. In men, prostatic carcinoma may rarely metastasize to the breast, presenting as gynecomastia, and is questionably related to estrogen therapy. Carcinoid tumors are a frequent source of metastasis to the breast.²¹⁴ Sarcomas may also metastasize to the breast, particularly rhabdomyosarcoma in children and adolescents.

What are the clinical features of metastatic tumors to the breast?

Most patients with mammary metastases are women who present within the first 2 years of the primary tumor. The tumors are predominantly well-circumscribed, rapidly growing, solitary, superficial tumors ranging in size from 1 to 3 cm. Less commonly, metastases present as multiple lesions or diffusely. With progression of disease, bilateral metastases (8% to 25%) may occur.²¹² Disseminated disease is usually evident before or at the same time as the mammary metastases. However, rarely, the primary may be occult, such that the mammary lesion masquerades as the primary tumor. Axillary lymph nodes may be involved in 25% to 48%²¹³ of cases, especially with lymphomas, melanomas, and carcinomas. Lymph nodes with metastatic carcinoma and melanoma signify systemic spread such that additional metastases may be present in the supraclavicular and contralateral axillary lymph nodes.

Radiographically, metastatic tumors to the breast are non-spiculated lesions that have discrete round shadows. Thus, they can be mistaken for well-circumscribed variants of duct carcinoma, such as medullary and colloid carcinoma. Initially, they present as solitary lesions that may progress to become multiple and bilateral. Most metastatic carcinomas lack calcifications, with the exception of ovarian and thyroid carcinomas.

The prognosis of metastatic tumors to the breast is dependent on the clinical characteristics of the specific primary neoplasm such that systemic treatment that is appropriate for the primary lesion should be instituted. Although the diagnosis of metastatic tumors to the breast may be made on core biopsy or aspiration, excisional biopsy may be necessary for an accurate diagnosis and to perform ancillary studies such as immunohistochemistry (discussed later) and electron microscopy. Mastectomy is usually not indicated except for local control of bulky, ulcerated lesions. Axillary lymph node dissection and radiotherapy may be supplemented as deemed necessary.

What are the pathologic features of metastatic tumors to the breast?

When confronted with an unusual clinical history or tumor morphology that is atypical of breast carcinoma, it is important to be aware of metastatic tumors in the differential diagnoses. Features suggestive of metastases include the presence of two or more well-circumscribed lesions with unusual

Figure 10-45 Histologic appearance of a metastatic melanoma to the breast showing a well-circumscribed nodule that displaces breast parenchyma (arrow).

Figure 10-46 High-power histologic appearance of a metastatic melanoma to the breast showing typical cytologic features such as highly pleomorphic cells with intranuclear inclusions and cytoplasmic melanin pigment.

morphology that surrounds and displaces normal-appearing breast tissue (Figs. 10-45 and 10-46). Elastosis, typical of IDC, is not usually present in metastatic tumors.

Some morphologic patterns of metastatic carcinomas that overlap with primary breast carcinomas include squamous, mucinous, clear cell, spindle cell, and papillary carcinomas. In such cases, a search for in situ carcinoma is useful but not definitive because it can also occur in isolation. Lymphatic invasion may be present, occasionally even in skin, mimicking inflammatory carcinoma.²¹⁵ Immunohistochemistry using hormone receptors may be partially helpful but cannot completely exclude tumors of müllerian origin. GCFDP-15 is expressed in normal breast and in up to 60% of breast carcinomas, particularly apocrine type. Thus, this marker may help distinguish müllerian from breast origin.

Pathology of Regional Lymph Nodes

Savitri Krishnamurthy

How is axillary lymph node status ascertained, and what is the role of pathologic assessment of axillary lymph nodes in breast cancer?

Axillary dissection is an important component of the surgical management of patients with breast cancer. Although axillary dissection does not have a proven therapeutic benefit, it does provide important prognostic information.

Axillary adipose tissue obtained during axillary lymph node dissection is manually dissected in the unfixed state to isolate lymph nodes, which are then submitted for histopathologic examination. Although axillary fat can be cleared using several agents to increase the yield of lymph nodes, which may lead to an increase in the number of both positive and negative lymph nodes, it will usually not result in change in stage of the breast tumor.¹ Use of these agents is not recommended for routine practice because the additional time and expense incurred does not appear to be justified by an increase in prognostic information.

Because other tissues, such as nerves, blood vessels, and firm areas of fat, may be mistaken grossly for lymph nodes, the final count of lymph nodes can be established only after histopathologic examination. Small lymph nodes measuring 0.5 cm are usually submitted whole, whereas lymph nodes measuring between 0.5 and 1 cm are bisected before submission. Lymph nodes containing grossly recognizable metastatic disease may not be submitted entirely because the largest dimension of metastasis can be recorded from gross contamination. Appropriately representative sections of lymph nodes that are most likely to demonstrate extranodal spread should be submitted to document the presence of metastasis and to measure extranodal extension. The size of such lymph nodes should be noted so that the amount of metastatic disease in such lymph nodes can be determined. No consensus has been reached regarding the processing of grossly benign lymph nodes larger than 1 cm. Recommendations include submitting one half of a bisected lymph node, submitting a representative sample, or processing up to one full cassette of tissue per lymph node.²⁻⁵

What are sentinel lymph nodes, and how can they be identified?

Sentinel lymph nodes (SLNs) are those lymph nodes that receive lymphatic drainage first from the organ that they

drain. Therefore, these lymph nodes are the first to harbor metastatic carcinoma. The status of SLNs is a strong predictor of the presence or absence of metastases in non-SLNs. SLN biopsy is sensitive and specific for predicting the regional lymph node status; thus, when SLNs are negative for metastatic carcinoma after a thorough pathologic evaluation, complete axillary dissection with its associated morbidity can be avoided.⁶⁻⁸

SLN mapping is most widely performed for axillary staging of patients with early invasive breast carcinoma, most often belonging to the T1 and T2 categories, and with a clinically negative axilla. The frequency of detecting metastasis in SLNs increases proportionately with primary tumor size. SLN mapping is successfully performed not only in patients with palpable breast tumors but also in those with nonpalpable, small breast tumors in whom needle localization is combined with lymphatic mapping.⁹ SLN mapping can also be successfully performed in patients treated with neoadjuvant chemotherapy.¹⁰ SLN mapping is not contraindicated in patients with a history of excisional biopsy.¹¹ A large biopsy cavity in the upper outer quadrant may, however, compromise lymphatic drainage in this region and may result in unsuccessful or false-negative SLN mapping. In patients with multifocal invasive carcinoma, the risk for having positive SLNs depends on the size of the largest invasive focus. Therefore, the incidence of metastasis in SLNs in patients with multifocal invasive carcinoma does not usually differ appreciably from the incidence in patients with a single tumor mass. However, SLN mapping in patients with multifocal invasive carcinoma is not unanimously recommended because of the higher probability of finding non-SLN metastases in these patients, even when their SLNs are negative, than in patients with a unifocal tumor.¹²

SLN mapping is generally recommended in patients with a relatively large, high-grade intraductal carcinoma because of the increased probability of finding associated invasion in the primary tumor and, therefore, the possibility of the occurrence of metastases in the SLNs.¹³

SLN mapping is performed by injecting a vital blue dye such as isosulfan blue, a radioactive tracer such as ^{99m}Tc-sulfur colloid, or a combination of these agents either around the site of primary tumor in the breast or after subdermal or intradermal injection over the tumor site.^{6,11,14,15} The blue dye is injected intraoperatively and is transported to the SLN through the lymphatic channels, thereby aiding in the localization and dissection of the SLN. Infrequently an allergic reaction to the blue dye can occur. Radioactive tracers are

A

B

Figure 11-1 Sentinel lymph node isolated after injecting radioactive tracers and blue dye. Note the sentinel lymph node (A) with a high radioactive count (B).

injected preoperatively, and their localization in the SLN can be detected preoperatively by lymphoscintigraphy and intraoperatively by using a gamma probe to detect gamma radiation (Fig. 11-1). The radiation exposure to staff involved in all aspects of SLN mapping, including the surgeons and pathologists, has been found to be low. Under normal circumstances and levels of workload, standard biohazard precautionary measures are sufficient to prevent direct radioactive contamination, and routine radiation monitoring of individuals involved with mapping and handling of SLNs is not required.¹⁶ A combination of radioisotope localization and blue dye injection technique is superior to using either procedure alone for the successful identification of SLNs in breast cancer. The mean number of SLNs per case is usually 2, with an average of 1 to 12. The false-negative rate of SLN mapping among women who also had axillary dissection is usually less than 5%.¹¹

Apart from being able to detect the SLN in the axillary region, SLN mapping can also identify SLNs located outside the area of axillary drainage. The most common extra-axillary location is the internal mammary lymph nodes, followed in frequency by the supraclavicular, interpectoral, and infraclavicular lymph nodes.¹⁷ Involvement of internal mammary lymph nodes occurs most often in patients with breast tumors located in the medial quadrants. No consensus has been reached regarding whether internal mammary SLN biopsy should be routinely performed. Some authors recommend removal of these nodes in all patients to improve staging and because their prognostic significance is as great as that of axillary SLNs. Others consider internal mammary SLN biopsy appropriate only for medially placed small breast tumors when either lymphoscintigraphy or the intraoperative gamma probe indicates internal mammary drainage of the isotope.^{11,18,19}

How is pathologic examination of the sentinel lymph nodes performed?

Thorough pathologic examination of SLNs is mandatory with the widespread use of SLN mapping for axillary staging in

patients with early invasive breast cancer and a clinically negative axilla. SLNs received fresh from surgery are examined grossly, and their dimensions are recorded. The best method for grossly sectioning the SLN has not been determined. The College of American Pathologists recommends that SLNs be sectioned as close to 2 mm as possible and submitted in their entirety for histologic evaluation, regardless of node size.²⁰

A single microscopic section from each lymph node block is considered sufficient for evaluation and would identify virtually all nodal metastasis larger than 2 mm. A College of American Pathologists consensus statement indicates that there are insufficient data at present to recommend routine step sectioning or routine cytokeratin (CK) immunostaining of axillary SLNs in breast cancer.²⁰

Metastases are more likely to be identified at the junction of the afferent lymphatics and nodal capsule.²¹ Afferent lymphatics enter the node on the convex surface, generally in the coronal plane; a less common entry point is on the flatter surfaces. When afferent lymphatics are sparse, they congregate at the poles of the lymph node.²² These lymphangiographic observations suggest that sectioning the node in the plane of the two longest axes may maximize the likelihood of detecting metastasis and may enhance determination of the dimension of the largest metastasis in the plane of section. In addition, long-axis sectioning reduces the number of sections per node, which facilitates embedding the tissue sections flatly in paraffin blocks. SLNs measuring less than 0.5 cm are bisected, whereas those measuring more than 1 cm are serially sliced at 2-mm intervals along the long axis for pathologic examination. Intraoperative evaluation of axillary SLNs aids the surgeon in deciding whether to complete the axillary dissection at the time of primary breast surgery. If the SLNs are found to be positive during intraoperative examination, axillary dissection can be completed during the primary breast surgery in one setting, thereby obviating a second surgical visit for completion of the axillary dissection alone.

Intraoperative assessment of SLNs can be performed by using frozen section, imprint cytology, or a combination of these two techniques. Each of these techniques has unique advantages and disadvantages. Frozen section provides an

Figure 11-2 Micrometastasis in the subcapsular region on a hematoxylin and eosin section (A) and on a cytokeratin immunostain (B).

intact tissue architecture, which eases interpretation of the tissue section, but there is a chance of losing micrometastatic disease while cutting through the tissue block during the preparation of a frozen section. Touch imprint cytology is easier and faster to prepare, allows sampling of both surfaces of a lymph node, and, most importantly, allows preservation of the entire tissue for optimal histopathologic evaluation. The reported sensitivities of frozen section and touch imprint cytology are highly variable, ranging from 57% to 87% for frozen section and from 29% to 94% for touch imprint cytology. Much of the variation is probably due to different methods being used for gross and final pathologic evaluation.²³ When SLNs contain multiple foci of metastases, the size of the largest deposit is used to classify the metastatic deposit in the SLN. Metastases are classified as macrometastases when they measure more than 2 mm and as micrometastases when they measure 2 mm or less (Fig. 11-2). When SLNs are sliced thin at 2-mm intervals, both frozen section and touch imprint smears are highly reliable in detecting macrometastatic disease but are usually not reliable for detecting micrometastasis (Figs. 11-3 and 11-4). Most false-negative readings are refuted by the discovery of micrometastases on permanent section after cutting through the tissue block. No consensus has been reached regarding the optimal intraoperative method for evaluating SLNs.

Similarly, no consensus among different laboratories has been reached regarding the final pathologic examination of SLNs. Various protocols have tested the use of multiple

sections stained with hematoxylin and eosin (H&E) and CK immunostaining for examining SLNs. When the SLN is sliced very thin for histopathologic examination, a single routine H&E section alone can detect macrometastasis in an SLN in most instances. Obtaining multiple sections or CK immunostaining facilitates detection of micrometastasis that may not be detected by examining routine H&E sections of the SLN. Examples of reported procedures include obtaining three H&E levels at 40- μ m intervals with a CK immunostain accompanying each level; two H&E levels separated by 40- μ m and one CK immunostain; and H&E and CK immunostain obtained on paired sections separated by 40 mm.²⁴⁻²⁶

The most frequent location of small metastatic carcinoma is the subcapsular region. Although it is easy to recognize small clusters of tumor cells, it can be difficult to identify scattered, single tumor cells, especially those of lobular carcinoma, on H&E sections. CK immunostaining of SLNs is valuable for highlighting scattered, single cells as well as for easing the detection of very small deposits of metastatic carcinoma in SLNs (Fig. 11-5). Dendritic reticulum cells belonging to the reticuloendothelial system and distributed throughout the lymphoid tissue, particularly in the subcapsular, paracortical, and medullary regions, are also CK positive. However, in contrast to the strong cytoplasmic and membranous staining seen in carcinoma cells, dendritic reticulum cells show a weak or moderate-strong cytoplasmic staining with branching processes emanating from their cytoplasm. Reverse transcriptase polymerase chain reaction (RT-PCR) has been used to

A

B

Figure 11-3 A, Sentinel lymph node with a macrometastasis replacing almost the entire lymph node. B, Imprint cytology of the same lymph node showing large sheets of tumor cells.

detect metastasis in SLN using messenger RNA (mRNA) markers such as CK19, CK20, carcinoembryonic antigen (CEA), and MUC-1.²⁷⁻²⁹ Because the high sensitivity of the procedure may lead to false-positive results and the detection of low levels of marker expression in normal cells, the significance of mRNA markers detected in SLNs with no evidence of metastasis by H&E or CK immunostain is presently unknown. The use of molecular methods to detect micrometastasis in SLNs remains investigational; these techniques are not used in clinical practice to examine axillary SLNs in breast cancer.

The results of a series of 696 patients who were followed for a median of 38 months at the John Wayne Cancer Institute in Santa Monica, California, led to recommendations for SLN evaluation similar to those of the College of American Pathologists. They found that the only patients with decreased 5-year disease-free and overall survival rates were those with nodal metastasis larger than 2 mm. The 5-year disease free survival rate was 95.1% for patients with SLNs negative by H&E and immunohistochemistry (IHC) and 98.3% for patients negative or equivocal by H&E but positive by immunohistochemistry. There was no significant difference in disease-free or overall survival rates between SLN-negative

patients and SLN IHC-positive patients ($P = .3775$, $P = .6593$). Thus, they concluded that metastasis detected by immunohistochemistry does not appear to adversely affect prognosis and that immunohistochemistry should not be routinely performed on SLNs, nor should treatment decisions be made until the results of ongoing multicenter trials are available.³⁰

How is a micrometastasis classified for staging by the American Joint Commission on Cancer?

New, uniform categories of micrometastasis have been established for the current American Joint Commission on Cancer (AJCC) staging system.³² If lymph node staging is based only on SLN biopsy, then “sn” for sentinel node is added to the pathology of nodes (pN) classification. Micrometastases have been further categorized and are designated pN1mi if they measure between 0.2 and 2 mm. Metastases smaller than 0.2 mm, whether detected by H&E or by CK IHC, have been designated as isolated tumor cells and are now designated as pN0(i+). When there are no tumor cells in the lymph node detectable by H&E and CK IHC, the designation pN0(i-) is

Figure 11-4 A, Sentinel lymph node with a micrometastasis measuring less than 2 mm. B, Imprint cytology of the same lymph node showing a single small cluster of tumor cells.

used. For cases in which no histologic metastasis is found, but RT-PCR is positive, the designation pN0(mol+) is used.

What is the significance of micrometastasis and occult metastasis?

Micrometastases by definition measure 2 mm or less. They can be detected in routine H&E sections of lymph nodes or in serial sections of initially negative lymph nodes by H&E, CK immunostaining, or molecular methods such as RT-PCR. Micrometastases discovered by the latter techniques other than H&E are referred to as occult micrometastases. Although occult metastases are usually small and therefore are micrometastases, they may also be larger than 2 mm. Several studies using a combination of serial sectioning and immunohistochemical detection found metastases in 25% to 31% of axillary node-negative patients.³²⁻³⁴ Occult micrometastases are detected more often in infiltrating lobular, mixed ductal, and lobular carcinomas than in pure, invasive ductal carcinoma. The size of the primary tumor and whether peritumoral lymphovascular emboli are present are predictors of occult metastases.

The clinical significance of micrometastatic disease remains controversial. Although some studies question the significance of metastatic deposits detected by serial sectioning and immunohistochemistry, most series have shown that nodal micrometastasis appears to have a small but significantly adverse effect on disease-free and overall survival.³⁵⁻⁴³ The largest study conducted by the Ludwig breast cancer study group found that patients with occult metastases detected by six additional serial sections had an overall 5-year survival rate of 79%, compared with 88% for patients without such foci; the disease-free survival rates were 58% and 74%, respectively.³⁶ A review by Dowlatshahi and colleagues³⁵ showed that all the studies that identified survival differences had large patient populations (range, 147 to 921 patients), a follow-up of at least 6 years, and the occult metastases detected by immunohistochemistry. Although this review concluded that occult metastases have important implications for prognosis and therapeutic decision-making process, there was no consideration of the size of occult metastases. At present, it appears that primary tumor size, length of follow-up, and the number of lymph nodes involved influence the prognostic significance of axillary micrometastases and occult metastases.

Figure 11-5 A, Sentinel lymph node with a single focus of micrometastasis on hematoxylin and eosin section. B, Note the uncovering of an additional adjacent focus of micrometastasis on a deeper level as demonstrated with the cyokeratin immunostain.

The significance of micrometastases and occult metastases in SLNs is not entirely clear. It is well recognized that whereas individual tumor cells detach from the primary tumor and circulate in the bloodstream, not all of these cells have the capability to survive and proliferate at distant sites. It is unlikely that all tumor cells detected in SLNs are clinically significant, and those micrometastases that are clinically significant cannot presently be identified.

What is the relationship between the status of sentinel lymph nodes and nonsentinel lymph nodes?

The status of SLNs is a strong predictor of whether metastases are present in the non-SLNs. Factors associated with metastasis in non-SLN when SLN is positive include macrometastatic disease in the SLN (>2 mm), extranodal extension of the SLN metastasis, more than one positive SLN, the presence of angiolymphatic invasion, and primary breast tumor size more than 2 cm.⁴⁵⁻⁵⁰ Among these factors, the size of the metastasis in the SLNs, the size of the primary breast tumor, and the presence of angiolymphatic invasion most strongly predicted the occurrence of metastases in non-SLNs upon univariate analysis. Only the size of the primary breast tumor and the number of positive SLNs have been reported to be significant prognostic factors on multivariate analysis. Of patients with

positive SLNs, 38% to 67% are reported to have no disease in non-SLNs. Micrometastases in patients with positive SLNs and a small primary breast tumor are associated with an absence or low prevalence of metastases in non-SLNs. In a series by Turner and associates, 26% of patients with SLN micrometastases had non-SLN metastasis; among these patients, only primary tumor size and peritumoral lymphovascular invasion were correlated with non-SLN metastasis.⁴⁹ Chu and coworkers performed a study on non-SLN metastases in patients with SLNs that contained only micrometastases.⁴⁷ None of the patients with pT1a and pT1b breast carcinoma and micrometastasis had non-SLN metastasis in this study. On the other hand, 6% and 10% of patients with pT1c and pT2 breast carcinoma, respectively, and micrometastasis had metastasis in non-SLN. Based on these low rates of metastasis in non-SLN, these investigators proposed that axillary dissection may not be necessary in patients with SLN micrometastasis from patients with T1 or T2 breast carcinoma. Viale and associates, however, found the frequency of metastasis in non-SLN to correlate significantly with the size of the SLN micrometastasis.⁵⁰ In their study, whereas 36.4% of patients with micrometastasis foci larger than 1 mm had metastases in non-SLN, only 15.6% of patients with micrometastases 1 mm or smaller had involvement of non-SLN. Based on available data, patients with T1 and T2 breast carcinoma and micrometastasis in SLN should undergo complete axillary dissection outside of clinical trials for adequate staging.

What is the significance of extranodal extension of metastatic breast carcinoma?

Extranodal extension refers to the extension of metastatic carcinoma beyond the confines of the nodal capsule into the perinodal soft tissue. Extranodal extension is usually observed in association with primary breast tumors larger than 2 cm and when four or more SLNs show metastatic carcinoma.^{51–55} The significance of extranodal extension as an independent prognostic factor in breast cancer is not entirely clear. Extranodal extension is a negative prognostic factor for overall and relapse-free survival. However, no compelling evidence exists to suggest that extranodal extension increases the risk for axillary recurrence of breast carcinoma. It appears that extranodal extension indicates a higher risk for systemic and local recurrence in patients who are already predisposed because of other unfavorable prognostic factors. No consensus has been reached regarding whether axillary radiation is beneficial in patients with extranodal extension of metastatic breast carcinoma.

What other entities may histologically mimic metastatic breast carcinoma in axillary lymph nodes?

Heterotopic glandular inclusions derived from breast or skin appendage glands can resemble metastatic, well-differentiated breast carcinoma.^{56–58} Unlike metastatic, well-differentiated breast carcinoma, which commonly involves nodal sinusoids, heterotopic glands occur in the capsule, perinodal tissue, or parenchyma of the lymph nodes but never in the sinusoidal spaces of the lymph nodes. Heterotopic glands are surrounded by myoepithelial cells, and in some instances they may also be present as lobules containing specialized intralobular stroma. Although heterotopic glands can very closely resemble metastatic carcinoma, the most important distinguishing feature between the two is the presence of myoepithelial cells in the former and their absence in the latter (Fig. 11–6).

Figure 11–6 Heterotopic glandular inclusion in an axillary lymph node. Note the presence of myoepithelial cells that are immunopositive for smooth muscle actin around the ductal epithelial cells of the glandular inclusion.

Nevus cell aggregates may enter into the differential diagnosis of metastatic carcinoma.^{59–63} They usually occur in the lymph node capsule and sometimes may extend into the lymph node parenchyma along the fibrous trabeculae. Nevus cell aggregates resemble cells of intradermal nevus or blue nevus and can easily be distinguished from metastatic carcinoma by the presence of fine, brown melanin pigment in their cytoplasm; the absence of mucin; and their immunopositivity for melanoma markers such as S-100, HMB45, and Melan A. Metastatic carcinoma, on the other hand, may contain mucin; is immunopositive for CK, epithelial membrane antigen (EMA), and gross cystic disease fluid protein-15 (GCDFP-15); and is negative for melanoma markers.

Vacuolated histiocytes can at times resemble mucin-containing cells of metastatic carcinoma. Unlike metastatic carcinoma, however, histiocytes with intracytoplasmic phagocytic vacuoles do not contain mucin, are negative for epithelial markers such as CK, EMA, and GCDFP-15, but are positive for histiocytic markers such as CD68, lysozyme, α_1 -antichymotrypsin, and α_1 -antitrypsin.

Hematologic disorders involving axillary lymph nodes, including extramedullary hematopoiesis, lymphoma, and leukemia, may be mistaken for metastatic carcinoma. They can be differentiated from metastatic carcinoma by demonstrating negativity for CK and positivity for pertinent hematopoietic markers by immunostaining.

Molecular Pathology Assays for Breast Cancer

W. Fraser Symmans and Giorgio Inghirami

Breast cancer is a biologically, pathologically, and clinically complex disease in which a patient's chance of survival remains uncertain despite intensive efforts to assess prognosis. Markers that are molecular targets for assay are numerous and complex. Different assays, different types of samples, small clinical studies, inconsistent conclusions, and complex associations between markers can prevent independent statistical significance. As a result of the explosion in knowledge concerning the molecular pathology of breast cancer, there is urgency to address clinical issues with these assays. However, before a new assay can be clinically useful, it must be compared with existing assays and markers and proved to be reproducible in different laboratories. There is a major shift in the way molecular pathologic assays are viewed: a shift from prognostic assessment to prediction of therapeutic response. In the past, these assays were used to supplement the prognostic information that was already obtained from tumor stage and grade. Two of those prognostic markers, estrogen receptor (ER) and *HER-2/neu*, began to be used to select patients for specific treatments when targeted molecular therapies were developed to block the ER and *HER-2/neu* cellular pathways. We provide a detailed discussion of the molecular pathologic assays to detect ER and *HER-2/neu* in breast cancer.

There are a growing number of other potential uses for molecular pathologic assays in the selection of treatments and prediction of likely response. A number of novel molecular therapies are either currently or soon to be in clinical trials, and the medical and pharmaceutical communities are actively pursuing the development of new assays to determine which patients are likely to benefit from specific molecular therapies. Furthermore, molecular pathologic assays are being studied for prediction of response to different cytotoxic chemotherapy agents. Increasing choice of effective treatments for breast cancer (itself a heterogeneous disease) enhances the need for laboratory tests that will help oncologists to select the best treatment regimen for each patient.

The biology of cancer cells involves disruptions of normal cell biology,^{1,2} and several excellent review articles address these cellular changes and their clinical implications in breast cancer.³⁻¹³ This chapter discusses the molecular pathologic assays that presently have relevance to the biologic and clinical understanding and management of breast cancer. We start with an overview of different clinical reasons for using molecular assays, then discuss performance of the different assays,

the critical pathologic steps in breast cancer, specific markers and their relationships to biologic and pathologic systems within breast cancer cells and the host response, and specific issues relating to molecular pathologic assays for breast cancer.

What is most important in evaluating a molecular pathologic assay?

An ideal breast cancer marker would provide prognostic information and therapeutic information, represent a critical step in tumor biology, and be a target for therapeutic intervention. In addition, the assay should be accurate, reliable and reproducible, time and cost efficient, and applicable to routine clinical samples. At this time, although no single marker fulfills all these criteria, certain markers are clinically useful, and others are promising.

What are the reasons for performing molecular assays?

Molecular assays have the potential to be used to identify women who are at increased risk for developing breast cancer or who have an early stage of breast cancer. Furthermore, assays may provide additional information about the prognosis and therapeutic possibilities for a woman with breast cancer, and they may have the potential to detect recurrent or metastatic disease.

Genetic Screening

Abnormalities of tumor suppressor genes (*p53*, *BRCA1*, and *BRCA2*) have been identified in women whose families have a higher frequency of breast cancer.^{14,15} These women represent a minority of breast cancer cases in the population, but they are targets for genetic screening. The genetics and epidemiology are fully discussed in Section I of this text.

Early Detection

Molecular pathologic assays do not at this time play a role in the early detection of breast cancer. Strategies to develop an assay of blood to detect breast cancer (analogous to prostate-specific antigen screening for prostate cancer) have not yet

proved successful. This is partly because a suitable molecular target has not been found. To date, there is not a molecule that is ubiquitously expressed in all breast cancer cells and that is specific to breast tissues. Even if there were, the follow-up diagnostic strategies would be more complicated for breast than for prostate cancer. Random needle biopsies (as performed in the prostate) would not be successful in breast tissues, and current breast imaging techniques cannot fully exclude the presence of a nascent breast cancer.

Cytology is being employed to identify patients at risk for development of breast cancer and to assess chemoprevention strategies. Fine-needle aspiration (FNA) of normal breast is used to obtain epithelial cells for cytologic and molecular analyses.^{16,17} The epithelial yield is relatively scant but is well suited for assays that are highly sensitive or include amplification. Repeat samples can be obtained for comparison at different times. One example would be to compare changes that occur after administration of a hormonal agent.¹⁸ Cytologic analysis of fluid obtained through the nipple is also being investigated as a method to obtain samples for microscopic or molecular studies. Cellular yield is also limited, except in cases of intraductal malignancy, but the cytologic appearance of those cells does indicate underlying pathology in the breast or risk for future breast cancer.^{19–23} The cellular component can be separated for immunochemistry or fluorescence in situ hybridization (FISH) assays on microscopic slides, or the whole fluid can be used to amplify DNA or messenger RNA (mRNA) (cyclic DNA [cDNA]), or to detect proteins.^{24–28}

There are two approaches to procure fluid from the ductal system of the breast. The simpler method is nipple aspiration, for which negative pressure is used to extract fluid from the pretreated nipple. Nipple aspiration fluid volume is much less than ductal lavage fluid volume, but the procedure is simpler, faster, and more easily tolerated. Ductal lavage requires needle cannulation of selected nipple ducts from each duct orifice at the tip of the nipple. The dependent ductal system is then lavaged with sterile fluid through the cannulated nipple duct. Generally, this is repeated for two or three nipple ducts, but samples are not obtained through all the nipple ducts. This procedure is much more time-consuming and costly than nipple aspiration, but it does obtain considerably more cellular and fluid sample and also represents more distal ducts. Epithelial cells and histiocytes are present in ductal fluids in varying numbers, but the fluid component is well suited for proteomic analyses, particularly to study secreted or shed proteins.^{26,27} Random FNA of the breast and nipple aspiration or ductal lavage do not target a specific lesion in the breast or localize sites of abnormality, but they are important to study global changes within breast tissues or to identify evidence of shed tumor cells in the ductal system.

Additional Information about the Primary Cancer

Most breast cancer markers are found either in the cancer cells or in the host tissue response. At this time, it is believed that the most important markers are within the breast cancer cells. The main biologic pathways in breast cancer cells are depicted in Figure 12–1, and specific markers will be further discussed in this context. When the breast cancer cells become invasive, they induce a desmoplastic response from the host tissues that consist of fibroblasts, histiocytes, and newly formed

Figure 12–1 Important cellular systems in a cancer cell: growth factor signals influencing DNA transcription and the cell cycle, hormone responses, cellular attachments, secreted cytokines and enzymes, and tumor antigens (Ags).

Figure 12–2 Finger-like extensions of cancer invading through desmoplastic stroma. The stromal response typically surrounds invasive cancers (H&E, $\times 200$).

blood vessels (angiogenesis). The new blood vessels formed by angiogenesis are crucial in providing blood supply, oxygen, and nutrients to the rapidly growing cancer cells. The fibroblasts and histiocytes of the desmoplastic response play a role in tumor growth, invasion of normal tissue, stimulation of angiogenesis, and immune response to the malignant cells. Receptors on cancer cells and host response cells, as well as specific molecules secreted by these cells, enable them to interact with nearby cells through molecular pathways (Fig. 12–2). These are usually paracrine interactions between adjacent cells; however, cancer cells can also exhibit autocrine signaling, in which the cell secretes molecules that stimulate its own receptors. The cellular biology of carcinoma cells is complex, and there are additional interactions with the host desmoplastic response (see Fig. 12–2), leading to complexity and variety in the molecular pathologic study of breast cancer. This information about the biology of the cancer cells is interpreted to determine prognosis or predicted responsiveness to available therapies.

Detection of Recurrent or Metastatic Disease

Molecular assays for breast cancer cells in the blood or in bone marrow aspirates may be valuable in detecting minimal residual or recurrent disease in women with a history of breast cancer.^{29,30} Likely targets are those that can be detected in metastatic disease and include epithelial cell antigens, specific mucins, and milk fat globulins, which are more specifically expressed in breast cancers.^{31–33} In such patients, it would be helpful to know the status of the original breast cancer in order to choose the appropriate target for molecular follow-up. For example, early recurrence of a tumor that overexpresses *HER-2/neu* can be identified in peripheral blood by a molecular pathologic assay for this antigen (enzyme-linked immunosorbent assay [ELISA]) or by amplification of the mRNA of the *HER-2/neu* gene (reverse transcriptase polymerase chain reaction [RT-PCR] assay).^{34,35} Detection of cytokeratin-positive cells (by immunocytochemistry) or detection of cytokeratin 19 (by RT-PCR) in the bone marrow of patients with newly diagnosed breast cancer is associated with shorter relapse-free survival.^{29,36} Evaluation of bone marrow aspirates during patient follow-up may detect patients more likely to relapse.³⁷ However, bone marrow aspiration for routine diagnostic evaluation and follow-up of breast cancer is not typical; thus, efforts have also been directed at detection methods for peripheral blood. The results of immunocytochemistry and RT-PCR in peripheral blood samples are less specific because the detection levels are lower, the molecules are not restricted to breast cancer, and there is a low rate of false-positive results in normal volunteers and patients with other types of malignancy.^{38–40} Future clinical studies are likely to deliver more accurate assays to detect circulating tumor cells that will be of practical clinical value.

How are commonly used assays performed?

Molecular markers in breast cancer cells are DNA, RNA, or proteins, reflecting the sequence from the genetic code (DNA) to the resultant protein functioning within the cell. Appropriate sample preparation is essential to the accuracy and correct application of these assays. Clinical and pathologic factors determine the form and amount of tissue available for molecular assays. Therefore, the choice of assay will be influenced by whether cancer cells are available from FNA; tissue imprints; or fresh, frozen, or fixed tissue samples.

DNA Content (Ploidy) and S-Phase Fraction

Nuclear DNA content can be measured from chemical stains that are imaged in cells using flow cytometry (cellular suspension) or image analysis (computerized microscopic imaging) to generate a histogram of the DNA content for each cell measured. The modal peak of the histogram is the DNA index (DI). If this index is the same as for normal control cells, the tumor is diploid ($0.9 \leq DI \leq 1.1$). Cancers that have abnormal cellular DNA content are hypodiploid (index < 0.9), aneuploid (index > 1.1), or tetraploid (index = 2). The DNA histogram also estimates the percentage of cells in G₂-M phase (double the DNA value of the DI) and cells in S phase of the cell cycle. The reported S-phase and G₂-M fractions are mathematically determined from the histogram data and can give an estimate of the proportion of the cells that are actively

dividing. In breast cancers, the tissue available for molecular pathologic assays is usually limited owing to the small size of the tumor and the higher priority for histopathologic analysis. There is usually insufficient tumor tissue to commit a sample for flow cytometry, but image analysis can be applied to tissue or cytology slides. Assays for DI and S phase are now infrequent in the assessment of breast cancer because similarly useful information is obtained from the histologic grade combined with an immunohistochemical stain for proliferating cells (discussed later). However, image analysis is often used in breast cancer cells to quantify immunohistochemical stains for proliferation markers, ER, and *HER-2/neu* (discussed later).

Immunocytochemistry

Most molecular markers in breast cancer are proteins that are detected using immunocytochemistry (Fig. 12–3). This technique uses specific antibodies to identify the target protein.⁴¹ The primary antibody binds to the target protein (antigen), and this bound antibody can then be detected by several methods. Usually, a labeled, specific secondary antibody identifies the primary antibody. The use of labeled secondary antibodies increases the sensitivity (by amplification) and the specificity of the assay. The labeled secondary antibody is then identified by a third reagent (e.g., avidin), which specifically binds to the labeled Fc end of the secondary antibody (e.g., a biotinylated secondary antibody). This reagent usually contains an enzyme (e.g., horseradish peroxidase or alkaline phosphatase) that converts a chemical substrate into a colored product, which can then be recognized using a microscope. Alternative mechanisms exist, some of which use fluorescent or heavy-metal labels.

Immunocytochemical staining is specific and reasonably sensitive when the optimal tissue preparation (storage, fixation, antigen retrieval) and staining conditions (antibody

Figure 12-3 Immunocytochemical detection of a cell surface antigen (Ag) by a specific primary (1°) immunoglobulin G antibody (Ab), which is then specifically bound by secondary (2°) Ab molecules recognizing the label at the Fc end of the 1° Ab. An enzyme label may be at the Fc end of the 2° Ab and will then catalyze an added substrate into a colored reaction product, which can be viewed under a microscope. Alternatively, the enzyme may be added to a third binding reagent, which recognizes the Fc end of the 2° Ab (e.g., labeled avidin binding to a biotinylated 2° Ab to form the avidin-biotin complex). This additional step adds sensitivity and specificity to the assay.

concentrations, incubation periods, buffers and washers) are established. Optimal conditions are essential if clinical decisions or prospective research studies are to rely on the assay.⁴² This immunologic technique can also be used to detect cancer cell proteins within the blood. Proteins within cells can also be quantitated using image analysis to measure the concentration of colored chromogen. Alternatively, proteins can be accurately quantitated using biochemical assays—for example, dextran charcoal ligand binding assays for ER and progesterone receptor (PR). Such biochemical assays may have the advantage of greater accuracy. However, biochemical assays often require considerable amounts of tissue, which are not available when small lesions are being studied. Biochemical assays also do not distinguish normal cells from cancer cells; hence, accurate tissue sampling is also essential.

In Situ Hybridization

In situ hybridization uses synthesized DNA probes to recognize specific DNA or RNA sequences within the cell. Probes can be designed to specifically identify sequences that represent molecular markers of breast cancer oncogenes.⁴³ Increased expression of the RNA sequence generally represents overexpression of the oncogene, and increased presence of the DNA sequence represents amplification of the oncogene. The specific DNA probe is labeled (radioactively or chemically), and the labeled probe can then be seen microscopically.

The main application of in situ hybridization in breast cancer diagnosis is to determine the number of copies of *c-erbB-2* gene that codes for *HER-2/neu* growth factor receptor protein (Fig. 12–4). The most common FISH assay is a commercially available kit that provides fluorescent-labeled probes that detect *c-erbB-2* and a centromeric sequence of chromosome 17 (cep17) and are visualized with different light filters. Therefore, the FISH assay for *c-erbB-2* is reported as the average number of copies of *c-erbB-2* per cancer cell nucleus (≥ 5 copies defined as amplification) or the ratio of the average numbers of gene copies of *c-erbB-2* compared with the

average number of copies of chromosome 17 (>2 defined as amplification). There are subtle implications for each method because the absolute number of copies of *c-erbB-2* gene may determine the protein expression level of *HER-2/neu* in the breast cancer, whereas the ratio of *c-erbB-2* to cep17 may correct for aneuploidy of chromosome 17 and select tumors with amplification of *c-erbB-2* gene on each copy of chromosome 17.⁴⁴ A CISH test is newly available for detection of *c-erbB-2* gene using a chromogen that is stable and visible with light microscopy.^{45,46} The hybridization signal is slightly less distinct than with fluorescence, and it is not possible to compare *c-erbB-2* copy number with a cep17 probe using CISH, but the method does not require a fluorescence microscope for interpretation. Cytologic samples provide FISH signals of excellent quality because the entire nucleus is present on the slide, so that all cep17 and *c-erbB-2* signals are represented in every cell.⁴⁷

Polymerase Chain Reaction

Specific hybridization assays can be performed on purified DNA and RNA from digested tumor samples. For direct hybridization, whole (entire) DNA is digested using selected enzymes that cleave DNA at known restriction sites, and the digested DNA is then hybridized to a selected DNA probe (currently synthesized as a specific sequence of bases) to detect the corresponding target sequence of DNA. The development of PCR has been a significant advance because it uses specific primers at each end of a selected DNA sequence to amplify that DNA sequence using a thermodynamic enzyme (taq polymerase). This allows small amounts of the target DNA to be amplified and detected, has diminished the number of tumor cells required to perform DNA studies, and has accelerated the progress of DNA and RNA studies. Cellular mRNA can be reverse transcribed into cDNA and then amplified using PCR (RT-PCR), and the product can be sequenced (automated) or detected by hybridization to a specific cDNA or oligonucleotide probe. Amplification and hybridization techniques are routinely used in the study of clinical research samples.

Molecular Cytogenetics

Newer techniques in cytogenetics are increasingly applied to breast cancer. FISH and nonfluorescent chromogenic in situ hybridization (CISH) are assays that are in use as clinical tests for *HER-2/neu*. FISH uses fluorescent-labeled DNA probes to specific regions of individual chromosomes⁴⁸ and can detect loss of regions of chromosomes (potential sites of tumor suppressor genes) as well as aneusomy of chromosome numbers and regions of increased copy number (potential sites of oncogenes). A related technique, called *comparative genomic hybridization* (CGH), uses whole-chromosome hybridization in which labeled normal chromosomes are hybridized to labeled metaphase cancer cell chromosomes. The distribution and intensity of the two labels (represented as two different colors) along the fusion chromosomes are measured using computerized image analysis.⁴⁹ Regions of the fusion chromosome where the cancer cell DNA is deleted will have the color of the normal chromosome label, whereas regions of fusion chromosome where the cancer cell DNA is amplified will have the color of the cancer cell chromosome label. CGH is currently a research assay.

Technical Considerations

The presence and quantity of any marker must also be assessed in benign and preneoplastic breast conditions as well as other disease states. This is particularly important for assays to detect residual or metastatic cancer. These different assays employ sensitive techniques requiring multiple sequential steps, and the results can therefore vary depending on the status of the marker within the cancer sample (e.g., degradation, clinical fixation, nature of the target marker), the reagents used (e.g., antigen retrieval methods, antibodies, probes, primers, buffers), and the conditions of reaction for each step (e.g., incubation period, concentration, temperature, washes). These variables can limit the clinical interpretation for a sample from a laboratory at a given time. Nevertheless, some markers have been shown to be prognostically relevant in breast cancer. Others may prove to be valuable in the future.

What is the clinical potential for gene expression microarrays in breast cancer?

Gene expression microarrays are high-density arrays of specific cDNA or oligonucleotide sequences that are printed onto a medium such as silicone or glass. Purified RNA from a breast cancer sample is reverse-transcribed to cDNA before colorimetric labeling and hybridization to the array. In the popular Affymetrix GeneChip platform (Affymetrix, Inc., Santa Clara, CA), the cDNA is then transcribed into cRNA before colorimetric labeling of the cRNA and hybridization to the array. The colored hybridization product is then detected and quantified using image analysis, and the numeric data are represented by computer software for viewing of the array with high expression of a gene shown as a red spot at the site of that probe and low expression of a gene shown as a green spot at the site of that probe. The numeric results are used for analysis, and those data are mathematically normalized to known controls. The relative expression levels of tens of thousands of known genes can be simultaneously evaluated from a single sample. This high-throughput technology can even be applied

to a single needle biopsy sample of breast cancer.^{50,51} To date, the results from this technology using clinical breast cancer samples have been promising. Unsupervised analysis of the overall gene expression profiles of different breast cancer samples have consistently demonstrated that ER activity is the principal determinant of overall gene expression in 50% to 60% of breast cancers and that the activity of *HER-2/neu* gene expression is an important secondary determinant of overall transcription.^{51–53} We already know from decades of clinical and laboratory studies that ER and *HER-2/neu* are critically important molecules in breast cancer, which supports the interpretation that information derived from microarray experiments is probably meaningful. ER and *HER-2/neu* are the most intensively studied molecules in breast cancer, and preliminary results indicate that the relative expression of these two genes from microarray experiments correlates well with the results of well-validated immunohistochemistry (IHC) and FISH assays performed on corresponding tumor sections.⁵¹

Gene expression data from transcriptional profiling of breast cancers can be used for different purposes, including molecular pathologic classification, selection of specific molecular therapies, prognostic analysis, and prediction of likely benefit from different available treatments.^{52–55} There is potential for this technology to address currently unmet medical needs in clinical oncology, such as prediction of response to different cytotoxic chemotherapy regimens and selection of molecular therapies.⁵⁶ Transcriptional profiling might even be adopted as an all-in-one testing modality for multiple prognostic and molecular markers and so realize its technologic potential for high-throughput analysis. Most known genes are represented in transcriptional profiles and can potentially be interpreted for clinical purposes. This presents a challenge because specific information gained from transcriptional profiles should first be defined and compared with existing pathologic assays, and then validated in clinical trials.⁵⁷ Only then can the information be used with confidence to decide patient care. There is already detailed knowledge about the coding base-pair sequence for many genes and the fidelity of DNA hybridization, and these support genomic microarrays as a testing platform. Available data are limited, but overall transcriptional profiles of human invasive breast cancers appear to be maintained in individual breast cancers during progression and after chemotherapy, indicating that the profile of transcriptional expression is generally quite stable.^{52,58} Relative stability of the gene expression profile in breast cancers also supports transcriptional profiling as an attractive platform for the development of molecular pathologic tests for routine diagnostics and patient care decisions.

What are the general biologic concepts in breast cancer progression?

Important biologic steps include the development of breast cancer cells from the epithelial lining of the ductal lobular system (neoplasia), independently accelerated cell growth and proliferation, then the invasion of these neoplastic cells through their surrounding basement membrane. Once invasive, the tumor cells can invade lymphatic and blood vessels and thereby spread to other sites in the body (metastasis)

(Fig. 12–5A). Metastatic cells can form clusters in association with blood components and are therefore able to withstand the physical stresses of the bloodstream (see Fig. 12–5B). These cells must adhere to the endothelial cells at the metastatic site, pass between these cells, and invade through the basement membrane of the blood vessels. Once at the metastatic site, they repeat the biologic steps of adhesion, invasion, and angiogenesis in order to produce a viable colony of metastatic carcinoma cells. It is unlikely that a single cancer cell has all the biologic abilities required to invade, spread, metastasize and continue to grow. Therefore, it is probably communities of tumor cells that collectively produce all the steps required for cancer dissemination.

A

B

Figure 12–5 A, Neoplastic transformation and invasion: normal breast epithelial cells fixed to a myoepithelial cell layer and basement membrane (*lower left*) develop in situ neoplastic transformation (*upper left*) and then become invasive through the basement membrane and interstitium with associated desmoplastic stroma (*center*) and angiogenesis (*lower right*). Once invasive, the cancer cells are capable of dissemination by vascular routes (*upper right*). B, To survive circulatory forces, cancer cells form microemboli binding to red and white blood cells, platelets, and fibrin. The attached white blood cells also augment intercellular adhesion to the vascular endothelium. Once adherent, the cancer cells must invade through the vascular basement membrane and interstitium before establishing a new tumor growth.

Which types of markers are important in breast cancer cells?

Markers in breast cancer cells can be grouped into different cellular systems (see Fig. 12–1), which will be discussed in greater detail next. These include the following:

1. *Cell growth and proliferation*, including growth factors, growth factor receptors, signal transduction proteins, DNA transcription proteins, control of the cell cycle, indicators of cell proliferation, and nuclear hormone receptors
2. *Cell death*, such as through apoptosis and necrosis
3. *Invasive and metastatic potential*, including cell adhesion molecules, stromal digestive enzymes, and the metastasis suppressor gene
4. *Other markers of chromosome and DNA content within cancer cells* (ploidy and cytogenetics), which can be used to study breast cancer cell populations

How are growth signals transmitted to the nucleus in breast cancer cells?

Cell Surface Receptors

There are many signaling pathways within cancer cells, but in breast cancer, the two most important growth factor receptors presently identified are *HER-2/neu* (*c-erbB-2*) and epidermal growth factor receptor (EGFR). Both receptors are of the membrane-bound tyrosine kinase receptor family and act by similar mechanisms (Fig. 12–6). Briefly, two adjacent receptors dimerize when the growth factor (ligand) binds. The ligand for *HER-2/neu* has been a subject of intensive recent research (see Chapter 3). Binding of the ligand to the extracellular domain of the paired receptors stimulates the tyrosine residues within the cytoplasmic component of the receptor molecules, which in turn activates a phosphorylation cascade involving the SH2 (src homology 2) proteins, transferring the growth signal onto the *ras* signal transduction pathway.

Figure 12–6 Comparison of *HER-2/neu* and epidermal growth factor receptor (EGFR; membrane-bound tyrosine [tyr] kinase receptor dimers), and demonstration of the ensuing phosphorylation cascade involving SH2 molecules and the *ras* pathway to relay the growth signal toward the nucleus. GAP, GTPase-activating protein; GNRP, guanine-nucleotide-releasing protein; GTP, guanosine triphosphate; PI kinase, phosphatidylinositol 3-kinase; SH2, src homology 2.

HER-2/neu

The oncogenic abnormality of *HER-2/neu* in breast cancer is principally amplification of the gene and overexpression of the protein. The role of the ligand of *HER-2/neu* is not certain at this time. The effect of *HER-2/neu* overexpression is to enhance growth signals within the breast cancer cell. The *HER-2/neu* gene is located on chromosome 17 (17q21), and DNA probes, as well as monoclonal antibodies, for the protein are available for use with clinical specimens.⁵⁹ *HER-2/neu* protein is overexpressed in about 20% to 30% of invasive breast carcinomas^{60–62} (Fig. 12–7). Of interest, *HER-2/neu* is overexpressed in 10% to 20% of cases of noncomedo ductal carcinoma in situ (DCIS) but is overexpressed in most (60% to 80%) cases of higher-grade comedo DCIS.^{62–64} Some studies have shown a prognostic predictive value for *HER-2/neu*—more strongly in node-positive cancers and less clearly in node-negative cancers.^{61,65–67} There are also data to suggest that *HER-2/neu* overexpression may predict response to adjuvant chemotherapy (discussed later).

Assays for *HER-2/neu* have become standard in clinical samples of invasive breast cancer to select patients who are eligible to receive trastuzumab (Herceptin) therapy. The importance of critical interpretation has been highlighted with IHC for *HER-2/neu*. IHC staining with antibodies to *HER-2/neu* is commonly seen in the cytoplasm of tumor and normal cells, but only circumferential cell membrane localization should be interpreted as true positive staining. Membrane staining is then assessed using a semiquantitative score (1+ to 3+) depending on intensity, and 2+ and 3+ staining is considered to be positive. The preanalytic fixation and antigen retrieval methods for *HER-2/neu* IHC are less problematic than for ER IHC (discussed later), but there is consistent discrepancy in the interpretation between central review and community pathologists that mostly affects scoring of 1+ and 2+ staining.⁶⁸ Normal breast epithelial cells do not express enough *HER-2/neu* on the cell membrane for IHC detection; therefore, interpretation of tumor staining should always be compared with normal breast epithelium as a negative control.

Figure 12–7 Immunohistochemical stain showing a circumferential membranous staining pattern for *HER-2/neu* that is of moderate intensity (2+) and restricted to the invasive breast cancer cells in a paraffin tissue section ($\times 400$). There was no amplification of the *HER-2/neu* gene copy number with the fluorescence in situ hybridization assay (*c-erbB-2*: cep17 = 1.29).

The IHC scoring system is semiquantitative and inevitably subjective; thus, there is known variability in the interpretation of negative versus 1+ staining, and for 1+ versus 2+ staining.^{69–72} Generally, 3+ staining is accepted as true overexpression for clinical purposes, and more than 90% have gene amplification. Although 2+ staining is defined as positive and 1+ staining is defined as negative by IHC, many laboratories perform FISH assay to assess *c-erbB-2* gene copy number in those cases because only 10% to 15% of 2+ tumors have gene amplification and less than 5% of 1+ tumors have gene amplification.^{72–74} If normal epithelial staining is present, some authors suggest subtracting the intensity score of the normal cells from the intensity score of the carcinoma cells to prevent false-positive results.⁷⁵

Epidermal Growth Factor Receptor

Epidermal growth factor receptor has been shown by immunocytochemistry to be overexpressed in about 35% of invasive breast carcinomas and has equivocal prognostic significance.^{76–78} There is an inverse correlation with estrogen receptor expression.⁷⁶ To date, treatment with targeted therapies to inhibit EGFR signaling has had limited success in breast cancer, and IHC expression of EGFR does not accurately predict therapeutic response.⁷⁹ However, a recent study in lung cancer demonstrated that tumors responsive to gefitinib (Iressa) treatment have deletion or mutation of the DNA sequence for the tyrosine kinase domain of EGFR.⁸⁰ If that proves to be the case in breast cancer, a better approach might be performing an assay to identify that genetic change rather than performing IHC for EGFR. Both epidermal growth factor (EGF) and transforming growth factor- α (TGF- α) stimulate EGFR.⁸¹ Other growth factor receptor molecules that can be amplified in breast cancer cells (but in fewer tumors) include insulin-like growth factor receptor,⁸² *int-2* oncogene product,^{83,84} *pS2*, and TGF- β receptor (which has an inhibitory effect on breast cancer cell growth).^{85,86}

Signal Transduction

Signal transduction proteins represent important biologic pathways of growth and survival signals in breast cancer cells. The main growth factor receptors in breast cancer (*HER-2/neu*, EGFR, and insulin-like growth factor receptor [IGFR]) signal through transduction networks from the cell membrane to the nucleus. The ras protein (p21) is an important membrane-bound signal transduction protein that recruits receptors and signaling molecules to coordinate a phosphorylation signal cascade (see Fig. 12–6). It is a guanosine triphosphate (GTP)-binding protein that is active when bound to GTP and inactive when bound to guanosine diphosphate (GDP). The ras protein contains a GTPase enzyme component that cleaves a phosphate group from the bound GTP and deactivates the ras protein. Mutations of the *ras* gene are one of the more important and common oncogene abnormalities in human cancer. These are usually point mutations that disrupt the GTPase enzymatic function of the *ras*, so that the protein cannot deactivate itself and is permanently turned on. Mutations of *ras* are uncommon in breast cancer,⁸⁷ but little is known about expression of nonmutated *ras* in this disease. This is partly because of a lack of specific antibodies to the different members of the ras protein family. Preliminary immunocytochemistry studies have indicated that ras protein (p21) is overexpressed in a significant proportion (20% to

60%) of invasive human breast cancers.^{88–91} Signal transduction from *ras* is mediated through *raf* and then bifurcates along a mitogen-activated protein (MAP) kinase pathway to stimulate growth and proliferation or along a PI3 kinase/AKT (protein kinase B) pathway to promote cell survival.^{92–94} *PTEN* (at 10q23) is a tumor suppressor gene that encodes a proapoptotic inhibitor of the PI3K/AKT pathway, and loss of *PTEN* function occurs from loss of heterozygosity (>40%), mutation (2% to 20%), or methylation in sporadic breast cancer, or from germline mutation in breast cancer that is associated with Cowden's syndrome.⁹⁴ It is passed on by the *ras* protein through a cascade of other enzyme transduction proteins (*raf*, MAP kinase-kinase, MAP kinase). MAP kinase is a common end point for other signal transduction pathways within cells.

Transcription Factors

MAP kinase phosphorylates nuclear proteins, including important DNA-binding proteins that control DNA transcription and cell proliferation. Two important examples of these proteins are *fos* and *jun*, which are the DNA-binding transcription factors involved in the proliferative response to growth factors and estrogen. These two proteins bind another transcription factor (AP-1), leading to direct DNA binding. Another important transcription factor in breast cancer is *myc* oncogene product, which has direct DNA binding in association with another protein called *max*. This *myc-max* pair binds to DNA in the regions known as E boxes, thereby activating promoters for genes (leading to transcription and replication of DNA). The control of *myc* activation is believed to be related to a third protein called *mad*, which replaces *myc*, binds to *max* at the E-box domains within DNA, and becomes inhibitory for promoters for the genes which had been activated by *myc*. Antibodies are available to detect these activating transcription factors (*fos*, *jun*, *myc*), and detection of these proteins is increased in a small proportion (<20%) of invasive human breast cancers.⁹⁰ Although these proteins provide an essential function in cells, increased levels have not been shown to be of independent prognostic significance in women with breast cancer.

Breast cancer cell proliferation— which assays are informative?

In clinical samples of breast cancer, the DNA histogram obtained by flow cytometry (sometimes by image analysis) provides a mathematical determination of the proportion of the cell population that is synthesizing DNA (in S phase) and the proportion of cells in G₂-M phase (Fig. 12–8). Clinical studies have indicated that S phase has prognostic value and correlates with histologic grade in breast cancer.^{95–102} Two markers associated with DNA proliferation are the antigen recognized by Ki-67 and proliferating cell nuclear antigen (PCNA). Ki-67 recognizes a large, nonhistone nuclear protein,^{103,104} and PCNA is a protein associated with a DNA polymerase enzyme.¹⁰¹ Both are expressed in proliferating cells^{102,105} and can be identified in nuclei in late G₁, S, or G₂-M phases of the cell cycle.¹⁰⁶ The immunocytochemical assay for PCNA gives less reliable results than that for Ki-67. A newer antibody (MIB-1) recognizes the same antigen as the Ki-67 antibody, can be reliably employed on paraffin tissue,^{107–110}

Figure 12–8 Diagram of the cell cycle showing when phosphorylation and dephosphorylation of retinoblastoma (Rb) protein occur, and the general phases when proliferation markers (Ki-67, MIB-1, and PCNA) are believed to be positive by immunocytochemical assay.

Figure 12–9 Immunohistochemical stain showing expression of the antigen detected by Ki-67 (MIB-1) in the nuclei of breast cancer cells in a paraffin tissue section (×200). The percentage of positive (dark-colored) cancer nuclei was calculated and expressed as a proliferation index of 5% to 10% (low).

and is the antibody of choice for immunocytochemical assays of formalin-fixed breast cancer specimens¹¹¹ (Fig. 12–9). There is generally an excellent correlation between expression of these proliferation markers and cell cycle analysis by flow cytometry,^{105,112,113} with mitotic figure counts,¹¹⁰ and with histologic grade.^{110,113,114} Some studies do not show close correlation of proliferation markers with S phase, but still show prognostic relevance.¹¹⁵ The immunocytochemical assays detect a greater population of cycling cells than S-phase alone. Numeric values for percentage cells in S phase or percentage cells expressing these other markers of proliferation are variable, and exact clinical cutoff points are not reliable. However, ranges of values that give relative prognostic information can be assigned. Generally, 10% to 15% and 25% to 35% are the ranges for the cutoffs among low, intermediate, and high proliferation indices in breast cancers.

How is the cell cycle controlled in breast cancer?

Breast epithelial cell proliferation is striking in some benign conditions (fibroadenomas) and even protective conditions of the breast (pregnancy). Increased proliferation is therefore not sufficient alone to explain the abnormal proliferation of breast cancer cells.¹¹⁶ There are two major checkpoints in the cell cycle, in late G₁ phase and in late G₂-M phase (see Fig. 12–8). The major controls of the cell cycle are pairs of cyclins and bound cyclin-dependent kinases (CDKs; cyclin-CDK pairs).^{117,118} The levels of these complexes determine cellular progression through the cell cycle by their interactions with other important transcription factors, such as retinoblastoma (Rb) protein.

Cyclin D and its complex with CDK (CDK-4 or -6) controls the checkpoint near the end of G₁ phase for cells to enter DNA synthesis (S phase) and become committed to replicate. When a cell passes through the late G₁ checkpoint, Rb becomes phosphorylated and remains so during the proliferation phases of the cell cycle. At the end of G₂-M phase, the Rb protein becomes dephosphorylated, and the cell exits the replicative phase (see Fig. 12–8). Cyclin D–CDK-4 complexes control Rb protein phosphorylation and therefore help to control the late G₁ checkpoint of the cell cycle (Fig. 12–10). During the resting phases of the cell cycle, the Rb protein binds to the E2F transcription factor, thereby preventing the transcription and proliferation effects of E2F binding to DNA. As cyclin D–CDK-4 levels increase at the end G₁ phase, they form complexes and bind to Rb protein. The Rb protein then releases E2F, which binds to DNA and activates transcription of target genes involved in cell proliferation and DNA replication (see Fig. 12–10), and the cell thereby enters the DNA synthesis phase. The Rb protein is an essential component of the cell cycle; however, abnormalities of this gene and protein are very rare in breast cancer.

Amplification of the cyclin D gene (located on chromosome 11q13) has been identified in about 20% of invasive breast carcinomas, and overexpression of the protein by

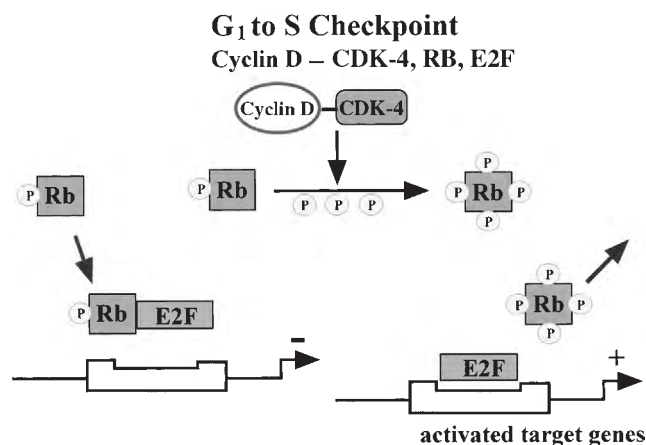

Figure 12–10 Diagram illustrating the role of cyclin D–CDK-4 complexes in phosphorylation of retinoblastoma (Rb) protein in a checkpoint between G₁ and S phase of the cell cycle. The E2F transcription factor is released to activate replication-associated gene transcription.

immunocytochemistry has been identified in about 80%.^{6,83} Few studies, however, and only limited sample numbers are available at present. There are specific inhibitors of the activity of cyclin D–CDK-4 complexes in late G₁ phase. These serve to prevent the phosphorylation of Rb protein and thereby prevent cells from entering S phase from G₁ phase. These inhibitors include *p16*, *p21*, and *p14*. One of these (*p21*) is induced by the *p53* tumor suppressor gene (discussed next). There are molecular inhibitors for all the cyclin-CDK pairs involving the cell cycle. An inhibitor of all of these cyclin-CDK pairs, *p21* probably has global inhibitory effects of the cell cycle progression.

An inhibitor of cyclin E–CDK-2 in late G₁ phase of the cell cycle (after cyclin D–CDK-4), *p27* was cloned from estrogen-treated MCF7 breast cancer cells and is frequently expressed and infrequently mutated (point mutation) in breast cancers.^{119,120} Recent clinical studies, using an immunocytochemical assay, suggest that elevated levels of cyclin E expression and decreased levels of *p27* expression have independent prognostic significance in breast cancer, including node-negative breast cancer in premenopausal women.^{121,122} Expression of *p27* was reduced in high-grade, but not low-grade, DCIS and was reduced in 20% of low-grade, 67% of moderate-grade, and 97% of high-grade invasive ductal carcinomas.¹²² Identification of a low-molecular-weight isoform of cyclin E has been described as a molecular marker of poor prognosis.¹²³ However, those assays require fresh tumor sample collection and more sophisticated laboratory techniques than standard IHC on a paraffin tissue section. The cyclin E isoform assay is currently performed in a single research laboratory, still needs independent validation, and hence is not currently used for routine clinical practice. These assays may well have a future role in the clinical laboratory. In summary, there are several levels of cell cycle control at specific checkpoints that use different tumor suppressor genes, cyclins, and their inhibitors.

Which tumor suppressor genes are important markers in breast cancer?

p53

The most important tumor suppressor gene in human cancer, *p53* is believed to play a significant role in breast cancer.^{124,125} The gene is located on chromosome 17 (17p21), and its protein product is a DNA-binding transcription factor for growth inhibitory factors that regulate the cell cycle and prevent entry into S phase.^{126–130} Expression of normal (wild-type) *p53* is increased in stressed cells, such as those exposed to ionizing radiation or chemotherapy.^{130,131} Wild-type *p53* is also able to induce apoptosis (active cell death) in damaged or stressed cells,^{132,133} activates genes involved in DNA repair,¹²⁵ and promotes differentiation and senescence of cells.¹²⁹ The overall effects are to prevent damaged cells from cycling, differentiate them into nonproliferative terminal stages, or kill severely damaged cells. Wild-type *p53* protein binds DNA as a tetramer,¹³⁴ enhances transcription of several genes (including *p21*, *GADD45*, and *mdm-2*), and also represses transcription of other genes (*fos*, *jun*, *myc*).^{129,135–137} Expression of *p53* is induced in late G₁ through the S phase of the cell cycle.^{127,131} It delays cells in G₁ phase so that DNA damage can be corrected

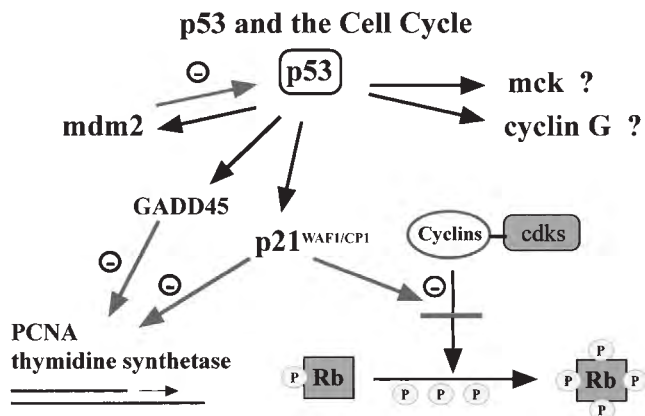

Figure 12-11 Diagram of the inhibitory influence of p53 protein on DNA synthesis (*bottom left*) and the G₁- to S-phase checkpoints of the cell cycle (*bottom right*) by inducing inhibitory molecules (p21 and GADD45).

before replication.^{129,130} The p53 protein is expressed in the nucleus; however, wild-type p53 is rapidly cleared, and therefore the protein is usually not detectable by immunocytochemical assays.^{124,129} Mutation of the *p53* gene (the most common abnormality) leads to a dysfunctional p53 protein, which can be detected by immunocytochemistry as increased amounts of p53 protein due to the delayed clearance of the abnormal protein.^{124,129} The genes induced by p53 binding to DNA include *p21* (*WAF-1/CP1*), *GADD45*, *bax*, and *mdm-2*¹²⁹ (Fig. 12-11). The p21 protein product inhibits cyclin D-CDK-4 binding of Rb protein (the late G₁ cell cycle checkpoint) and also inhibits DNA replication enzymes such as PCNA and thymidine synthetase.^{126,138} The ras, MAP kinase signal transduction pathway has also been shown to induce *p21* expression in a p53-independent manner.¹³⁹ *GADD45* also inhibits these DNA replication enzymes. The mdm-2 protein binds to and inhibits p53 protein in a negative feedback effect.¹⁴⁰ This protein has not yet been shown in breast cancer but is a significant abnormality in some sarcomas.¹⁴¹

The role of wild-type p53 in apoptosis is more definitive in breast cancer cells than in hemopoietic and lymphoid cells.¹⁴² This may partly explain why hematologic malignancies respond to chemotherapy and ionizing radiation more reliably than most solid malignancies.¹⁴² Activation of wild-type p53 stimulates transcription of proapoptotic molecules, such as *bax*, *PIG3*, *PUMA*, *Noxa*, and *p53AIP1*, and there is also evidence that wild-type p53 can directly enter mitochondria and stimulate apoptosis.¹²⁵ Mutant p53 may be involved in cellular resistance to necrosis in the center of expanding tumors. One study has suggested that clones of p53 mutant cancer cells may be able to survive in this anoxic environment.¹⁴³ Whether this mechanism is due to an influence of p53 on necrosis or apoptosis has not been completely determined.

Detection of p53 by immunocytochemistry (Fig. 12-12) implies dysfunctional (mutated or bound) p53 protein. This can be detected in about 40% of invasive breast carcinomas^{42,144-146} and in 20% to 40% of DCIS (particularly higher-grade comedo DCIS).^{63,144,145,147} Overexpression of p53 is believed to have prognostic significance, particularly in node-positive and higher-grade breast cancer.¹⁴⁸ Overall, the literature contains mixed results concerning the prognostic

Figure 12-12 Immunohistochemical stain showing expression of p53 in the nuclei of breast cancer cells in a paraffin tissue section (×100). The proportion of positive (*dark-colored*) cancer nuclei is calculated and reported as more than 90% (high).

value of p53 overexpression in node-negative patients.^{67,149} Overexpression of p53 is associated with increased cell proliferation (S phase, Ki-67, PCNA, MIB-1), histologic grade, and lack of hormone receptor expression.^{42,144,146,148,150-153} Some data suggest an association between p53 expression and *HER-2/neu* overexpression,¹⁴⁴ perhaps only in high-grade carcinomas,¹⁴⁸ although other data indicate no correlation.^{42,146} Loss of the stabilizing effect of wild-type p53 is associated with greater genomic instability in breast cancers,¹⁵⁴ which could lead to the development of new, biologically aggressive clones within the tumor.

BRCA1 and BRCA2

BRCA1 is a tumor suppressor gene on chromosome 17 (17q) that is sometimes mutated in hereditary breast cancer.^{15,155} Women with *BRCA1* mutations often have cancers with aneuploidy, high histologic grade, and an increased frequency of medullary features,¹⁵⁶⁻¹⁵⁸ but their long-term survival may not be different.^{157,159} *BRCA1* encodes a 220-kD protein that has nuclear localization and inhibits the cell cycle through G₁-S, S, and G₂-M phases.¹⁶⁰ *BRCA1* regulates expression of genes during cellular stress and repairs double-stranded DNA damage.¹⁵⁹ The *BRCA1* gene can be screened for mutations; this technique is presently employed in genetic screening programs for heritable breast cancer (see Chapter 20). *BRCA1* expression is increased during lactation and late pregnancy (times at which a woman is relatively protected from breast cancer)^{161,162} and can be induced by estrogen (and possibly tamoxifen).^{163,164} Germline mutation of *BRCA2*, a tumor suppressor gene located on chromosome 13 (13q), accounts for a similar proportion of hereditary breast cancer families as *BRCA1*.¹⁶⁵ The gene product of *BRCA2* is critical for the repair of double-stranded DNA breaks.¹⁶⁶ Unlike p53, somatic mutation of *BRCA2* (or *BRCA1*) in solid tumors is extremely rare.¹⁶⁶ Decreased expression of *BRCA1* or *BRCA2* does occur in sporadic breast cancer, and this is thought to be due to somatic deletion of one copy of the gene.¹⁶⁶ Hypermethylation of the promoter sequence for the remaining copy of *BRCA1* is occasionally identified, and this completely silences the

expression of *BRCA1*, but this is not the case for *BRCA2*.¹⁶⁶ However, EMSY is a novel protein that was recently shown to bind *BRCA2* after its induction following irradiation.¹⁶⁷ The normal function for EMSY is to inactivate *BRCA2* after DNA repair, but the authors identified amplification of the gene for EMSY (11q13.5) in 13% of breast cancers, and this was associated with node positivity and worse survival.¹⁶⁷ In 60% of these tumors, EMSY was coamplified with cyclin D1 (also at 11q13), suggesting a possible double oncogenic lesion in those cases.¹⁶⁷

What assays are used to evaluate hormone receptors in breast cancer?

Hormone receptor expression may indicate a better prognosis in premenopausal woman (PR slightly stronger than ER), although the main reason for routinely performing these assays is the predictive value of response to hormonal therapy. ER and PR levels are often similar within a breast cancer. PRs are closely related to ER activity. There are several forms with different tissue expression and activity. The PR level is widely considered to be an indicator of the integrity of the ER pathway. Immunocytochemical,¹⁶⁸ immunoenzymatic,¹⁶⁹ and biochemical (ligand binding)¹⁷⁰ assays are available for ER and PR

(Table 12–1). Fresh or frozen cancer tissue is required for immunoenzymatic and biochemical analyses. Many carcinomas are small and require fixation and complete histologic evaluation of the entire tumor. In these cases, hormone receptors can be studied using immunocytochemistry. There is excellent correlation between biochemical and immunocytochemical techniques.^{171–173} Biochemical assays can be limited by sampling of normal (instead of malignant) cells, by endogenous hormone bound to and blocking recognition of receptors (in premenopausal women),¹⁷⁴ and by truncated or mutated receptor protein, which does not bind hormone but is still transcriptionally active.¹⁷⁵ In recent years, antibodies have been developed to reliably detect ER and PR in formalin-fixed paraffin-embedded tissue.^{176,177} These antibodies are readily used on routine histologic materials (Fig. 12–13) and have largely replaced biochemical assays as the standard assay.^{174,176,178,179}

The reagents to be used for clinical ER testing using IHC now require approval by the U.S. Food and Drug Administration (FDA) because the results of the ER IHC test are the main determinant of whether a patient with breast cancer is eligible for hormonal therapy.^{180,181} This recent measure by the FDA acknowledges the change in how ER status is used in patient care. Although it is important to maintain the quality and reliability of reagents used to perform IHC for ER,

Table 12–1 Summary of Assays Used to Measure Estrogen and Progesterone Receptors in Clinical Breast Cancer Specimens

Assay	Tissue	Hormone Receptor Assays			
		Paraffin?	Amount	Measure	Positive
Biochemical	GT	No	1 mg	Quantitation of ligand binding	>10–15 fmol/mg
Immunoenzymatic	GT	No	1 µg	Immunologic quantitation of receptor in cytosol	>10–15 fmol/mg
Immunocytochemical	FroT, FixT, TI, FNA	Yes	1 slide ea	Positive nuclei (%) (image analysis)	>10%

Paraffin?, can assay be used on formalin-fixed paraffin-embedded tissue sections?; Amount, recommended minimum amount of pure tumor; Positive, values representing positive receptors status; GT, ground tissue piece (fresh or frozen); FixT, fixed tissue section (5 µm usually); FroT, frozen tissue section; TI, tissue imprint onto glass slide; FNA, fine-needle aspirate; ea, each assay.

B

Figure 12–13 Immunohistochemical stain for estrogen receptor (ER) in the nuclei of breast cancer cells in paraffin tissue sections from a core biopsy (×200). One tissue core (A) demonstrates weak, equivocal nuclear staining (low expression), but the other tissue core (B) from the same paraffin block demonstrates stronger staining in the nuclei of most cancer cells. This case demonstrates the differences that can occur in the ER immunohistochemistry assay from tissue fixation and antigen-retrieval methods, even in a single tissue block.

and standardization of reagents is enforceable by the FDA, this measure does not resolve two main problems with the IHC assay for ER.^{180,181} Stringent evaluation of the IHC test for ER has shown that the antigen-retrieval protocol is the most important variable of staining result.^{182–184} Generally, fixed tissue sections are immersed in a buffered solution and cooked in a microwave oven at high temperature setting for 30 minutes.¹⁸² Insufficient antigen retrieval can produce false-negative IHC results. Excessive antigen retrieval can lead to nonspecific background staining or loss of the antigen epitope. Antigen-retrieval methods also depend on the type and duration of tissue fixation and histochemical processing; thus, many laboratories optimize their own retrieval methods using control tissues.¹⁸² A standardized antigen-retrieval protocol is not an FDA requirement, and tissue fixation and processing methods are also not standardized.¹⁸¹ A recent study indicated that the duration of microwave cooking was the most important determinant of staining quality.¹⁸² Obviously, the quality and extent of antigen retrieval determines staining intensity in paraffin-embedded tissues, and this significantly influences the interpretation of staining results.

Most pathologists report the percentage of positively stained cancer nuclei and use a 10% threshold for definite positive status, ignoring the overall intensity of staining.¹⁸² Limited staining of less than 10% of the cancer nuclei can occur and is considered to be low expression that is equivocal. The H score was devised to combine the product of nuclear staining intensity (0 to 4) and the percent tumor area with each intensity score, to give a total of 0 to 400. The H score is time-consuming to perform and has not been widely adopted.¹⁸² A semiquantitative interpretation of ER IHC (combines percent positivity and intensity) has been proved in clinical studies to predict response to tamoxifen more accurately than ligand-binding assays,^{185,186} but this method is still not widely used.¹⁸² Systems that include the intensity and frequency of nuclear staining demonstrate higher response rates in metastatic breast cancer related to level of ER expression (responses in 25% negative, 46% intermediate, and 66% high expressors).¹⁸⁶ Computerized image analysis systems also seek to quantify intensity and distribution of staining but require additional cost and time to perform.

The gain from IHC has been greater confidence that ER expression is being assessed in the cancer cells and applicability of IHC to archival and routine diagnostic materials that can be performed in any laboratory (see Fig. 12–13). However, during this time, the quality of information provided by these different assays has not improved much, whereas the clinical utilization of ER information has radically changed from ER status as one of the prognostic markers to ER status as the main determinant to choose endocrine treatment.

ER in the nucleus is composed of three main components: a central DNA-binding domain, flanked by AF-1 and AF-2 domains. Estrogen (ligand) binds into a central site in the AF-2 domain, and a hydrophobic cleft forms, attracting coactivator proteins to bind. Coactivator proteins also bind the AF-1 domain. Coactivation is greatly enhanced by the changed conformation when estrogen is bound and enables the DNA-binding domain to bind to specific estrogen response elements in the promoter regions of certain genes, directly influencing their transcription. Nuclear ER is present in every breast epithelial cell but is detectable using IHC only when the level of expression is increased. This is the concept behind use

of IHC for ER as the assay to select patients for endocrine therapy.¹⁸⁷ Binding of the receptor hormone complexes to DNA induces promoters for a variety of genes, which are then transcribed. Those genes define the ER-related transcriptional profile and encode a variety of growth, proliferative, and secretory proteins that define the biology of ER-positive breast cancer.^{52,53,188,189}

ER has recently been described in the cell membrane and is bound to caveolin within cell membrane rafts.^{190,191} Transactivation of other receptors present in these rafts (EGFR, IGFR, *HER-2/neu*) leads to signaling to multiple kinase cascades, such as MAPK (ERK) and PI3K/AKT, that influence cell proliferation and transcription of genes.^{190,192–194} This occurs in tumors that are positive for ER and EGFR or *HER-2/neu*.^{194,195} There is also activation of *bcl-2* and *bcl-XL* (phosphorylated by JNK) to promote survival.¹⁹⁶ This membrane signaling by ER probably contributes to tamoxifen resistance because it bypasses the antagonistic action of tamoxifen in the nucleus.¹⁹⁰ However, because aromatase inhibitors markedly reduce estrogen levels in the tissues, the combination of aromatase inhibitors with agents that inhibit signal transduction molecules (tyrosine kinases, farnesyl transferase, cyclin-dependent kinases) has been proposed.^{190,197}

Are markers of breast cancer cell death available and informative?

The relevance of this question pertains to the ability of cancer cells to survive in conditions that would normally lead to cell death, to continued proliferation with severe DNA abnormalities that would normally be fatal, and to the effectiveness of chemotherapy and radiation therapy against cancer cells. Breast cancer cells can die by two different mechanisms. One mechanism is necrosis, due, for example, to inadequate blood supply to a region of tumor; the other mechanism is apoptosis (active individual cell death). Necrosis is documented histologically, without need for molecular assays.

Apoptosis is an active, multistep process by which cells release proteases and DNases to digest themselves. This process is seen in normal cells as a response to endocrine effects; damage (radiation, toxins, drugs, viral infection); cytokines (tumor necrosis factor, TGF- β); and disruption of cells from their extracellular matrix or neighboring cells, from electrolyte disturbances, or from disrupted linkage between growth and proliferative signals.¹⁹⁸ It is proposed that the common mechanism for inducing apoptosis is disruption of the link between proliferative drive within the cell nucleus and the required growth signal from receptors and transduction pathways.¹⁹⁸ For example, cells that overexpress *c-myc* (transcription factor) are very susceptible to apoptosis.¹⁹⁹ The specific DNase enzymatic destruction of DNA in apoptosis leads to fragmented DNA.^{198,200} In situ detection of DNA fragments allows detection of apoptotic cells and determination of apoptotic indices within tissue sections of tumors.²⁰¹

A normal protein (*bcl-2*) is expressed in the cytoplasm of cells and prevents them from undergoing apoptosis.²⁰² The *bcl-2* protein binds to another protein (*bax*), negating the apoptosis-promoting activity of *bax*.²⁰³ Antibodies are available for the immunocytochemical detection of *bcl-2*, and this has been studied in breast cancer, showing favorable

prognosis in women whose cancer strongly expresses *bcl-2*.^{204,205} There is a functional relationship between ER activity and *bcl-2*,^{205,206} as well as between wild-type *p53* activity and *bcl-2*.²⁰⁷ Survivin is an upstream inhibitor of mitochondrial apoptosis that has increased nuclear expression in up to 60% of breast cancers and is associated with improved survival.^{208,209} Activation of estrogen receptor increases the expression of both *bcl-2* and survivin.²¹⁰ Preliminary data suggest that reduced *bcl-2* expression may indicate response to chemotherapy.²¹¹ Transcription factors (*myc* and E2F) and tumor suppressor genes (*p53* and *PTEN*) have a role in the control of apoptosis.¹⁹⁹ Therefore, the systems of cell growth, proliferation, and death are related.

How does chromosomal telomere integrity affect breast cancer?

Mortality of normal cell lineages occurs in normal aging because the telomeric ends of chromosomes are shortened with successive divisions until eventually the lineage is exhausted. Activation of telomerase is common in breast cancer but not normal breast tissue.²¹² This enzyme maintains the ends of chromosomes, effectively producing immortality of the cancer cell lineage. A PCR-based telomere repeat amplification protocol (TRAP assay) was developed to identify a specifically repeating nucleotide sequence that is synthesized on the ends of the telomeres by telomerase.^{213,214} Newer assays are easier to perform; they use RT-PCR or IHC to recognize the active enzyme domain and use human telomerase reverse transcriptase (hTERT) or in situ hybridization to recognize an internal RNA component (hTR).^{215,216} These assays have demonstrated that increased telomerase expression is associated with more proliferative breast cancers and poorer disease-free survival.^{215,216}

Which markers assess breast cancer invasion and metastasis?

An invasive breast cancer has the ability to spread by metastasis to other organs, and it is this systemic disease that is the most important determinant of patient survival. Normal breast cells are strongly bound to their neighboring cells and to the underlying basement membrane by adhesion proteins. To invade, breast cancer cells must be able to dissociate from their neighbors, pass through the basement membrane and the extracellular matrix, and bind to new structures in order to pull themselves through the tissues (see Fig. 12–5A). The fact that pathologists detect stromal desmoplastic response in invasive breast cancer indicates that the invasive component of the tumor and the host stromal response are intimately associated (see Fig. 12–2). These same processes are required when the cells invade through tissue and through blood vessel walls, travel in the bloodstream, attach to distant endothelial sites, invade outside vessels, and establish tumor growths at distant sites (metastasis) (see Fig. 12–5B).

Cell Adhesion

Cell adhesion molecules join adjacent cells and the extracellular matrix and link the cell membrane to the underlying protein cytoskeleton. In breast cells, these cell adhesion proteins

Figure 12–14 Diagram of the main cellular adhesions in epithelial cells. Cadherins are involved in intercellular adhesion, whereas integrins generally mediate adhesion of the cell to basement membrane. Cytoskeletal filaments (actins, cyokeratins) attach to the adhesion units.

include cadherins and integrins (Fig. 12–14), which are families of different proteins. Reduced expression of E-cadherin has been shown in invasive breast cancer, correlating with higher histologic grade.^{217–219} The different pattern of invasive growth seen in lobular carcinoma is largely explained by loss of expression of E-cadherin (Fig. 12–15). E-cadherin gene encodes an adhesion molecule that is critical for intercellular attachment of epithelial cells. In lobular carcinomas, there is no expression of E-cadherin protein at the cell membrane, owing to loss of a gene allele (loss of heterozygosity [LOH]), mutation (encoding a protein that is secreted and not able to form intercellular attachments), or silencing of gene expression due to hypermethylation of the promoter site.^{220–223} Therefore, E-cadherin is not expressed at the cell membrane, and the carcinoma cells have minimal intercellular attachment. Loss of E-cadherin expression also occurs in lobular carcinoma in situ (LCIS), explains the characteristic discohesive appearance of the epithelial cells in that lesion, and is related to subsequent development of invasive lobular carcinoma.²²⁴ A recent publication compared the overall gene expression profiles between ductal and lobular types of invasive cancer and identified differential gene expression in very few genes.²²⁵ The most significant difference was reduced expression of E-cadherin in lobular carcinomas.²²⁵ Expression of osteopontin, survivin, and cathepsin B genes was also significantly decreased in invasive lobular cancer.²²⁵ Although complete loss of expression of E-cadherin is usual in invasive lobular carcinoma, reduced expression of E-cadherin does occur in some invasive ductal carcinomas and is related to a more infiltrative growth pattern²²⁶ (see Fig. 12–15). In this context, it is possible to consider lobular carcinoma of the breast as a variant of invasive carcinoma (rather than a specific histologic type), in which lost expression of a single gene product (E-cadherin) influences intercellular attachment and imparts a characteristic pattern of infiltrative growth.

Integrins are heterodimer pairs of different α and β chains (many combinations exist), which form attachments to the extracellular matrix and to adjacent cells and also act as growth-signaling peptides through their interactions with other cytoplasmic proteins beneath the cell membrane.²²⁷ In normal breast, these molecules are preferentially expressed in

Figure 12-15 Immunocytochemical stain demonstrates a membranous staining pattern of E-cadherin in invasive ductal carcinoma cells (A) that is lost in poorly differentiated invasive carcinoma with a single-cell invasive pattern (B). Note that epithelial cells of a normal duct (B, lower left) stain for E-cadherin ($\times 200$).

myoepithelial cells and the base of epithelial cells.^{228,229} In invasive cancers, there is loss of polarity and reduced overall expression of integrins in the malignant cells.^{228,229} Reduced expression of β_1 and β_4 chains has been shown in DCIS.²³⁰ The hyaluronic acid receptor (CD44) has also been indicated as a marker of tumor differentiation in breast cancer.²³¹

Enzymes

Proteolytic degradation of the extracellular matrix occurs by three main enzyme families. These are cathepsins, plasminogen activators, and matrix metalloproteinases (stromelysins, type IV collagenases, and interstitial type I collagenases). These enzymes can be secreted by breast cancer cells or by desmoplastic host stromal cells; all have been identified in invasive breast cancers and have been related to the likelihood of metastasis. These enzymes are usually secreted in an inactive proenzyme state and then activated in the extracellular space. Specific molecular inhibitors can inhibit their activity. In addition, growth factor and hormone effects permit transcriptional control of the genes for these enzymes, with transcription factors binding to specific gene control sites and subsequent inhibition or promotion of gene transcription.

Cathepsin D is a lysosomal proteolytic enzyme that also has growth factor properties and can be secreted by breast cancer or stromal cells.²³² The prognostic significance of cathepsin D expression has been evaluated in numerous studies using different assays. Studies using Western blot assays (cytosol protein levels) have shown increased enzyme levels to be associated with more aggressive outcome,²³³ although immunocytochemical assays have not detected significant independent prognostic value for cathepsin D.²³⁴ Therefore, the prognostic significance of cathepsin D levels remains controversial. Cathepsin D levels are closely associated with ER activity in breast cells²³⁵; therefore, in breast cancer cells, they may be related to the integrity of the ER system.²³⁶

Urokinase plasminogen activator (uPA) binds to a cell membrane receptor; activates plasminogen, matrix metalloproteinases, and collagenase IV; and can digest fibronectin.²³⁴ Immunoassays of cytosol extracts have indicated that high

uPA levels correlate with poor prognosis in breast cancer.²³⁴ This effect may be more marked when there are low levels of the inhibitor of uPA (PAI-2).²³⁷ The cell membrane receptor for uPA has been identified on breast cancer cells as well as macrophages in the desmoplastic stroma.^{238,239} Recently, ELISAs for the cytosolic ratio of uPA to inhibitor of plasminogen activator inhibitor type 1 (PAI-1), and for tissue inhibitor of metalloproteinase type 1 (TIMP-1), have been reported to achieve independent prognostic significance.²⁴⁰⁻²⁴³

The matrix metalloproteinases are a family of enzymes that include interstitial (type I) collagenases, type IV collagenases, stromelysins, and membrane-type metalloproteinases.^{234,244-246} As a group of enzymes, they can digest almost any protein in the extracellular matrix. Type IV collagen is the main component of basement membranes and is presumed to be a major barrier to invasion; however, there are inconsistent (and limited) data concerning the utility of immunocytochemical assays for type IV collagenases as prognostic markers in breast cancer.^{247,248}

Other Markers of Invasion and Metastasis

A metastasis suppressor gene (*nm-23*) has been described.²⁴⁹ Loss of this suppressor gene product has been associated with more frequent metastatic disease²⁵⁰; however, there are also conflicting prognostic data.²⁵¹

How is the host desmoplastic stromal response related to breast cancer markers?

The invasiveness of breast cancer cells is histologically related to the desmoplastic stromal response. The major components of the stromal response are the activity of stromal fibroblasts and histiocytes and the induction of angiogenesis to create a new capillary network to supply the tumor.

Stromal cells can influence tumor growth through paracrine stimulation or inhibition of cancer cells through cytokines and growth factors. These stromal cells can also secrete enzymes to degrade the extracellular matrix. These are

normal functions for these cells in wound healing, and it is believed that cancer cells may use these natural processes to their own advantage in the process of invasion. Tenascin is an extracellular matrix glycoprotein expressed in embryogenesis (mediating epithelial–mesenchymal interactions) as well as in some malignancies. Cancer and stromal cell expression of tenascin has been reported as an adverse prognostic marker in breast cancer.²⁵²

Angiogenesis is a critical component of tumor growth. Tumor cells and the associated host cells can induce angiogenesis through cytokines such as fibroblast growth factor- β . This again is a normal activity in wound healing but is uncontrolled in breast cancer. There is increased requirement for blood supply in rapidly growing and invasive tumors, leading to angiogenesis. Immunocytochemical assays for endothelial cell antigens (factor VIII, CD34) will demonstrate these capillaries, and vessel density within the tumor can be counted. Vessel density correlates with invasiveness, metastasis, and clinical behavior in breast cancers,^{253–256} but not all results have supported vessel density as a prognostic marker.^{257,258} Breast cancer cells produce and secrete vascular endothelial growth factor (VEGF) to stimulate angiogenesis by activating VEGF receptors on endothelium. VEGF expression is probably higher in *HER-2/neu*-positive breast cancers.²⁵⁹ High levels of cytosolic VEGF in tumor extracts (measured by ELISA) are associated with significantly shorter disease-free survival.^{260–262}

The immune response to breast cancer cells involves cytotoxic T lymphocytes (cell-mediated immunity), which can kill cancer cells by releasing toxic granules (perforin) or by binding Fas antigen and inducing apoptosis.²⁶³ However, this probably has a negligible influence on the growth, invasiveness, and clinical outcome of invasive breast cancers. Tumor-associated lymphocytes are infrequently a significant histologic component of these tumors.

How heterogeneous are cells within breast cancer?

Most studies of molecular pathologic assays involve single samples from breast cancers. There is some evidence that breast cancers can be quite heterogeneous. Evaluation of DNA content (ploidy) shows heterogeneity in 30% to 50% of breast cancers if samples are studied from four or more areas of each cancer.^{264–266} Analysis of all lymph node metastases and multiple primary tumor samples in heterogeneous tumors (by DNA ploidy) showed that DNA clones are stable during metastasis.^{267,268} These clones are identifiable as a significant population ($\geq 25\%$) in the primary tumor, but different nodal metastases contain different DNA clones.²⁶⁷ These findings indicate established heterogeneity of DNA ploidy clones within the primary tumor and the different metastases and show that different clones from the tumor can metastasize (retaining their DNA indices) and establish a majority in each metastasis.²⁶⁷ However, neither diploid nor aneuploid clones appeared to have a metastatic advantage.²⁶⁷ Cytogenetic analysis showed loss of specific chromosomal regions in only some of the tumor cells in 15% to 45% of breast cancer samples,²⁶⁹ indicating clonal heterogeneity within the tumor. Cytogenetic clones within the lymph node metastases were always present within the primary tumor,²⁶⁹ consistent with the DNA ploidy studies discussed earlier.²⁶⁷

Single samples of primary tumor and nodal metastases have approximately similar proliferative indices, although there is considerable variance.²⁷⁰ There is marked heterogeneity of proliferative activity if multiple samples are studied by any of the assays for proliferative activity.^{267,271,272} In one study of 101 patients followed for 5 years, only the means of the proliferation indices (three to eight samples measured) were of prognostic significance, whereas the highest values and the degrees of heterogeneity (coefficients of variance) were not significant.²⁷¹

Little is known about heterogeneity of *HER-2/neu* or *p53* expression. Generally, if the primary tumor overexpresses *HER-2/neu*, its nodal metastases will mostly overexpress this oncoprotein.^{267,273} Cancer cells frequently develop genetic damage because of inherent genetic instability. Breast cancer cells with abnormal *p53* have been shown to have greater genomic instability.¹⁵⁴ This is associated with more frequent oncogene activation, such as *HER-2/neu* expression.¹⁵⁴ Many genetic alterations are fatal or are not advantageous to the tumor cells; however, as dominant subclones develop, they overtake the tumor population.^{274–276} This is a mechanism of cancer progression, and clonal heterogeneity should be considered as part of the evolving biology of breast cancer.

It is important to appreciate that there is no single definition of clonality in breast cancer; therefore, the concept of multiclonality depends on which molecular assay is being studied. For example, some breast cancers have been shown to be clonal by some molecular techniques (X-chromosome inactivation pattern and restriction fragment length polymorphisms of other chromosomes), whereas DNA indices of the same breast cancers were heterogeneous.²⁷⁷ A different group used similar techniques and found monoclonality of the X chromosome in predominantly intraductal carcinoma compared with heterogeneity in atypical ductal hyperplasias and papillomas.²⁷⁸ This may be evidence that breast neoplasia begins as a monoclonal cell population but that heterogeneous subclones emerge as the disease progresses. The degree of heterogeneity within a single tumor would therefore depend on the state of tumor progression and the relative biologic aggressiveness of the different subclones that emerge.

Should molecular pathologic assays achieve independent prognostic significance?

The molecular pathologic pathways within breast cancer cells are complicated, and there is considerable overlap between different biochemical pathways and systems. Examples we have discussed include *p53* and its role in the cell cycle, gene transcription, and cell death; ER activation and its influence on PRs, growth factors, signal transduction, and proteolytic enzymes; the interactions between cancer cells and host stromal cells; and the overlap between different cell surface receptor systems, signal transduction pathways, and DNA transcription factors. It is understandable, therefore, that an individual molecular pathologic assay is unlikely to serve as a single independent prognostic determinant in such a complex biologic system. These assays do, however, study critical cancer cell functions that relate directly to growth survival, invasion, and metastasis. It is hoped that further refinement of these biologic pathways in cancer cells, and a more critical interpretation of the results of expanding clinical studies

using these assays, may focus attention on molecular systems within cancer cells rather than placing the emphasis on the prognostic significance of an individual molecule.

Can molecular pathologic assays predict response to therapy?

The difficulties in determining the prognostic significance of molecular markers from clinical outcome studies (outlined earlier) also apply to studies on the effects of therapy. However, the role of breast markers in predicting therapeutic responses will be an important area for future prospective clinical studies. Studies have found that certain markers do provide indications of potential therapy responses; some (ER and PR) have established clinical utility, whereas most require further research before any clinical value can be ascribed.

Antiestrogens

About 50% to 60% of newly diagnosed breast cancer patients are eligible for endocrine therapy on the basis of a positive IHC result (ER staining of $\geq 10\%$ cancer cell nuclei).¹⁸⁷ The current IHC test for ER has a high negative predictive value because patients with ER-negative breast cancer are highly unlikely to benefit from endocrine therapy.¹⁸⁷ However, the positive predictive value of response for patients with ER-positive breast cancer is weaker (50%), depending on whether the tumor is positive for ER and PR (50% to 70% respond) or ER only (30% respond).¹⁸⁷ The hormone receptor assays (estrogen and progesterone) provide reliable and valuable information concerning response to antiestrogen therapy. Expression of *pS2* in ER-positive cancers implies a good response to antiestrogens.²⁷⁹ This probably reflects the integrity of the ER pathway because *pS2* is an estrogen-induced gene. There are also data to suggest that patients with ER-positive cancer may not respond as well to antiestrogen therapy if the cancer cells overexpress *HER-2/neu*.²⁸⁰ A breast cancer cell line transfected with mutant *p53* did not develop antiestrogen resistance,²⁸¹ but clinical studies are not available.

Trastuzumab (Herceptin)

Monoclonal antibodies to *HER-2/neu* are available for clinical use and were used in the initial clinical trials of trastuzumab therapy²⁸² (clones 4D5 and CB11), but these may not be optimally sensitive. The FDA-approved HercepTest (DAKO) uses a polyclonal antibody cocktail that enhances the sensitivity of *HER-2/neu* detection but may compromise its specificity. Indeed, the HercepTest yielded a positive score in nearly 60% of breast carcinomas (expected frequency of 25% to 30%) and in 54% of samples from a group of 59 cases in which there had been no prior IHC staining using a monoclonal antibody (CB11).²⁸³ This was attributed to poor specificity of the polyclonal antibody used in the HercepTest.²⁸³ However, the HercepTest yielded a positive score in 58% of samples from a group of 48 cases in which there had been no prior IHC staining using the concentrate for the polyclonal HercepTest antibody (DAKO) and in which FISH had also shown no *HER-2/neu* gene amplification.⁷⁴ It was claimed that the scoring system of the HercepTest is prone to overestimation of IHC staining intensity because the normal epithelium is also positive in some cases.⁷⁴ This depends on the antibody selected and the laboratory methods. In our study of HercepTest, the

normal breast epithelium was always negative.²⁸⁴ Response rates from trastuzumab are lower for 2+ IHC staining tumors compared with 3+ staining tumors. In many laboratories, IHC is used as a primary screen, with FISH testing of all 2+ cases or primary FISH-based testing.²⁸⁵ In a study of single-agent trastuzumab in 111 patients, the response rates for 3+ IHC staining was 35%, versus 0% for 2+ IHC staining, and the response rate was 34% for FISH amplified, compared with 7% for nonamplified, breast cancer.²⁸⁵ In another study of breast cancer treated with trastuzumab and paclitaxel, patients with *HER-2/neu*-overexpressing tumors had overall response rates from 67% to 81%, versus 41% to 46% in patients with normal expression of *HER-2/neu*.²⁸⁶ FISH-based testing is more expensive and not as widely available as IHC, but some have suggested that FISH is actually more cost-effective if trastuzumab therapy is restricted to those with *HER-2/neu* amplification.²⁸⁷

Radiation Therapy

Radiation is most effective in proliferating cells; therefore, cell cycle-related proteins are likely molecular targets for predictive assays. Abnormalities of *p53* have been suggested to increase cellular resistance to radiotherapy,²⁸⁸ but reliable clinical data relating to breast cancer are not yet available.

Chemotherapy

High S-phase fraction has been shown to predict for improved response to chemotherapy.^{289–291} Other data suggest that *HER-2/neu* overexpression may adversely predict outcome to CMF (cyclophosphamide, methotrexate, 5-fluorouracil) chemotherapy^{292–294}; however, contradictory findings were published for doxorubicin-based therapy.²⁹⁵ Cultured human breast cancer cells with *HER-2/neu* overexpression have recently been shown to develop resistance to paclitaxel (Taxol) chemotherapy.²⁹⁶ Recent data suggest that patients whose tumors express *p53* (immunocytochemistry of paraffin-embedded tissue) may have a poorer response to CMF chemotherapy; the study sample was small, however, and results were not statistically significant.²⁹⁷ Matched-pair analysis of tissues before and after CMF chemotherapy showed altered *p53* expression in 40% of cases, suggesting clonal selection after therapy.²⁹⁸ There is strong evidence that apoptosis (and the role of *bcl-2* and *bax*) is important in the response of hematologic malignancies to chemotherapy and radiotherapy,²⁹⁹ but the influence of this cellular process in breast cancer is not fully understood.¹⁴² Early data indicate a possible role for *bcl-2* assays in predicting response to therapy.^{204,205,300} Immunocytochemical assays may be performed to detect drug resistance proteins, most importantly P glycoprotein (MDR-1). This is a multidrug resistance protein that, if present, actively pumps drug molecules out of cancer cells and is associated with resistance to chemotherapy.²⁹¹

There is considerable potential for high-throughput technologies, such as gene expression arrays, to identify responsive and resistant molecular profiles to predict likely response to chemotherapy regimens. To achieve this, the molecular profiles must be obtained and validated in the context of clinical trials that have meaningful outcomes. An example of this is complete pathologic response (pCR) from neoadjuvant chemotherapy that has an associated excellent long-term survival.^{301,302} Using gene expression microarrays from needle biopsies in a training set of 24 newly diagnosed breast cancers,

a 74-gene-expression profile was developed to distinguish the tumors that subsequently achieved pCR from those that had residual invasive carcinoma after 6 months of preoperative chemotherapy with paclitaxel, then 5-fluorouracil, doxorubicin, and cyclophosphamide.³⁰³ The same methods were then used to evaluate a validation set of 18 new patients who received the same medical and surgical management. The 74-gene profile from the pretreatment needle biopsy sample predicted there would be pCR for three patients, and all three achieved pCR.³⁰³ There were three additional pCRs in the other 15 patients for whom the 74-gene-expression profile did not predict complete response.³⁰³ These pilot data are promising but far from mature. The training set was limited (24 patients) and probably did not encounter the diversity of gene expression profiles that are associated with complete response, and hence some complete responses in the validation set were not correctly predicted.³⁰³ It is hoped that expansion of this and other clinical studies will lead to new predictive assays for response to chemotherapy.

What are the effects of chemotherapy and radiotherapy on breast cancer markers?

There are few data to address this question, and the results are not consistent. Some evidence suggests that proliferative activity is reduced, whereas *HER-2/neu* and *p53* expression is increased.³⁰⁴ It has also been shown that proliferative activity decreases following chemotherapy if the cancer had a high level of proliferation originally, that this phenomenon is dependent on the chemotherapeutic regimen, and that *p53* expression is decreased.³⁰⁵ The data from these studies may only reflect the more advanced stage of tumors that are treated with chemotherapy before surgery and may not be relevant to earlier stages of disease.

What are surrogate end-point biomarkers?

The concept of surrogate end points for breast cancer broadly encompasses any marker that predicts for future outcome. The more specific context in which this term is used here involves molecular pathologic markers as predictors of risk for future breast cancer or for response to chemoprevention strategies. The purpose is to speed up clinical trials by studying earlier, intermediate changes without having to wait years for prospective clinical follow-up before results are known. These biomarkers can be sought in samples from FNA, nipple fluid aspiration, or tissue from previous breast biopsies. Identification of aneuploidy and abnormal expression of several markers (ER, EGFR, *HER-2/neu*, *p53*) has been reported in fine-needle aspirates of “normal” breast in women at higher risk for developing breast cancer (family history or previous atypical or neoplastic breast biopsy) than women at lower risk.³⁰⁶ These data are very early, however. Chemoprevention biomarkers should be related to the mechanism of action of the therapeutic agent to be tested (e.g., PR expression in an antiestrogen trial) and should be identifiable in precancerous breast tissue.³⁰⁷ At this time, there are no clinically accepted surrogate end-point biomarkers, although potential targets include cell proliferation markers, *HER-2/neu*, *p53*, hormone receptors, and cytogenetic imbalances.^{307–309} Heterogeneity of

biomarkers in breast cancer is an important issue to be addressed before this approach will be clinically meaningful.

Should molecular pathologic assays be performed on in situ breast cancer?

Presently, the most important information concerning DCIS is the histologic absence of invasion and the cytologic-histologic grade. Sometimes, the histopathologic appearance is indefinite. In such cases, immunohistochemical stains that recognize myoepithelial cells are used to determine whether a myoepithelial cell layer surrounds the groups of cancer cells. These assays detect antigens associated with myofilament organization (e.g., smooth muscle actin and calponin) or nuclear *p63* expression.^{310–312} Absence of myoepithelium indicates invasion (see Fig. 12–6). The interpretation of these stains for myoepithelium in such cases is often challenging because there are increased numbers of myofibroblastic cells in the reactive stroma of invasive or in situ carcinoma (and these share expression of many of the same markers), and pre-existing myoepithelial cells in a duct or lobule distended by in situ carcinoma can become attenuated and difficult to identify. Furthermore, these studies are often performed on small needle biopsy samples with known limitations of incomplete sampling and artifacts of tissue compression and disruption. Nonetheless, the implications of determining the presence or absence of invasion for patient management justify the use of these stains in biopsy samples to address this important diagnostic issue.³¹²

Conceptually, in situ carcinoma is a preinvasive, localized phase of breast carcinoma and thus is managed by surgical or radiotherapy management; it does not require systemic therapy. There has been a recent shift in this paradigm since adjuvant hormonal therapy with tamoxifen has been shown to prevent (or delay) the onset of subsequent invasive breast cancer in women with previous DCIS.³¹³ Tamoxifen is currently being offered to women with DCIS.³¹⁴ Therefore, many laboratories have begun to test DCIS routinely for ER and PR (see Fig. 12–5), although there is not yet a published paper to confirm that the benefit is restricted to hormone receptor-positive DCIS. It is expected that most LCIS and low-grade DCIS should be positive for ER (see Fig. 12–5), whereas the ER status of intermediate- and high-grade DCIS is unpredictable from histopathologic appearance alone.³¹⁵ High-grade DCIS has interesting biologic and molecular characteristics. This lesion tends to be locally extensive within the ductal system and may involve single-cell (pagetoid) intraductal spread. Typically, the lesion is histopathologically associated with necrosis, apoptosis, and evidence of cellular proliferation. There is usually a high proliferation index (Ki-67 expression), and most high-grade DCIS cases have abnormal *p53* or overexpression of *HER-2/neu*.^{62,316} The frequency of *p53* and *HER-2/neu* abnormalities in high-grade DCIS (50% to 70%) is much higher than in invasive cancer (20% to 30%).^{62,317,318} In concurrent high-grade DCIS and invasive cancer, the status of *HER-2/neu* is usually the same.³¹⁷ High-grade DCIS with abnormal *p53* expression and high proliferation may be more likely to develop local recurrence.³¹⁹ This suggests that some high-grade DCIS lesions are locally aggressive but are delayed in their progression to invasive disease, despite frequent abnormalities of *p53* and *HER-2/neu*.³¹⁷ At

the current time, IHC assays for ER and PR are routinely performed on breast cancers with a final diagnosis of DCIS.

Which of these assays should be routinely performed on clinical specimens?

Most of the assays presented in this chapter are not routinely performed at the present time in a clinical setting but are subjects for clinical research studies. The assays that are routinely performed on clinical specimens of invasive cancer in all patients are an immunohistochemical assay for ER and PR and an immunohistochemical or FISH assay for *HER-2/neu*. These are necessary for possible therapy selection. Many laboratories will perform a proliferation assay, such as IHC for MIB-1 (Ki-67) or S-phase analysis using flow cytometry, particularly for node-negative breast cancer and T1 tumors. Some laboratories also perform a DNA ploidy analysis (DNA index determination) and IHC for p53 protein. It is becoming increasingly common that laboratories will perform IHC for ER and PR if the final diagnosis is DCIS because chemoprevention with an antiestrogen therapy may be considered if the DCIS is ER positive. It is possible that immunocytochemical assays for cell cycle-related proteins may be adopted in routine use, such as cyclin D1, p27, and cyclin E, although the current need is greater for predictive assays than for prognostic assays.

Surveillance Strategy for Detection of Breast Cancer

Stephen A. Feig

Breast cancer screening, the periodic examination of women to detect previously unrecognized disease, has usually been performed by mammography, physical examination (PE), and breast self-examination (BSE), alone or in combination. By definition, a breast cancer screening test is performed only on women with no clinical abnormality to suggest breast cancer, although they may be at increased risk because of factors such as age, family history, or nulliparity. Requirements for a screening test differ from those for a diagnostic test and include adequate sensitivity to detect early disease, acceptable specificity to minimize false-positive examinations, low risk, and acceptable cost and cost-to-benefit ratio. Because the ultimate goal of screening is reduction in deaths from breast cancer, demonstration of a statistically significant reduction in breast cancer mortality in a randomized clinical trial (RCT) is considered the gold standard of success. Thus far, this result has been documented for mammography but not for PE or BSE alone.

BENEFIT FROM EARLY DETECTION

How effective are clinical examination, mammography, and other imaging tests?

Mammography, PE, and BSE are complementary: each should be capable of detecting cancers that are missed by one or both of the other modalities. However, smaller tumors with higher survival rates are more likely to be detected by mammography than PE or BSE.^{1,2}

The Breast Cancer Detection Demonstration Project (BCDDP) screened 280,000 women throughout the United States with both mammography and PE from 1973 to 1981.¹ In this program, which was sponsored by the American Cancer Society (ACS) and National Cancer Institute (NCI), 39% of cancers were found by mammography alone, 7% by PE alone, and 51% by both mammography and PE. Detection at PE was lowest among earlier-stage lesions. BCDDP results indicated that mammography was the most sensitive means of early detection but that screening will be most effective when both modalities are used. Today, major improvements in mammography allow detection of even earlier lesions than was possible during the BCDDP era.³ However, the relative

efficacy of any detection method depends on the quality of the examination being performed.

Both ultrasound and magnetic resonance imaging (MRI) may detect some cancers missed by mammography and are currently under investigation to determine whether they might be effective as supplementary screening tests, especially in women at high risk and in those with dense breasts.² However, many questions regarding detection rates, false-positive biopsy results, costs, examination, and interpretation time need to be answered before ultrasound or MRI can be recommended for routine screening.

Digital mammography appears to have comparable sensitivity and specificity to conventional mammography. A large multicenter screening study of digital mammography is currently in progress to obtain a more precise comparison.²

Other modalities, such as thermography, which measures variation in breast temperature; light scanning (transillumination), which records transmission of light through the breast; and radionuclide scans, such as ^{99m}Tc sestamibi, should not be used for screening because they are much less effective than mammography in detecting very small lesions.

Why is decreased mortality a better measure of benefit than improved survival?

The 20-year survival rate for breast cancers detected at the BCDDP was 81%, substantially higher than the 20-year survival rate of 53% for breast cancers in the largely nonscreened U.S. population.⁴ Although these results are impressive, there are several reasons why “improved” survival rates among women who volunteer to be screened do not necessarily establish benefit from screening. These include selection bias, lead-time bias, length bias, and interval cancers.⁵

Selection bias refers to the possibility that women who volunteer for screening differ from those who do not volunteer in ways that may affect their respective survival rates. Lead-time bias implies that screening may advance the date of detection but not alter the date of death from breast cancer. Length bias postulates that cancers detected at screening contain a disproportionate number of less aggressive lesions. Even if undetected, such cancers might never result in death. Finally, higher survival rates among screen-detected cancers may be negated by lower survival rates among faster-growing interval

cancers that are undetected by mammography and surface clinically between screenings.

Considering these potential biases, benefit from screening cannot be proved by observation of improved survival rates. Rather, such proof requires prospective comparison of breast cancer death rates among study group women offered screening and control group women not offered screening in an RCT.

What are the results from randomized clinical trials?

Protocols and results for seven randomized trials of breast cancer screening by mammography alone or in combination with physical examination are shown in Table 13–1.^{6–12} Among seven randomized screening trials, six have shown evidence of benefit. Breast cancer mortality reduction was statistically significant in each of three trials (Health Insurance Plan of Greater New York [HIP], Swedish Two-County, and Edinburgh) and in combined results from the Stockholm, Malmö, Östergötland, and Gothenburg, Sweden, trials, and marginally significant in the Gothenburg trial. Only one trial, the National Breast Screening Study of Canada (NBSS-2), failed to show any benefit for mammography. In that trial, women receiving annual mammography and physical examinations were compared with those being screened by physical examination alone.¹⁰ Possible explanations for the NBSS-2 results include poor technical quality of mammography and a faulty protocol that allowed preferential allocation of women with advanced breast cancer into the study group.¹³

Why has screening of women aged 40 to 49 years been controversial?

Initial reports from the HIP trial found a difference in breast cancer death rates between study and control groups for women aged 50 years and older at entry that was apparent by year 4. Such a difference for women aged 40 to 49 years did not emerge until 7 to 8 years of follow-up. By 18 years of follow-up, the reduction in breast cancer deaths among study women aged 40 to 49 years at entry was 23%, the same as for those aged 50 to 64 years at entry. Yet even then, benefit for younger women was not statistically significant according to Shapiro and colleagues.⁶ This lack of statistical significance was a consequence of the relatively smaller number of younger women enrolled and their lower breast cancer incidence. Despite these explanations, the HIP trial results led to controversy regarding screening women in their 40s.⁵

The fact that the data for women aged 50 to 59 years and for those aged 60 years and older at entry when analyzed separately also lacked statistical significance was largely ignored. Moreover, Chu and associates subsequently found a statistically significant mortality reduction of 24% for women aged 40 to 49 years at entry into the HIP trial.¹⁴

There were two reasons why some observers were still not convinced. First, the delay in benefit for younger women in the HIP trial was also seen in all subsequent RCTs. Second, statistically significant benefit for younger women was not seen in any other individual trial until 1997.

The controversy intensified in 1992 with publication of the 7-year follow-up report from the NBSS-1 trial that found no evidence of benefit from screening women aged 40 to 49 years.¹⁵ There are several explanations for these disappointing

Table 13–1 Randomized Trials: Results for All Ages Combined

Trial (Dates)	Age at Entry (yr)	No. of Mammography Views	Mammography Frequency (mo)	Rounds (No.)	CBE	Follow-up (yr)	RR (95% CI)	Mortality Reduction (%)
HIP (1963–1969)	40–64	2	12	4	Annual	18	0.77 (0.61–0.97)	23*
Malmö (1976–1986)	45–69	1–2	18–24	5	None	12	0.81 (0.62–1.07)	19
Two-county: Kopparberg, Östergötland (1979–1988)	40–74	1	23–33	4	None	20	0.68 (0.59–0.80)	32*
Edinburgh (1979–1988)	45–64	1–2	24	4	Annual	14	0.71 (0.53–0.95)	29*
NBSS-2 (1980–1987)	50–59	2+ CBE versus CBE	12	5	Annual	13	1.02 (0.78–1.33)	–2
Stockholm (1981–1985)	40–64	1	28	2	None	8	0.80 (0.53–1.22)	20
Gothenburg (1982–1988)	40–59	2	18	4	None	14	0.77 (0.60–1.00)	23

*Statistically significant. Mortality reduction = 1 – RR.

CBE, clinical breast examination; CI, confidence interval; HIP, Health Insurance Plan of Greater New York; NBSS, Canadian National Breast Screening Study; RR, relative risk for death from breast cancer in study group/control group.

Data from references 6 to 12.

results. First, the technical quality of mammography was poor. During most of the trial, more than 50% of the mammograms were poor or completely unacceptable, even as assessed by the standards of the day.¹³ Second, the randomization process through which women were assigned into study and control groups was flawed and may have allowed preferential allocation of women with breast masses into the study group. As a likely consequence, an excess of late-stage breast cancers was found in the study group compared with the control group.¹³

Is there now proof of benefit for screening women aged 40 to 49 years?

Beginning in 1993, several successive meta-analyses of combined data for multiple RCTs were performed to accrue a greater number of women-years of follow-up than possible from any one RCT alone. Although the earliest meta-analyses suggested little if any benefit, subsequent meta-analyses published in 1995 and 1996 based on longer-term follow-up showed a statistically significant mortality reduction of 24% for women aged 40 to 49 years at entry into the seven population-based RCTs^{16–18} (Table 13–2). The most recent meta-analysis, published in 1997, found statistically significant mortality reductions among women invited to screening in their 40s: 18% for all eight RCTs (NBSS-1 included) and 29% for the five Swedish RCTs (see Table 13–2).¹⁸ Thus, with increasing length of follow-up, successive meta-analyses have shown progressively greater and statistically significant mortality reductions from screening for women in their 40s.

Table 13–2 Most Recent Meta-analyses of Randomized Clinical Trials Showing Statistically Significant Mortality Reduction for Women Aged 40 to 49 Years

Trials	Follow-up (yr)	Mortality Reduction (%)
All eight trials*	10.5–18.0	18
Seven trials†	7.0–18.0	24
Five Swedish trials	11.4–15.2	29

*All eight trials: Health Insurance Plan of Greater New York (HIP), five Swedish trials (Two-County, Stockholm, Malmö, Gothenburg), Edinburgh, National Breast Screening Study of Canada (NBSS-1).

†Seven trials: all trials except NBSS-1.
Data from references 16 to 18.

Moreover, meta-analyses are no longer necessary because two other RCTs besides the HIP study¹⁴ have now shown statistically significant mortality reductions for younger women: 45% for women who began screening at ages 39 to 49 years in the Gothenburg, Sweden, trial and 36% for women who began screening at ages 45 to 49 years in the Malmö, Sweden, trial^{19,20} (Table 13–3).

Should women aged 75 years and older be screened?

The question of mammographic screening for elderly women is clinically relevant because there are almost 10 million women aged 75 years and older in the United States. The life expectancy for an average woman at age 75 is 12 years²¹ and is even longer for those in good general health. Reduction in breast cancer mortality among women aged 50 years and older becomes apparent within 4 years from entry into randomized trials.²² Therefore, older women have a long enough life expectancy to benefit from screening long before they might die from other causes. Strictly speaking, benefit from screening women aged 75 years and older has not been proved because this age group was not included in any RCT. Nevertheless, there is no biologic reason why early detection should not be effective for these women. Survival rates according to stage of disease are almost as high in older as in younger women. The detection sensitivity of mammography is higher in elderly women owing to their generally more fatty breast composition. Therefore, screening mammography should be performed on women aged 75 years and older if their general health and life expectancy are good.²

Why do randomized trials underestimate the benefit from screening?

There are several reasons why results from all RCTs have underestimated the benefit to an individual woman undergoing screening with modern mammography. These include (1) mammographic image quality below today's standards, (2) use of only one mammographic view per breast, (3) noncompliance of some study group women, (4) contamination of the control group, (5) excessively long screening intervals, and (6) inadequate number of screening rounds.

Table 13–3 Most Recent Follow-up of Randomized Clinical Trials Showing Statistically Significant Breast Cancer Mortality Reduction for Women Aged 40 to 49 Years

Trial (Dates)	Age at Entry (yr)	No. of Mammography Views	Mammography Frequency (mo)	Clinical Breast Examination	Follow-up (yr)	Mortality Decrease (%)
HIP (1963–1969)	40–49	2	12	Annual	18.0	24
Malmö, Sweden (1976–1990)	45–49	1–2	18–24	None	12.7	36
Gothenburg, Sweden (1982–1988)	39–49	2	18	None	12.0	45

First, there have been many technical improvements in mammographic technique since the early 1980s when nearly all trials were conducted. Better image quality facilitates detection of early breast cancer.³ Second, women in the RCTs were mostly screened with one view per breast. A two-views-per-breast examination, today's standard, has been shown to detect more cancers than are found using a mediolateral oblique (MLO) view alone.²³

Two other reasons why RCTs underestimate the benefit from screening are that not all study group women accept the invitation to be screened (noncompliance), whereas some control group women obtain screening outside the trial (contamination). Yet, to avoid selection bias, an RCT must compare the breast cancer death rate among all study group women, both screened and unscreened, with that among all control group women, including those who are screened on their own initiative. Thus, both "noncompliance" of some study women and "contamination" of control group women reduce the calculated benefit from RCTs.

Fifth, randomized trials have also underestimated the potential benefit because screening intervals have been generally much longer than the annual intervals now recommended.² Numerous studies indicate that greater benefit should result from annual screening, especially for women in their 40s, in whom breast cancer growth rates are faster.^{24–26} Based on a tumor growth rate model, Michelson calculated that annual screening would result in a 51% reduction in the rate of distant metastatic disease, compared with a 22% reduction at a screening interval of 2 years.²⁷

Several investigators have used mathematical models of actual RCT data to calculate the benefit to an average woman who is screened every year and where results are not affected by noncompliance and contamination.^{17,23,26} For example, based on an observed 45% reduction in breast cancer mortality among women aged 39 to 49 years offered screening every 18 months at the Gothenburg trial, Feig calculated that the mortality reduction could have been as high as 65% with annual screening at the observed 80% compliance rate and as high as 75% at a 100% compliance rate.²⁶

Finally, the fact that no randomized trial had more than four or five screening rounds represents a sixth reason why such trials may underestimate the potential benefits from screening. Such relatively short trials limit the mortality reduction with estimates that can be made using standard methods of measurement. Screening needs to be performed not only frequently but also over much longer time periods in order to reach a steady state, when the greatest mortality reduction will be apparent. Using a new method of moving averages, Miettinen and colleagues calculated a 55% reduction in breast cancer deaths for women aged 55 to 69 years at entry into the Malmö Screening Trial.²⁸ This value was much higher than the 26% mortality reduction reported by Andersson and Nystrom, who had included data from before year 8, when benefit had not yet peaked, and from after year 11, when benefit was being diluted.²⁸

What are the current screening mammography guidelines?

Less than 5% of all breast cancers occur before age 40 years and less than 0.3% before age 30 years, compared with 19%

for women aged 40 to 49 years. Therefore, screening mammography is not advised for most women until age 40 years. Screening in their 30s may be considered only for those very few women who are in an extremely high-risk group for developing breast cancer at an early age.²

The time between screenings can affect the benefits. Mounting evidence indicates that breast cancer in younger women has a shorter lead time than cancer in older women.^{23,25,29} Lead time is the average time between actual detection at screening and clinical finding in the absence of screening. Accordingly, many major medical organizations now recommend that women aged 40 to 49 years be screened annually^{2,25,30} (Table 13–4). This recommendation replaces the previous recommendation that women in this age group receive screening mammography every 1 to 2 years and is justified by the more rapid growth of breast tumors among younger women. Some individuals have suggested that the interval between screenings can be lengthened as a woman ages. Nevertheless, it is likely that even in older women, some faster-growing cancerous tumors will become clinically apparent between biennial screenings, reducing the screening benefit. Women and their physicians should be aware that the major reason for accepting a longer screening interval at any age is a presumed reduction in screening cost, but some consequent reduction in screening benefit will occur. Screening guidelines of major medical organizations and advocacy groups are also shown in Table 13–4.

How valid is the most recent screening controversy?

Based on results from randomized trials conducted over the past quarter of a century and involving more than 500,000 women, there has been consensus in the medical community in favor of screening mammography. In the face of such near-unanimous agreement, two recent articles by Götzsche and

*American Academy of Family Physicians does not recommend screening after age 70 years.

Olsen made the seemingly incredible claim that none of the trials provided any convincing evidence that screening prevents breast cancer deaths.^{31,32} The Gøtzsche and Olsen papers received enormous publicity because of the sensational nature of their claim, which questioned the widely held belief in the efficacy of early detection. The arguments and counterarguments are complex and have been summarized in detail elsewhere.^{33,34} Fortunately, all of the conclusions reached by Gøtzsche and Olsen have been subsequently refuted in the peer review literature.

For example, Gøtzsche and Olsen suggested that the reductions in breast cancer death rates were due to age differences between study and control groups rather than the screening process itself. Gøtzsche and Olsen were unaware that when screening trials use cluster randomization rather than individual randomization, such relatively small age differences are not only expected but also acceptable.³⁴ In fact, after adjustment for age, mortality rates were only minimally different: 31% versus 30% for women aged 40 to 70 years, in the Swedish Two-County Trial, and 45% instead of 46% for women aged 39 to 49 years in the Gothenburg, Sweden, trial.^{34,35} Thus, there was no way that these small differences in age could have altered the overall conclusion that screening results in a substantial reduction in deaths from breast cancer.

Gøtzsche and Olsen also jumped on the fact that no statistically significant decrease in death rates from all causes combined had yet been shown in any of the Swedish trials. This observation was interpreted by Gøtzsche and Olsen to mean that any benefit from reduction in breast cancer deaths would be countered by increased deaths from other causes. This incorrect conclusion disregarded the fact that breast cancer accounts for only about 5% of total mortality. Thus, even the largest individual trial would be unlikely to demonstrate any statistically significant decrease in all-cause mortality. On this issue too, Gøtzsche and Olsen were proven wrong. Subsequent to publication of the second Gøtzsche and Olsen paper, Nystrom and coworkers were in fact able to find a 2% decrease in all-cause mortality among study group women in five Swedish trials combined.³⁶ Additionally, Tabár and colleagues observed a significant 19% reduction in deaths from all causes among breast cancer cases in the group invited to screening in the Two-County trial.³⁷ Thus, the Gøtzsche and Olsen conjecture regarding all-cause mortality was incorrect.

Although the reports by Gøtzsche and Olsen received considerable publicity in the U.S. media, no medical organization or government has changed its screening policy on the basis of their conclusions. Indeed, after review of the Gøtzsche and Olsen papers, 10 leading medical organizations, including the American Academy of Family Physicians, American Cancer Society, American College of Obstetricians and Gynecologists, American College of Physicians—American Society of Internal Medicine, American College of Preventive Medicine, American Medical Association, Cancer Research Foundation of America, National Medical Association, Oncology Nursing Society, and the Society of Gynecologic Oncologists, reaffirmed their support of screening in a full-page public service announcement in the *New York Times* on January 31, 2002. Also, the National Cancer Institute and the U.S. Preventive Services Task Force concluded that despite the Gøtzsche and Olsen contentions, the results from randomized screening trials were still valid. Elsewhere, the Swedish National Board of Health and Welfare, the Danish National Board of Health,

the Health Council of the Netherlands, the European Institute of Oncology, and the World Health Organization dismissed the Gøtzsche and Olsen arguments and concluded that the evidence for benefit was convincing.^{33,34}

Have breast cancer death rates been reduced by service screening in Scandinavia?

After the success of the Swedish randomized trials, organized service screening mammography became routine in nearly all Swedish counties by the 1990s. Unlike randomized trials, which are primarily conducted as clinical research studies, service screening is mainly performed as a public health initiative. Nevertheless, results from service screening projects have provided strong confirmation that screening mammography is effective in reducing breast cancer mortality.³⁸

A recent study by Tabár and colleagues measured the effect of mammography in a population in whom service screening is offered to all women aged 40 years and older.³⁹ The authors compared breast cancer death rates in two Swedish counties over three periods of time: 1968 to 1977, when virtually no women were screened; 1978 to 1987, when half the population was offered screening in the RCT; and 1988 to 1996 after completion of the trial, when screening was offered to all women and 85% of the population was being screened.

When compared with breast cancer death rates among women aged 40 to 69 years in the prescreening era, breast cancer death rates in 1988 to 1996 were reduced 63% for screened women and 50% for the entire population (85% screened plus 15% nonscreened) (Table 13–5). During this time, reduction in death rates from breast cancer for screened women were similar to those for women screened during the trial, that is, 63% versus 57%. However, during the RCT trial period (1978 to 1987), only half of the population was offered screening. For that era, breast cancer death rate reduction in the entire population was only 21%.

It seems probable that screening, rather than advances in treatment, was responsible for nearly all the benefit. The relative risk for breast cancer death among nonscreened women age 40 to 69 years was similar (1.0, 1.7, and 1.19, respectively) during the three consecutive periods. Moreover, the breast cancer death rate for women aged 20 to 39 years, virtually none of whom were screened, showed no significant

Table 13–5 Reduction in Population Death Rates from Breast Cancer, Women Diagnosed Between Ages 40 and 69 Years in Two Swedish Counties*

Screening Status	1978–1987 Randomized Trial	1988–1996 Service Screening
Screened	57%	63%
Invited to screening	43%	48%
Screened plus nonscreened	21%	50%

*Time of diagnosis either 1978–1987 or 1988–1996, compared with death rates from cancers diagnosed during 1969–1977 before screening began. All results were statistically significant at 95% confidence interval.

Data from Tabár L, Vitak B, Chen H-H, et al. Beyond randomized controlled trials: Organized mammographic screening substantially reduces breast carcinoma mortality. *Cancer* 2001;91:1724–1731.

difference (1.0, 1.10, and 0.81, respectively) during these three consecutive periods.

Possibly, women who agree to be screened have selection bias factors that apart from the screening process improved their survival rates. Even assuming the maximum effect of selection bias, screening was shown to reduce breast cancer deaths by at least 50%.

A study by Duffy and associates assessed the effect of service screening in seven Swedish counties.⁴⁰ Among women aged 40 to 69 years, breast cancer mortality was reduced 44% for screened women and 39% for women offered screening compared with the prescreening era. Based on breast cancer mortality trends, it was estimated that only 12% of the mortality reduction was due to improved therapy and patient management apart from the screening process.

Results from these and other service screening studies in Sweden and Finland indicate that the reductions in breast cancer mortality found in the randomized trials can be obtained and exceeded in non-research-organized service screening settings.³⁸ These programs effectively refute the claim by Gøtzsche and Olsen that the benefits seen in the randomized screening trials were not real because of supposed flaws in randomization and ascertainment of cause of death.³³

ADVERSE CONSEQUENCES AND COSTS OF SCREENING

The ability of screening mammography to substantially reduce breast cancer deaths is now well established and should no longer be subject to debate. Comparison of screening benefits with costs and adverse consequences, however, may reveal legitimate concerns. Such comparisons are discussed in the remainder of this chapter and can help determine when screening should begin and how often it should be performed. We must also seek ways to reduce these risks without reducing cancer detection rates.

Breast compression: can discomfort be avoided?

The benefits from breast compression include the ability to obtain better images at a lower radiation dose. Improvement in breast compression devices and techniques over the past 30 years have allowed higher cancer detection rates and more comfortable examinations.³ When properly performed, mammography usually is not painful.⁴¹ Following some simple recommendations can minimize discomfort. First, vigorous compression is not necessary; rather, the breast should be compressed only until the skin is taut. Compression should be applied gradually and gently. The patient should let the technologist know of any excessive discomfort so that no further compression will be applied. Patients who experience tenderness just before their menstrual periods may want to schedule mammography at some other time. In such cases, a mild analgesic before mammography may be helpful. It is important to minimize any discomfort from mammography so that women will not be reluctant to undergo periodic screening.

How often should screening patients be recalled for additional imaging?

When screening mammograms are “batch interpreted,” the patient leaves the imaging center immediately after her standard two-views-per-breast screening mammogram is performed and checked for image quality by the technologist. The images are then placed on a rotating film viewer and interpreted in batches by a radiologist at some later time. Patients receive their results by mail. If mammographic findings indicate that supplementary views or sonography are needed, the patient is telephoned and asked to return another day.

Because batch reading is much more efficient and cost-effective than on-line interpretation, it is the only practical way to perform screening mammography at the current low reimbursement levels and high demand for screening. In contradistinction, on-line interpretation is necessary for diagnostic mammography because of the high percentage of abnormal studies and the need to tailor each examination to the patient’s clinical problem.

Recall rates refer to the percentage of patients asked to return for additional imaging workup after batch interpretation of screening mammography. Batch interpretation can be performed successfully only if recall rates are maintained within acceptable limits. Recall rates that are too high cause patient inconvenience and anxiety as well as increasing the cost and reducing the efficiency of the screening process. If recall rates are too low, some subtle cancers may be missed, and some benign lesions may be subjected to biopsy unnecessarily because supplementary views and sonography were not performed.

On the basis of published reports of recall rates for well-conducted screening programs, the American College of Radiology recommends that recall rates be maintained at 10% or less.⁴² The upper limit should probably be 7% or less for women who have had a recent previous mammogram. Hunt and colleagues found that recall rates for such women could be 30% lower than those for women having their initial mammogram.⁴³

What are acceptable rates for false-positive biopsy results?

Excessive biopsies lead to anxiety and discomfort for the patient and also increase the cost of screening mammography. Positive predictive value (PPV) refers to the percentage of biopsies in which malignancy is found. The American College of Radiology recommends that the positive predictive value when biopsy is recommended (PPV₂) should be 25% to 40%.⁴² PPV results will be affected by patient age, risk factors, and presence of clinical signs and symptoms. Results from several centers have found that the PPV₃ (number of cancers detected per number of biopsies performed) for screening women aged 40 to 49, 50 to 59, 60 to 69, and 70+ years are about 22%, 35%, 45%, and 50%, respectively.^{44,45} Although the PPV is lower for women in the 40- to 49-year-old group, it is still acceptable. Complete imaging workup, including supplementary mammographic views and sonography; follow-up rather than biopsy for lesions that appear probably benign;

and second opinions for problematic cases can all reduce false-positive biopsy rates.

Is screen-detected ductal carcinoma in situ a real cancer?

Coincident with the increasing use of mammography has been a marked increase in the incidence of ductal carcinoma in situ (DCIS). Before the era of mammographic screening, DCIS represented less than 5% of all malignancies of the breast.⁴⁶ DCIS now accounts for 20% to 40% of all nonpalpable cancers detected at screening.⁴⁶ With appropriate treatment, the survival rate for patients with DCIS should be 99.5%.⁴⁶ DCIS may be considered a frequent but nonobligate precursor of fatal breast cancer. In other words, all cases of invasive ductal carcinoma are believed to develop from DCIS, but not all cases of DCIS may progress to invasive ductal carcinoma.

Justification for the use of DCIS as an index of benefit from screening depends on how often and how rapidly DCIS evolves into invasive ductal carcinoma. As of yet, no direct method exists for determining the natural progression of DCIS. If patients with DCIS were never to undergo biopsy and the DCIS were left to develop into invasive ductal carcinoma, there would be no way to establish that the initial lesion was DCIS. If DCIS is completely excised, then its natural history has been stopped, and there is no proof that it would have evolved into invasive ductal carcinoma.

Several follow-up studies of DCIS treated with biopsy alone also shed light on the invasive potential of DCIS. The lesions in these studies were categorized as benign at initial histologic review, so wide excision was not performed. In one study, researchers found development of invasive ductal carcinoma at the biopsy site in 53% of cases within 9.7 years.⁴⁶ Another study showed development of invasive ductal carcinoma in 28% of cases by 10 years and 36% of cases within 24 years.⁴⁶ Recurrence rates for DCIS in series such as these have suggested to some observers that DCIS is unlikely to progress to invasive disease.

There are two reasons why these studies should lead to just the opposite conclusion. First, these studies underestimate the invasive potential of DCIS because they involved only cases of low-grade DCIS, that is, all histologic subtypes of DCIS except for comedocarcinoma, the most aggressive subtype. Comedocarcinoma typically accounts for 32% to 50% of all cases of DCIS detected at mammographic screening.⁴⁶ Second, these studies included some cases in which the DCIS lesion was completely removed and other cases in which some DCIS remained in the breast when biopsy margins were not sufficiently wide. Invasive ductal carcinoma would be expected only in this latter subgroup.

Are detection rates too low and false-positive biopsy rates too high to justify screening women aged 40 to 49 years?

Women aged 40 to 49 years have a lower incidence of breast cancer, a faster rate of breast cancer growth, and a tendency to have denser, more fibroglandular breast tissue, for which mammography is less sensitive. As a consequence, screening

detection rates for women in their 40s are somewhat lower than those for women in succeeding decades. Biopsy PPV is also lower for women in their 40s. However, both detection rates and PPVs for women aged 40 to 49 years are well within acceptable limits.

Some investigators have used inappropriate methods of comparison to suggest that detection rates are too low and false-positive rates too high to support screening women aged 40 to 49 years. Methods such as pooling data for women aged 40 to 49 years with data from younger women, pooling data for women aged 50 to 59 years with data from older women, and the exclusive use of data from the initial (prevalence) screening result in an inaccurate portrayal of screening outcomes for women in their 40s. Such improper assessment led Kerlikowske and colleagues to make the misleading statement that screening women younger than 50 years old will detect only 20% as many cancers per 1000 women screened, will require 4 times as many diagnostic procedures per cancer detected, and will cause 2.5 times as many false-positive biopsy results for each cancer detected, compared with screening older women.⁴⁷

Proper assessment of the accuracy of screening mammography for women aged 40 to 49 years requires comparing data from that age group only with data for women aged 50 to 59 years. The use of data from initial (prevalence) screening alone may be misleading. The use of data from subsequent (incidence) screening alone is preferred, but combined data from prevalence and incidence screenings may also be used. Such an assessment will indicate that screening of women aged 40 to 49 years will detect at least 63% to 80% as many cancers, require 1.7 times as many diagnostic imaging procedures, and result in 1.3 to 1.4 times as many false-positive biopsy results for cancers detected⁴⁸ (Table 13–6).

What is the radiation risk from screening mammography?

Misperceptions regarding radiation risk from mammography persist even though no woman has ever been shown to have developed breast cancer as a result of mammography, not even from multiple examinations over many years' time at doses much higher than the current dose of 0.40 rad (0.004 Gy) for a two-view-per-breast examination. Such concern is based on the observation that some groups of women, such as Japanese atomic bomb survivors and North American women given radiation therapy for benign breast conditions such as postpartum mastitis or monitored with multiple chest fluoroscopies during treatment for tuberculosis before 1940, were found to be at increased risk for breast cancer.⁴⁹ Among these women, excess risk was observed for doses from 100 to more than 1000 rad (1 to 10 Gy).

The hypothetical risk for mammography is based on a linear extrapolation from these high-dose studies. If there is any risk from mammography, it is extremely low and is lowest for those who are exposed at ages older than 35 years. The current mean breast dose of 0.4 rad (0.004 Gy) from mammography is markedly less than the mean glandular dose of 3.2 rad (0.032 Gy) from the mammography film systems that were used at most facilities until 1973.⁴⁹

Screening benefits can be compared with radiation risks. On the basis of results from screening trials, we know that

Table 13–6 Relative Benefits and Risks of Screening According to Age Groups Being Compared

	Age Groups Being Compared (yr)	
	30–49 vs. 50–69*	40–49 vs. 50–59†
Detection rates	20%	63%–80%
Diagnostic procedures per cancer detected	4×	1.7×
False-positive biopsy results per cancer detected	2.5×	1.3–1.4×

*Prevalent screen data.

†Prevalent and incident screen data.

Data from Feig SA. Age-related accuracy of screening mammography: How should it be measured? *Radiology* 2000;214:633–640.**Table 13–7** Detection Benefits and Radiation Risks from Annual Screening Mammography of 1,000,000 Women Aged 40 to 74 Years

Parameter	No. of Women
Lives saved	18,900
Possible deaths caused	21.6
Benefit-to-risk ratio	875 : 1
Net benefit in lives	18,878

Data from Feig SA. Risk, benefit and controversies in mammographic screening. In Haus AG, Yaffe MJ (eds). *Physical Aspects of Breast Imaging: Current and Future Considerations*. 1999 Syllabus, Categorical Courses in Radiology Physics. Oak Brook, IL, Radiological Society of North America, 1999, pp 99–108.

annual screening can reduce deaths from breast cancer detected among women aged 40 to 49 years by at least 35% and deaths from breast cancer detected among women at 50 and older by at least 46%.⁵⁰ Possible deaths from radiation exposure from mammography can be estimated using a linear relative risk extrapolation of risk found among populations that received extremely high doses. Calculations based on these assumptions indicate that 18,900 deaths from breast cancer can be averted when 1,000,000 women are screened annually from age 40 years until age 74 years, and that at most 21.6 excess deaths might be caused by radiation (Table 13–7). Thus, even if there is a risk from multiple mammographic examinations at a dose of 0.4 rad (0.004 Gy) each, the benefit from annual screening for women aged 40 years onward exceeds that theoretical risk by at least 875 : 1.⁵⁰

Is screening mammography cost-effective?

The cost-effectiveness of screening mammography can be calculated based on the mortality reduction observed in the Swedish screening trials and current costs of screening in the United States. A recent study estimated that annual screening mammography beginning at age 40 years and continuing until age 79 years would cost \$18,800 per year of life expectancy saved.⁵¹ This estimate for the cost-effectiveness of screening mammography is in the same general range of other commonly accepted interventions such as screening for cervical cancer and osteoporosis⁵² (Table 13–8). The cost per year of life gained from annual screening mammography is higher than that for screening for colorectal cancer but is much lower than that for the use of seat belts and air bags in automobiles.

Table 13–8 Median Cost Per Life-Year Saved for Annual Mammographic Screening of Women Aged 40 to 79 Years and Other Selected Types of Lifesaving Interventions

Intervention	Median Cost per Year of Life Saved (\$)
Colorectal screening	3000
Cholesterol screening	6000
Cervical cancer screening	12,000
Antihypertensive drugs	15,000
Osteoporosis screening	18,000
Mammography screening	18,800
Coronary artery bypass surgery	26,000
Automobile seat belts and air bags	32,000
Hormone replacement therapy	42,000
Renal dialysis	46,000
Heart transplantation	54,000
Cholesterol treatment	154,000

Data on nonmammographic interventions from Tengs TO, Adams M, Pliskin J, et al. Five hundred life-saving interventions and their cost-effectiveness. *Risk Anal* 1995;15:369–390; data on cost-effectiveness estimate for screening mammography from Rosenquist CJ, Lindfors KK. Screening mammography beginning at age 40 years: A reappraisal of cost-effectiveness. *Cancer* 1998;82:2235–2240.

Although the cost per year of life gained for screening mammography is less than that for renal dialysis or heart transplantation, these interventions are needed for only a tiny fraction of the population. Because screening mammography is advised for all women aged 40 years and older, its total program cost must also be considered. In the United States, 62.6 million women are 40 to 89 years of age. If every one of these women obtained an annual screening mammogram at a cost of \$90, the total cost would come to \$5.6 billion per year. The total annual cost for all U.S. health care expenditures, however, is even more staggering: \$1.3 trillion for the year 2000. Thus, even if every woman 40 to 89 years of age obtained an annual mammogram, the total cost would be only 0.43% of the national expenditure on health care. At present, 59% of all U.S. women aged 40 to 89 years report having had a screening mammogram in the past year. At this compliance rate, screening mammography at a cost of \$90 would account for 0.25% of all U.S. health care expenditures.⁵³

This year, 192,200 women in the United States will develop breast cancer, and 40,200 women will die from previously diagnosed breast cancer. It is often stated that when women living to age 85 years are included, 1 of every 8 U.S. women will eventually develop breast cancer during her lifetime. Because of screening mammography and early treatment, most women who develop breast cancer today will not die from their disease. Breast cancer, although the most common cancer among women and the second-most common cause of cancer death among women, accounts for only 3.9% of all causes of death among women in the United States.⁵³ Nevertheless, allocation of 0.4% of all national health expenditures (or about 0.8% of all national health expenditures for women) to substantially reduce the death rate from a disease that accounts for 3.9% of all deaths among women would seem to be a reasonable policy.

Moreover, early detection will also reduce other health care expenditures, including treatment of advanced primary cancers, diagnosis and treatment of distant metastases or recurrent disease, loss of work productivity, short-term disability, long-term disability, and terminal care costs.

Clinical Assessment of Breast Cancer and Benign Breast Disease

Matthew N. Harris

Breast cancer ranks highest among women's health concerns, and the incidence rates are highest in industrialized nations such as the United States, Australia, and countries in Western Europe.^{1,2} The incidence of breast cancer increased in many countries during the 20th century, largely reflecting global changes in reproductive patterns and regional increases in mammography.³ In spite of this, many women have rarely if ever had a mammogram or physical examination of their breasts. Breast cancer is a progressive disease, and small tumors are more likely to be at an early stage, have a better prognosis, and are more successfully treated.⁴

ASSESSMENT OF BREAST CANCER

What are the reasons for patient delay in seeking medical attention for breast problems?

Delay in seeking medical attention falls into three general categories: (1) economic, (2) ignorance, and (3) psychological. First, the costs of medical attention are significant for the poor, those with inadequate insurance coverage, and those with other financial obligations.⁵ Second, many older women were not taught to recognize the significance of a breast mass or other presenting symptoms. There is a notion that as long as pain is not present, there is no problem. Third, an in-depth study of the psychological reasons for patient delay in diagnosis by Gold⁶ identified six psychological causes: (1) fear of cancer, mutilation, or a change in the relationship with the husband; (2) shyness or false modesty regarding examination of the breast; (3) negativism—some women raised in a hostile environment may become introverted and delay attention until the process is advanced; (4) depression causing the woman to ignore her health; (5) compulsion toward another goal so that all other aspects of life are ignored; (6) lack of breast tactility. In Gold's study, 47% of women never experienced emotional sensations associated with their breasts and tended to ignore them and therefore were not likely to discover an abnormality.

The fact that a patient consults a physician concerning breast disease may suggest knowledge about the importance of early detection, but it may also reflect a situation of “desperation” after a long period of procrastination, doubt, and misunderstanding.

What are the essential components of the clinical history?

The physician must bear in mind that the patient may be very anxious and that much can be done to allay apprehension. It is advantageous to have a second person present to participate and lend moral support. The patient may not hear or understand the discussion both before and after the physical examination. Although the patient or her partner often requests to take notes, it should be discouraged during the initial interview and can be reserved for the postexamination discussion.

In many instances, an anxious patient will volunteer information quickly and without pause. The patient should be asked to listen to the questions and answer them individually. If at the end of the interview all of the details of the history have not been covered, additional information can be added.

The physician must be discreet at all times during the interview, and patients must be informed of their Protected Health Information (PHI).⁷ Certain questions may embarrass the patient in front of her partner or significant other, and these questions can be reserved for the more private setting of the examining room. This is particularly important when dealing with younger women who have been accompanied to the interview by a parent. One cannot predict the relationship between patient and parent; if this relationship is open and is made known to the physician, a full discussion can be carried out without hesitation. Records of previous examinations and consultations, prior biopsy results, mammograms, and other pertinent data should be available at the time of the initial examination.

When a physician is asked to provide a second opinion, it is preferable that the physician review the history with the patient without the prior discussion or conclusion revealed, so that an unprejudiced decision can be made. At the end of the

consultation, the previous opinion can be critically reviewed, and the patient will have confidence that she has received a truly independent opinion.

The interview is opened with a personal greeting, and the patient who has not been referred by a physician is asked the source of the referral. Not uncommonly, this is another patient, and a sense of rapport rapidly develops between patient and physician.

The chief complaint is often a "lump in the breast." The history regarding a "lump" should include the date of onset or the date of detection, whether it is tender, and whether the patient conducts self-examinations and at what frequency. A careful history may help differentiate between the acute onset of a cyst of the breast and a mass of a more chronic nature, more likely a solid tumor, whether benign or malignant. Skin retraction, often a sign of a neoplasm, may be extremely subtle, but certainly the patient should be asked if she has noted any such changes.

If the complaints are nonspecific, the patient is questioned about whether she has a mass, any nipple discharge, and a history of injury to her breasts. The patient is asked whether she has had previous breast surgery and what the findings were. Tenderness and pain in the breast are the second most common complaints, and these may or may not be associated with a mass or what is perceived as a mass by the patient or her referring physician. The duration of symptoms should be recorded, as should whether the patient has sought other opinions in the past for a similar or the same problem.

Menstrual history is important and should include the age at menarche, the regularity of the menstrual cycle, and the date of the most recent menstrual period. The time of the menstrual cycle may be reflected in breast changes and may influence the findings on physical examination. Menstrual history should include the date of onset of menopause. Frequently, this is a protracted period of time, and the patient notes "irregularity" consistent with early menopausal changes. In addition, she may describe symptoms of menopause such as "hot flashes," dyspareunia, and irritability.

Both age at menarche and age at menopause are related to a woman's chance of developing breast cancer. Early menarche and late menopause lead to an increased total lifetime number of menstrual cycles and a corresponding 30% to 50% increase in breast cancer risk.⁸ Conversely, late menarche and early menopause lead to reduction in breast cancer risk of a similar magnitude. Oophorectomy before a woman reaches menopause lowers her risk for breast cancer by about two thirds. Pregnancy at a young age, especially before 20 years of age, markedly reduces the incidence of subsequent breast cancer. Nulliparity and age older than 30 years at first live birth are associated with nearly a doubling of the risk for subsequent breast cancer. Pregnancies not ending in the birth of a viable fetus do not reduce the risk for breast cancer. A nursing history should be obtained as well, although it may have little impact on breast cancer risk.

Nipple discharge, although relatively common and usually benign in origin, is often frightening. Evaluation of the patient with nipple discharge should begin with a thorough history. It is important to differentiate spontaneous from induced discharge, single duct from multiple duct discharge, and unilateral from bilateral discharge. The character of the discharge should be categorized as potentially related to a neoplasm

(serous, serosanguineous, bloody, or watery) or probably benign (various shades of green, gray, or brown).

What are the relevant issues related to the patient's history of hormonal therapy?

The patient is questioned on the use of hormones, both parenterally and by suppository, and the use of oral contraceptives. The type of hormone and the reason it is being taken are important.

The Women's Health Initiative, in a large multi-institutional study, enrolled more than 16,000 postmenopausal women aged 50 to 79 years to prospectively assess the risks and benefits of hormone replacement therapy using the most commonly prescribed form of estrogen plus progestin or estrogen alone.⁹ In July 2002, the National Institutes of Health suddenly halted the estrogen plus progestin arm of the study because interim analysis of the data indicated that the risks of continued hormone replacement therapy outweighed the benefits. In addition to the expected increase in the risk for stroke, women in the study arm also showed an unexpected increase in the risk for coronary disease. Of relevance here as well, this large randomized prospective study demonstrated a 26% increase in the risk for breast cancer over a 5-year period. The study indicates that an increased risk for breast cancer is only in current or recent users of hormone replacement therapy. Of known users who stopped hormone replacement therapy more than 5 years previously, the risk was no greater than in someone who had never used it.

Olsson and associates,¹⁰ in a study from Sweden, reported that longer use of hormone replacement therapy containing progestins significantly elevates breast cancer risks, whereas hormonal therapy containing estradiol does not.

In a randomized trial conducted by Chlebowski and associates on the influence of estrogen plus progestin on breast cancer and mammography in healthy postmenopausal women, 16,608 postmenopausal women aged 50 to 79 years with an intact uterus were randomly assigned to receive conjugated equine estrogens plus medroxyprogesterone acetate or placebo.¹¹ Significantly, relatively short-term combined estrogen plus progestin use increased the incident breast cancers, which were diagnosed at a more advanced stage, compared with placebo use, and also substantially increased the percentage of women with abnormal mammograms. The results suggest that estrogen plus progestin may stimulate breast cancer growth and hinder breast cancer diagnosis.

Additional data presented by Li and associates on the relationship between long durations and different regimens of hormone therapy and the risk for breast cancer concluded that the use of combined estrogen and progestin hormone replacement is associated with an increased risk for breast cancer, particularly invasive lobular carcinomas, whether the progestin component was taken in a sequential or a continuous manner.¹² Of interest is the fact that women using unopposed estrogen replacement therapy even for 25 years or longer have no appreciable increase in the risk for breast cancer, although the associated odds and ratios were not inconsistent with a possible small effect. The increase in risk is greater in those using combination hormone replacement therapy for longer durations (uses for 5 to 14.9 years), and those who used combination hormone replacement therapy

for more than 15 years had a 1.5-fold increased risk for invasive ductal carcinoma and a 3.7-fold increase in the risk for invasive lobular carcinoma.

Postmenopausal women have a greater risk than men of developing Alzheimer's disease. The use of estrogen plus progestin and the incidence of dementia and mild cognitive impairment in 4532 postmenopausal women was evaluated as part of the Women's Health Initiative memory study in a randomized controlled trial by Schumaker and associates.¹³ In this well-controlled study, it was concluded that estrogen plus progestin therapy increased the risk for probable dementia in women aged 65 years or older. In addition, estrogen plus progestin therapy did not prevent mild cognitive impairment in these women. The data support the conclusion that the risks of estrogen plus progestin outweigh the benefits.

In another study from the Women's Health Initiative, a randomized trial was conducted by Wassertheil-Smoller and associates concerning the effect of estrogen plus progestin on stroke in postmenopausal women.¹⁴ This study, involving 16,608 women aged 50 to 79 years, with an average follow-up of 5.6 years, concluded that estrogen plus progestin increased the risk for ischemic stroke in generally healthy postmenopausal women. Excess risk for all strokes attributed to estrogen plus progestin appeared to be present in all subgroups of women examined.

Rapp and associates,¹⁵ as part of the Women's Health Initiative memory study, conducted a randomized controlled trial of the effect of estrogen plus progestin on global cognitive function in postmenopausal women. They, too, found that although most women receiving estrogen plus progestin did not experience a clinically relevant adverse effect on cognition compared with placebo, a small increased risk for clinically meaningful cognitive decline occurred in the estrogen plus progestin group.

Clinically, hormone replacement therapy may cause swelling and tenderness of the breasts as well as increased density on mammography. Benign breast problems such as cysts are uncommon after menopause in the absence of exogenous hormones. Signs and symptoms include breast pain, a change in the size and shape of the breast, nipple discharge, and changes in the appearance of the skin.

What questions related to family history are relevant?

A family history of breast cancer is of great importance because heredity is a major risk factor.^{16–18} About 7% of breast cancers and 10% of ovarian cancers are thought to be associated with an autosomal dominant pattern of inheritance. Two high-penetrance breast cancer susceptibility genes, *BRCA1* and *BRCA2*, have been identified as accounting for most (about 85%) hereditary breast cancers. Mutations in these two genes are also responsible for most hereditary ovarian cancers, with 70% attributed to *BRCA1* and 20% to *BRCA2*.^{19–24} Genetic testing may be an important risk-assessment tool for patients whose family histories include multiple or early-onset breast or ovarian cancers. The *BRCA* mutations are also associated with an increased risk for prostate, pancreatic, and male breast cancer, although the risk for these is still small compared with breast and ovarian cancer. Hereditary risk for breast or ovarian cancer should be considered when there is early-onset breast cancer (usually before age 50 years) or

ovarian cancer, especially in more than one family member. Therefore, any woman diagnosed with breast cancer before age 50 years or with ovarian cancer at any age should be asked about first-, second-, and third-degree relatives on either side of the family with either of these diagnoses. In addition, the threshold for genetic testing should be lower in individuals who are members of ethnic groups in which *BRCA* mutations are known to be more prevalent, such as those of Ashkenazi Jewish descent. The patient's ethnicity may also influence her decision to have *BRCA* testing. For the near future, precisely estimating an individual woman's absolute risk for breast cancer must mainly rest on reproductive, family, and clinical history as well as genetic testing as detailed in Chapters 2 and 20.

The American Society of Clinical Oncology (ASCO) recommends that cancer predisposition testing be done to search for mutations of the *BRCA1* and *BRCA2* genes when (1) the patient has a strong family history of cancer or very early onset of disease, (2) the tests can be adequately interpreted, and (3) the results will influence the medical management of the patient or family member.²⁵ Genetic testing for breast and ovarian cancer susceptibility should be performed only with the individual's fully informed consent. Pretest and post-test counseling are important components of genetic testing, and genetic testing should be preceded by appropriate pretest and post-test follow-up care. Counseling should include a discussion of the risk to relatives as well as the availability and success of risk-reducing options such as surveillance, prophylactic mastectomy, prophylactic bilateral salpingo-oophorectomy, or risk-reducing drug therapy.

The recommended surveillance for patients with hereditary breast-ovarian cancer mutations includes breast self-examination (BSE) starting at age 18 years, semiannual breast examinations by a physician starting at age 20 years, annual mammography starting at age 25 years, and transvaginal ultrasound, Doppler color-flow imaging, and CA-125 testing annually after age 30 years.

What are the risks with a past history of treatment for Hodgkin's disease?

Prior treatment for Hodgkin's disease is a known risk factor for a second malignancy. A study by Ng and Mauch from the Brigham and Women's Hospital and Dana-Farber Cancer Institute in Boston indicated that survivors of Hodgkin's disease have a 4.6-fold increased risk for developing a second malignancy compared with the general population.²⁶ The effect of age and Hodgkin's disease diagnosis on subsequent cancer risk was most pronounced for breast cancer, and the relative risk for breast cancer was significantly increased in women diagnosed with Hodgkin's disease when younger than 30 years. The increased risk for breast cancer was of borderline significance in women diagnosed between 30 and 35 years of age. After age 35 years, the risk was not significantly increased. The risk for a second malignancy was significantly associated with extent of treatment exposure, including the radiation field size and the addition of chemotherapy to radiation therapy. The risk appeared to be the highest among patients who relapsed after combined-modality therapy and those who received further salvage therapy.

Travis and associates²⁷ conducted a matched case-control study of breast cancer within a cohort of 3817 female 1-year

survivors of Hodgkin's disease diagnosed at 30 years of age or younger. There was a greater risk for the development of breast cancer in patients who received moderately high doses of radiation to the breast than in those who received lower doses and no alkylating agents. Risk increased to eightfold with high doses of radiation. Increased risks persisted for 25 years or more following radiotherapy. Treatment with alkylating agents alone resulted in a decreased risk for breast cancer compared with treatment with combined alkylating agents and radiotherapy, which resulted in a 1.4-fold increased risk. Those who received radiation to the ovaries had a lower risk, suggesting that hormonal stimulation is important for the development of radiation-induced breast cancer.

What is the relevance of a past history of breast surgery?

If there is a past history of surgical procedures on the breast, the reports should be obtained.^{28,29} "Atypical" breast disease, including lobular neoplasia, noted on a previous biopsy, is important for final decision making.³⁰⁻³⁴ Mammograms with full reports should be available for review. The remainder of the history should be devoted to obtaining information elicited at all thorough examinations, including previous surgery, medical problems, and medications, particularly those medications that may affect hemostasis at surgery, such as aspirin, anti-inflammatory drugs, vitamins, and some herbal remedies.

What is the role of breast self-examination?

The main thrust in the treatment of breast cancer has been toward earlier diagnosis. The patient's role in diagnosis may include performing periodic BSE.

Beginning in their 20s, women should be told of the benefits and limitations of BSE. The importance of prompt reporting of any new breast symptoms to a health professional should be emphasized. Women who choose to do BSE should receive instruction and have their technique reviewed on the occasion of their periodic health examination. It is acceptable for women to choose not to do BSE or to do BSE irregularly.

An additional role of BSE is to increase awareness of normal breast composition so that changes can be detected. Even regular BSE performers commonly detected their breast cancer incidentally, suggesting that there was a component of increased body awareness in addition to the self-performed physical examination.

Recent data have indicated that the rate of biopsy for benign disease is higher in women who regularly perform BSE as compared with women who do not regularly perform BSE.³⁵ The U.S. Preventive Services Task Force concluded that the evidence is insufficient to recommend for or against teaching or performing routine BSE.³⁶ However, incidental self-detection of breast cancer still accounts for a significant percentage of cases.

Up to 50% of patients presenting with breast complaints have no evidence of a breast abnormality. If the health professional is unable to appreciate any breast abnormality, it is prudent to have the patient return for reexamination within a relatively short period of time, or a referral can be made to an

appropriate facility with experience in breast examination. Skinner and associates,³⁷ in a multivariate analysis, noted that treatment for breast cancer by a surgical oncologist resulted in a 33% reduction in the risk for death at 5 years.

What is the recommendation for clinical breast examination?

In addition to BSE, it is recommended that average-risk, asymptomatic women in their 20s and 30s have clinical breast examination (CBE) performed at least every 3 years. Asymptomatic women aged 40 years and older should have CBE annually. Women at average risk should begin annual mammography at age 40 years, and older women in reasonable good health should continue to be screened with annual mammography as well. Women at increased risk for breast cancer, as determined by a qualified health professional, may require earlier initiation of screening and shorter screening intervals.

How is the patient instructed in breast self-examination?

At the New York University (NYU) Medical Center and the NYU Cancer Institute, "shower cards" describing BSE have been made available to patients (Fig. 14-1).

BSE is performed monthly, and the patient looks for lumps, thickening, discharge, or any changes in the breast. If the patient is menstruating, the best time to perform self-examination is a week after the start of the period. It is important that pregnant and lactating women continue to perform monthly self-examinations. If the menopause has been passed, an easy date to remember is chosen, such as the first day of the month.

The patient is instructed to stand in front of a mirror. With arms at the sides and then raised above the head, she should look carefully for changes in the size, shape, and contour of each breast (Fig. 14-2). Specifically, she should observe for puckering, dimpling, or changes in the skin texture. Each nipple should be *gently* squeezed and any discharge recorded (Fig. 14-3). BSE can also be performed lying down. A pillow is placed under the right shoulder, and the right hand is placed behind the head. The right breast is examined with the left hand (Fig. 14-4). With the fingers flat, the breast is gently pressed in a circular motion, starting at the outside top edge and spiraling toward the nipple (Fig. 14-5A and B). The underarms and the area below the breast should be included (Fig. 14-6). This is then repeated for the left breast. In the shower, the right arm is raised, and the left hand is used to examine the right breast (Fig. 14-7). With the fingers flat and using a circular motion, every part of the breast is palpated, including the underarm, gently feeling for a lump or thickening. This is repeated for the left breast.

It is important to remind the patient that the purpose of regular BSEs is not to diagnose breast cancer but rather to detect any changes in the breast. If a lump or thickening is felt or a discharge or change in breast size or shape is noted, a health professional should be contacted as soon as possible. Most lumps are not indicative of cancer, and BSEs are free and take only a few minutes each month.

Breast Self-Examination

In Front of a Mirror

With arms at your sides, look carefully for changes in the size, shape and contour of each breast. Look for puckering, dimpling or changes in the skin texture. Gently squeeze each nipple and look for discharge. Repeat with your arms raised above your head.

Lying Down

Place a pillow under your right shoulder, and your right hand behind your head. Examine your right breast with your left hand. With fingers flat, gently press using an up and down pattern or a circular motion, starting at the outside top edge and spiraling toward the nipple. Include your underarm and the area above and below your breast. Repeat for your left breast.

In The Shower

Raise your right arm and use your left hand to examine your right breast. With fingers flat (using the up and down or circular pattern as you used lying down) touch every part of the breast, including the underarm, gently feeling for a lump or thickening. Repeat for your left breast.

Donated by the Landsberg Zale Surgical Oncology Research Fund

What You Should Know

Breast cancer is a progressive disease, and small tumors are more likely to be successfully treated. The purpose of breast self-examination (BSE) is to encourage you to be aware of how your breasts look and feel in order to recognize any changes and promptly report them to a health-care professional. Although there is some disagreement about the value of BSE, the self-detection of breast cancer still accounts for a significant percentage of cases found at an early stage.

REGULAR MONTHLY SELF-EXAMS ARE FREE AND TAKE ONLY A FEW MINUTES.

What You Can Do

As part of monthly BSE, you should look and feel for lumps, thickening, nipple discharge, or any changes in the shape or size of your breasts. Most lumps are not cancer.

If you are menstruating, the best time to perform a self-exam is a week after the start of your period. It is important for pregnant and nursing women to continue to perform monthly breast self-exams. Your obstetrician-gynecologist should review any modifications needed for you to perform the exam. If you are past menopause, choose an easy date to remember, such as the first day of each month.

Clinical Breast Exams and Mammography

For women in their 20s and 30s at average risk of breast cancer who do not have symptoms, it is recommended that clinical breast examinations (CBE) be performed at least every three years by a health-care professional. Asymptomatic women age 40 and over should have CBE annually. Women at average risk should begin having a mammogram each year starting at age 40, and older women in reasonably good health should continue to have regular mammograms. Women at increased risk of developing breast cancer, as determined by a qualified health-care professional, may need screening earlier and more frequently.

What are the components of the physician’s breast examination?

The patient should be escorted into a well-lighted examining room with an available x-ray view box. She is asked to undress at least to the waist and should be given a gown or similar appropriate covering so that she can feel comfortable if there is a short delay until the time of the physical examination. Although the patient has given a complete history and has informed the physician of the area of concern, it is suggested that the patient not show the physician the specific area until the physical examination is completed. In this way, the findings can be corroborated without prejudice. If, of course, the physician does not ascertain the area, the patient should be questioned directly about where she feels there is a problem.

The examination begins with the head and neck and the skin, including the skin of the upper extremities and the back.

It is not uncommon to find disorders of the thyroid, cervical lymph nodes, and the skin, some even suggestive of carcinoma or melanoma (Figs. 14–8 and 14–9). The size of the breasts should be noted, and difference in size recorded (Fig. 14–10). Many women have breasts that are not identical in size, and small size discrepancies are rarely a sign of malignancy. The patient should be questioned about whether she was aware of a difference in size, if present, as a recent change in size may indicate a pathologic process. One specific abnormality related to chest wall asymmetry is Poland’s syndrome, which consists of hand and digital abnormalities in association with absence or hypoplasia of the pectoralis major muscle, asymmetry of the chest wall, and hypomastia on the involved side.

The patient is asked to raise her arms, and the breasts are examined for evidence of skin retraction, dimpling, or a mass that protrudes from the breast (Figs. 14–11, 14–12, and 14–13). Although retraction is often a sign of malignancy, benign lesions of the breast such as fat necrosis can also cause retraction. Other benign causes include previous surgical

biopsy and superficial thrombophlebitis of the breast (Mondor's disease) (Fig. 14-14).

Edema of the skin of the breast (peau d'orange) may be present as a result of obstruction of dermal lymphatics by tumor cells. However, it may also be caused by extensive metastatic axillary lymph node involvement, by primary disease of the axillary nodes, or subsequent to axillary lymph node dissection with or without radiation therapy. Erythema of the breasts may have an infectious cause, as with cellulitis or abscess, but a diagnosis of inflammatory carcinoma should be considered as well (Figs. 14-15 and 14-16).

It is extremely important to inspect the inframammary regions because this component of the examination is often overlooked by patient and physician alike (Fig. 14-17). Lesions in this area are often neglected and diagnosed at an advanced stage because they are not perceived on casual examination by the physician on palpation or by the patient unless she looks in the mirror when doing BSE. Skin lesions of

the breast should be noted and the area of the nipple-areolar complex carefully examined for evidence of crusting, eczematoid changes, and other epithelial changes (Fig. 14-18). If dimpling, skin retraction, nipple inversion, or a mass is observed on inspection, attention should be directed to those areas by palpation with the patient in the sitting position and again in the supine position.

Inspection is completed with the patient contracting her pectoral muscles by pressing her hands against her hips (Fig.

Figure 14-13 Obvious tumor mass in the right breast on inspection.

Figure 14-14 Mondor's disease: superficial thrombophlebitis of the breast.

14-19). This maneuver, which puts tension on the suspensory ligaments, often highlights areas of skin retraction not readily apparent with the arms relaxed.

The breast examination is continued by palpation with the patient in the sitting position. The breasts are examined simultaneously with attention to any differences in contour or a palpable thickening or mass (Fig. 14-20).

Palpation of breast tissue between fingers or squeezing the breast may result in a false perception of a mass; this is a common error of inexperienced examiners and women attempt-

ing self-examination (Fig. 14-21). Comparing the breasts is often helpful in determining whether a questionable area requires further evaluation.

The relative sparsity of breast tissue in the subareolar region often gives the impression of a periareolar “shelf” or “ridge,” particularly in larger breasts. This should not be mistaken for a mass and is usually bilateral.

The axillae should be thoroughly examined with the patient in the sitting position, with the arms relaxed and with the patient supported by the physician’s nonexamining hand. The axillary tissue should be firmly palpated under the pectoralis muscle, with pressure exerted and the axillary tissue pressed against the chest wall (Fig. 14-22A and B). The examining hand is then gently rolled over any palpable mass. This examination may be somewhat uncomfortable for the patient but

Figure 14-24 Breast examination by the physician. The patient is supine and the breasts are palpated for changes in contour, thickening, or a mass.

need not be a prolonged process. The skin of the axillae should be observed. A patient may believe she has a breast mass when the problem is really one of the skin, such as an epidermoid inclusion cyst, a cyst of the sweat gland apparatus, or hidradenitis suppurativa. Axillary breast tissue can be appreciated as well and should be carefully evaluated (Fig. 14-23). In obese patients, the axillae, and sometimes the supraclavicular areas, may contain a soft to rubbery fat pad that can be mistaken for adenopathy. Lymph nodes may be palpable or present within them.

The patient is then asked to assume the supine position, and the breast examination is carried out as described in the discussion of BSE (Figs. 14-24 and 14-25). Note is made of any mass in the breast, tenderness, nipple discharge, or skin retraction. The axillae are again palpated in this position (Fig. 14-26).

It may be difficult to determine whether a palpable mass is solid or cystic. The history may be of some help in that cystic lesions are more likely to be of sudden onset and tender. If a mass feels like a cyst, aspiration is attempted to obtain fluid.

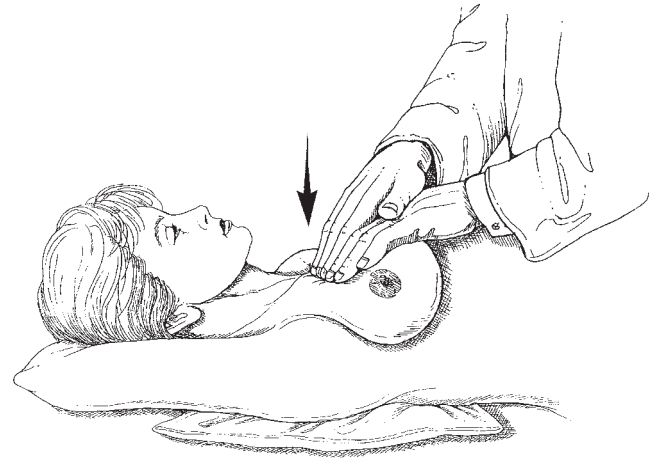

Figure 14-25 Breast examination by the physician. The breast is palpated with the tufts of the fingertips applying gentle pressure.

Figure 14-26 Breast examination by the physician. The axillae are palpated with the patient supine.

If the mass is no longer palpable after aspiration, one of the criteria for a benign cyst of the breast has been met. If, however, the fluid appears to be bloody or if the mass does not disappear completely on palpation after aspiration, further investigation is warranted. If the lesion is not a cyst but solid, further diagnostic procedures are mandatory with fine-needle aspiration biopsy, image-directed biopsy, or excision. If there is some doubt about whether a palpable mass is cystic or solid, breast ultrasonography with attention to the area in question is helpful. The radiologist or surgeon may then proceed with cyst aspiration under ultrasound guidance or with other appropriate biopsies. Of course, if a mammogram or an ultrasonogram is available at the time of the examination and an obvious cyst is both palpable and seen on the imaging studies, a cyst aspiration should be performed.

In patients who have had an augmentation mammoplasty, the prosthesis may be palpable, most often as a globular smooth mass underlying the breast. On occasion, the valve of the prosthesis can be felt and may be mistaken for a significant breast lesion. These valves have a characteristic discoid outline on palpation. If there is any question concerning the findings on palpation, confirmation can usually be obtained by history and ultrasound imaging, if necessary.

Any palpable finding not matched in a mirror-image location in the opposite breast is a reason for concern, including

ill-defined asymmetrical thickenings. It is impossible to rule out breast cancer on clinical grounds alone. Failure to be impressed with physical examination findings was cited as the most common reason for a delay in the diagnosis of breast cancer and the second most frequent cause of legal action against physicians, and the most expensive.³⁸

It is appropriate, and often helpful, to review mammographic findings on the x-ray view box with the patient so that she has a clear perception of what microcalcifications or a solid or cystic lesion looks like and the extent of the process. With the use of image-guided biopsies and the availability of a well-trained cytologist, the patient can be given at least a preliminary diagnosis within a short period of time. This will help allay apprehension and will allow the patient and the physician to discuss further treatment if indicated. With the increased use of image-guided biopsies, most patients will have definitive surgery with a fairly accurate preliminary diagnosis.

What is the role of screening in the clinical assessment?

The American Cancer Society estimates that in 2005, 212,930 women will be diagnosed with invasive breast cancer and an additional 58,490 with in situ breast cancer. It estimates that 1690 men will be diagnosed with breast cancer, and 40,410 women and 460 men will die of the disease.³⁹ It is widely acknowledged that when breast cancer is diagnosed and treated at an early stage, the chances for long-term survival are better; and furthermore, smaller lesions are more amenable to breast-conserving surgery.

Ghafoor and associates,⁴⁰ in a recent report from the American Cancer Society, described the trends in incidence, mortality, and survival rates of female breast cancer in the United States by race and ethnicity. Breast cancer incidence has increased among women of all races combined and among white women since the early 1980s. The increasing incidence in white women predominantly involves small (<2 cm) and localized-stage tumors, although a small increase in the incidence of regional-stage tumors and those larger than 5 cm occurred since the early 1990s. The incidence among African American women stabilized during the 1990s for all breast cancers and for localized tumors. African American women are more likely than white women to be diagnosed with large tumors and distant-stage disease. Other racial and ethnic groups have a lower incidence than white or African American women. However, the proportion of disease diagnosed at advanced stage and with larger tumor size in all minorities is greater than in white persons. Death rates decreased by 2.5% per year among white women since 1990 and by 1% per year among African American women since 1991. A disparity in mortality rates increased progressively between 1980 and 2000, so that by 2000, the age-standardized death rate was 32% higher in African Americans than in white women. The authors point out that 63% and 29% of breast cancers, respectively, are diagnosed at local- and regional-stage disease, for which the 5-year relative survival rates are 97% and 79%, respectively.

O'Malley and associates,⁴¹ using data from the Surveillance, Epidemiology and End Results program (SEER), noted that

after adjustment for multiple factors, African Americans continued to have slightly but significantly poorer survival after breast carcinoma compared with whites, whereas the survival of Hispanics and Asians did not differ from that of whites.

Naik and associates⁴² studied the epidemiologic and pathologic characteristics of indigent breast cancer patients in a public city hospital in comparison to national standards. The medical records of 188 patients were retrospectively reviewed. The authors concluded that indigent patients among all ethnic and racial backgrounds present with more advanced disease when compared with national statistics reported by the SEER program.

Two components of delay have been identified: (1) delay by a woman in seeking care for breast cancer symptoms, and (2) delay by the patient, provider, and system during the evaluation, diagnosis, and initiation of treatment of breast cancer. A study by Bedell and associates⁴³ addressed the problem of delay in diagnosis and treatment of breast cancer. They noted that nearly half of the diagnostic interval delay in the public hospital results from systemic factors such as general scheduling delays or time spent waiting for appointments and diagnostic procedures to be scheduled and completed, waiting for reports and results, and waiting for retrieval of lost or missing records. Missed diagnosis was the most common reason for provider delays in the diagnostic interval. Missed diagnoses occurred when cancer symptoms were ignored, treatment for presumed infection was instituted, a mass was present and biopsy was not performed, or a suspect finding was not followed up. Complaints of a breast mass must be aggressively pursued, and dominant masses should undergo biopsy. A normal mammogram does not rule out the need for a biopsy. Education of women to follow routine screening recommendations, to recognize breast cancer symptoms early, and to recognize benefits of early detection is important. Minority and uninsured women are at particular risk. Language, culture, and financial barriers in this population may necessitate more outreach and support.

The Gothenburg Breast Screening Trial⁴⁴ reported a randomized controlled trial of mammographic screening for breast carcinoma with 21,650 women in the screened group and 29,961 women in a control group. The screening interval was 18 months. Age-specific analyses yielded greater mortality rate reduction for the groups of women aged 39 to 44 years, 45 to 49 years, and 55 to 59 years, but there was no mortality rate reduction in the group of women aged 50 to 54 years. The authors observed a 20% to 30% reduction in breast carcinoma mortality with mammographic screening. The results also suggested that a reduction in mortality in women younger than 50 years of age might also be achieved with a short screening interval.

A Swedish trial conducted by Tabar and associates⁴⁵ reported a 30% reduction in mortality associated with the invitation to screening of women aged 40 to 74 years, with the reduction being 34% for women aged 50 to 74 years and 13% for women aged 40 to 49. These authors suggest that much, although not all, of the smaller effect of screening on mortality in women aged 40 to 49 years was due to faster progression of a substantial proportion of tumors in this age group and the rapid increase in incidence during this decade of life. It was estimated that a 19% reduction in mortality would result from an annual screening regimen.

What is the radiation risk from mammography?

The possibility of radiation risk from mammography has been a subject of debate, specifically in the screening of women between the ages of 40 and 49 years. In 1975, Dr. John Bailar, Editor of the *Journal of the National Cancer Institute*, called public attention to the potential radiation risk of screening mammography. Although conceding that for women older than 50 or 60 years, “the radiation risk may be small in relation to the expected benefit,” he concluded that the routine use of mammography in screening asymptomatic women “may eventually take as many lives as it saves.”⁴⁶ Since that time, concerns have lessened as randomized trials have proved the benefit of screening in women between the ages of 40 and 49 years. In addition, with improvements in technology, there has been a sevenfold national reduction in mean glandular dose to the breast from 1974 to 1992, and there are numerous studies indicating that the risk from radiation is negligible compared with the benefit from screening.

Feig⁴⁷ summarized the assessment of radiation risk from screening mammography. The female Japanese survivors of the Hiroshima and Nagasaki atomic bombings represent the largest of all available populations of women who received high doses of radiation and from which estimates of the risk for radiation-induced breast cancer can be derived. The longest follow-up of the Japanese women to date was reported by Tokunaga and associates in 1994.⁴⁸ Excess relative risk for breast cancer in exposed women compared with nonexposed women was found with doses of 250 to 500 mGy among Japanese atomic bomb survivors, but there was no evidence of excessive risk below 250 mGy. After the hypothetical risk for developing a fatal breast cancer from mammography is calculated from the relative risk estimate that Tokunaga and associates derived from the follow-up of Japanese atomic bomb survivors, it may then be compared with the number of fatal cancers prevented by mammographic screening as observed in randomized screening trials. Mettler and associates⁴⁹ have made it clear that the risk is negligible compared with the proven benefit from screening.

In a meta-analysis of seven randomized trials by Smart and associates, a significant reduction in mortality from breast cancer resulted from screening frequencies that ranged from 12 to 33 months, when combined with adequate follow-up.⁵⁰ Feig⁴⁷ concluded that over a period of 20 years, studies comparing benefits and risks of mammographic screening have reduced the level of concern regarding radiation exposure of asymptomatic women, and the benefit-to-risk ratios from actual screening may be even more favorable than those calculated in the Mettler study.

What special considerations apply to the clinical evaluation of young women?

Breast cancer in women younger than 40 years requires special consideration. These women are often more aware of the necessity for examination and mammography than their older counterparts. In view of this, particularly with the increasing use of mammography in women between the ages of 30 and

40 years, it appears that the incidence of breast cancer in young women is rising. However, the nature of the lesion discovered in many instances may be quite different from that seen in older women. The findings range from minute intraductal neoplasms, manifested by a tiny cluster of microcalcifications on mammography, to invasive lobular carcinoma, which is difficult to detect on mammography in dense breasts and is often discovered on physical examination at a more advanced stage.

Among the 211,300 new cases of breast cancer diagnosed in 2003, about 6% were in women younger than 40 years. The absolute number of breast cancer cases nearly doubled in young women from 1970 to 1990, but the incidence of disease has changed very little because of the marked increase in the young population as a whole.

Examination of young women’s breasts is more difficult, and the examiner usually has a low index of suspicion, which may lead to delay in diagnosis. Young women’s breasts are often nodular, may be disparate in size, and may change with menstrual cycle. If cyclic changes are suspected, the patient can be reexamined after a short interval, usually 10 to 12 days after onset of the menstrual period. The importance of a short-term physical reexamination cannot be overemphasized. However, in very young women, the most common tumor is a fibroadenoma, and the patient can be reassured that these are common and benign and can be safely excised.

What are the most common breast lesions in younger women?

Fibroadenomas and fibronodular breast tissue are the most common masses in women younger than 25 years, as discussed later in this chapter. It is uncommon for women in this age group to have either a breast cyst or breast cancer. Fibroadenomas are perhaps the easiest to diagnose clinically because the mass is smooth and mobile. In contrast, as women approach the fourth decade of life, breast cysts become common. One of the major responsibilities of the clinician is to establish that a palpable abnormality is a cyst and not a solid mass. This can be done with either needle aspiration or ultrasound, although needle aspiration is preferred because it provides simultaneous therapeutic drainage if a cyst is present. Palpable cysts should be drained for several reasons: (1) to establish the diagnosis of the cyst as benign, (2) to provide an expeditious diagnosis, (3) to provide relief of pain in a woman who has a cyst under tension, and (4) to provide an optimal breast examination interpretation free of interfering masses.⁵¹

What are the potential problems in the clinical evaluation of younger women?

Approaching the fourth decade, when breast cysts become more common, the incidence of breast cancer also rises. During these years, breast examination may become difficult and the cause of any palpable breast mass equally difficult to predict with any certainty. The use of estrogen replacement therapy additionally confounds the issue.

A review of the litigation literature found that more than two thirds of women who sued physicians over delay in the

diagnosis of breast cancer were younger than 50 years of age.⁵² This underscores the fact that any woman with a breast lump, no matter what her age, must have breast cancer included in the differential diagnosis.

The first step in evaluation of a premenopausal woman with a potential abnormality is to perform an examination when ovarian hormones exert the least influence, usually 10 to 12 days after onset of menstruation. If a palpable asymmetrical abnormality is present or persistent, full evaluation can take place.

In women older than 30 years, diagnostic mammography is usually recommended. The workup must proceed even if the mammogram is normal. False-negative results do occur, especially in a premenopausal woman, whose mammogram can be difficult to interpret because of dense glandular breast tissue.

Delay in diagnosis is not unlikely in younger women. Winchester⁵³ discussed information from the National Cancer Database supporting this assertion. Nearly 50% of women older than 50 years had T1 tumor (<2 cm), whereas 29.7% of women 30 years or younger had T1 lesions. Conversely, about 50% of women younger than 30 years had tumors larger than 2 cm, compared with 30.8% of women older than 50 years. There was a fivefold greater incidence of inflammatory carcinoma in women younger than 30 years relative to those older than 50 years.

Age is the single most important risk factor for breast cancer. The risk increases throughout a woman's life, and the annual incidence of breast cancer in women in the United States 80 to 85 years old is 15 times higher than that in women 30 to 35 years old. African American women younger than 50 years have a higher age-specific incidence of breast cancer than their white American counterparts, but older African Americans have a lower age-specific incidence than older white Americans. Breast cancer incidence among Hispanic women living in North America is only 40% to 50% as great as that among non-Hispanic white women. Asian women born in Asia have an extremely low lifetime risk for breast cancer, but their daughters born in North America have the same lifetime risk for breast cancer as an American white woman.⁸

Velentgas and Daling⁵⁴ reviewed the literature on breast cancer risk, comparing older and younger women. The relative risk in younger women versus older women was elevated if the woman was African American, had her first pregnancy at a late age, had a low parity, took birth control pills at an early age or for a long period of time, had a positive family history for breast cancer, and had atypical hyperplasia diagnosed on a breast biopsy.

What special considerations apply to the clinical assessment of the pregnant or lactating woman?

Breast cancer is the most frequently diagnosed malignancy during pregnancy and lactation, but fortunately, the occurrence is relatively uncommon. Wallack and associates⁵⁵ reviewed the literature over several decades and reported that pregnancy was associated with 0.2% to 3.8% of all breast cancers. Some studies have shown that the prognosis is no different from that for breast cancer occurring in age-matched, nonpregnant controls.⁵⁶ However, a recent study by Siegelman-Danieli and associates compared 38 breast cancer

patients with 40 primary tumors and with a history of fertility drug therapy (FDT) to other breast cancer groups: women with pregnancy-associated breast cancer and premenopausal women born during the same calendar years and not exposed to hormonal manipulations or recent pregnancy.⁵⁷ Compared with controls, tumors of patients with FDT exposure presented at advanced stages and were more likely to be estrogen receptor and progesterone receptor negative and of poor histologic grade. Survival was stage dependent.

The important consideration in breast cancer occurring in pregnancy and lactation is delay in diagnosis. Among pregnant patients reviewed by Bunker and Peters, only 7% received treatment within 1 month of the detection of a palpable mass; a delay of 6 months or more between detection and diagnosis was recorded in 50%.⁵⁸ In a more recent study of 63 patients referred to the Memorial Sloan-Kettering Cancer Center, Petrek and associates observed that in more than 50% of patients diagnosed as having breast cancer postpartum, a mass had been palpated during pregnancy and followed clinically.⁵⁹

The physiologic changes in the breast during pregnancy probably account for a significant portion of diagnostic delay. The breast becomes increasingly difficult to examine, particularly early in pregnancy, when there may be nodularity and hypertrophy; and as the breast becomes larger during pregnancy, palpation is even more difficult. It is incumbent on the obstetrician or health professional caring for the pregnant patient to do a thorough breast examination at the first prenatal visit, with immediate follow-up of any suspicious finding.

As with nonpregnant patients, fine-needle aspiration may be used for differentiating a solid from a cystic mass or galactoceles. Ultrasonography and ultrasound-guided biopsy may be diagnostic. If a solid mass is encountered, an open biopsy is favored because the pathologist often reports cellular atypia and lactational changes during pregnancy. Mammograms are not particularly useful in pregnant women; a high false-negative rate is probably due to the density of the breast tissue. There may also be some concern about the possible effect of radiation on the fetus. Breast biopsy during pregnancy constitutes a negligible risk for the mother and fetus and serves the purpose of making a diagnosis and allaying apprehension.

During the third trimester of pregnancy, a bloody discharge from the nipple may be noted. This has been ascribed to vascular engorgement or an exaggerated proliferation of the mammary epithelium. The patient should be reassured that this is most likely a physiologic variant. However, follow-up is indicated after delivery, and if the condition persists for more than 4 to 6 weeks, surgical investigation is warranted. The development of galactoceles during late pregnancy and lactation is not uncommon, and these can be diagnosed with needle aspiration. Mastitis during pregnancy is treated with antibiotics; postpartum and lactational abscesses can usually be managed with aspiration, culture, and appropriate antibiotic therapy. If a mass persists after therapy, open biopsy is mandatory.

What additional clinical concerns apply to younger women?

Most young breast cancer patients today are likely to receive chemotherapy. The long-term effects of adjuvant

chemotherapy on both physical and emotional stability are important. Premature ovarian failure increases the risk for development of osteoporosis. The risk for cardiovascular disease may be increased as well. Chemotherapy and radiation therapy may have toxic effects, particularly cardiac toxicity with the use of doxorubicin. Pregnancy after treatment for breast cancer does not adversely affect survival. However, careful individual counseling in this regard is necessary because risk factors are not the same for all patients.

What special considerations apply to the clinical evaluation of elderly women?

The risk for breast cancer increases throughout a woman's life, and the annual incidence of breast cancer in the United States for women 80 to 85 years old is 15 times higher than that in women 30 to 35 years old.⁸

About half of all breast cancers occur in women older than 65 years. The diagnosis of breast cancer is made by the discovery of a palpable mass in 60% to 80% of women, and it appears that a greater proportion of elderly women present with palpable breast masses than do younger women. It is interesting to note that younger women tend to have screening mammography less frequently and that screening mammography in the older age group appears to be much more effective. This is most likely because the breasts of older women are less dense, and abnormalities can be detected against the more radiolucent background of glandular atrophy and fatty replacement. Given the 12-year average of life expectancy of a 74-year old woman, a recent National Cancer Institute on Aging Consensus Forum on "Breast Cancer Screening in Older Women" recommended continuing the same guidelines for mammography for women who are in good general health and older than 74 years.⁶⁰

Law and associates⁶¹ have reviewed breast cancer in elderly women in depth. They note that the presence of comorbid conditions clearly adversely affects survival and is important in choosing treatment strategies. Survival data from several studies show that between 13% and 55% of women older than 65 years with breast cancer died of causes other than breast cancer. In view of this, elderly patients run the risk for receiving "suboptimal" breast cancer treatment. Some women are inappropriately excluded from potential curative therapy because of an inadequate evaluation of these so-called morbid conditions. Healthy women, irrespective of age, have a similar tolerance to and outcome from standard surgical therapy for early-stage breast cancer.

Two retrospective studies of patients aged 80 years or older with primary surgery show that mastectomy-related mortality (1% to 3%) and morbidity (wound complications, 10% to 16%) were comparable to those for younger patients.^{62,63} In addition, the 5-year overall survival rates of patients with stage I and stage II disease ranged from 39% to 65%. Five- and 10-year overall survival rates are not inferior for elderly women with local regional tumors treated surgically compared with younger women.

Recent data suggest that breast cancer in elderly women does not present as more advanced disease, nor is survival significantly inferior to that of younger women. Unless comorbid conditions adversely affect life expectancy or tolerance to therapy, older women should be treated with standard

surgical procedure for early-stage disease. The advantages of treatment options should be considered in the light of physiologic rather than chronologic age.⁶⁴ Therefore, the approach to the elderly patient at the outset of the clinical assessment should be with the same intent to treat and cure as for the younger patient.

As stated previously, and particularly with the elderly, a responsible companion should accompany the patient at the time of the initial interview and physical examination. Often the elderly patient is somewhat confused, may have difficulty hearing, and may be extremely reticent to accept a surgical procedure at a time of life when there may be "little to live for." The emotional stress of cancer has to be dealt with and may require professional consultation; it certainly requires understanding family and friends.

What considerations apply to the clinical assessment of men?

Breast cancer in men accounts for less than 1% of all breast cancers diagnosed in the United States. The American Cancer Society estimates that in 2005, 1690 men will be diagnosed as having breast cancer, and 460 men will die of the disease.³⁹ A centrally located mass is the most common presentation, followed by nipple retraction, nipple discharge, and ulceration. Fixation to the skin is frequent, and axillary adenopathy occurs in about 40%. However, the accuracy of clinical evaluation of the axilla is poor, with false-positive rates ranging from 8% to 50%, and with false-negative rates from 18% to 40%.⁶⁵

Gynecomastia is a much more common condition and on physical examination demonstrates characteristics similar to those of breast cancer. It is reported in 36% of normal adult men, increases with age, and is found in 12% to 40% of men with breast cancer, depending on whether it is defined clinically or histologically. The known causes of gynecomastia are numerous and are discussed in Chapter 36. Other conditions causing a breast mass in men include inflammatory lesions, sarcomas, metastases to the breast, and trauma.

Mammography can be employed to distinguish male breast cancer from gynecomastia. In addition, the cytologic features of male breast cancer are similar to those described for female breast cancer, and fine-needle aspiration biopsy is usually diagnostic.

Campagnaro and associates⁶⁶ recently published a case report of cystosarcoma phyllodes of the male breast. The patient had gynecomastia bilaterally as well as a well-circumscribed subareolar mass in one breast. The authors suggested that phyllodes tumor occurs in males in roughly the same proportion as that of any breast cancer in males, and that its perceived rarity is a result of its overall low incidence rate when compared with other breast cancers.

What special concerns apply to the clinical assessment of patients with diabetes?

Women with long-standing insulin-dependent diabetes mellitus and dense mammary glandular tissue can have benign breast masses clinically resembling cancer. Soler and Khadori⁶⁷ originally described this association in 1984. They

noted that some women with type 1 diabetes and limited joint mobility of the hand (cheiroarthropathy) also had well-defined painless fibrous breast lumps. Gump and McDermott⁶⁸ named the condition “diabetic fibrous breast disease.” Byrd and associates⁶⁹ described the characteristic change as a connective tissue overgrowth with vasculitis and some proliferation of duct epithelium not associated with an increased risk for breast cancer.

Logan and Hoffman⁷⁰ have elucidated the criteria for the consideration of the diagnosis. These include a prolonged history of insulin-dependent diabetes mellitus, mammographically dense glandular tissue, and one or more exceedingly hard, irregular, freely movable, discrete, painless, clinically palpable breast masses with neither skin change nor distortion of the breast contour. These masses reveal strong acoustic shadowing on ultrasound studies and are firmly resistant to the to-and-fro movement of the needle used for fine-needle aspiration. Realizing that diabetes confers no immunity from breast cancer, all authors agree that these patients can be followed by careful clinical examination and repeated fine-needle aspiration and cytologic study.

What are the clinical findings after surgery?

Breast examination in patients who have had previous surgery may be difficult. Included are patients who have had a biopsy, segmental excision for carcinoma with or without radiation therapy, a mastectomy, or reduction or augmentation mammoplasty.⁷¹ Fluid accumulations at a surgical biopsy or excision site in the immediate postoperative period are common. To the patient, this feels like a “mass.” The physician, however, may anticipate this finding, and aspiration will confirm the clinical impression of a seroma. It is not unusual that within the first 3 months, an area of induration can be felt around a biopsy site, most likely due to fibrosis and fat necrosis. If the induration persists beyond this time, however, fine-needle aspiration or core biopsy is warranted (Fig. 14–27). Ultrasonography may also be of help. Seromas persisting after the 3-month period are relatively uncommon, and their presence can be diagnosed by ultrasound and aspiration.

The incidence of postoperative hematoma after excisional breast biopsy ranges from 0.5% to 4%. Common causes include inadequate hemostasis, altered coagulation function secondary to ingestion of nonsteroidal anti-inflammatory agents, aspirin-containing compounds, vitamin E, herbal remedies, and, less frequently, bleeding disorders. Patients presenting with an enlarging hematoma within hours of surgery are usually returned to the operating room after evaluation of hemostatic parameters for evacuation of the hematoma and control of the bleeding. When the patient presents more than 24 hours after surgery, analgesics and support usually make the patient more comfortable. Once the hematoma has liquefied, as evidenced by fluctuance under the incision, aspiration may give some relief as well. Hematomas under pressure may drain spontaneously through the incision 1 or 2 weeks after surgery, and the remainder may be expressed through a small opening in the incision. Spontaneous hemorrhage into breast cancers or cysts is rare but can occur. Cytologic evaluation of the fluid is often negative for cancer cells. If a breast mass does not completely

Figure 14–27 Recurrent carcinoma of the breast with skin retraction 1 year after “lumpectomy” and radiation therapy.

resolve after aspiration of blood and fluid, excisional biopsy is important to rule out a malignancy.

Although breast implant rupture is a well-known complication of breast implant surgery, little is known about the timing and frequency of the ruptures. In Europe, silicone breast implants are still a preferred implant for cosmetic and reconstructive breast surgery, whereas in the United States, saline implants have been standard since 1992. The Food and Drug Administration is studying the safety and rate of failure of silicone implants. Rupture of saline implants becomes apparent shortly after its occurrence, with absorption of the leaking saline. By contrast, silicone gel implant rupture often remains unnoticed by both patient and physician because the leaking silicone is kept in place by the surrounding fibrous scar membrane, and no visible reabsorption occurs.

A study by Holmich and associates⁷² was designed to measure the incidence of implant rupture by repeated magnetic resonance imaging (MRI) among women with silicone breast implants. Implants were diagnosed as “definite” or “possible rupture.” In a 2-year period, 10% of 271 patients studied had definite ruptures, and 7% had possible ruptures. The overall rupture incidence for definitive rupture was 5.3 ruptures per 100 implants per year. The rupture rate increases significantly with increasing implant age. Double-lumen implants were associated with substantially lower rupture risk than single-lumen implants. For modern implants, they estimated a rupture-free survival of 95% at 5 years and 83% to 85% at 10 years. A minimum of 15% of modern implants can be expected to rupture between the 3 and 10 years after implantation.

The need for mammography in the postoperative period is subject to clinical judgment. It may be particularly useful in patients operated on for microcalcifications. Induration secondary to fat necrosis is also common after reconstructive procedures, particularly a transverse rectus abdominis myocutaneous (TRAM) flap. Fine-needle aspiration biopsy or

core biopsy is indicated if there is any doubt concerning the nature of the palpatory findings.

Induration and scar formation are not uncommon after reduction mammoplasty. The physical findings are usually confined to the surgical scar, but any doubtful findings should be assessed with an appropriate biopsy. In the event of an augmentation mammoplasty with prosthesis in place, care must be taken to avoid puncture of the implant.

Follow-up of patients after mastectomy requires diligent examination of the upper and lower flaps as well as the axilla. Although recurrence is not common after mastectomy, early detection is important so that measures can be taken for diagnosis and treatment of recurrent disease. Once again, needle aspiration biopsy of suspicious area or nodes is extremely helpful for an expeditious diagnosis.

Lymphedema of the upper extremity after axillary lymph node dissection is a well-recognized risk. Some degree of lymphatic obstruction in the arm and breast is not uncommon after breast conservation therapy (segmental excision, axillary dissection, and radiation therapy) as well. In the immediate postradiation period, the breast is often edematous and indurated, and there may be superficial excoriation of the skin as well as erythema and even peau d'orange. On occasion, cellulitis may develop, which may be indolent and very slow to respond to antibiotic therapy. Staren and associates⁷³ discussed the dilemma of delayed cellulitis after breast-conserving therapy. The cellulitis may take several weeks to clear with antibiotics, and it may recur or persist. If there is no resolution after 4 months of therapy, a biopsy is necessary to rule out recurrent carcinoma.

A rare and almost universally fatal complication of lymphedema following mastectomy is the development of lymphangiosarcoma (Fig. 14–28). First described by Stewart and Treves,⁷⁴ at inception it may be mistaken for ecchymosis, but the process progresses to form bluish red nodules, which eventually ulcerate and drain.

Figure 14–28 Lymphangiosarcoma, left chest wall. This patient had mastectomy and radiation therapy 5 years previously.

Postirradiation sarcomas are a rare complication of radiation therapy.⁷⁵ They should be suspected when a patient presents with increasing pain or swelling in the irradiated area. Physical examination may reveal edema, tenderness, neurotropic deficit, and perhaps a palpable mass. The skin overlying the irradiated area may show atrophy, fibrosis, telangiectasia, hyperpigmentation, dermatitis, and ulceration. Biopsy is mandatory.

What are the clinical findings after breast trauma?

Trauma to the breast is not uncommon, and most instances of breast trauma are mild and self-limited. However, if patients fail to present in the acute period and the clinical signs of trauma are absent with palpable breast masses, careful evaluation and follow-up with biopsy is essential because 9% to 20% of women with breast cancer have a history of antecedent trauma. Most patients with a history of trauma in the acute phase present with tender masses, usually with overlying ecchymosis early in the postinjury period. In addition, there may be erythema and edema, and in severe trauma, the breast findings may serve as a marker for more serious thoracic injuries. Rupture of implants or of the fibrous capsule surrounding the implant has been reported in women who have undergone augmentation mammoplasty or implant reconstruction. Removal and replacement of the implant is important. In addition, we have seen several instances of fluid accumulation, usually serous, after strenuous exercise and the lifting of heavy weights in women who have breast implants. They describe a sudden enlargement of the breast mound, often without pain. Diagnosis can be confirmed using ultrasound and subsequent ultrasound-guided aspiration and cytologic evaluation of the fluid obtained. Spontaneous healing can be expected.

A breast hematoma can occur secondary to a surgical procedure, including fine-needle aspiration, stereotactic core biopsy, mammotome biopsy, and excisional biopsy, as previously discussed. In general, it is recommended that a mammogram be obtained before aspiration or that mammography be delayed for at least 2 weeks after aspiration to prevent difficulty in diagnosis.

How does mammography complement clinical assessment?

Although most physicians agree that mammography is an effective screening tool, only 8% to 15% of asymptomatic women have mammography as part of a routine annual evaluation. Only 15% to 20% of women older than 50 years of age have ever had a mammogram.⁷⁶ Aside from the screening of asymptomatic women, patients with tumors, areas of asymmetry, nipple discharge, skin retraction, or axillary adenopathy should also be evaluated by mammography. It is not very useful in teenagers because of the density of their breasts but is indicated if the rare malignant process is suspected. The false-negative rate for mammography is about 10% to 15%; therefore, physical examination must accompany mammography in making a therapeutic decision.

Mammography is an extremely important element in the diagnosis of a neoplasm in the breast. Merely reading a mammographic report, particularly from a facility with which the surgeon is not familiar, often is not enough. If the films are available for review by the surgeon, palpable abnormalities can be corroborated with the mammogram. The radiologist may not have the results of the clinical examination when the mammogram is read, and the clinician must communicate with the mammographer concerning the physical findings. This relationship between the mammographic facility and the clinician is imperative, and doubts should be reassessed if necessary and the patient reexamined both clinically and mammographically with attention to the areas of concern.

If clinical examination, mammographic evaluation, and aspiration biopsy are in concordance concerning the presence of benign disease, a greater than 99% predictive value can be obtained.⁷⁷ The woman then can be given the options of follow-up or biopsy. Those who choose to be followed are usually seen for at least one follow-up visit in 3 months and then can be seen at 3- to 6-month intervals. If any change occurs on clinical examination or mammography, biopsy is warranted.

All patients with a history of lobular neoplasia or carcinoma of the breast, a family history of carcinoma of the breast, intraductal papillomatosis, or gross cystic disease should have mammography at routine intervals. The recommendations of the American Cancer Society and the American College of Radiology regarding screening mammography for asymptomatic women have been discussed. Mammographic abnormalities that warrant further evaluation include masses, microcalcifications, stellate densities or architectural distortion, and a "changing mammogram," as is discussed in Chapter 15.

How does ultrasound complement clinical assessment?

Ultrasound is most helpful and accurate in the evaluation of dense breasts and in differentiating between cystic and solid masses.⁷⁸ With new techniques, masses as small as 5 mm may be localized and ultrasound-guided aspiration biopsies or core biopsies performed.

Vetto and associates⁷⁹ described a "modified triple test" (physical examination, ultrasonography instead of mammography, and fine-needle aspiration) in diagnosing palpable breast lesions in younger women. In this group of 55 patients younger than 40 years, with the longest follow-up being 45 months, there was a high degree of diagnostic accuracy without the need for routine open biopsy, with an overall reduction in patient expense.

Louie and associates⁸⁰ conducted a study to determine the validity of applying criteria routinely used to manage palpable breast cysts to the management of mammographically detected, nonpalpable breast lesions characterized as indeterminate by ultrasound. Of 139 indeterminate lesions, 78 were consistent with "complex cysts"; in 61, the cystic-versus-solid nature was indistinguishable. All 71 complex cyst lesions that contained nonbloody fluid and resolved were completely benign. Of 7 complex cysts that had incomplete resolution, bloody aspirate, or both, 2 were malignant. Of 61 cystic-versus-solid lesions, 29 and 32 were primarily solid and cystic,

respectively. Three of the 29 solid lesions were malignant. Of the 32 cystic lesions, all 26 that contained nonbloody fluid and resolved completely were benign, whereas 1 of 6 lesions that had incomplete resolution, bloody aspirate, or both was malignant. Solid or incompletely resolved lesions underwent core or open biopsy. Louie and associates concluded that the criteria for management of palpable breast cysts could be applied to the management of ultrasound-indeterminate nonpalpable breast lesions.

Chen and associates⁸¹ compared the duration and rates of underestimation and complete excision for nonpalpable breast lesions using either intraoperative ultrasonographically guided excisional biopsy (IUGE) or directional vacuum-assisted biopsy (DVAB). Although they feel that percutaneous ultrasonographically guided core needle biopsy is preferable to stereotactic biopsy for nonpalpable breast lesions, underestimation and false-negative results can occur. The study demonstrated that with DVAB, a complete excisional biopsy could be obtained, with sonographic corroboration of 95% at 3-month and 1-year follow-up. Patients with atypical ductal hyperplasia or malignancy had an open surgical procedure. There were no false-negative results, no underestimation of the disease, and no requirement for re-excisional biopsy.

How does breast magnetic resonance imaging complement clinical assessment?

Breast MRI is a developing technique for the evaluation of patients with primary breast carcinoma. Identification of microscopic multifocal or multicentric disease generally is considered to result in higher rates of local recurrence and thus is a contraindication for breast conservation. Estimates of the frequency of multifocality and multicentricity in breast carcinoma vary widely and, depending on the specific criteria used, may range from 7% to 63%. Preoperative identification of these patients is important for their appropriate surgical management.

Bodrosian and associates⁸² conducted a retrospective review of 267 patients with primary breast tumors who had MRI studies before undergoing definitive surgery. The overall sensitivity of MRI for detecting primary, intact breast tumors was 95%. Planned surgical management was altered in 69 of 267 patients (26%), and in 49 of those patients (71%) there was pathologic verification of malignancy in the surgical specimen, confirming the need for wider or separate excision or mastectomy. Forty-four of 267 patients (16.5%) had conversion of planned breast conservation to mastectomy. In a statistical analysis, change in management was associated significantly with histology; management was altered in 11 of 24 lobular tumors (46%) compared with 58 of 243 ductal tumors (24%).

Criteria for the selection of patients for breast MRI remain indeterminate. The authors noted that subgroup analysis from their series suggested that patients with invasive lobular carcinoma might benefit from preoperative staging with breast MRI studies. MRI evaluation probably would not change the overall mastectomy rate; instead, MRI might help to identify patients who are likely to fail breast conservation therapy. The authors also emphasized that, given the high sensitivity but generally low specificity of MRI, validation of MRI-identified

suspicious lesions by core or excision biopsy is necessary before recommendation for mastectomy is made.

Quan and associates,⁸³ noting the difficulty in predicting extent of disease in the breasts of patients with invasive lobular carcinoma, studied the utility of MRI in finding otherwise unsuspected cancer in the ipsilateral or contralateral breasts in these patients. Suspicious lesions separate from the primary tumor were found by MRI in 61% of 62 patients studied. Nineteen of 51 patients with an ipsilateral finding had MRI-guided biopsy, which revealed cancer in 11 (22%). Twenty of 53 patients with a contralateral finding had MRI-guided biopsy, which revealed cancer in 5 (9%). It seems apparent that MRI identifies multicentric and contralateral cancer in patients with invasive lobular carcinoma, particularly in the ipsilateral breast.

Lieberman and associates⁸⁴ performed a retrospective review of the records of 367 asymptomatic women with normal mammograms who had a high risk for developing breast carcinoma (i.e., women who had prior breast carcinoma, biopsy-proven lobular carcinoma in situ or atypia, or a family history of breast carcinoma), whose first breast MRI screening examination occurred at the Memorial Sloan-Kettering Cancer Center during a 2-year period. The number of “probably benign” interpretations was determined, and follow-up data were obtained. The authors noted that short-term follow-up is widely accepted for tracking nonpalpable mammographic lesions that are probably benign. In prior studies, nonpalpable, probably benign lesions were reported in 3% to 11% of mammograms. Subsequent malignancy was found in 0.2% to 2% of probably benign lesions; most malignancies were identified because of interval change at short-term follow-up mammography when lesions were small and in an early stage, with excellent prognosis.

In the Lieberman study, most patients had mammography within 6 months of breast MRI. A “probably benign” interpretation was given to 89 (24%) of 367 women. Follow-up MRI was performed for 70 (79%) of 89 women, with a median follow-up time of 11 months. Twenty women subsequently underwent biopsy at a median of 9 months after MRI, owing to progression on follow-up MRI or for other reasons. Malignancies were found in 9 women, constituting 45% of the 20 women who underwent biopsy and 10% of the 89 women with probably benign lesions. In six of the nine women who developed malignant disease (7% of the 89 women in the study), the malignancy was detected by follow-up MRI of an area that previously was interpreted as probably benign. Tumor histology was ductal carcinoma in situ in 5 patients and infiltrating ductal carcinoma in 4. The authors concluded that a “probably benign” interpretation was given to 24% of high-risk women at their first breast MRI screening examination, and that in 7% to 10% of women with probably benign interpretations, malignant disease subsequently developed in an area initially judged to be probably benign.

What is the role of needle aspiration biopsy in clinical assessment?

The combination of a thorough history and physical examination in conjunction with mammography will differentiate benign from malignant disease in most women. However,

confirmation of the diagnosis can be made only by microscopic examination of tissue. In this regard, clinical judgment is extremely important, and if there is any doubt about the nature of any mass in the breast, biopsy is indicated. In very young women (i.e., <25 years of age), small, clinically benign areas of nodularity may be re-evaluated at appropriate intervals. However, if they increase in size, they should undergo biopsy. With the availability of numerous biopsy techniques and qualified aspiration cytologists, a diagnosis can often be made and definitive therapy instituted within a short time. In the instance of a fine-needle aspiration biopsy of a clinically suspicious mass when a diagnosis of cancer is not made, a surgical biopsy is mandatory to exclude malignancy.

Aspiration biopsy involves the use of a fine needle and syringe to aspirate cells from a suspicious area, smearing them on a glass slide, fixing them, and then staining for cytologic evaluation (Fig. 14–29), as detailed in Chapter 17. Stereotactic techniques may be used to evaluate nonpalpable nodules of the breast. Vazquez and associates⁸⁵ evaluated the reliability of stereotactic aspiration biopsy of 373 nonpalpable nodules of the breast. They found that a high sensitivity for the detection of a malignant lesion could be maintained when there is conservative management of well-defined nodules without microcalcifications that remain stable mammographically and are benign on fine-needle aspiration.

As previously noted, the timing of needle aspiration of a breast lesion is important in relation to mammography. If needle aspiration is done before mammography, the diagnostic mammogram should be delayed for at least 2 weeks because false-positive mammograms may result secondary to hematoma formation. This is also true for ultrasound examinations of the breast following needle aspiration.

When a mass is aspirated and found to be solid, excisional biopsy is usually advised. However, if the fine-needle aspiration biopsy sample is optimal and if a skilled cytopathologist interprets the specimens, fine-needle aspiration may be used to differentiate between the patients who require open biopsy and those who can be managed with periodic follow-up examination, provided that the chance of a malignant lesion is considered to be remote (Fig. 14–30).

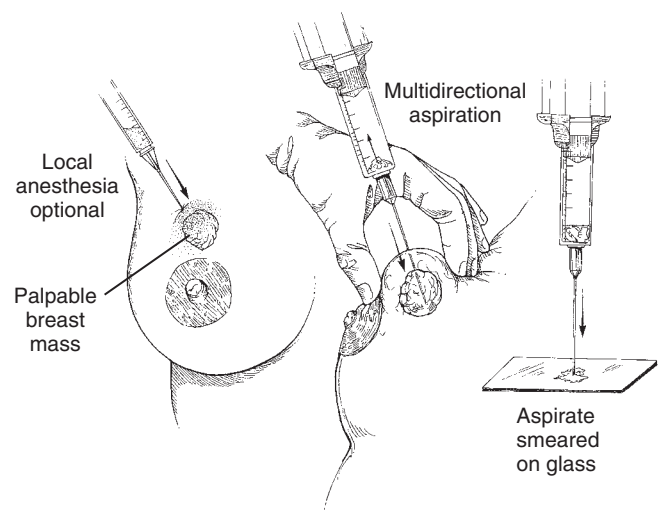

Figure 14–29 Aspiration biopsy of a palpable breast mass. Multidirectional aspiration allows wider tissue sampling.

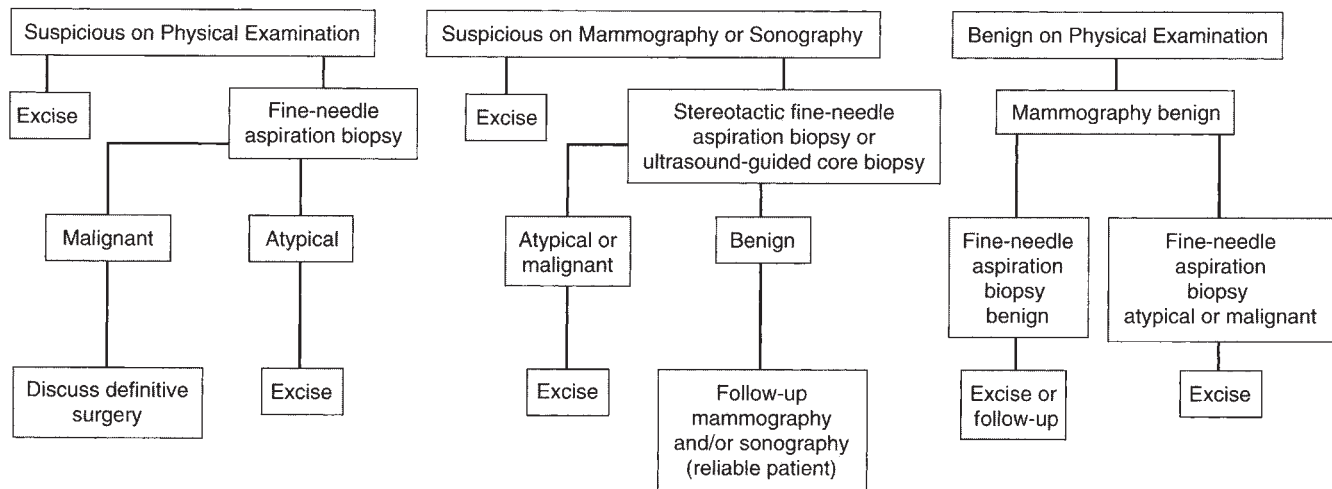

Figure 14-30 Management of solid breast masses.

The accuracy of fine-needle biopsy has been established. The false-positive rate for the procedure is low, averaging about 0.17%.⁸⁶ The advantage of the procedure is that it can rapidly establish a preliminary diagnosis of malignancy or possible malignancy, offering the patient the opportunity to discuss treatment options within a very short time. Some surgeons use the results of fine-needle aspiration biopsy for definitive diagnosis. In many instances, however, it may be more prudent to confirm the impression gained from aspiration biopsy with a core biopsy, mammotome biopsy, or an open biopsy with frozen section, especially if there is any question clinically.

The false-negative rate of fine-needle aspiration biopsy has been found to be between 0.4% and 35%. The most common reason for a false-negative result is inadequate sampling, which may be due to lack of communication between surgeon and cytopathologist or due to an inexperienced cytopathologist. Other reasons for false-negative results include tumors 1.0 cm or smaller, which may have been missed by the aspirating needle. The use of stereotactic fine-needle aspiration biopsy as well as ultrasound-guided aspiration biopsy enhances the ability to detect lesions and reduces the false-negative rate.

Aspiration of fibrotic tumors may result in a false-negative result, as may aspiration of tumors with necrosis or edema. The surgeon must be particularly aware of the possibility of a well-differentiated neoplasm (i.e., tubular carcinoma) as well as infiltrating lobular carcinoma, in situ ductal and lobular carcinoma, colloid carcinoma, and papillary carcinoma. In these instances, aspiration biopsies often are read as showing "atypia," and open biopsy is necessary.

At present there is no proven, feasible, reliable, and noninvasive method of identifying high-risk women who have occult atypical hyperplasia. Random, periareolar bilateral breast fine-needle aspirations in women at elevated risks for developing breast cancer on the basis of a family history or an elevated 10-year Gail risk score have been shown to detect breast epithelial cell atypia in 21%. In the series by Fabian and associates, an additional 49% of high-risk women were found to have epithelial hyperplasia without atypia.⁸⁷ Bilateral breast fine-needle aspiration is a promising method for detecting cellular atypia in high-risk women. However, there is a large

possibility of sampling error inherent in this procedure, and the extent of atypia cannot be determined reliably. In addition, if atypical cells are detected in nipple aspirate fluid, it is generally not possible to localize the duct or segment that yielded the atypical cells because fluid from several ducts can pool on the nipple during the aspiration procedure.

Does ductal lavage complement clinical assessment?

Ductal lavage (DL) is a procedure that has been developed to enhance the tolerability, efficiency, and reproducibility of collecting breast duct epithelial cells for cytologic analysis as part of breast cancer risk evaluation. Appropriate candidates for DL include women who are at elevated risk for development of breast cancer and for whom a finding of atypical breast epithelial cells on cytology would alter their clinical management.⁸⁸ Regardless of whether a woman is at elevated risk for development of breast cancer, DL has no proven clinical utility in the evaluation of an abnormal breast examination, mammogram, or other breast imaging study.

Brogi and associates⁸⁹ performed DL in the affected breast of 26 women undergoing mastectomy for carcinoma and in the clinically normal breast of 4 additional women undergoing risk-reducing mastectomy. Four (14%) of 29 DL samples showed marked atypia, 10 (34%) showed mild atypia, and 15 (52%) were benign. No DL sample was clearly malignant. Two DL samples from breasts with extensive lobular carcinoma in situ showed mild atypia. The study confirmed that sampling of mammary epithelium by DL is not useful in the diagnostic screening and identification of carcinoma.

DL is not a breast cancer early-detection tool, and any abnormal imaging or physical exam finding requires standard evaluation and consideration for biopsy. Likewise, DL should not be used as a screening test in high-risk women who have dense breasts on mammograms or who otherwise wish or require another breast screening evaluation, because there are no data indicating that DL is useful in detecting occult breast cancer. High-risk women who have a history of estrogen receptor- or progesterone receptor-positive breast cancer, ductal carcinoma in situ or biopsy-proven atypical ductal

hyperplasia, atypical lobular hyperplasia, or lobular carcinoma in situ are generally not suitable candidates for DL because a finding of atypical cells in duct fluid does not further elevate risk. Women who are already taking tamoxifen or who have finished 5 years of treatment for invasive breast cancer, ductal carcinoma in situ, atypical ductal hyperplasia, atypical lobular hyperplasia, or lobular carcinoma in situ; women who have a family history of breast cancer; or women with an elevated Gail risk are not appropriate candidates for DL because there are no data to guide treatment recommendations in this setting. There is no proven role for DL in serially monitoring breast cytology in high-risk women who are taking or have taken tamoxifen.

Is there a role for galactography in the evaluation of nipple discharge?

Galactography, a specialized radiologic procedure involving contrast injection of the ductal system, may allow for more accurate localization of lesions and thus a more conservative surgical excision. However, accurate differentiation of benign from malignant lesions is not possible with this technique. The procedure is useful for distally or peripherally located lesions that otherwise might be missed by standard major duct excision. A negative galactographic, mammographic, or cytologic result should not deter surgical excision if neoplasm is suspected.

How does breast endoscopy complement clinical assessment?

The presence of a single-duct spontaneous bloody nipple discharge is an indication for surgical biopsy. The most common lesion identified is an intraductal papilloma in the immediate retroareolar region. Because duct excision often requires resection of the entire ductal system, intraoperative mammary duct endoscopy has been used for direct visualization of intraductal abnormalities during surgical resection. This may be particularly useful in young patients in whom complete duct excision may not be warranted and may lead to subsequent inability to nurse. Smith⁹⁰ described a minimally invasive method of excising nipple ducts using cannulation in order to preserve nipple function in women of childbearing age.

Submillimeter endoscopes are now available. Dooley,^{91–93} who described operative breast endoscopy for bloody nipple discharge in 27 patients, found a lesion accounting for the bleeding in 26 of them. Cancers were identified in 2 patients, and in these patients, a more proximal papilloma was noted in the same ductal system. The author concluded that the high incidence of multiple lesion identification suggests that the classic blind resection of a limited distance of duct in the retroareolar space may significantly underestimate the extent of proliferative disease.

Dietz and associates⁹⁴ reviewed their experience with 119 patients with pathologic nipple discharge undergoing ductoscopy-directed duct excision. In this study, a preoperative ductogram was obtained in 70 patients and was positive in 53 (76%). In the same group, ductoscopy was positive in 63 (90%). They found 5 carcinomas, 84 papillomas, and 16 instances of hyperplasia. Hyperplasia and carcinoma were

significant predictors of unsuccessful cannulation. In 22 patients, ductoscopy visualized multiple lesions or abnormalities beyond 4 cm. Their conclusions are similar to those of Dooley in noting that lesions deep within the ductal system can be identified and removed and that these would likely have been missed by blind duct excision.

BENIGN BREAST DISEASE

Benign breast disease is far more frequent in clinical practice than is cancer of the breast. Many patients with symptomatic breast conditions will assume that they harbor a malignancy because of the publicity that surrounds cancer of the breast. The problems facing the clinician are to ensure an accurate diagnosis and to reassure the patient that the condition is benign.

How is fibrocystic disease characterized?

The various entities that are classified under the term *fibrocystic disease* include cystic disease, fibrous disease, and sclerosing adenosis. Fibrocystic disease represents a spectrum of clinical entities, from an epithelium-lined cyst at one end to sclerosing adenosis at the other. Histopathologic changes seen in fibrocystic disease consist of hyperplasia of duct epithelium, duct papillomatosis, blunt duct adenosis, apocrine metaplasia, and adenosis. The usual patient with true cystic disease is in her 30s or 40s. Breast discomfort or frank pain frequently accompanies cystic changes and tends to be increased at the time of menstruation.

Benign breast abnormalities consisting of nodularity on physical examination lead to biopsy by age 50 years in just under 20% of women in North America.⁹⁵ Benign breast disease that on pathologic examination is nonproliferative, including cysts, ductal ectasia, mild hyperplasia, and simple fibroadenoma, does not increase breast cancer risk.

Fewer than 5% of women without proliferative changes on biopsy develop breast cancer over the subsequent 25 years, but nearly 40% of women with a family history of breast cancer and atypical hyperplasia subsequently develop breast cancer.⁹⁶ Biopsy before the age of 50 to 55 years is associated with a fivefold to sixfold increase in the risk for breast cancer, whereas biopsy at older ages is associated with only half this risk.

Proliferative benign breast disease, however, including lobular and ductal hyperplasia, sclerosing adenosis, intraductal papilloma, and lobular or ductal hyperplasia with atypia and radial scar, does elevate breast cancer risk. Proliferative disease with atypia has been shown to increase the relative risk for developing invasive breast cancer by fourfold to fivefold.⁹⁷ Most atypical ductal and lobular hyperplasia lesions are diagnosed as incidental findings on breast biopsy, and about 10% to 12% of these lesions are detectable as mammographic or palpable abnormalities.

About 60,000 breast biopsies per year in the United States are found to contain atypical hyperplasia. Considerable epidemiologic evidence supports atypical hyperplasia as a significant risk marker and one that is associated with a 0.8% to 1% risk per year of developing invasive breast cancer. In addition, two large prospective studies have provided insights into the

predictive value of cytologically identified atypical breast epithelial cells. Wrensch and associates^{98,99} summarized their analysis with 20 years of follow-up of women who were found to have epithelial cell atypia in their nipple aspirate fluid. These women had a fivefold elevated risk for developing invasive breast cancer compared with women without atypical cells in their nipple aspirate fluid. Women who had both a family history of breast cancer and atypical epithelial cells in their nipple aspirate fluid were found to have an 18-fold elevated risk for developing breast cancer.

Fabian and associates⁸⁷ found occult hyperplasia with atypia on cytologic examination of bilateral breast periareolar fine-needle aspiration in 21% of high-risk women. Women who had both a 10-year Gail risk of at least 4% and fine-needle aspiration–detected evidence of hyperplasia with atypia had a 5% per year risk for developing breast cancer in the ensuing 4 years.

How is fibrocystic disease characterized clinically?

As discussed previously, nonproliferative lesions of the breast include cysts, papillary apocrine change, epithelial-related calcifications, and mild hyperplasia of the usual type. Cysts are fluid-filled, round to ovoid structures that vary in size from microscopic to grossly palpable. Papillary apocrine change is characterized by proliferation of ductal epithelial cells in which all cells show granular eosinophilic cytoplasm, apocrine metaplasia, and apical cytoplasmic protrusions. Epithelial-related calcifications are frequently observed in breast tissue and may be seen in normal ducts and lobules or any pathologic condition in the breast. Calcifications may also be seen in breast stroma as well as in blood vessel walls. Mild hyperplasia of the usual type demonstrates an increase in the number of epithelial cells within a duct. The risk for subsequent breast cancer among these patients is not increased even in patients with a family history of breast cancer. It has been demonstrated, however, that there may be an increased risk for developing breast cancer in patients with gross cysts and a family history of breast cancer.

Proliferative lesions without atypia constitute a group including moderate or florid hyperplasias of the usual type, intraductal papillomas, and sclerosing adenosis. Sclerosing adenosis is often an incidental microscopic finding but may appear as a palpable mass (so-called adenosis tumor). Of importance is the fact that on pathologic examination, it may exhibit a pattern mimicking infiltrating carcinoma, particularly because it is often associated with microcalcifications on mammography. However, the microcalcifications tend to be more diffuse in sclerosing adenosis than in carcinoma. These lesions are associated with a somewhat elevated risk for the subsequent development of breast cancer, and often the only means of differentiating this lesion from carcinoma is biopsy.

Patients with atypical hyperplasia of the ductal type or lobular type have a substantial increased risk for developing breast cancer. This is particularly true in patients with atypical hyperplasia and family histories of breast cancer approaching that of patients with lobular carcinoma in situ. Studies suggest that the hormonal milieu modifies breast cancer risk in women with atypical hyperplasia. The studies also demonstrated that the risk for breast cancer in patients with atypical

hyperplasia of both the ductal and lobular types is about equal in both breasts. These findings suggest that atypical hyperplasia is best considered a marker of increased risk rather than a precursor lesion.

Most women are conscious of some degree of breast engorgement during the 3 or 4 days preceding the onset of menstruation; this does *not* constitute fibrocystic disease, and the patient should be reexamined at a different time in her menstrual cycle if she is seen just before her menses are due. Often, a distinct improvement will be noted in the second week following the onset of menses. In most instances, reassurance and appropriate breast support will be adequate; occasionally, weight reduction or judicious use of diuretics is indicated.

The patient with diffuse, small cystic changes and significant surrounding fibrosis who has very nodular and painful breasts frequently presents a clinical problem. Again, it must be emphasized that a great deal of new growth takes place in the mammary gland with each menstrual cycle and that premenstrual and occasionally preovulatory pain and breast engorgement are not necessarily indications of fibrocystic disease. Where normal physiologic changes end and pathologic fibrocystic disease begins may be very difficult to determine clinically. The term *fibrocystic disease* should be reserved for situations in which there is true objective evidence of a pathologic state.

Minton and associates^{100,101} postulated a relationship between the intake of caffeine and breast pain. They suggested that methylxanthines caused cellular proliferation in the breast by increase in cyclic adenosine monophosphate, either by inhibition of phosphodiesterase breakdown of cyclic adenosine monophosphate or by increased catecholamine release. Subsequent studies have not verified the assumption that breast pain can be relieved by abstention from caffeine or chocolate.

How is a cyst evaluated?

For the patient who presents with a dominant mass, well circumscribed and fluctuant, a tentative diagnosis of “cyst” is justified. Occasionally, the mass will be under great tension and feel like a solid tumor. Tenderness and a rather sudden appearance of the lesion by history reinforce the clinical impression of a cyst. Appropriate treatment of such a lesion is aspiration.

The breast should be prepared with an antiseptic solution and the lesion immobilized between the second and third fingers of one hand. With the opposite hand, a 19-gauge needle on an appropriate-sized syringe is inserted into the lesion at a right angle to the skin (Fig. 14–31). The cyst fluid is aspirated and the needle withdrawn. Pressure is applied to the area (Fig. 14–32). Local anesthesia is not required for a cyst aspiration.

After aspiration, it is essential that the breast be reexamined for the presence of a mass. If the aspirate is bloody, if the mass does not completely disappear, or if a subsequent mammogram is suggestive of a concurrent malignancy, a biopsy is indicated (Fig. 14–33). The patient should be informed of this before the aspiration.

Cytologic evaluation of cyst fluid is unlikely to be rewarding. It should be done when the aspirate is frankly bloody or

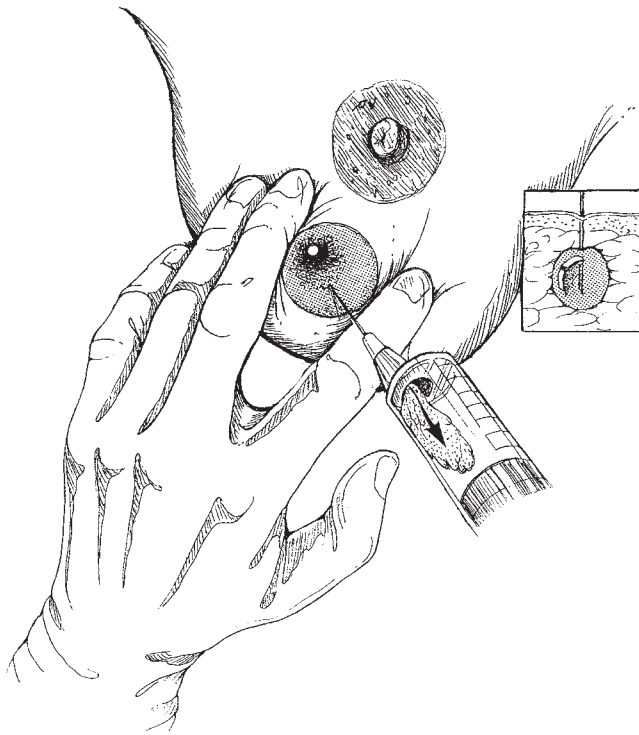

Figure 14-31 Aspiration of a breast cyst. The cyst is immobilized between two fingers, and a 19-gauge needle is used to aspirate.

Figure 14-32 Aspiration of a breast cyst. Pressure is applied after the needle is removed.

if a relatively small amount of fluid is obtained in relation to the size of the lesion and the lesion does not disappear with the aspiration. Cytopathologic examination of cyst fluid may be helpful in postmenopausal patients who are not on hormone replacement therapy because it is unusual for a woman

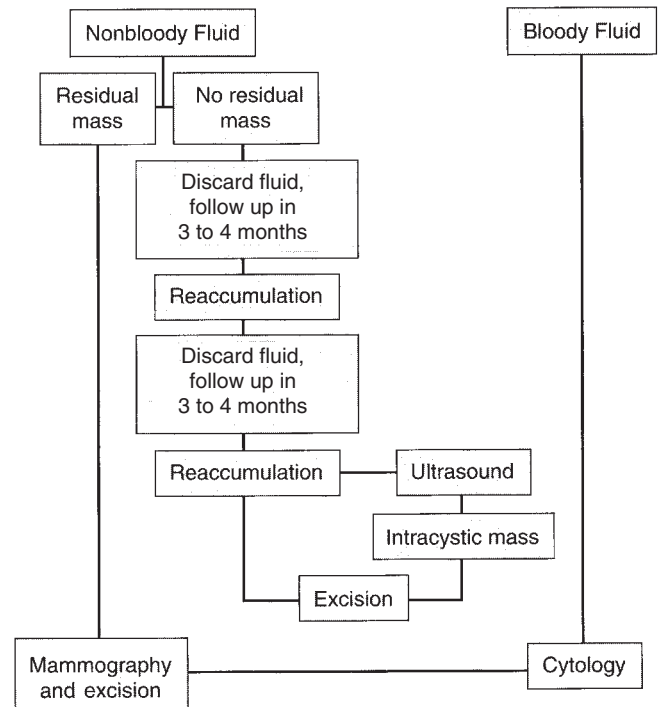

Figure 14-33 Management of breast cysts with aspiration.

to form a benign cyst in these instances. Biopsy after cyst aspiration is indicated for a cyst that reaccumulates in the same location after several aspirations. Ultrasound examination of recurrent cysts may detect a solid component in a cyst wall, and a core biopsy can be obtained. This may reveal a papilloma or intracystic carcinoma. Follow-up examination after aspiration of breast cysts should be carried out within a 3- to 4-month period.

How is mammary duct ectasia characterized clinically?

Mammary duct ectasia is the most common inflammatory condition of the breast. It evolves when a terminal duct beneath the nipple and areola dilates with lipoid material and cellular debris. A discharge that occurs is often thick and yellow-brown. As the disease progresses, inflammatory changes may result in thickening of the duct wall and shortening and retraction of the nipple. When the duct epithelium is broken, the material lodged within the lumen discharges itself into the surrounding tissue, and a mass may result. The inflammatory cells usually consist of lymphocytes and plasma cells or may be entirely made up of plasma cells (hence, the term *plasma cell mastitis* used occasionally to designate this entity). An abscess may develop and, if incised for drainage, can lead to recurrent fistulization. The process usually occurs in the perimenopausal woman, although it has been reported in all age groups. In a patient with recurrent discharge or persistent discharge, ductal excision may be performed. This is usually done in situations in which the discharge is particularly annoying to the patient or in which blood has been detected and a malignancy must be considered. In the presence of a mass, particularly with nipple retraction (when mammary duct ectasia

Figure 14-34 Periareolar fistula secondary to subareolar abscess.

mimics carcinoma), an excisional biopsy is required. Enlarged lymph nodes can sometimes occur with this condition. Careful examination of the remainder of the breast and mammography are important adjuncts in the management of these patients because a coexisting carcinoma may be present. Another indication for surgery with this entity is a persistent fistula in the periareolar region (Fig. 14-34). Excision of the fistula sometimes requires removal of the entire ductal system as well as partial excision of the nipple.

What are the causes of nipple discharge?

The most common causes of nipple discharge identified from surgical specimens are solitary papillomas and papillomatosis, which are benign conditions (Fig. 14-35). A second common cause of nipple discharge is duct ectasia, a benign condition associated with the loss of elastin within the duct walls and a chronic plasma cell inflammatory infiltrate. Fibrocystic disease may lead to a spontaneous nipple discharge. The discharge may come from several ducts, with fluid of varied coloration, often green (Fig. 14-36). The least frequently observed cause of nipple discharge is carcinoma. Because carcinoma is occasionally associated with bloody nipple discharge, it is imperative that a biopsy of involved ducts be performed. Intraductal papillomas are more common in premenopausal women; the older the patient, the more likely that a bloody discharge is due to carcinoma.

Intraductal papilloma may also produce a clear, yellowish discharge. Mammography should be performed in patients who are to undergo surgery for spontaneous nipple discharge. Nevertheless, a biopsy is required. To ensure that the involved duct or ducts are included in the specimen, careful palpation of the periareolar region with pressure applied toward the nipple, one quadrant at a time, should be performed before surgery. This will help localize the most likely source of bleeding.

Figure 14-35 Bloody nipple discharge from a single duct secondary to intraductal papilloma.

Figure 14-36 Multiple-duct, multicolored discharge secondary to fibrocystic disease and duct ectasia.

When there is a spontaneous bloody discharge by history but the physician is unable to elicit this in the office, the nipple may be coated with collodion and the patient asked to return in a week. The collodion is then stripped from the nipple or dissolved with acetone, and if the duct has become engorged with blood, the source can be easily demonstrated with mild pressure.

At times, it is difficult to determine the color of the discharge as it exits from the nipple. It is best to visualize the discharge against a white background, such as a white surgical

Figure 14-37 Eczema of the nipple, indistinguishable from Paget's disease. The diagnosis was made by biopsy.

Figure 14-38 Psoriasis of the areola.

sponge. A discharge that appears bloody at a quick glance may actually be dark green. It should also be emphasized that the nipple discharge should be *spontaneous* to be considered pathologic. Persistent squeezing may produce a discharge in many *normal* patients.

Changes in the epithelium of the nipple and areola, often associated with itching or nipple discharge, warrant nipple biopsy (Figs. 14-37 and 14-38). A wedge of the nipple-areolar complex can be obtained under local anesthesia and the edges reapproximated with minimal deformity.

An occasional patient may present with extensive papillomatosis of the nipple, a benign condition often clinically indistinguishable from Paget's disease (Figs. 14-39 and 14-40). An appropriate biopsy will establish the diagnosis.

A spontaneous nipple discharge may not be pathologic in all instances. A serous or milky discharge can occur in patients

Figure 14-39 Papillomatosis of the nipple. The diagnosis was made by biopsy.

Figure 14-40 Paget's disease of the nipple.

using oral contraceptives.^{102,103} This discharge is usually bilateral and may be accompanied by a limited increase in breast size. As already mentioned, a bloody nipple discharge may occur in the last trimester of pregnancy and should resolve after delivery.

Persistent nonpuerperal bilateral milky discharge may be caused by a pituitary adenoma, particularly when associated with amenorrhea, infertility, and visual field loss. Further diagnostic evaluation should include determination of prolactin levels; if they are persistently elevated, the patient

should undergo imaging studies (computed tomography scans, MRI) of the sella turcica region and visual field testing. Other endocrine causes of galactorrhea are drugs (antihypertensives, phenothiazines, and tranquilizers) and transient hyperprolactinemia secondary to nipple stimulation and chest trauma, including thoracotomy.

The clinical features suggesting a benign or a malignant neoplasm as the origin of nipple discharge include the following: spontaneous discharge; unilateral localization; confinement to one duct associated with a mass; bloody, serous, serosanguineous, or watery discharge; old age; and male gender. The results of cytologic evaluation of the discharge may be inconclusive or misleading, and the utility of this procedure is questionable.

As discussed previously in this chapter, ductoscopy, galactography, and possibly DL may be used to diagnose lesions causing nipple discharge.

How are benign papillary lesions of the breast characterized clinically?

Solitary intraductal papillomas are tumors of the major lactiferous ducts, most frequently observed in women 30 to 50 years of age. The clinical presentation in most patients is a bloody nipple discharge, as discussed previously. A palpable mass close to the areola may be present, but most of these lesions range in size from 0.3 to 0.5 cm. Bilaterality is uncommon. Solitary intraductal papilloma does not represent a major risk for subsequent cancer development. However, surgical excision and analysis is necessary to differentiate this lesion from intraductal papillary carcinoma.

Gutman and associates¹⁰⁴ questioned the hypothesis concerning the benign nature of solitary breast papillomas. In a retrospective analysis of 95 papillary lesions, they noted that 10% of solitary papillomas were associated with breast carcinoma, and an additional 9% presented with invasive or non-invasive carcinoma within the papillomas. The risk for associated malignancy was not significantly different between solitary ductal papilloma and multiple papillomas.

Multiple peripheral papillomas occur less frequently than solitary papillomas and are often bilateral. Although they may present as a mass, or much less often with nipple discharge, with the current increased use of ultrasonography, small peripheral papillomas are being discovered and the diagnosis confirmed by ultrasound-guided biopsy. Studies have indicated that there is an increased risk for cancer associated with multiple peripheral intraductal papillomas, and complete excision with careful follow-up of both breasts is recommended.¹⁰⁵

How is fat necrosis characterized clinically?

A large portion of the breast is composed of fat, particularly in the older patient, in whom it replaces glandular tissue. An area of fat necrosis may follow trauma or may result from erosion of stagnant lactiferous ducts with extrusion of the contents into the surrounding fat. Initially, an inflammatory reaction will develop as macrophages envelop degenerated lipids. A healing phase then occurs, with proliferation of connective tissue clinically resulting in a firm lesion that can mimic cancer.

The incidence of prior trauma is probably quite high, but many patients may not remember a minor traumatic incident. Evidence of ecchymosis may be present on physical examination, but often this has resolved before the patient is seen.

Surgical trauma secondary to biopsy and reduction mammoplasty can also lead to fat necrosis, as can the injection of foreign materials such as paraffin, silicone, and narcotics into the breast. More important today is the fact that conservative treatment of breast carcinoma with lumpectomy and radiation therapy may also result in fat necrosis. Autologous fat injection using the liposuction technique to fill in irregular contours and small soft tissue defects in the breast may lead to fat necrosis secondary to the poor blood supply in the injected fat. A more common occurrence of fat necrosis may be seen in patients who, after total mastectomy with or without axillary dissection, choose reconstruction with a TRAM flap. These patients may present with a firm, nontender mass at the periphery of the transplanted flap. The findings mimic recurrent carcinoma. However, the temporal relationship of this occurrence to the flap procedure militates against a recurrence. If there is any doubt, aspiration biopsy is indicated.

The classic mammographic findings associated with fat necrosis include dystrophic calcifications and lipid cysts that may or may not be calcified. Patients who present soon after trauma with physical sequelae such as ecchymoses and painful masses in the breast can be safely observed. Breast masses may initially increase in size and later become smaller as the acute inflammatory process resolves. If patients present later with painless masses and histories of trauma that cannot be substantiated, a diagnosis of fat necrosis must be established by biopsy.

How are fibroadenomas characterized clinically?

Fibroadenoma is the most commonly appearing tumor in the female breast between puberty and 30 years of age. It usually presents as a palpable mass and may be present on a mammogram as a nodular density. The mass is classically well defined, rubbery in texture, and mobile. Mammographically, it may be seen as a well-circumscribed nodule that may or may not contain coarse calcifications. Although they present most frequently in younger patients, the exact prevalence of fibroadenomas is unknown. Once thought to be benign neoplasms, fibroadenomas are now believed to represent a hyperplastic process that involves the terminal ductulobular unit and its surrounding connective tissue. A study by Dupont and associates¹⁰⁶ noted a small but definite increased risk for breast cancer development (relative risks of 1.3 to 1.9). Unlike other benign breast lesions, such as atypical hyperplasia, in which the breast cancer risk decreases over time, the risk associated with fibroadenomas appears to be persistent. However, this has little impact on clinical management. Infrequently, carcinoma may occur in association with a fibroadenoma. The most frequent finding is lobular carcinoma in situ, but intraductal, infiltrating ductal, and infiltrating lobular carcinoma have also been observed. The prognosis of carcinoma limited to a fibroadenoma is excellent.

In older lesions and in postmenopausal patients, the stroma may become hyalinized, calcified, or even ossified. Fibroadenomas may undergo partial, subtotal, or total

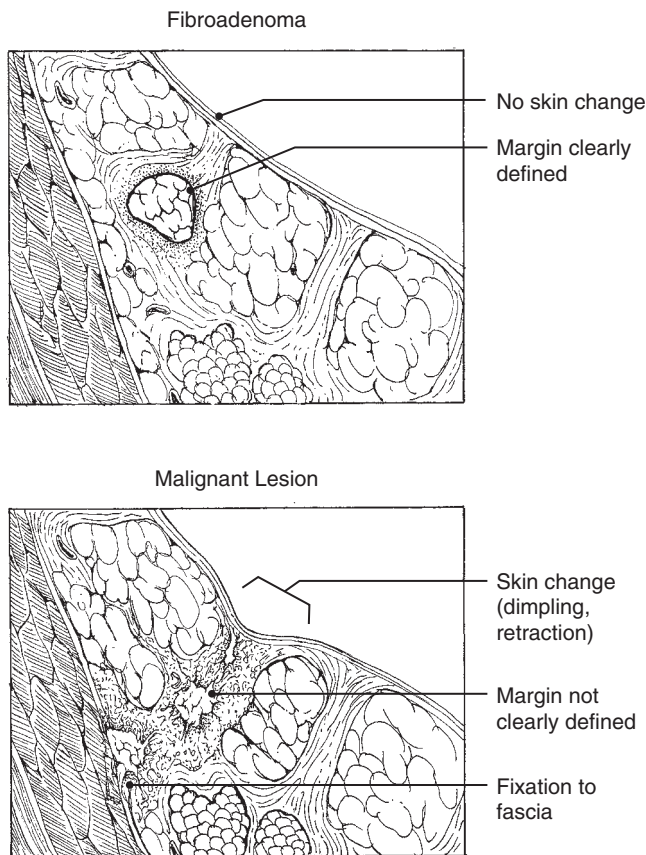

Figure 14-41 Clinical characteristics of a fibroadenoma compared with those of a malignant lesion.

infarction, with pregnancy and lactation the most common predisposing factors.

Fibroadenomas may occur in any part of the breast and are frequently multiple (Fig. 14-41). Subsequent fibroadenomas (after initial excision) are common as well. In the younger age group, in which a malignant diagnosis is extremely remote, reassurance of the patient and her family is most important. Reexamination after a short time in the middle of the patient's menstrual cycle has been useful because occasionally a prominent mammary lobule may be mistaken for a fibroadenoma and may regress. Because these lesions may increase in size, particularly under the influence of oral contraceptives, other hormonal stimulants, or pregnancy, excision seems most prudent to establish a diagnosis with certainty and eliminate the presence of a dominant mass. Recently, with the availability of accurate stereotactic evaluation, many physicians are recommending stereotactic or ultrasound-guided core biopsies of suspected small and nonpalpable fibroadenomas, particularly to differentiate them from phyllodes tumors.^{107,108} If the diagnosis is confirmed, the patient may be observed with follow-up physical examination and follow-up imaging procedures.

How are adenomas of the breast characterized clinically?

Adenomas of the breast are well-circumscribed tumors composed of benign epithelial elements with sparse,

inconspicuous stroma. This differentiates these lesions from fibroadenomas. The so-called tubular adenoma usually occurs in young women as well-defined, freely movable nodules that resemble fibroadenomas. Clinically, they present in a similar fashion as the fibroadenoma and the differentiation is only noted on pathologic examination.

Lactating adenomas occur as one or more freely movable masses during pregnancy or in the postpartum period. These lesions are well circumscribed, lobulated, and usually softer than the tubular adenoma. They may represent nodular foci of hyperplasia in the lactating breast. Diagnosis can be established by aspiration biopsy.

How are adenomas of the nipple characterized clinically?

Adenomas of the nipple have been described by a variety of names, including florid papillomatosis of the nipple ducts, subareolar duct papillomatosis, papillary adenoma of the nipple, and erosive adenomatosis of the nipple. They may appear as solid, gray-tan, poorly demarcated tumors in the nipple and subareolar region or as no gross lesion in evidence at all. In advanced lesions, glandular epithelium extends onto the surface of the nipple, a phenomenon that results in the clinically evident reddish, glandular appearance, making it somewhat difficult to distinguish from Paget's disease of the nipple. In most instances, the lesion is entirely benign; however, biopsy and subsequent total excision are necessary to distinguish the lesion from carcinoma. Reports of recurrence most likely represent instances in which the initial resection failed to remove the lesion completely.

How is juvenile papillomatosis characterized clinically?

Rosen and associates¹⁰⁹ described a clinical pathologic entity known as juvenile papillomatosis in 1980. These patients, usually younger than 30 years, most often present with a discrete mass, mistaken clinically for a fibroadenoma. Pathologic findings included duct papillomatosis, apocrine and nonapocrine cysts, papillary apocrine hyperplasia, sclerosing adenosis, and duct stasis. Cytologic atypia (74%) and necrosis (17%) were not uncommon.

Several studies have indicated that juvenile papillomatosis may represent a marker for families at risk for coincidental or subsequent breast cancer.^{110,111} The frequency of a positive family history exceeds 50%, and affected family members are most likely to be their mothers or maternal aunts. From 10% to 15% of patients with juvenile papillomatosis also have breast carcinoma, and these women are usually in the upper quartile of the age distribution for the lesion. With few exceptions, the carcinoma is within, and appears to arise from, the juvenile papillomatosis. A review of 41 patients with at least 10 years of follow-up after the diagnosis of juvenile papillomatosis (median, 14 years) found that 10% of patients subsequently developed breast carcinoma after an interval of 5 to 15 years. The carcinomas were intraductal; one with microinvasion.¹¹² Presently, the frequency of carcinoma in juvenile papillomatosis patients does not warrant considering this to be a precancerous lesion.

How is Mondor's disease of the breast characterized clinically?

Mondor's disease of the breast is an uncommon condition first reported in 1869 by Fagge¹¹³ and later discussed in detail in 1939 by Mondor¹¹⁴ as superficial thrombophlebitis of the lateral thoracic or superior thoracoepigastric veins (see Fig. 14–14). It usually presents as a tender subcutaneous cord in the breast sometimes associated with dimpling of the overlying skin but without systemic signs of infection. Its causes include benign conditions such as trauma, infections, breast surgery, excessive physical strain, and rheumatoid arthritis. Associated carcinoma has been reported in 5% to 12.7% of cases.¹¹⁵ Mammography should be performed to rule out an underlying malignancy. It has also been found following breast conservation surgery and radiation therapy. The process is usually self-limited and resolves spontaneously in 2 to 10 weeks. Local application of heat and nonsteroidal anti-inflammatory agents can give some relief of symptoms.

How are granular cell tumors of the breast characterized clinically?

Granular cell tumors, uncommonly found in the breast, may simulate carcinoma on clinical, mammographic and pathologic examination.¹¹⁶ These tumors typically appear between puberty and menopause and most often occur in the upper inner quadrant of the breast, in contrast with carcinoma, which occurs most frequently in the upper outer quadrant. Patients present with a palpable mass, and retraction or fixation to the underlying muscle or chest wall is not uncommon. In addition, they resemble scirrhous carcinoma on mammography.

Granular cell tumors are almost invariably benign and are treated by wide local excision. They are most likely of neurogenic rather than myogenic origin.¹¹⁷

How is warfarin-induced breast necrosis characterized clinically?

Flood and associates¹¹⁸ in 1943 first described a patient with an unusual type of localized hemorrhagic necrosis of skin and subcutaneous tissue of the breast caused by therapy with oral anticoagulation, warfarin. Subsequently, several other cases have been reported. Heparin does not appear to be a predisposing agent. Warfarin-induced breast necrosis is self-limited and fails to respond to a variety of treatments, including steroids, vasodilators, vitamin K, dextran, hypothermia, and symptomatic nerve blocks. Wide excision or simple mastectomy, which may require skin graft for flap closure, is the only effective treatment.

CONCLUSION

Clinical assessment, with attention to a thorough history and physical examination and the use of the adjunctive procedures described in this chapter, will hopefully lead to earlier

diagnoses and an improved outlook for women and men with breast cancer. The ultimate goal is prevention, but until that time, early detection is the key to prolonged survival and possible cure.

Mammographic Diagnosis of Breast Cancer

Julie Mitnick

Mammography has become accepted as the single most effective technique to detect breast cancer before it becomes palpable and to aid in decreasing mortality from this cancer.¹ Improvements in mammography have been responsible for the current high proportion of breast cancers that are detected as ductal carcinoma in situ (DCIS)—that is, tumors less than 1 cm in diameter and without axillary lymph node metastases.² The benefits of mammographic screening were first defined by the early study of Shapiro and his colleagues, who participated in the Health Insurance Plan of Greater New York (HIP).³ They demonstrated that women older than 50 years who had screening mammography had cancers that were significantly smaller and had an improved survival compared with women who did not have screening mammography. The efficacy of mammography for the detection of breast cancer in younger women was first shown in the Breast Cancer Detection Demonstration Project (BCDDP), in which 35% of cancers in women younger than 50 years were detected only by mammography.⁴ Subsequently, other studies have become available to demonstrate the benefit of screening women younger than 50 years.⁵ A controversial report by Olsen and Gøtzsche received a great deal of attention in the media.^{6,7} These authors cited technical flaws in early studies of screening mammography and concluded that there is no reduction in mortality from mammography. However, other experts after considerable analysis found the critique itself biased and continue to support the benefits of screening mammography.^{8,9}

When did mammography enter into standard diagnostic practice?

The first reproducible technique for radiographic imaging of the breast was described by Egan in 1960.¹⁰ His report of 53 cases of clinically occult malignancies detected by mammography in 2000 consecutive patients suggested that mammography might be used for breast cancer screening in asymptomatic women.¹¹ The prototype x-ray units “dedicated” to mammography were produced in France in 1965. A molybdenum target and a built-in compression device provided more detailed images with better contrast and lower radiation dose.¹² The initial high-definition

intensifying screen was developed for use in mammography in 1970.¹³

Xeroradiography became the predominant method for mammography after its introduction in 1971. The Xerox image was preferred because microcalcification visibility was amplified by an edge enhancement effect and xeromammograms could be viewed in ambient light without a view box. Further improvement in the film-screen combination led to better contrast and visibility of calcifications with decreased scattered radiation. When radiation exposure by the film-screen technique was decreased and the detail of the images obtained by the film-screen combination was improved, this technique came to be preferred over xeromammography.¹⁴ In 1989, the Xerox corporation discontinued production of its xeromammography units because of declining interest. Since then, attention has been focused on obtaining optimal imaging with the film-screen combination, and more recently with digital full-field mammography.

What are the two types of mammography?

There are two types of mammography, screening and diagnostic. Screening mammography aims to detect breast cancer in an asymptomatic individual. Screening examinations use two standard mammographic views. Processing of the films may take place later, at a separate site, termed “batch” processing. Diagnostic mammography is considered to be a problem-solving type of study. The patient may be symptomatic; for example, she may feel a lump in her breast, or her physician may have a concern based on the clinical examination. This study often includes additional views such as magnification views or spot films. The diagnostic evaluation determines whether a mammographic finding is suspicious for cancer. According to Kopans, the distinction between the two types of mammography is that screening detects breast abnormalities that may represent cancer, whereas diagnostic evaluation attempts to determine, with the greatest possible specificity, which of the abnormalities is actually cancer.¹⁵ A second type of diagnostic mammogram is one performed on a woman who has had an abnormal screening mammogram and for whom further evaluation has been requested.

What are the current recommendations for mammography?

Current recommendations for performing mammography by age for asymptomatic women with average risk according to the American Cancer Society are presented below.¹⁶ These guidelines were issued in 1997 and confirmed in 2003:

- Screening should begin by age 40 years
- Screening should be performed every year after age 40 years
- Yearly clinical breast examination should begin at age 40 years; it should be performed every 3 years during ages 20 to 39 years

These guidelines are not accepted as optimal by everyone, and the interval for appropriate screening in women younger than 50 years is controversial. The U.S. Preventive Services Task Force recommended as of 2002 that women 40 years and older receive a mammogram every 1 to 2 years with or without a clinical breast examination.¹⁷ This represents a change over the previous guidelines by including women in their 40s for routine screening. The American Cancer Society guidelines do not have an upper age limit for screening. As long as a woman is in good health, screening is suggested.

Using current high-quality technique, mammography is now considered by many to be as effective in detecting cancer in the 40- to 49-year age group as in the over-50 age group.⁵ Technical improvements in mammography, such as full-field digital mammography, have made the evaluation of younger women with denser breasts less problematic than in the past. The composition of the individual's breast tissue (e.g., the relative amount of fat and glandular components) may be more important than the specific age. Women may have breasts that are quite dense even though they are older than 50 years of age, and some women younger than 50 years can easily be assessed by mammography because their breasts are not dense. Aggressive screening of women 40 to 49 years of age to detect occult cancers has been urged, and technical problems and poor study design have been cited as responsible for the failure of the Canadian National Breast Screening Study to demonstrate a decrease in mortality in the under-50 age group.¹⁸ Liberman and associates suggest that the benefits of screening may apply to even younger women.¹⁹ They reviewed the results of screening mammography and breast biopsy results in women 30 to 39 years old screened through the Memorial Hospital BE SMART! Program and found that the rate of cancer detection was comparable to that for women 40 to 49 years of age.

It has been suggested that certain high-risk individuals be screened yearly below age 40 years. These include women with a personal history of breast cancer, high-risk conditions such as lobular carcinoma in situ, atypical duct hyperplasia, or *BRCA1*- or *BRCA2*-positive genetic testing. Also included are women who have had chest irradiation for lymphoma or who have a strong family history of premenopausal breast cancer.

What is the radiation dosage of mammography?

The average radiation dose at the present time of two-view mammography at an American College of Radiology–approved facility is 0.25 cGy.²⁰ At this dose range, the benefit

has been estimated to exceed the risk by a factor of about 100 in women older than 50 years and by a factor of more than 25 in women younger than 50 years.¹⁷ According to Feig, the benefit to women younger than 50 years may be even greater.²⁰ A more detailed discussion of the benefits of screening mammography is provided by Feig in Chapter 13.

What is full-field digital mammography?

Because the sensitivity of mammography has been demonstrated to reveal only about 75% of breast cancers, there has been an emphasis on developing newer technologies for screening. The prototype for digital mammography occurred in 1996 and was approved by the U.S. Food and Drug Administration (FDA) in 2000. The fluorescent film and screen used with standard mammography is replaced with a digital detector. This detector records the x-rays as electrical signals that are then converted to digital information. Digital detectors have greater latitude and contrast resolution. The digital mammograms can be interpreted from a computer workstation rather than film. At some sites film is still printed because of greater ease in performing comparison with prior film-screen examinations. However, Pisano and associates found that there was no significant difference in the diagnostic accuracy and speed of interpretations with soft-copy and printed-film displays.²¹ Digital mammography is particularly valuable for imaging women with dense breasts, for the evaluation of subtle microcalcifications, and for the timely performance of needle localization procedures. The use of digital mammography has been shown to decrease the radiation exposure of needle localizations by as much as 50%.²² The clinical performance of digital mammography is to some extent dependent on the physician's familiarity with the technique. Published reports, to date, do not demonstrate a significant difference in cancer detection between prototype digital and film-screen mammography in initial studies. Digital mammography has been found to result in fewer recalls for screening.²³ Further benefit may be demonstrated in the future with technologic advances of digital mammography.

What are the standard mammographic views?

High-quality mammography depends on proper technique and skillful performance of positioning as well as accurate interpretation of the films. There has been a renewed emphasis on the importance of technical aspects of mammography with the implementation of the Mammography Quality Standards Act in 1992, which requires that specific standards be met for a facility to receive accreditation. For a mammogram to be of optimal quality, adequate compression must be applied to the breast to separate overlapping structures, decrease the amount of radiation required to produce the image, and obtain sharp images²⁴ (Fig. 15–1). The standard mammogram consists of the mediolateral oblique (MLO) and the craniocaudal (CC) views, both of which are included in a two-view screening mammogram and a diagnostic mammogram. The MLO is considered the most important view because it includes most of the breast when performed correctly²⁴ (Fig. 15–2). The pectoral muscle is in an oblique position, extending down to at least the level of the nipple.

Figure 15-1 Importance of adequate compression during the mammogram. *A*, Implant-displaced craniocaudal view with inadequate compression. *B*, Adequate compression of the implant-displaced view has a 0.3-cm infiltrating carcinoma (*arrow*). Scar markers are at the sites of previous benign biopsies.

Figure 15-2 Correct patient positioning for the mediolateral oblique view. Note inclusion of the axillary tail and inframammary fold.

Figure 15-3 Schematic representation of the compressed breast for the craniocaudal view. This view can optimally visualize the medial aspect of the breast.

The axilla is at the superior aspect of the image, and the inframammary fold should be present at the lower. The CC view optimally visualizes the medial aspect of the breast, and in many mammograms it shows the pectoral muscle at the posterior aspect of the film (Figs. 15-3 to 15-5). According to Eklund and Cardenosa, in the exaggerated CC view (XCC), the lateral aspect of the breast can be pulled in as a final maneuver by the technologist when performing this film, thus reducing the need for an extra view.²⁴ The XCC view is helpful if there is a prominent tail of the breast.

In some cases, additional views are necessary to evaluate a physical or a mammographic finding that is not completely defined by the routine views. Most frequently required additional views include spot compression and magnification views (Figs. 15-6 to 15-10). With spot compression, intense compression is applied to a specific area of the breast, improving the detail of the region. Magnification views can be obtained with or without spot compression and are used to assess microcalcifications and to determine the details of a specific area of the breast such as the border characteristics of a mass (see Fig. 15-4). The 90-degree lateral view is helpful to remove overlapping breast tissue that is seen on the MLO view. In combination with the MLO view, it is possible to determine whether a lesion is medial or lateral in position when it is not seen on the CC view.

Other views may also be needed when performing a diagnostic mammogram. These include angled views, in which the breast is rolled to remove adjacent or overlying tissue; the cleavage view, which images the most medial portion of both breasts on the same film; and the Cleopatra view, to visualize the lateral aspect of the breast in an angled position. A tangential view has the tube angled to bring a specific region of the breast close to the skin surface. It is frequently used to differentiate whether calcifications are within the skin or the breast tissue. “Lumpograms” are performed by pulling on a palpated abnormality, thereby removing adjacent breast and

Figure 15-4 A, Proper positioning of the mediolateral oblique view with the inframammary fold open shows a spiculated mass. B, Specimen radiograph has a 0.7-cm moderately differentiated infiltrating duct carcinoma.

Figure 15-5 Importance of proper positioning for mammography. The mediolateral oblique view must include the pectoral muscle so that lesions deep in the posterior breast can be detected. A, The small mass (arrow) overlying the edge of the pectoral muscle was an infiltrating 0.6-cm cancer. B, A 62-year-old woman presented with a palpable spiculated mass in the left breast. A percutaneous ultrasound-guided biopsy confirmed the diagnosis of cancer.

A **B**
Figure 15-6 Value of the magnification view. *A*, Increased density is present in the retroareolar region of the craniocaudal view in this 48-year-old woman. *B*, Spot magnification view shows an irregular mass and microcalcifications and areolar thickening due to infiltrating lobular carcinoma.

Figure 15-7 Value of the spot magnification view. The mammogram has a 0.8-cm irregular mass. The magnification view reveals an adjacent site of malignant microcalcifications (*arrow*) not appreciated on the routine views. The pathology of the mass was infiltrating duct and histiocytoid lobular carcinoma with ductal carcinoma in situ.

A **B**
Figure 15-8 *A*, The craniocaudal view has a new small questionable density at the inner left breast. *B*, The spot magnification film clearly shows a mass with an irregular posterior border that was a 0.6-cm ductal carcinoma.

Figure 15-9 Spot magnification view shows pleomorphic microcalcifications with a ductal distribution. The histology was high-grade ductal carcinoma in situ with infiltrating ductal carcinoma. When aligned along the course of a duct, microcalcifications are highly suspicious.

Figure 15-10 A, Subtle, low-density irregular mass (*arrow*) at the outer right breast. B, The spot film has a persistent mass. An ultrasound-guided core biopsy revealed a 0.4-cm infiltrating lobular carcinoma.

Figure 15-11 A "lumpogram" of a desmoid tumor. The mammographic findings simulate the findings of an infiltrating cancer.

compressing that region with a spot film, to obtain better detail (Fig. 15-11).

What is the mammographic appearance of breast cancer?

The mammographic appearance of breast cancer is varied, and its detection depends on the interpretive skills of the radiologist. In many instances, there is overlap between benign

Table 15-1 Mammographic Appearance of Proven Cancers of the Breast (n = 1314)

Mammographic Finding	Number (%)
Clustered microcalcifications	589 (45%)
Spiculated mass	355 (27%)
Round, oval, lobular, or irregular mass	249 (19%)
Architectural distortion	87 (7%)
Focal asymmetric density	34 (2%)

and malignant entities, and mammography alone may not be specific enough to differentiate them. Even the most suspicious appearance for cancer, a spiculated mass, can have benign histology, such as surgical scarring, fat necrosis, or radial scar. Further evaluation of a finding that the radiologist determines is suspicious for cancer may require additional films, sonography, or percutaneous or surgical biopsy.

The Breast Imaging Reporting and Data System (BI-RADS) lexicon has been developed to obtain uniformity in the description of findings on the mammogram.²⁵ This descriptive system enhances understanding of the likelihood that a particular mammographic finding is a cancer. We retrospectively reviewed the mammographic appearance of our proven cancers, both palpable and nonpalpable, according to the American College of Radiology (ACR) terminology (Table 15-1). These are cases for which a malignant diagnosis was confirmed by histopathology. Clustered microcalcifications were the most common indicator of cancer in this series. The term *focal asymmetrical density*, according to the ACR lexicon, is used to describe a density with a similar shape on two views

but lacking the borders of a discrete mass. Asymmetrical breast tissue is judged relative to other areas in the breast and includes a greater volume of breast tissue, greater density, or more prominent ducts. There is no focal mass present, and it usually represents a normal variation. It may be deemed significant when there is an associated palpable mass. Other less common findings are skin thickening, nipple retraction, trabecular thickening, and axillary adenopathy.

According to federal regulations, every mammogram must have, in its impression, an overall assessment of the likelihood of a finding's being cancer. This promotes understanding among the radiologist, clinician, and patient of the relative risk for cancer's being present. The overall assessment categories for the BI-RADS coding is as follows:

- Category 0: Incomplete: needs additional imaging evaluation, or comparison with prior studies
- Category 1: Negative
- Category 2: Benign finding
- Category 3: Probably benign; short term follow-up suggested
- Category 4: Suspicious for malignancy
- Category 5: Highly suspicious for malignancy
- Category 6: Proven breast cancer

According to Liberman and associates,¹⁹ the findings that are most likely to have a positive predictive value for being cancer (BI-RADS category 4 or 5) are spiculated masses or linear or branching calcifications.

Why obtain mammography for patients with palpable masses?

Suspicious palpable masses detected by clinical examination should be evaluated by mammography to determine the

extent of the cancer within the breast and to identify other occult sites of cancer within the same and the opposite breast. Identification of other sites of cancer will likely affect the surgical treatment (e.g., whether conservation is possible). Most palpable findings detected by clinical examination prove to be benign following surgery, and mammography helps to identify the nonmalignant palpable mass and thereby avoid surgery. When a benign mass such as a cyst is suspected, mammography should be performed before aspiration or core biopsy. A breast sonogram may also be of help to further evaluate the nature of the mass. The dominant mass that is palpated and aspirated may be a cyst, but an occult cancer adjacent to it may be detected on the mammogram (Fig. 15–12). If a cancer is palpated, imaging of the same and contralateral breasts may detect other clinically occult sites of cancer.

How frequently are breast cancers missed by mammography?

Mammography cannot detect all breast cancers. For women with dense breasts, such as young women and those with a fibrocystic condition, it may be difficult to visualize a cancer. With problem-solving additional views or technique tailored to the individual, however, information may often be obtained even in young symptomatic women with dense breasts.

The sensitivity of mammography is in the range of 68% to 92%.²⁶ The problem of missed breast cancers has been attributed to several causes: technical faults, observer errors, and the intrinsic limitations of mammography itself. Technical factors include proper positioning and adequate compression (see Fig. 15–7). Observer errors have been analyzed by Bird and associates, who reviewed 320 cancers, 77 (24%) of which they

Figure 15–12 *A*, Small carcinoma is partially obscured by a large cyst. Architectural distortion is present at the superior aspect of the 3-cm oval mass. *B*, The mass was aspirated and was a cyst. A spot film of the distorted area showed a tiny invasive duct carcinoma.

missed mammographically.²⁷ They found that diagnostic errors were more likely to occur for developing densities and that missed cancers were most often small, irregular densities in the retroareolar or retroglandular portions of the breast. Missed cancers were unlikely to demonstrate microcalcifications and were more likely to occur in women with dense breasts. Forty (52%) of their missed cancers could be identified in retrospect, on earlier mammograms. Fourteen (18%) of the cases that were missed, according to the authors, were incorrectly interpreted as benign. Dense breasts, diffuse nodularity, and breast implants may cause difficulty in detecting a cancer by mammography.

The use of double reading for mammographic interpretation has been demonstrated to detect 15% more cancers than interpretations by a single radiologist.²⁸

An alternative to double reading is the use of computer programs to help in detecting an abnormality on the mammogram. Reports have shown that computer-aided detection (CAD) algorithms are able to detect breast abnormalities on screening mammograms and reduce the number of false-negative findings. In a prospective study of 12,860 patients who had screening mammography with CAD, there was a 19.5% increase in the number of cancers found.²⁹ In a different study, the CAD system was found to have no effect on radiologist performance, despite high sensitivity, probably owing to the many false-positive markings.³⁰ Zheng and coworkers reported that the sensitivity for the detection of clustered microcalcifications is high at 96% but that sensitivity for mass is only 66.7% to 70.8%.³¹ The authors also noted that the abnormalities in their study were visible on both views and that they were not particularly subtle. Further improvements must be achieved in the detection of masses for CAD systems to be sufficiently reliable for general use, and for the possibility of achieving the increased sensitivity of a second reader. These authors also cautioned that the use of CAD may be problematic from a medicolegal viewpoint if an area marked on an earlier mammogram later develops into a cancer.³¹ CAD has not been found beneficial for the detection of architectural distortion on the mammogram, an often subtle and important presentation of breast cancer.³² It has been reported that the reproducibility of the CAD systems is currently insufficient for clinical routines.³³

What are the medicolegal ramifications of mammography?

Publicity regarding the success of mammography has been accompanied by unrealistic claims for the reliability of this technique to detect breast cancer. The rise in lawsuits charging delay in diagnosing breast cancer may be partially due to a misunderstanding that all breast cancers can be detected by mammography. Summarized data from the Physicians Insurance Association of America (PIAA), based on the pooled results of selected insurance companies with lawsuits instituted for a claim of a missed diagnosis of breast cancer, were issued in 1990 and again in 1995.^{34,35} These two reports found that most claimants were younger than 50 years, frequently found their own breast mass, and often were incorrectly diagnosed as having a fibrocystic condition. Our own review of lawsuits in New York State and other reports confirmed these findings^{36–38} (Table 15–2). The PIAA reports

Table 15–2 Complaint of Plaintiff in Legal Actions (n = 37)*

Complaint Category	Complaint	No. (%)
1	Plaintiff felt a lump; physician failed to obtain a biopsy specimen or refer to a specialist	22 (60)
2	Plaintiff felt a lump; physician failed to order mammography	6 (16)
3	Physician failed to examine properly and palpate breasts, and detect a palpable lump	2 (5)
4	Physician failed to read mammogram properly	3 (8)
5	Physician failed to warn that pregnancy can reactivate breast cancer	1 (3)
6	Physician ignored suspicious findings on mammogram and recommendation of biopsy	1 (3)
7	Physician failed to properly treat already diagnosed breast cancer	2 (5)

*Several of these actions involved more than one category of complaint. Modified from Mitnick JS, Vazquez MF, Plesser KP, et al. Breast cancer malpractice litigation in New York State. *Radiology* 1993;189:673–676.

showed that in 1990, gynecologists were the physician specialty most frequently sued. In 1995, radiologists were more often cited, probably owing to the increased number of screening mammograms being performed. Both the failure to perform mammograms and an over-reliance on this technique when it is negative have led to lawsuits in which a delay in diagnosis was purported.

Ikeda and associates have reported that there is a subset of nonspecific mammographic findings that do not warrant recall but that were the subtle findings where cancer later developed.³⁹ They believe that a failure to act on these nonspecific findings does not constitute an interpretation below the standard of care. In their study, the most common nonspecific finding on prior mammograms that they believed should not be considered an error was a density seen on only one view. They found that these densities are indistinguishable from randomly distributed islands of breast tissue that are common in fibrocystic disease. They have noted that in the setting of a malpractice allegation, the mere presence of a finding on a prior mammogram does not indicate liability. Mammograms should be viewed in the temporal sequence in which they were obtained, and a retrospective analysis of a nonspecific finding at the site of cancer development is not malpractice. They noted that just because “something is visible where cancer develops subsequently does not mean that a defendant radiologist was negligent in choosing not to recommend recall for additional imaging.”

Because of the highly litigious nature of mammography, fewer radiology residents are choosing to practice breast imaging. In a survey of radiology residents, causes of disinterest in interpreting mammograms included fear of lawsuits, low pay, and mental stress.⁴⁰ There is currently a nationwide shortage of radiologists willing to read mammograms.

Berlin has reported that the current system of malpractice awards is such that even if a panel of highly educated experts

agree that no negligence has occurred, if a woman has a witness who will testify that a breast cancer was missed on an earlier mammogram, she is likely to be successful in the lawsuit.⁴¹

What are interval breast cancers?

Interval breast cancers are cancers diagnosed during the 12 months after a normal screening mammogram and clinical examination (Figs. 15–13 to 15–15). They have traditionally been thought to be more aggressive forms of breast cancer, with a poor prognosis for survival. DeGroot and colleagues reported 21 patients with interval breast cancers, with 24% having stage II and 25% having stage III disease at the time of diagnosis.⁴² In contrast, Koivunen and associates did not find their interval cancers to be more aggressive.⁴³ They evaluated 24 patients with interval breast cancers and found that 54% had stage II disease and none had more advanced disease. Their patients with interval breast cancers were characterized by increased density of the breasts and greater difficulty in diagnosis by mammography. Physical examination was also less reliable in their patients because they had diffuse nodularity or fibrocystic conditions. Their conclusion was that interval breast cancers are not a subset of biologically more aggressive cancers but are cancers that are more difficult to diagnose by mammography and clinical examination. A series by Burrell and associates of 90 interval cancers had 51 (57%) true positive, 20 (22%) false negative, 7 (8%) mammographically occult, and 12 (13%) unclassified.⁴⁴ The false-negative cases were most often found to be areas of architectural distortion at mammography. There was no significant difference

in the patterns of breast parenchyma for these categories of interval cancer. Their interval cancers were larger and more likely to have lymph node metastases and to have a poorer prognosis than screening-detected cancers.

What is the radiologist's role in the surgical excision of a clinically occult lesion?

Clinically occult mammographic abnormalities that require excision, such as suspicious microcalcifications or architectural distortion, should be preoperatively localized by the radiologist to achieve a successful surgical biopsy. Outpatient needle localization breast biopsies (NLBBs) for nonpalpable abnormalities have become a standard surgical practice similar to that used for the removal of palpable abnormalities. A report from the New England Medical Center in Boston found that when local anesthesia for NLBB is used, the chance of missed lesions is less than 2%, and complication rates are comparable to those for biopsy of palpable lesions.⁴⁵ This failure rate using NLBB was slightly lower than that found from 17 series in the literature that the authors reviewed, which was 2.8%. Reported complications related to the needle localizing device and cited as causes for missing the lesions included transection or breakage of the localizing device, retraction of the wire into the breast, entrapment of the wire below the pectoralis fascia, and poor positioning of the localizing wire. We have found these complications to be extremely rare, with the most common rare complication being a minor vasovagal reaction. A similar experience was reported by Helvie and associates, who evaluated complications of patients undergoing needle localization and aspiration procedures: of 172 patients

Figure 15–13 Interval breast cancer. *A*, Mediolateral oblique view of the right breast is unremarkable. *B*, One year later, a 1.2-cm lobular carcinoma developed in the superior breast.

Figure 15-14 Interval breast cancer. *A*, The mediolateral oblique view of a screening mammogram was normal. *B*, One year later, there is a subtle asymmetrical density (*arrow*) that was poorly differentiated duct carcinoma.

Figure 15-15 Craniocaudal view of the right breast was negative (not shown). One year later, there has been development of an interval high-grade invasive duct carcinoma. The mass was circumscribed with irregular borders, findings that were highly suggestive of the malignant diagnosis.

who underwent needle localization, 13 (8%) had vasovagal reactions.⁴⁶

Several needle localizer systems are widely used. The three most popular systems are the Kopans, Homer, and Hawkins needle localizer systems. The Kopans system (Cook, Bloomington, IN) allows for a moderate amount of traction on the wire during surgery. The disadvantage is that the wire cannot be repositioned (Figs. 15-16 and 15-17). The Homer system (North American Instrument, Glens Falls, NY) is easy to use and has a retractable wire. When the J-shaped memory wire is delivered, the needle may be left in place and used as a nontransectable guide for the surgeon. The disadvantage is that the needle and wire are relatively easy to pull out with moderate traction. The Hawkins I system (National-Standard Medical Products, Gainesville, FL) has a tip that is withdrawn into an outer cannula once the barb is deployed. The barb exits from the cannula at an acute angle, allowing for moderate traction at surgery. It is reported to have greater anchoring strength than the Kopans system.⁴⁷

The approach for the needle localization procedure should be carefully planned. Generally, the shortest distance from the skin to the lesion is used. Some surgeons prefer a needle entry close to the areolar margin. Once the suspicious area is localized within the fenestrated grid, an intradermal injection of local anesthetic can be given at the site of approach of the localizer needle. Using the tube light as a guide, the needle is inserted to the proper coordinate location indicated on the scout film. As the needle is inserted into the breast, a change in texture may occasionally be noted as the needle reaches the suspicious lesion. The needle should be advanced just beyond that point. It is better to “overshoot” the lesion than to be short of it. Next, the compression device is released while

Figure 15-16 Kopans wire in place for the preoperative localization of invasive lobular carcinoma. The wire extends through a subtle area of distortion of the breast architecture.

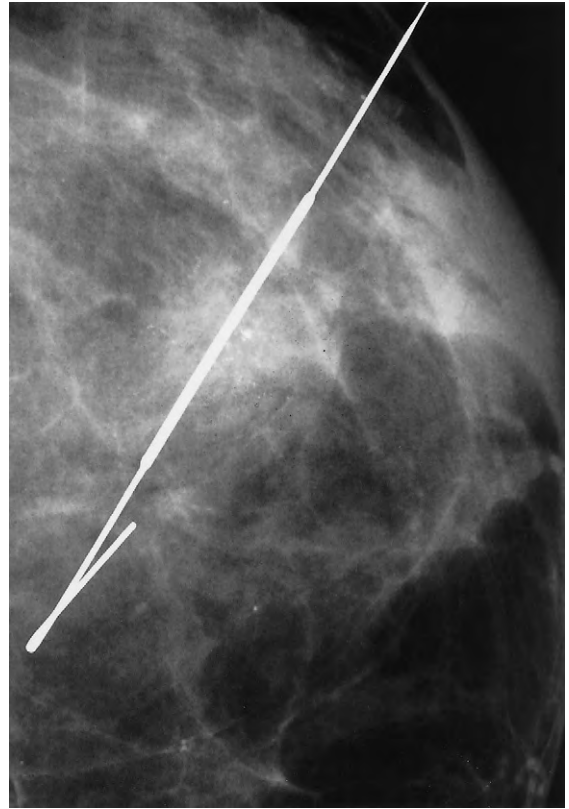

Figure 15-17 Kopans wire has microcalcifications at the thick segment of the wire. The microcalcifications were excised, and the histology was solid and cribriform ductal carcinoma in situ.

the needle is protected from contacting the edges of the coordinated grid window. Final films are obtained with the wire in place, and the site to be excised is marked on both films. These films accompany the patient to the operating room as a guide for the surgeon. Needle localizations can also be performed using ultrasound guidance. Mammographic films are obtained after placement of the wire to confirm the correct wire placement. Bracketing wires may be used for preoperative needle localization to delineate the boundaries of a mammographic lesion, such as a broad region of suspicious microcalcifications, to help encompass the entire lesion (Fig. 15-18). In a report by Liberman and colleagues, bracketing wires were most often used for large calcified lesions that were highly suggestive of malignancy (e.g., BI-RADS category 5 lesions).⁴⁸ These authors emphasize that the complete removal of the calcifications does not ensure clear histologic margins at resection. The advantage of ultrasound localization is that there is no radiation exposure except for the final films demonstrating wire position. Also, because the patient is supine, there are fewer vasovagal reactions, and the time to perform the localization is lessened. With the increasing use of sonography to evaluate the breast, more needle localizations are being performed with this technique. We routinely use sonography to localize most nonpalpable entities, except for microcalcifications.

Figure 15-18 A stereotactic mammotome biopsy had malignant microcalcifications. The Micromark clip and residual microcalcifications were bracketed with preoperative localization wires seen in the specimen radiograph. Bracketing of malignant microcalcifications may aid the surgeon to achieve clear margins.

Figure 15-19 Linear and branching microcalcifications in a 45-year-old woman are classic comedocarcinoma.

Does needle localization cause cancer dissemination?

The issue of whether preoperative needle localization can lead to an increase in local breast cancer recurrence was addressed by Kopans and associates.⁴⁹ Seventy-four women with nonpalpable breast cancer were evaluated, all of whom had preoperative needle localization with a follow-up of at least 3 years. The authors analyzed only preoperative placement of guides parallel to the chest wall, but they concluded that this specific localization approach does not increase local recurrences. They suggest that an anteroposterior approach may have an additional theoretical increased potential of seeding malignant cells. For this reason, many surgeons attempt to include the needle track in the surgical specimen. A report of 29 surgical breast specimens from patients who had undergone a variety of needling procedures, including needle localization, before surgery revealed epithelial displacement mimicking stromal invasion.⁵⁰ The clinical implication of this finding is controversial and requires further evaluation with larger numbers of patients.

How is ductal carcinoma in situ characterized mammographically?

The increasing use of mammography has led to a higher detection rate of clinically occult DCIS, most cases of which are detected as clustered microcalcifications (Figs. 15-19 through 15-28). Pleomorphic or heterogeneous microcalcifications or those that are linear or branching have a higher probability of being malignant. The linear microcalcifications

Figure 15-20 A new cluster of pleomorphic microcalcifications is ductal carcinoma in situ.

can be due to filling of the duct by the necrotic debris of breast cancer. Frykberg and associates found that from 1985 to 1993, there was a 14-fold increase of in situ lesions among all diagnosed breast cancers.⁵¹ It has been estimated that DCIS now accounts for about 25% to 40% of all breast cancers detected by mammography. The average size of these lesions has concomitantly decreased. Lagios reported that the average size of DCIS in his series was 6 mm.⁵² DCIS, with its malignant cells confined to the ducts, is subdivided into comedocarcinoma and noncomedocarcinoma subtypes. Evans and associates compared the mammographic and pathologic features of 131 screening-detected and symptomatic cases of DCIS.⁵³ They found that there was a larger proportion of comedocarcinoma in the screening-detected group. The symptomatic group was more likely to have diffuse involvement of the breast and had larger regions of clustered microcalcifications. Comedocarcinoma is characterized on microscopic examination by central necrosis and at mammography by microcalcifications that are elongated with a castlike pattern along the duct configuration (see Fig. 15-19). The microcalcifications of the noncomedo subtypes may appear more variable, with more irregular forms or a granular appearance (see Fig. 15-26). Focal areas of increased opacity may be present in comedocarcinoma, either with or without microcalcifications. This was found to correlate with a fibrous stromal reaction at histology.⁵⁴ Kinkel and associates found these regions of increased opacity in 25% of their patients with clustered microcalcifications and in 8% of patients without microcalcifications, all of whom had proven comedocarcinoma.⁵⁴ Although most cases of occult DCIS have been found to be detected by microcalcifications, more unusual forms of presentation of DCIS having an atypical appearance have been described by Ikeda and Andersson and include ill-defined masses, architectural distortion, and dilated ducts.⁵⁵ Harris

Figure 15-21 Multicentric carcinoma. *A*, Clustered punctate microcalcifications (*arrow*) are oriented along a duct toward the nipple. *B*, A mass was also present in the superior breast that was not well visualized on the mammogram but was excised for biopsy under ultrasound guidance. The hypoechoic irregular mass was easily detected by a breast sonogram. Both sites proved to be cancer, and the patient underwent mastectomy.

Figure 15-22 A palpable mass in a 38-year-old woman was high-grade ductal carcinoma in situ (DCIS). The heterogeneous microcalcifications have a segmental distribution typical of DCIS.

Figure 15-23 Multicentric ductal carcinoma in situ. A magnification view has multiple clusters of malignant microcalcifications that were throughout the breast. Punctate, linear, and coarse calcifications are present.

Figure 15-24 Comedocarcinoma. A screening mammogram has a new cluster of microcalcifications. There is a linear calcification in the center of the cluster. A faint separate site of microcalcifications was also ductal carcinoma in situ (DCIS) in this patient with multifocal DCIS.

reported a case of DCIS that appeared as a branching tubular opacity with peripheral coarse calcifications. With this appearance, DCIS may be difficult to distinguish from vascular calcifications.⁵⁶ In a review by Stomper and coworkers of 100 cases of DCIS, an indistinct round or oval mass was present in 18%, an irregular or poorly defined mass in 64%, a spiculated mass in 14%, and architectural distortion in 4%.⁵⁷ These soft tissue findings were attributed to direct involvement by tumor into an expanded lobule and to periductal fibrosis or elastosis. In an early report, we described 13 small, round, or oval masses that were well circumscribed and had microcalcifications that proved to be DCIS.⁵⁸

Liberman and associates have reported that calcifications highly suggestive of malignancy account for about 10% of nonpalpable lesions referred for biopsy.⁵⁹ These calcifications include linear or branching clustered microcalcifications. Based on their experience, they recommend stereotactic biopsy of the calcifications using an 11-gauge vacuum-assisted automated device because there is a greater likelihood that a single operation for definitive treatment may be performed. They found that only 16.2% of women with breast cancer who had a diagnostic surgical biopsy had a single operation for treatment. This compared with 71.4% of women who had a stereotactic biopsy. They report that the significantly greater chance of having a single operation after stereotactic biopsy allows for better treatment planning by anticipating the need for wide excision or mastectomy.

Figure 15-25 A cluster of calcifications on a screening mammogram in a young woman with a positive family history of breast cancer (*arrow*). On initial inspection the calcifications appear coarse, but numerous fine microcalcifications were also within the cluster. Although not typical of ductal carcinoma in situ, coarse calcifications may also occur with this entity.

What is the role of specimen radiographs?

Careful correlation between intraoperative specimen radiography and preoperative mammography is important to verify complete excision of the mammographic lesion. Because successful breast conservation therapy is believed to be dependent on the demonstration of complete removal of the lesion, preoperative magnification views may be obtained for assessment of other sites of involvement by DCIS manifested as microcalcifications. Some of the microcalcifications may be extremely faint and not visualized by conventional radiographs (see Fig. 15-27). Morrow reviewed a study by Holland and concluded that there is underestimation of DCIS by as much as 20 mm if magnification views are not performed.⁶⁰ These films may be useful to diagnose multicentric

Figure 15-26 Multiple clusters of punctate microcalcifications were micropapillary ductal carcinoma in situ in a 33-year-old patient. There is also a palpable, partially obscured mass that was infiltrating duct carcinoma.

Figure 15-27 This specimen radiograph has heterogeneous clustered microcalcifications at the thickened segment of a wire used for preoperative needle localization. There was a barely perceptible new cluster of microcalcifications on the mammogram. A 0.3-cm focus of comedo-type DCIS was excised.

Figure 15-28 Recurrent carcinoma. *A*, A 37-year-old woman had a prior excision of microcalcifications that were ductal carcinoma in situ (DCIS). A routine mammogram performed 3 years later has pleomorphic microcalcifications that were recurrent DCIS. At times, it may be difficult to differentiate recurrence from fat necrosis in the lumpectomy site. *B*, Heterogeneous microcalcifications and architectural distortion were recurrent cancer. Multiple foci of invasive ductal and cribriform DCIS were found at excision. The DCIS extended beyond the edges of the infiltrating cancer.

A

B

disease (involvement of more than one quadrant) and multifocal disease (involvement of more than one site confined to one quadrant). Imaging after breast-conserving therapy for DCIS may include magnification views of the lumpectomy site before radiotherapy to ascertain that there are no residual microcalcifications that might require re-excision. Similarly, because most recurrences develop at the site of the original primary tumor, magnification views of the lumpectomy site can be performed to help detect local failures (see Fig. 15–28). Although some have advocated the routine use of magnification views following lumpectomy, others have found them to be useful only when there is a questionable finding on the initial images.^{61,62} We generally perform magnification views of the lumpectomy site if the original presentation of the cancer is clustered microcalcifications. A postlumpectomy mammogram with magnification views is helpful to ensure adequate removal of all demonstrable disease.

How are benign microcalcifications characterized radiographically?

Most clustered microcalcifications that are excised (i.e., about 80%) are due to a benign entity, such as a fibrocystic condition or sclerosing adenosis. Benign microcalcifications are frequently punctate and have a diffuse distribution. On occasion, if they represent milk of calcium in microcysts, they have a “teacup” configuration on a 90-degree lateral view. Recommendations for biopsy of clusters of microcalcifications for less than five particles in a cluster are unusual because there is a low likelihood of cancer. Eggshell calcification or rim calcification may be due to fat necrosis or calcification in the wall of a cyst. Other benign calcifications include skin calcifications, vascular calcifications, and large rodlike calcifications that are due to duct ectasia. Suture calcifications have a distinctive benign appearance and are readily identified. Dystrophic calcifications that form in the irradiated breast or after trauma are usually larger than 0.5 mm and often have lucent centers. At times, it may be difficult to distinguish early dystrophic calcifications from recurrent cancer. Coarse calcifications, although generally benign, can occasionally be associated with malignancies (see Fig. 15–25).

How are infiltrating ductal carcinomas characterized radiographically?

Most cancers detected by mammography are invasive ductal carcinoma, not otherwise specified (NOS). These cancers have a variety of mammographic presentations, including a spiculated mass; developing density; a circumscribed, irregular, or lobulated mass; and regional architectural distortion (Figs. 15–29 to 15–41). A spiculated mass, with extensions produced by an associated desmoplastic reaction, is most characteristic of invasive ductal carcinoma (IDC) (see Figs. 15–29 and 15–30). When a very small or subtle region of abnormality is present, the ability to detect the cancer may depend on the density of the surrounding breast parenchyma; when there is greater tissue density, the cancer may be more difficult to detect. In this situation, sonography may be valuable to confirm the presence of a suspicious mass, and ultrasound-guided large core needle biopsy may be performed (Figs. 15–42 and

Figure 15–29 A spiculated mass (*arrow*) is posterior to a cyst in the outer right breast. The patient had a previous benign biopsy. This infiltrating ductal cancer is within fibrocystic breast tissue. When a cancer is within dense fibrocystic tissue, it may be difficult or impossible to visualize.

15–43; see also Fig. 15–28). Microcalcifications often are associated with a spiculated lesion, extending radially along the course of ducts from the main tumor mass or near the mass, indicating an extensive intraductal component and having poorer prognostic implications (see Fig. 15–33). Stomper and Connolly evaluated 101 mammograms of patients with IDC and found that carcinomas without microcalcifications that appear as masses or regions of architectural distortion, or as palpable masses with no abnormality detected by mammography, were not associated with an extensive intraductal component. The lesions associated with microcalcifications were likely to have an extensive intraductal component.⁶³ In the past, clusters of microcalcifications were assessed by excisional biopsy. More recently, it has been shown that the use of stereotactic biopsy with an 11-gauge needle and vacuum assistance is an efficient and cost-effective alternative.⁵⁹ A preoperative diagnosis of malignancy in women with suspicious microcalcifications may help to delineate the lesion and achieve clear margins. In evaluating women with more than one area of microcalcifications, a stereotactic biopsy may be useful to determine whether conservation is possible.

How is infiltrating lobular carcinoma characterized radiographically?

Infiltrating lobular carcinoma (ILC), representing 5% to 15% of all breast cancers, may be difficult to diagnose by

Figure 15-30 This high-density spiculated mass is easily detected because it is surrounded by fatty tissue. Even very small lesions may be detected when bordered by fat.

Figure 15-31 This palpable mass with irregular borders was moderately differentiated infiltrating duct carcinoma. The patient was a 45-year-old woman whose mother died at age 29 years of breast cancer.

A

B

Figure 15-32 *A*, A new lobulated mass (*arrow*) with partially obscured borders was infiltrating duct carcinoma. *B*, The corresponding sonogram of the mass shows the microlobulated border.

Figure 15-33 A, A spiculated mass has linear microcalcifications extending along ducts. B, The microcalcifications indicate the associated ductal carcinoma in situ.

Figure 15-34 A spot film of a palpable irregular mass that was infiltrating poorly differentiated duct carcinoma also had ductal carcinoma in situ as indicated by microcalcifications.

Figure 15-35 Infiltrating duct carcinoma. A high-density mass (arrow) with irregular borders in the central left breast. There is a dense axillary lymph node that was positive for metastatic disease.

Figure 15-36 A round mass (*arrow*) with partially obscured borders developed adjacent to a prior benign biopsy. The border characteristics made this mass suspicious, and the needle biopsy showed infiltrating duct carcinoma.

Figure 15-37 A 75-year-old woman had a rapidly growing mass with irregular borders that was found to be poorly differentiated infiltrating duct carcinoma with metaplasia.

Figure 15-38 *A*, Well-circumscribed carcinoma. A lobular mass in the outer half of the right breast on the craniocaudal view has distinct borders. Although medullary, colloid, and intracystic carcinomas are known to present as well-circumscribed masses, the most common well-circumscribed carcinoma is infiltrating ductal, not otherwise specified, which this proved to be. *B*, Corresponding sonogram shows the hypoechoic lobulated mass.

Figure 15-39 A subtle region of architectural distortion corresponded to palpable thickening in this patient with a silicone breast implant. It proved to be a well-differentiated infiltrating duct carcinoma, visualized on this implant-displaced view. Arrows outline an area of architectural distortion that proved to be an invasive duct carcinoma.

mammography and by palpation. Five patterns of mammographic presentation of ILC were described by Mendelson, with the most frequent being a focal region of asymmetrical density⁵⁸ (Figs. 15-44 and 15-45). The spread of this cancer in the classic single-file configuration was proposed as being responsible for its subtle appearance as a poorly delimited mass. Sickles refers to the mammographic findings of ILC as “atypical,” often preventing early diagnosis of this cancer.⁵⁹ Our experience, based on a retrospective review of 102 cases of proven ILC, had a spiculated mass as the most common appearance, similar to the findings of Helvie.^{60,61} Negative mammography has traditionally been described as occurring more frequently with ILC than IDC. Microcalcifications have also been found less frequently with ILC than with IDC in most series. There is a high incidence of bilaterality and multifocality with ILC, and of metastatic spread with unusual sites of deposits, including the gastrointestinal tract, ovary, uterus, and peritoneum.⁶² Various studies have found the prognosis to be either better, the same as, or worse than that of IDC.⁶²

How is tubular carcinoma characterized radiographically?

Tubular carcinoma, a variant of infiltrating ductal carcinoma, is being detected with increasing frequency and at a smaller

Figure 15-40 Multifocal carcinoma. A spot magnification view has multiple masses and sites of architectural distortion, all of which were invasive ductal cancer. Ductal carcinoma in situ was also present at the site of microcalcifications.

Figure 15-41 Virtually the entire breast has been replaced with high-grade infiltrating duct carcinoma that is extending from the superior to inferior right breast.

Figure 15-42 *A*, Round mass in the outer right breast has heterogeneous, mainly peripherally located microcalcifications and coarse calcifications. Although the preoperative impression was that of a fibroadenoma, because of the atypical appearance of the calcifications, the lesion was excised. *B*, The specimen radiograph has the fibroadenoma and the localizing wire.

Figure 15-43 *A*, Heterogeneous microcalcifications and coarse calcifications in a young woman were suspicious for malignancy. The patient underwent a stereotactic mammotome biopsy, and a benign fibroadenoma was diagnosed. *B*, The specimens have abundant calcium.

A

B

Figure 15–44 A and B, A tiny mass with irregular borders in the right breast at the 6-o'clock axis was a 0.5-cm invasive lobular carcinoma. Despite its small size and moderate density, the cancer was detectable because of the surrounding fatty tissue.

Figure 15–45 An asymmetrical density in the upper outer left breast was infiltrating lobular carcinoma. This represented an interval change on the mammogram.

average size as a result of screening mammography. Winchester and associates recently reported the median tumor diameter to be 1 cm⁶⁴ (Fig. 15–46). They suggest that the larger tubular cancers may have a more aggressive course and are evolving into typical IDC. Tubular carcinomas are

usually found when they are nonpalpable, in women younger than those with nonspecific IDC. The pathologic use of the term *tubular carcinoma* requires that at least 75% of the lesion be composed of tubular elements. Some pathologists suggest that tubular carcinomas arise from papillary or cribriform intraductal carcinoma, whereas others suggest that they evolve from radial scars.^{65,66} Regarded as a well-differentiated cancer with a favorable prognosis, it has also been reported to be associated with an increased incidence of multicentricity and contralateral cancers. A 32% rate of incidental DCIS within this tumor following excision has been reported.⁶⁴ Although there is controversy regarding the proper treatment for this cancer, 20% of Winchester's patients had axillary nodal metastases.⁶⁴ These cancers most frequently appeared as spiculated masses at mammography in the series by Liebman and coworkers.⁶⁷ They suggest that the spiculated appearance of tubular carcinoma is characteristic and that because of its smallness, it can be differentiated by mammography from other cancers. However, Elson and associates found a variety of mammographic presentations for this type of cancer, including a mass, mass with calcifications, architectural distortion, and asymmetrical density.⁶⁸

How is mucinous carcinoma characterized radiographically?

Mucinous (colloid) carcinoma of the breast, accounting for 1% to 7% of breast cancers, has received relatively little attention in the radiologic literature. It is a well-differentiated, distinct type of invasive adenocarcinoma characterized by the extracellular mucin that embeds the tumor cells. It is usually detected in older patients with an average age of 65 years. Although it was traditionally thought to have a favorable prognosis and a lower incidence of metastases than less differentiated infiltrating ductal carcinoma NOS, one series noted metastatic disease in about 30% of patients.⁶⁹ The classic

Figure 15-46 Tubular carcinoma. *A*, The mediolateral oblique view shows a 5-mm spiculated mass overlying the pectoral muscle (*arrow*). These slow-growing, well-differentiated neoplasms often present as tiny spiculated lesions. *B*, Spot magnification views may be necessary to delineate the spiculated nature of these lesions (*arrow*).

mammographic features of pure mucinous carcinoma have been described by Conant and associates as a mass with either indistinct or microlobulated margins rarely having calcifications⁷⁰ (Figs. 15-47 and 15-48). We have found several mucinous carcinomas that had coarse calcifications simulating those in fibroadenomas. Wilson and associates evaluated 20 patients with mucinous carcinoma and found that a more sharply circumscribed and distinct border was found for the pure mucinous carcinomas and that irregular margins were found with tumors of mixed mucinous and NOS type.⁷¹ The irregularity of contour is thought to result from fibrosis associated with the nonmucinous component of the tumor. Mixed-type mucinous tumors tend to be larger at the time of diagnosis and to have a less favorable prognosis than the pure type.

How is medullary carcinoma characterized radiographically?

Medullary carcinoma of the breast, an uncommon subtype of infiltrating ductal carcinoma, is associated with an improved survival rate and younger age compared with survival and age of women with infiltrating ductal carcinoma NOS. The

specific pathologic characteristics associated with this tumor include a predominantly syncytial growth pattern, microscopic completely circumscribed margins, mononuclear stromal infiltrate, and anaplastic cytologic details.⁶⁵ A report by Rubens and associates of 30 cases of breast cancer originally diagnosed as medullary carcinoma at Massachusetts General Hospital stated that only 9 (30%) were in fact typical medullary carcinomas.⁷² Using strict histologic criteria for medullary carcinoma, the remaining cases were reclassified as atypical medullary carcinomas in 7 (23%) and infiltrating ductal carcinoma NOS in 14 (47%). It has been suggested that the too frequent diagnosis of this type of cancer may lead to a false impression of a more favorable outcome and undertreatment.⁷² The typical appearance of medullary carcinoma at mammography is an oval or round circumscribed mass, with varying degrees of lobulation without calcifications (Figs. 15-49 and 15-50). At ultrasound, there is a well-defined hypoechoic mass with an inhomogeneous texture and enhanced through transmission. Central necrosis may be seen in large mucinous cancers.⁷³ According to Kopans, despite the so-called typical imaging characteristics of medullary carcinoma, there are no criteria to reliably distinguish medullary carcinomas from infiltrating ductal carcinomas NOS.⁷⁴ Liberman and coworkers found that mammography could not

Figure 15-47 A 63-year-old woman had a palpable mass that was colloid carcinoma. It is sharply circumscribed, as is typical of this type of cancer. Colloid carcinoma may also appear as low-density masses when there is abundant mucin within the tumor.

Figure 15-48 A well-circumscribed mass in the medial left breast was colloid carcinoma. The sonogram (not shown) showed a corresponding hypoechoic mass with microlobulated borders. The diagnosis was made by a needle biopsy under ultrasound guidance.

Figure 15-49 A craniocaudal view of a medullary carcinoma (*arrow*) has ill-defined and lobulated borders. Medullary carcinomas may also have sharply circumscribed borders.

Figure 15-50 Medullary carcinoma may have associated coarse calcifications, as in this mass in the center of the left breast.

Figure 15-51 Papillary carcinoma. This 65-year-old woman who had previous benign biopsies found a mass in the subareolar region of the left breast. The location and age of the patient were suggestive of this diagnosis.

distinguish medullary carcinoma from atypical medullary carcinoma (e.g., cancers that had most, but not all, the requisite histopathologic criteria).⁷⁵ Most cancers diagnosed as medullary carcinomas by mammography ultimately prove to be infiltrating ductal carcinoma NOS after excision, with the usual survival prognosis.

How is papillary carcinoma characterized radiographically?

Papillary carcinomas are rare, comprising only 1% to 2% of breast cancers.⁷⁶ With their indolent growth, excellent prognosis, and low incidence of metastases, recognition of the presence of this cancer relies on mammography when there is no palpable mass or nipple discharge.⁷⁶⁻⁷⁸ The mammographic appearance has been described by Soo and associates, who differentiate the in situ papillary cancer into an intraductal type and an intracystic type.⁷⁶ The in situ papillary cancer can extend within a ductal system, the intraductal type, or may be within a cystic structure, the intracystic type. Intraductal papillary carcinomas are most often detected as clustered microcalcifications, and the intracystic type is usually seen as a well-circumscribed mass or multiple adjacent masses, usually in the retroareolar region (Figs. 15-51 and 15-52). Sonography of the intracystic papillary cancer can show both cystic and solid components in the mass.⁷⁹ It may appear as a cystic mass with or without septations. Solid

Figure 15-52 A large subareolar mass was an intracystic papillary carcinoma. It is indistinguishable from a benign papilloma by mammography. A giant fibroadenoma and a phyllodes tumor may also have an identical appearance.

papillary masses may project into the cyst. Invasive papillary carcinomas may have either mammographic pattern but more often occur as intracystic lesions.⁷⁶ A focus of irregularity in a round mass may suggest invasion. Intracystic fluid is thought to result from secretory activity by the neoplastic epithelial cells and from intracystic hemorrhage.⁸⁰ Cytology of the aspirated fluid has been reported as being negative for malignant cells and cannot be relied on for diagnosis.⁸⁰ The differential diagnosis of the intracystic type of cancer includes benign lesions, such as fibroadenomas and papillomas, and circumscribed malignant lesions, such as medullary carcinoma, colloid carcinoma, and metastatic lesions to the breast. When there are multiple peripheral masses that are solid on ultrasound, it may be impossible to distinguish papillary carcinoma from multiple papillomas, which is considered to be a precursor to this type of cancer.⁸¹

A nipple discharge may be caused by a solitary papilloma or by cancer. A ductogram may be used to identify the site of origin of the discharge. This may facilitate a more minimal volume excision of the responsible intraductal lesion. A solitary filling defect is most commonly associated with an intraductal papilloma, whereas multiple filling defects are more likely to be malignant.

How is malignant phyllodes tumor characterized radiographically?

Malignant phyllodes tumor (cystosarcoma phyllodes) is a relatively rare tumor that is distinguished from benign phyllodes tumor by the high mitotic count, cellular atypia, stromal overgrowth, and infiltrating margins. Local recurrences and hematogenous metastases occur in 20% to 25% of cases.⁸²

Figure 15-53 Phyllodes tumor. This large oval mass has almost entirely replaced the normal breast tissue and produced asymmetrical enlargement of the right breast.

Mammographically, these tumors often appear identical to fibroadenomas, with sharply circumscribed margins of a round, ovoid, or lobulated mass (Figs. 15-53 and 15-54). A report by Liberman and associates of 51 phyllodes tumors showed nonspiculated soft tissue masses in 49, with only 4 having calcifications.⁸³ They found that benign and malignant phyllodes tumors could not be distinguished by either mammography or ultrasound, which demonstrated hypoechoic masses. The sonographic features have been described as showing a lobulated, smoothly marginated mass with a heterogeneous echo pattern. At times, cystic spaces within the mass can be identified. Fine-needle aspiration may also be unreliable to distinguish benign from malignant phyllodes tumors. The history of rapid growth of a circumscribed mass found on interval mammography may be helpful when considering this diagnosis before excision or core biopsy. Magnetic resonance imaging (MRI) has been investigated as a modality to distinguish benign and malignant phyllodes tumors, but overlapping enhancement patterns have made this technique unreliable.⁸⁴ Treatment of phyllodes tumor is complete excision with wide margins. Mastectomy may be performed for recurrent phyllodes tumor.⁸⁵

How are extramammary metastases to the breast characterized radiographically?

Breast metastases from extramammary primary sites are uncommon, but the incidence varies depending on whether

Figure 15-54 This patient had a rapidly enlarging mass in the axillary region. It proved to be a benign phyllodes tumor. It has circumscribed borders and increased density.

lymphoma and leukemia are included in the series (Fig. 15-55). The classic mammographic appearance of a cancer metastatic to the breast is a sharply delineated solid round mass that can be superficial in location and mobile by clinical examination.⁸⁶ At times, multiple round masses that may be confused with benign masses such as fibroadenomas may be detected. Calcifications within the metastatic lesions are unusual, but there are case reports of calcifications in the metastases of ovarian and medullary thyroid cancer.^{87,88} The most common origin of extramammary metastases are melanoma, lung, sarcomas, ovary, and, less often, gastrointestinal and genitourinary tract primaries (Figs. 15-56 to 15-58). In males, carcinoma of the prostate may metastasize to the breast and the nipple. When metastatic cancer cells involve the lymphatics and blood vessels diffusely, skin thickening may be observed at mammography and, if extensive, may even simulate an inflammatory carcinoma. When lymphoma involves the breast, enlarged dense axillary lymph nodes may be visualized at mammography (Fig. 15-59). On occasion, these nodes may be distinguished from those secondary to metastatic breast cancer; in the latter case, they may be spiculated. The spiculated appearance correlates with extranodal extension of tumor into perinodal fat.⁸⁹

How is inflammatory carcinoma characterized radiographically?

Inflammatory carcinoma of the breast, accounting for only 1% of all breast cancers, is defined by its clinical presentation with a specific inflamed appearance. The involved breast has

Figure 15-55 A woman with a known diagnosis of melanoma presented for a screening mammogram and was found to have a circumscribed mass that was a metastasis. This mass has slightly indistinct borders. Other lesions that may metastasize to the breast include lung, lymphoma, ovarian, and renal cell carcinoma.

Figure 15-56 A solitary mass of increased density was found on a routine screening mammogram. The diagnosis of metastatic lymphoma was made by needle biopsy in this patient, who had a history of previously treated lymphoma.

Figure 15-57 Metastatic bladder cancer was responsible for these circumscribed round masses.

Figure 15-58 Metastatic renal cell carcinoma. A large lobulated mass with irregular borders in the center of the breast is an unusual appearance for a metastatic lesion. Metastatic lesions are more commonly sharply demarcated lesions.

Figure 15-59 A and B, Bilateral enlarged axillary lymph nodes without fatty hila in a woman with lymphoma.

erythema and edema of the skin, often with a peau d'orange appearance. Inflammatory carcinoma is most often the result of a poorly differentiated ductal carcinoma with vascular dilation and lymphatic reaction and blockage owing to tumor emboli. Mammography may not demonstrate the underlying primary cancer, but it typically shows diffuse trabecular thickening or increased density secondary to the obstructed lymphatic drainage (Figs. 15-60 and 15-61). There is skin thickening, which may be difficult to appreciate without digital mammography. Enlarged axillary lymph nodes may be seen; these can shrink following chemotherapy. Other causes of edema of the breast may give an identical pattern. Loprinzi and associates found that patients who have undergone partial mastectomy, breast biopsy, or axillary lymph node biopsy may present with a clinical syndrome that may mimic inflammatory carcinoma.⁹⁰ Surgical biopsy was required to rule out inflammatory carcinoma in several of their patients with this syndrome. In these patients, the clinical syndrome resembling inflammatory carcinoma is due to interruption of lymphatic vessels and associated lymphostasis. A retrospective review of 43 women with inflammatory carcinoma found the most frequent mammographic finding to be skin thickening, present in 92% of patients.⁹¹ Diffuse increased density was present in 81%, trabecular thickening was seen in 62%, axillary adenopathy was present in 58%, and malignant-appearing microcalcifications were seen in 23%. A mass was present in only 15% of the patients. An earlier report had a higher incidence of masses in their series.⁹²

Figure 15-60 Inflammatory carcinoma of the breast. The left mediolateral oblique view shows diffuse trabecular thickening and enlarged axillary lymph nodes.

Figure 15-61 Inflammatory carcinoma. Note the skin and trabecular thickening that is most prominent in the anterior aspect of the breast seen on this craniocaudal view. The differential diagnosis for this appearance includes inflammatory mastitis, postradiation change, edema, and metastatic disease.

What are the radiographic characteristics of unusual tumors of the breast?

Unusual tumors of the breast do not generally have a distinct appearance and are diagnosed by histology after core biopsy or excision. *Adenoid cystic carcinoma* of the breast has histology similar to that found in salivary glands. Buchbinder and Baker reported a case of a slow-growing, well-defined, mammographically benign-appearing mass that proved to be an adenoid cystic carcinoma.⁹³ About 125 cases have been reported. The prognosis of this tumor is favorable, with a 3% mortality rate and metastases in 6%.⁹³ Other tumors of the breast with histology related to the salivary glands have included benign tumors such as *pleomorphic adenoma* and *myoepithelioma*, malignancies, and *mucoepidermoid carcinoma* of the breast. *Apocrine carcinoma* is characterized histologically by granular eosinophilic cells and by masses at mammography that may be of low density. *Granular cell tumors*, with histologic features of neural differentiation, are generally considered benign, but rare malignant granular cell tumors have been reported.⁹⁴ Both the benign and malignant granular cell tumors may have mammographic and clinical features that mimic a scirrhous carcinoma of the breast. *Fibromatosis*, or *desmoid tumor* of the breast, is a rare benign tumor in young patients characterized by proliferation of spindle cells that invade the involved breast tissue locally (see Fig. 15-11). This lesion does not metastasize but has been reported to invade the chest wall. Complete excision with wide

margins is required because it tends to recur; in one series, the recurrence rate was 23%.⁹⁵ These tumors can appear identical to scirrhous carcinomas at mammography and by physical examination.

Sarcomas of the breast often have a history of a rapidly increasing breast mass, which may be mobile by clinical examination. At mammography, they may have smooth margins and may be identical in appearance to giant fibroadenomas or phyllodes tumors, with increased density with respect to the surrounding breast tissue (see Fig. 15-54). *Osteogenic sarcomas* of the breast mass have osseous trabeculae within the mass and in the metastatic lesions. *Angiosarcomas* of the breast are smoothly margined or lobulated masses, rapidly enlarging in size. They may occur as a complication of radiation treatment. A metaplastic carcinoma of the breast is a high-density mass that may be microlobulated and may have solid and cystic components on sonography. Variations of metaplastic carcinoma include matrix-producing carcinoma, spindle cell carcinoma, squamous cell carcinoma, and carcinosarcoma. These cancers are extremely rare and have been published as case reports.^{96,97}

How is male breast cancer characterized radiographically?

Male breast cancer is an unusual occurrence, accounting for only 0.5% of all breast cancers and for less than 1% of all cancers in men.⁹⁸ A painless, hard subareolar mass is the most common presentation, with a median duration of symptoms before diagnosis of 6 to 18 months. The mammogram demonstrates a noncalcified mass in most instances (Fig. 15-62). The mass is usually spiculated but can also appear well circumscribed. In a review of 23 cases of proven male breast cancer at Memorial Hospital, Dershaw and associates found a noncalcified mass in 17 (74%) and a mass with microcalcifications in 2 (9%).⁹⁹ Three of their male breast cancers had negative mammography; in one, the cancer was reported to be obscured by gynecomastia. Only one of the cases in their series presented with microcalcifications without an associated mass, and these were punctate. Eighty-two percent of their cancers were subareolar in location. Because benign tumors of the breast are rare in males, the differential diagnosis is usually gynecomastia, in which there is a characteristic proliferation of the ducts in the subareolar region.¹⁰⁰ Either fine-needle aspiration biopsy or core needle biopsy can be performed to differentiate cancer from gynecomastia, and biopsy is useful if there is a question of gynecomastia obscuring cancer. Most cases of male breast cancer are infiltrating ductal carcinomas; noninvasive cancer is rare. Because screening mammography is not performed for men, patients with DCIS have their disease detected when they are already symptomatic, with the usual mode of presentation being a mass or nipple discharge. Other histologic subtypes of breast cancer occur in men less commonly than in women. Owing to the rarity of lobules in men, infiltrating lobular carcinoma and lobular carcinoma in situ are noted only as case reports in the literature.¹⁰¹ The prognosis of breast cancer is less favorable for men than for women.¹⁰² It has been recommended that men whose physical examinations show a mass, ulceration, or inflammatory changes should have aspiration or surgical biopsy.¹⁰⁰

Figure 15–62 Male breast cancer. This 70-year-old man had a nontender palpable subareolar mass with associated nipple inversion. A large ill-defined subareolar mass has associated pleomorphic microcalcifications on the oblique view. There is an intramammary lymph node that was positive for metastatic disease.

What are the radiographic benign simulators of infiltrating ductal carcinoma?

There are specific entities that may simulate the spiculated mass that occurs with infiltrating ductal carcinoma. These include surgical scar, radial scar, desmoid tumor, and stromal fibrosis. Surgical scars can be identified by the history of a previous biopsy and by demonstrating stability or decreasing mass when compared with previous mammograms. They are usually not problematic to diagnose by mammography, particularly if there is changing appearance on different views.

A radial scar, or radial sclerosing lesion, has a fibroelastic core surrounded by a spiculated arrangement of ductal structures. Although it is considered entirely benign by some pathologists, others focus on its premalignant potential, possibly as a precursor to tubular carcinoma of the breast.^{66,103} Mammographic criteria used to identify radial scar and to distinguish it from carcinoma include the presence of elongated radiating spicules with a central lucency and the absence of a palpable mass^{104–106} (Figs. 15–63 to 15–66). The presence of microcalcifications associated with a spiculated lesion has been described as being more frequent with both radial scar and cancer.^{106,107} The mammographic criteria to diagnose radial scars are not completely reliable. We retrospectively reviewed 255 spiculated lesions that were excised

and found that translucent centers could be identified in cancer, and that a radial scar could have a central density (see Fig. 15–63). Whenever a spiculated density that is suspected of being a radial scar is identified, it should be excised because it can be a low-grade cancer, and histologic evaluation is required to differentiate a radial scar from carcinoma.¹⁰⁷

Desmoid tumors, composed of spindle cells, are unusual and invade the breast locally (see Fig. 15–11). They have a high rate of recurrence if not completely excised, but they do not metastasize. Although the involved breast tissue is generally clearly identifiable by mammography and by physical examination, at surgery it may be difficult to differentiate involved from uninvolved tissue, resulting in re-excision for wider margins.⁹⁵

Fat necrosis secondary to scarring may appear as a spiculated mass with or without calcifications (Fig. 15–67). Focal fibrosis of the breast (FFB) is an entity that has hypocellular fibrous tissue that may appear on mammography as a mass, architectural distortion, or asymmetrical density. Revelon and colleagues found that in their series of 44 patients with FFB, 37 were present on mammography; two lesions with architectural distortion were reported as highly suggestive of malignancy and were surgically excised.¹⁰⁸

A minor indicator of breast cancer, prominent veins, may also occur when there is superior vena cava obstruction. This may be seen with advanced lung cancer (Fig. 15–68).

Figure 15-63 *A*, Radial scar. This benign entity has the long, fine spicules radiating from the center of the lesion with a lucent center and associated microcalcifications. The central lucency is due to entrapped fat. A radial scar may have an appearance identical to cancer, and the diagnosis must be confirmed by histology. *B*, This spot magnification film of a tiny spiculated mass with a central lucency may be confused with a radial scar. It proved to be an infiltrating duct carcinoma.

Figure 15-64 This radial scar with its characteristic long spicules involves almost the entire breast.

Figure 15-65 *A*, Tiny spiculated lesion (*arrow*) developed posterior to a lumpectomy scar for infiltrating lobular carcinoma. The core biopsy performed under ultrasound guidance had atypia. It was excised after needle localization. The lesion proved to be a radial scar. *B*, The spot magnification view of the spiculated mass shows that its mammographic features are identical to those of an infiltrating cancer. There is a skin marker at the lumpectomy site, where the patient previously had an infiltrating duct cancer removed.

Figure 15-66 *A*, Spot film has a subtle spiculated mass with a dense nidus that proved to be a radial scar. The central density is unusual for this lesion and, when present, makes differentiation from cancer more difficult. *B*, The sonogram of the radial scar has a hypoechoic mass with shadowing.

Figure 15-67 Fat necrosis may simulate cancer. This woman had a tubular carcinoma excised and 8 years later developed a spiculated mass with calcifications. The mainly peripheral location of the coarse calcifications and the lucency in the center of the mass are mammographic features that are suggestive of the diagnosis of fat necrosis. Because of the overlapping features with cancer, biopsy was performed to confirm the diagnosis.

Figure 15-68 Superior vena cava obstruction may cause dilation of veins in the breast, as in this patient with advanced lung cancer. Note the enlargement of the vein at the medial aspect of the left breast. There is obstruction of the drainage of the tributaries of the veins of the breast. Dilated veins can also be one of the minor mammographic findings that may indicate the presence of breast cancer.

CONCLUSION

While efforts to diagnose breast cancer by techniques other than mammography are being investigated, mammography remains the most effective modality to detect this cancer before it becomes clinically evident. As a result of mammography, in many cases an early diagnosis of breast cancer is possible, when the lesions are small and axillary lymph nodes are more likely to be negative for metastatic disease. It can be expected that further improvements in mammography will continue to increase the yield of lesions that are detected before they become invasive.

Sonographic Diagnosis of Breast Cancer

Barbara Baskin, Orna Hadar, Stacey Tashman, Stacey Vitiello, and Stefanie Zalas

Since the early 1990s, breast ultrasound has assumed an important role in the detection and diagnosis of breast cancer. Without using ionizing radiation, it readily provides information regarding the nature of a lesion, often differentiating cystic from solid immediately. It is used to perform preoperative needle localizations and to guide core biopsies expediently and with minimal discomfort to the patient. It has become popular among both patients and physicians as a reliable adjunct to mammography.

ULTRASONOGRAPHY

When should a patient be referred for a breast ultrasound?

A patient older than 30 years with a palpable area of concern should undergo diagnostic mammography followed by a breast sonogram (Figs. 16–1 to 16–9). It is important to note that 3% to 4% of women with breast cancer presenting with a palpable lump will have negative combined mammogram and sonogram results.^{1,2} A suspicious clinical impression should not be overruled by negative test results.

Breast sonography is recommended as the initial imaging technique for palpable abnormalities in women younger than 30 years and in lactating and pregnant women.³

Breast ultrasound is also indicated to further characterize mammographic masses and for additional evaluation of patients with questionable mammographic findings (Figs. 16–10 to 16–12). Breast sonography can also be used to guide interventional procedures such as fine-needle aspiration, core biopsy, or preoperative wire localization.

Magnetic resonance imaging (MRI) is currently more sensitive and accurate than ultrasound for evaluating silicone implants for possible rupture. When MRI cannot be performed, ultrasound is a less accurate alternative.⁴

Screening ultrasound in patients with known breast cancer is advocated by some investigators. This is a result of studies revealing additional cancer foci in the ipsilateral or contralateral breast in about 14% of screened women with an index

focus of cancer previously diagnosed.^{5,6} However, this is not currently considered to be the standard of care.

Although some centers perform whole-breast screening sonograms, especially in patients with mammographically dense breasts, the American College of Radiology and the American Institute of Ultrasound in Medicine consider ultrasound as a screening study for occult masses to be an area for research at the current time.³

How should a surgeon respond to a patient who asks to be referred for a screening breast sonogram?

Clinical breast examination and mammography are considered the accepted standard of care as screening tests for breast cancer. However, they are far from ideal. The overall sensitivity of mammographic screening has been estimated at 85%.⁷ This sensitivity decreases significantly in women with dense fibroglandular tissue on their mammogram. In fact, a series of 11,130 women screened in a private practice setting revealed a mammographic sensitivity for breast cancer at 98% for fatty breasts, with only 48% sensitivity in the most dense breasts.⁸ Even if all women were to comply with annual mammographic screening, the estimated mortality reduction would be only about 50%.⁹ These results exacerbate understandable anxiety among many clinicians in the United States, where delay in the diagnosis of breast cancer is a frequent reason for medical malpractice litigation.

Dense breast tissue is common, especially in younger women. About 62% of women in their 30s, 56% of women in their 40s, 37% of women in their 50s, and 27% of women in their 60s have at least 50% parenchymal density on mammography.¹⁰ To better serve these women for whom mammography may be suboptimal, a second-level screening test for breast cancer is sought. Many educated, medically savvy patients are currently requesting screening breast sonograms, before the standard of care has included this examination in the accepted arsenal of screening tools for breast cancer.

To date, there is no randomized blinded controlled trial to evaluate the contribution of ultrasound to breast cancer screening using mortality as an end point. However,

Figure 16-1 A 45-year-old woman with a palpable mass in the left upper outer quadrant. Sonography reveals a cluster of simple cysts corresponding to the palpable finding.

Figure 16-2 A 45-year-old woman with a palpable, tender mass in the left breast at the 12-o'clock axis, which appears as a 1.1-cm hypoechoic mass sonographically, likely representing a complex cyst. Ultrasound-guided aspiration is performed. The lesion aspirates to resolution, confirming its benign cystic nature.

A

B

Figure 16-3 *A*, A 67-year-old woman with a palpable mass in the right breast at the 6-o'clock axis. Mammographically, this corresponds to a densely calcified mass, consistent with a benign calcified fibroadenoma. *B*, Sonography reveals a hypoechoic mass with intense posterior acoustic shadowing due to the dense calcification.

Figure 16-4 A 39-year-old woman with a palpable mass in the right 3-o'clock subareolar location. Sonography reveals a large mixed cystic and solid mass. Ultrasound-guided core biopsy results in a diagnosis of a papilloma, for which surgical excision is recommended.

A

B

Figure 16-5 *A*, A 38-year-old woman with a palpable right axillary mass, marked with a radiopaque "BB" on the mammogram. *B*, Sonography is performed, demonstrating a benign lymph node with a hypoechoic cortex and echogenic hilus, corresponding to the palpable finding.

Figure 16-6 A 55-year-old woman with saline implants and a palpable nodule. Sonographically, the palpable finding corresponds to a normal valve on the implant.

Figure 16-7 An 82-year-old woman taking warfarin sodium (Coumadin) who has a palpable mass in the right axilla. Sonography reveals a mixed hypoechoic and hyperechoic 3-cm mass in the pectoralis muscle, consistent with an intramuscular hematoma. Follow-up to resolution is recommended.

Figure 16-8 A 57-year-old woman with a history of anal cancer treated 10 years ago with radiation therapy. She presents with a palpable mass in the right lateral breast. Sonography is performed, demonstrating a mixed-echogenicity 2.4-cm mass. Ultrasound-guided core biopsy yields a diagnosis of metastatic squamous cell carcinoma, consistent with anal cancer.

Figure 16-9 A 39-year-old woman with a history of treated melanoma in the left upper arm 3 years ago, presenting with a palpable left axillary mass. This corresponds sonographically to a 2.7-cm solid mass in the left axilla, with a diagnosis of metastatic melanoma in a lymph node on ultrasound-guided core biopsy.

A

B

Figure 16-10 A, A 63-year-old woman with a 2-cm partially obscured mass in the right subareolar region on screening mammography. B, Sonography demonstrates a benign simple cyst corresponding in size and location to the mammographic finding.

A

B

Figure 16-11 A, A 65-year-old woman with a 7-mm spiculated mass in the right subareolar region on screening mammography. B, Sonography reveals a 9 x 7 mm irregular mass, corresponding to the mammographic finding. Ultrasound-guided core biopsy yields a diagnosis of invasive ductal carcinoma.

A

B

Figure 16-12 *A*, A 47-year-old woman with a 1-cm mass with indistinct margins in the left lower inner quadrant on her baseline mammogram. *B*, Corresponding to the mammographic mass, in the left breast at the 8:30 axis, there is a 1-cm hypoechoic solid mass, which on ultrasound-guided core biopsy results in a diagnosis of invasive ductal carcinoma.

A

B

Figure 16-13 *A*, Screening sonography performed on a 67-year-old woman with mammographically dense breasts reveals a 1.1-cm irregular mixed-echogenicity mass. This is diagnosed as an invasive ductal carcinoma on ultrasound-guided core biopsy. *B*, Presurgical wire localization is performed with sonographic guidance. A mammographic view with the localizing wire in place demonstrates the mammographically occult nature of this mass.

in several single-center studies, the utility of screening sonography in women with dense breasts for finding mammographically occult, nonpalpable breast cancers has been demonstrated^{8,11-15} (Figs. 16-13 to 16-16). Each of these studies has resulted in cancer detection rates of 0.3% to 0.4% for screening sonography alone, which is similar to that of screening mammography.¹⁶⁻¹⁸ In addition, the cancers found in these studies with sonography alone are similar in size and stage to those detected only with mammography. Therefore, it is likely that finding these early cancers at ultrasound before they present mammographically or clinically would result in

improved survival to the women in whom they are found. Among other factors, patient survival is directly related to tumor size at diagnosis.¹⁹

When discussing screening sonography with a patient, a few key points should be contemplated.²⁰ First, women with nondense breasts should not be referred for a breast sonogram because the likelihood of discovering a mammographically occult cancer is extremely low. Second, the accuracy of a breast sonogram is highly dependent on the skill of the person performing the study. Most series describe results with radiologist-performed scans, although one study reports

Figure 16-14 A, A 48-year-old woman with mammographically dense breasts requests screening sonography, which demonstrates a subtle 8-mm hypoechoic mass in the right breast at the 9-o'clock axis. Ultrasound-guided core biopsy results in a diagnosis of invasive ductal carcinoma. B, Presurgical wire localization is performed with sonographic guidance on the morning of the patient's lumpectomy. A mammographic image with the wire in place is shown. The mass is mammographically occult.

success with technologists trained specifically in breast screening.¹⁴ Breast ultrasound for the most part is a real-time examination, more akin to physical examination than to other static imaging modalities. The patient should also be aware that in the published series, there was a 2% to 6% risk for an unnecessary aspiration or biopsy as a result of screening sonography^{8,11-15} (Figs. 16-17 to 16-19). However, the minimally invasive nature and near-negligible morbidity from an ultrasound-guided aspiration or core biopsy should be taken into account. The likelihood of the excised lesions' being malignant ranged from 5% to 16%,^{8,11-15} lower than the expected yield from lesions excised because of an abnormality on screening mammography. The patient needs to be informed that even if both screening mammography and sonography are performed, there is still at least a 2% to 4% risk that a cancer, if present, will not be found.^{2,8} Finally, the patient should know that third-party payers currently do not reimburse facilities for screening sonography, and the patient will be expected to accept financial responsibility for the examination.

A large-scale study to assess the efficacy of screening breast sonography is now in its earliest stages. If successful, this may lead to a broader study with death as an end point.²⁰ Until this is realized, the individual patient and clinician must weigh the potential risks and benefits of screening sonography.

What is the recommended technique for performing breast ultrasound?

Breast ultrasound should be performed with a high-resolution linear array transducer of at least 7.5-MHz frequency. Focal zone settings should be optimized for limited

lag time, and gain settings adjusted so that breast fat appears gray. The patient should be positioned so that the area of the breast being evaluated is of minimal thickness. For example, the supine oblique position with the patient's arm above the head is used to study the outer quadrants of the breast. A lesion should be viewed in two perpendicular projections; one view is insufficient. At least one set of images of a finding should be obtained without calipers. The maximum dimensions of a mass should be recorded in at least two dimensions. Labeling should include right or left breast; quadrant or clock face location with distance from the nipple, or location shown on a diagram of the breast; and the orientation of the transducer (i.e., radial or antiradial, longitudinal or transverse). Occasionally, for evaluation of superficial lesions, a standoff pad may be helpful (Figs. 16-20 and 16-21).

The patient's mammogram should be correlated with the sonogram at the time of the examination. Comparison to prior sonograms is necessary if lesion follow-up is to be performed. If indicated, physical examination should also be directly correlated with the sonographic findings.^{3,21}

What is the sonographic appearance of breast cancer?

Traditionally, breast sonography has been used to distinguish solid from cystic lesions. Studies have been performed to further characterize solid masses as having either malignant or benign features.²²⁻²⁴ It is commonly accepted that certain sonographic features are considered suspicious for malignancy and others of benignity. The landmark study by Stavros and colleagues²² classified masses based on several sonographic characteristics. Characteristics supporting a malignant

A

B

C

Figure 16-15 A and B, A 60-year-old woman with a negative screening mammogram. C, At the patient's request, screening sonography is performed, revealing an 8-mm irregular hypoechoic mass in the left breast at the 12-o'clock axis. This is diagnosed as invasive ductal carcinoma and ductal carcinoma in situ with ultrasound-guided core biopsy.

Figure 16-16 Screening sonography demonstrates a 1-cm ill-defined hypoechoic mass in the left breast at the 11:30 axis. Ultrasound-guided core biopsy yields a result of infiltrating tubular carcinoma.

Figure 16-17 A 38-year-old woman has a negative screening mammogram, revealing heterogeneously dense breasts. Screening sonography demonstrates a 1.7-cm circumscribed hypoechoic mass, which is diagnosed as a fibroadenoma on ultrasound-guided core biopsy.

A

B

Figure 16-18 *A*, A 31-year-old woman referred for a palpable mass in the right breast at the 12-o'clock axis. Diagnostic mammogram is negative. Sonographically, there is a septated cyst, which corresponds to the palpable finding. This is aspirated to resolution with ultrasound guidance. *B*, Screening sonography of the remainder of the breasts reveals a lobular, septated, hypoechoic mass in the right breast at the 6-o'clock axis. Ultrasound-guided core biopsy is performed, yielding a diagnosis of pseudoangiomatous stromal hyperplasia.

appearance on sonography are spiculation; taller-than-wide (antiparallel) growth; angular margins; marked hypoechogenicity; shadowing; presence of calcifications; duct extension; branching pattern; and microlobulations.²²

Spiculation (Figs. 16-22 and 16-23) appears as alternating hyperechoic and hypoechoic lines extending out from a mass.²² As a result of the resolution of sonography, spiculation may appear as an echogenic halo, thicker along the lateral portions of the mass (where the spiculations extend out perpendicular to the sonographic beam) in a hypoechoic fatty background.²⁵

Antiparallel growth (see Figs. 16-22 and 16-23) is defined as occurring when any portion of the mass is larger in the anteroposterior dimension than in either the sagittal or transverse plane.

Angular margins (see Fig. 16-23) occur in the bases of Cooper's ligaments.²⁵

Hypoechogenicity (see Figs. 16-22 and 16-23) of a mass is defined in relation to the surrounding breast fat. The fibroglandular tissue is echogenic, and all other imaged tissue would appear hypoechoic to the fibroglandular tissue.

Shadowing (see Figs. 16-22 and 16-23) is a result of decreased through transmission of the sound waves as they pass through the mass and its surrounding desmoplastic response.²²

Calcifications (Fig. 16-24) are not usually seen sonographically; rather, they are visualized on mammography. When calcifications are seen sonographically, they are usually associated with a mass. They may appear as bright punctate echoes that give the impression of being larger than their true size

Figure 16-19 A 62-year-old woman with a negative mammogram, revealing dense breasts. Screening sonography demonstrates a 7 × 5 mm irregular hypoechoic mass, taller than wide. This is diagnosed as an organizing hematoma fat necrosis on ultrasound-guided core biopsy.

Figure 16-20 A 61-year-old woman with a palpable mass in the left lower inner quadrant. Sonography is performed with a stand-off pad owing to the superficial location of the lesion. Corresponding to the palpable finding, there is an 8-mm hypoechoic mass within the skin, demonstrating a skin tract, consistent with a benign epidermoid inclusion cyst.

A

B

C

Figure 16-21 *A*, Spot compression view from a diagnostic mammogram in a 71-year-old woman with a palpable mass in the right retroareolar region. There is a partially obscured mass in the right medial subareolar location. *B*, Sonography performed without a standoff pad results in a suboptimal image. *C*, Sonography performed with a standoff pad demonstrates a superficial, lobulated, 1.2-cm hypoechoic mass corresponding to the palpable abnormality. Pathology from ultrasound-guided core biopsy reports poorly differentiated ductal carcinoma.

Figure 16-22 This moderately differentiated infiltrating ductal carcinoma is hypoechoic and spiculated and has angular margins.

Figure 16-24 Calcifications are present within this heterogeneous poorly differentiated infiltrating ductal cancer.

Figure 16-23 This infiltrating lobular cancer is microlobulated, hypoechoic, and spiculated. Growth is in an antiparallel orientation.

Figure 16-25 This 2.5-cm irregular angulated hypoechoic infiltrating well-differentiated ductal cancer demonstrates duct extension.

Figure 16-26 This infiltrating lobular carcinoma demonstrates multiple macrolobulations and microlobulations as well as posterior acoustic shadowing.

but do not create posterior acoustic sound attenuation.²⁶ The hypoechoogenicity of the mass provides more contrast for detection of the calcifications.⁴ When the microcalcifications are seen associated with a mass on ultrasound, there is a higher incidence of invasive cancer.²²

Duct extension can be observed extending from the mass toward the nipple, whereas branching is defined as extending from the mass away from the nipple²² (Fig. 16-25).

Microlobulated margins measure 1 to 2 mm each, and the risk for malignancy increases with the number of microlobulations²² (Fig. 16-26).

Figure 16-27 This oval hypoechoic, wider than tall, solid, well-circumscribed mass has a pseudocapsule. The stability of morphology and size support a benign etiology.

Figure 16-28 This invasive papillary carcinoma is macrolobulated and well circumscribed, with posterior acoustic enhancement. The inferior aspect is heterogeneous.

If a single malignant feature is present, the sonographic abnormality cannot be called benign, and biopsy must be performed. In the absence of suspicious findings, benign findings must be identified.²⁵ Benign features include intense hyperechogenicity, an ellipsoid shape, two or three gentle lobulations (at most), and a thin echogenic pseudocapsule²² (Fig. 16-27).

One study found that a thin echogenic capsule was a feature most predictive of benignity²³; however, other studies indicate that this characteristic has high interobserver variability and is therefore less useful.²⁴ Irregular shape, margins, shadowing, echogenic halo, and antiparallel growth are the best predictors of malignancy.^{4,23,24}

Despite best attempts to construct clearcut guidelines, malignancies sometimes appear benign. High-grade cancers may appear circumscribed rather than spiculated and can have enhanced through transmission²⁵ (Fig. 16-28). Cellular cancers that do not generate a desmoplastic response (i.e., medullary carcinomas) would not generate shadowing. Necrotic cancers can have enhanced through transmission but typically possess other suspicious features that would lead to biopsy.

Which cancers have benign characteristics?

Three subtypes of ductal carcinoma, composing 10% of all primary breast cancers,²⁷ typically appear as well-

Figure 16-29 A medullary cancer appears as a circumscribed, round mass with homogeneous echoes and posterior acoustic enhancement.

Figure 16-30 A colloid cancer presents as a well-circumscribed complex solid and cystic mass with posterior acoustic enhancement.

circumscribed masses that mimic the sonographic appearance of benign entities. These infiltrating carcinomas, which have relatively good prognoses, are medullary, colloid, and papillary carcinoma.

Medullary carcinoma, composing 5% of cancers,²⁸ is seen as rounded or lobulated, well-circumscribed, almost anechoic masses with enhanced through transmission, similar in appearance to debris-filled cysts^{27,29} (Fig. 16-29).

Colloid carcinoma makes up only 1% to 2% of cancers. It contains few malignant cells suspended in abundant mucinous material.²⁸ It appears as a rounded or oval, well-circumscribed mass with low-level echoes. The through transmission of sound is variable, ranging from posterior acoustic enhancement to posterior shadowing²⁷ (Fig. 16-30).

Figure 16-31 A papillary solid cancer with invasive duct carcinoma appears as a sharply circumscribed oval mass.

Figure 16-32 A papillary ductal carcinoma in situ with invasion appears as a well-circumscribed, heterogeneously hypoechoic, macrolobulated mass with posterior acoustic enhancement.

Papillary carcinoma is a rare malignancy²⁸ that appears as a well-circumscribed mass with enhanced through transmission. It commonly presents as a complex cystic mass, as solid tissue projecting into a cyst or duct, or as a solid well-circumscribed mass²⁷ (Figs. 16-31 and 16-32). Papillary cancer may be entirely intraductal or have areas of invasion. It can appear identical to benign papillomas (see Fig. 16-4). Because malignancy and atypia can be focal in this lesion, a papilloma diagnosed with core needle biopsy may require surgical excision.^{30,31}

What is the sonographic appearance of infiltrating lobular carcinoma?

Infiltrating lobular carcinoma constitutes 7% to 10% of all breast cancers.³² It often produces subtle or no mammographic findings. With high-frequency transducers,

Figure 16-33 Infiltrating lobular cancer appears as an ill-defined, heterogeneous mass with microspiculations and posterior shadowing.

Figure 16-34 Infiltrating lobular cancer appears as an extensive area of intense acoustic shadowing. This patient presented with an extremely firm, immobile right breast. Mammography revealed only bilaterally dense breasts with scattered calcifications.

sonography has been reported to have a sensitivity of 87.7%³² and can often confirm the presence of a lesion when mammography shows subtle architectural distortion.³² The most common appearance of infiltrating lobular carcinoma is a heterogeneous, hypoechoic mass with angular or poorly defined margins and posterior acoustic shadowing (Fig. 16-33). Not uncommonly, focal shadowing without a discrete mass (Fig. 16-34) or a lobulated well-circumscribed mass is seen on ultrasound.³²

What is the sonographic appearance of inflammatory breast cancer?

Inflammatory breast carcinoma, which presents clinically, has characteristic sonographic features (Fig. 16–35). In a study by Gunhan-Bilgen and associates,³³ 96% of 142 inflammatory breast cancers demonstrated sonographic features of skin thickening, 68% demonstrated dilated lymphatic and vascular channels, and 80% demonstrated a solid mass.

Can benign lesions have a suspicious sonographic appearance?

Several benign lesions mimic the sonographic appearance of cancer. Radial scars, also known as *radial sclerosing lesions*, can be indistinguishable from carcinoma. A radial scar may

Figure 16–35 Skin thickening and dilated vascular or lymphatic channels are demonstrated within this inflammatory cancer.

appear as an irregular, hypoechoic mass with ill-defined borders and posterior acoustic shadowing (Fig. 16–36). Because the lesion is often more conspicuous on sonography, ultrasound can confirm subtle or equivocal mammographic findings of distortion and be used to direct percutaneous core needle biopsy. Histologically the radial scar is a central fibroelastic core surrounded by cystic proliferative changes. Excisional biopsy is recommended for complete examination of the lesion and to remove any ductal carcinoma in situ (DCIS), atypia, or small cancers with which they are infrequently associated.^{34–36}

Diabetic mastopathy is a rare diagnosis of unknown etiology that is made in the setting of long-standing insulin-dependent diabetes mellitus in premenopausal women. It is associated with palpable, hard, irregular, nontender mobile breast masses. Sonographically, it is seen as regions of intense acoustic shadowing (Fig. 16–37), mimicking the sonographic appearance of carcinoma (see Fig. 16–34). The diagnosis can be made on core needle biopsy with histology demonstrating stromal fibrosis, periductal and perivascular lymphocytic opacities, and epithelioid fibroblasts.³⁷

Fat necrosis can also be indistinguishable from breast cancer. It often presents as a palpable mass with a history of surgical or noniatrogenic trauma. The process of fat necrosis results from saponification of fat by tissue and blood lipases, resulting in a sterile inflammatory process. It is extremely varied in its sonographic appearance, ranging from that of a benign-appearing, well-circumscribed, anechoic oil cyst (Fig. 16–38), to a complex cystic mass, to that of a malignant-appearing, irregularly marginated, hypoechoic shadowing mass with architectural distortion (Fig. 16–39). The complex cystic lesions may evolve in sonographic appearance over time, becoming either more cystic or more solid. It has been reported that fat necrosis can decrease in sonographic size over time.³⁸

Gynecomastia is a benign condition that causes a tender subareolar lump or enlargement of the male breast. It is important to differentiate this process from male breast

A

B

Figure 16–36 A radial scar (A) appears identical to a small tubulolobular cancer (B). They are spiculated, antiparallel, hypoechoic masses with posterior acoustic shadowing.

cancer. There is an overlap in the appearance of the benign and malignant diseases on both mammography and sonography. The combined use of these modalities may improve the accuracy of the diagnosis. Typically, gynecomastia on ultrasound will be seen as subareolar hypoechoic or hyper-

Figure 16-37 Diabetic mastopathy appears as a large, focal, irregularly margined area of shadowing.

Figure 16-38 An oil cyst appears as a thin-walled anechoic mass at a site of a surgical scar.

echoic fibroglandular tissue^{4,39,40} (Fig. 16-40). Malignancy in the male breast appears similar to that in the female breast.

Abscesses can also be sonographically indistinguishable from breast cancer. They occur most frequently in the

Figure 16-39 The central bright echogenic ring is pathognomonic of a calcified oil cyst typically seen within fat necrosis. This lesion presented as a clinically suspicious, firm, palpable lump. Ultrasound demonstrates, in addition to the ring, an ill-defined, spiculated, hypoechoic mass with posterior acoustic shadowing, identical to cancer. The suspicious mass represented an interval change from a previous sonogram. Biopsy confirmed the lesion to be fat necrosis.

A

B

Figure 16-40 This case of gynecomastia presented as a palpable, tender mass in a 59-year-old man. It appears as a 3-cm irregularly margined, heterogeneously hypoechoic, subareolar mass (A). A more typical appearance of gynecomastia was seen on mammography (B), but because of the sonographic discordance, surgical excision was performed.

Figure 16-41 An abscess is seen in an 18-year-old woman who presents with a tender inflamed palpable mass. It is seen as a complex cystic mass with thick walls, a few septations, low-level echoes, and posterior acoustic enhancement.

retroareolar region. Those that are cultured yield multiple organisms, including anaerobes.⁴¹ They may also occur away from the nipple in women with underlying predisposing abnormalities such as diabetes, immunosuppressive conditions, severe skin excoriation, or surgical wounds. The abscess appearance varies from oval lesions with well-circumscribed margins, low-level internal echoes, and posterior acoustic enhancement, to complex cystic masses with thick, irregular walls, internal septa, and debris (Fig. 16-41). Although the diagnosis may be clinically suspected from a painful, warm, erythematous breast mass, fine-needle aspiration biopsy may be necessary to rule out an inflammatory cancer. Needle aspiration also allows for evacuation and culture of the abscess contents. Following treatment, sonography should document resolution of the mass. A treated, unresolved mass may necessitate biopsy.³⁰

What is the role of ultrasound in the evaluation of implants?

Because of the high incidence of nonspecific findings in both intact and ruptured implants, the role of sonography is limited. Equivocal or positive findings on sonography merit further evaluation with MRI, which has been shown to be accurate in the diagnosis of implant rupture.^{4,42,43} Sonography can, however, provide valuable information regarding the integrity of an implant. The presence of an anechoic interior and a clearly defined contour can reliably predict an intact implant with a negative predictive value for rupture of 91%.^{42,44}

The “snowstorm sign,” an intensely echogenic focus with echogenic posterior artifactual echoes extending from it, is associated with extracapsular rupture.⁴⁵ This is associated with free silicone extending into the surrounding tissue. Although this is 100% diagnostic of rupture, it is a relatively insensitive sign seen in only 23% of ruptured implants.^{42,45}

Figure 16-42 This palpable finding demonstrates a hypoechoic round mass with an echogenic halo. This is a hematoma that resolved to sonographic completion.

A finding highly suggestive of intracapsular rupture is a “stepladder” arrangement of echogenic lines. This is indicative of the collapsed implant envelope floating within the silicone that is being contained by the fibrous capsule. Generalized increased echogenicity within the implant and coarse echogenic aggregates in the implant have also been found to be indicative of rupture. Linear echoes, however, are not indicative of rupture; they are often seen in intact implants and are related to folds of the intact implant capsule.⁴²⁻⁴⁴

What is the sonographic appearance of the postoperative breast?

Breast sonography can identify postsurgical alterations. These can include fluid collections, skin thickening, fat necrosis, and scar tissue. These postoperative changes are accentuated and prolonged by radiation therapy. The recurrence of tumor can also be identified at the site of a previous lumpectomy.

Postsurgical fluid collections usually represent seromas or hematomas. A mass at the biopsy or lumpectomy site in the first year after surgery likely reflects a fluid collection.⁴⁶ Most fluid collections resolve within the first year, and after 18 months almost 100% of collections have resolved.⁴⁶ Fluid collections as a result of benign biopsies typically resolve earlier than those secondary to lumpectomy. The sonographic appearance is commonly that of a complex cystic mass at the biopsy or lumpectomy site. Septations, loculations, or a thickened wall may be evident in a hematoma or seroma (Figs. 16-42 to 16-46).

Edema and skin thickening occur after lumpectomy and radiation therapy, appearing sonographically as increased skin thickness and hypoechoogenicity in the areas of edema. In 70% of the cases, these changes have resolved by 2 to 3 years after treatment. In 20% to 30%, however, these changes persist.⁴⁶ These changes are more prominent in the periareolar and inferior portions of the breast.⁴⁷

As previously discussed, fat necrosis can occur after surgery. The sonographic appearance is varied. It can appear as an irregular hypoechoic mass with variable shadowing. Mammographically, fat necrosis may appear as a spiculated mass. When the mammographic appearance is that of an oil cyst, the sonographic appearance is usually an anechoic,

Figure 16-43 This hematoma at a prior biopsy site is a circumscribed, predominantly isoechoic oval mass with heterogeneous hypoechoic areas within it.

Figure 16-44 This complex cystic mass with septations, loculations, and posterior acoustic enhancement at the lumpectomy site is a hematoma.

Figure 16-45 A circumscribed hypoechoic oval mass with posterior acoustic shadowing at the lumpectomy site is a postoperative seroma.

Figure 16-46 An irregular, hypoechoic mass at the biopsy site was aspirated and represents a postoperative seroma.

Figure 16-47 A complex mass with variable shadowing at the lumpectomy site represents fat necrosis.

round, well-defined mass with or without posterior acoustic enhancement or shadowing (see Fig. 16-38). It can also appear as a complex cystic mass with internal echoes or soft tissue component (Fig. 16-47). The appearance of fat necrosis should remain stable or decrease in size over time. Biopsy may be needed for a definitive diagnosis, however.

The distinction between postoperative scar and tumor recurrence can often be difficult clinically, mammographically, and sonographically. Both scar and carcinoma can appear spiculated. The history, physical examination, and observation over time are important tools to use for differentiation. Scar tissue contracts and decreases in size and conspicuity over time as it matures. This can occur in the first 1 to 2 years.⁴⁶ If a sonographically stable mass changes in appearance, such as increasing in size or nodularity, recurrence should be suspected. The sonographic appearance of a scar is that of a linear hypoechoic area with posterior acoustic shadowing. Scar tissue can have irregular margins. Scar tissue is usually seen deep to the cutaneous scar extending to the skin surface (Fig. 16-48).

Sixty-five percent of recurrences occur within a few centimeters of the site of excision.⁴⁶ The sonographic appearance

is that of an irregular hypoechoic mass with posterior acoustic shadowing. Difficulty in distinguishing scar tissue from recurrence can be lessened if sonograms are evaluated in sequence (Fig. 16–49). If there is a new or enlarging nodular mass near the known scar, carcinoma should be suspected. Biopsy may be necessary to distinguish between the two.

ULTRASOUND-GUIDED PERCUTANEOUS BIOPSY

What is ultrasound-guided percutaneous biopsy?

With the institution of routine annual mammographic screening at age 40 years, there has been an increase in the number of nonpalpable mammographic abnormalities

Figure 16–48 A linear hypoechoic band of tissue extending to the skin represents scar tissue.

requiring further diagnostic imaging. As stated earlier in this chapter, ultrasound has become one of the most important diagnostic imaging modalities for lesion characterization. Many of these lesions will be characterized as indeterminate or suspicious, thus requiring biopsy. In the past, it had been customary to obtain histologic confirmation of these nonpalpable lesions using preoperative needle localization followed by surgical excision. Currently, ultrasound provides one means for accurate image-guided percutaneous biopsy⁴⁸ as well as preoperative needle localization of nonpalpable lesions. Ultrasound-guided percutaneous biopsies include ultrasound-guided core biopsy, vacuum-assisted biopsy, and fine-needle aspiration.

What are the indications for ultrasound-guided core biopsy?

Ultrasound-guided core biopsy is indicated to obtain histologic diagnoses of indeterminate or suspicious solid masses seen sonographically. These percutaneous core biopsies are performed to obtain tissue diagnosis so that definitive treatment options can be determined. For example, a suspicious mass, detected on a routine mammographic screening examination and sonographically apparent, may undergo percutaneous biopsy under ultrasound guidance. With the confirmation of malignant histology combined with imaging and clinical findings, along with patient preference, the surgical treatment option of lumpectomy with sentinel lymph node biopsy may be selected prior to surgery. Another example is a patient with multiple suspicious or indeterminate masses in the same breast quadrant (multifocal distribution) or in two or more quadrants (multicentric distribution). Masses in varying locations in the breast can undergo percutaneous biopsy under ultrasound guidance to facilitate the planning of the surgical treatment option of mastectomy.⁴⁹ In both examples, ultrasound-guided core biopsy allows the patient to undergo one surgery in what traditionally was a two-stage procedure. Additionally, indeterminate sonographically apparent masses may undergo percutaneous biopsy. If

Figure 16–49 An irregular, spiculated, predominantly hypoechoic mass at the lumpectomy site represents recurrence (A). An irregular hypoechoic mass with posterior acoustic shadowing at the lumpectomy site represents scar tissue (B).

this yields benign histology, these patients do not require surgical excision.

Masses sonographically characterized as probably benign are normally managed with short-term sonographic follow-up.²² Ultrasound-guided core biopsy can be performed, however, if the patient will be unavailable for follow-up, has planned breast surgery, is pregnant, or is anxious. Ultrasound-guided core biopsy may be performed for probably benign lesions in patients with carcinoma in the ipsilateral breast before breast-conserving surgery.⁵⁰

Finally, ultrasound-guided core biopsy may be performed to obtain tissue diagnosis following insufficient cytology from a prior fine-needle aspiration.

What are the contraindications for ultrasound-guided core biopsy?

Contraindications for ultrasound-guided core biopsy include coagulopathy or anticoagulation therapy in patients who are unable to discontinue it. Other less common contraindications are allergy to local anesthetics and inability to cooperate with the procedure.

How accurate is ultrasound-guided core biopsy?

Excellent accuracy of ultrasound-guided core biopsy has been reported. Parker and coworkers reported 100% agreement in results from 14-gauge automated core needle biopsies of 40 lesions that underwent surgical excision.⁴⁸ Another 132 lesions were followed for 12 to 36 months with no cancers found. These authors concluded that ultrasound-guided core biopsy has an accuracy approaching surgical excision and thus provides an alternative to surgical biopsy. Parker and colleagues also reported a low false-negative rate for ultrasound-guided core biopsies of small masses (<1.5 cm) using 11-gauge vacuum-assisted technique.⁵¹ This false-negative rate is attributed to the fact that this technique results in removal of the image-evident lesion 90% of the time. However, the overall accuracy of any image-guided percutaneous biopsy requires that the histopathologic findings be correlated with the imaging findings to establish concordance or discordance. For example, if a lesion exhibited suspicious sonographic characteristics and a core biopsy yielded benign histology, the radiologist would deem this discordant. At this point, surgical excision of the entire lesion would be warranted to confirm histology. On the other hand, if a lesion exhibited primarily benign sonographic morphology and yielded benign histology after ultrasound-guided core biopsy, the radiologist would deem these findings concordant. In this scenario, sonographic follow-up would be recommended for continued surveillance and identification of potential false-negative findings.⁵²

What are the advantages of ultrasound-guided core biopsy?

The advantages of ultrasound-guided core biopsy over other image-guided core biopsy techniques include accessibility of ultrasound equipment, patient comfort (because these

procedures are performed in the supine and supine oblique positions), and absence of ionizing radiation. Technical advantages include easy accessibility of all areas of the breast, including lesions in proximity to the chest wall and axilla, and the ability to perform these biopsies in real time.⁵³ Compared with surgical biopsy, ultrasound-guided core biopsies are faster and less invasive, with minimal scarring to the breast.

Ultrasound-guided core biopsies decrease the number of surgical procedures performed on patients. Liberman and associates reported that patients who had not undergone percutaneous biopsies of nonpalpable cancers required significantly more subsequent surgeries than those who had.⁵⁴ White and colleagues reported that patients with a preoperative diagnosis of breast cancer from image-guided percutaneous biopsy had fewer positive margins at lumpectomy because preoperative diagnosis facilitated wider margins at initial surgery, resulting in a decreased number of surgical procedures performed in these patients.⁵⁵

Ultrasound-guided core biopsy provides a financial benefit as well. Liberman and coworkers reported a 56% decrease in the cost of diagnosis when percutaneous biopsy is used instead of surgical biopsy.⁵⁶

What are the disadvantages of ultrasound-guided core biopsy?

Because ultrasound-guided core needle biopsy provides a sampling of lesions, the disadvantage of histologic underestimates exists. A sonographically guided core needle biopsy of a mass yielding DCIS may at the time of surgery reveal invasive components of the tumor not detected in the core needle biopsy. Meyer and associates reported that, of lesions yielding atypical ductal hyperplasia at 14-gauge automated core biopsy, 56% yield carcinoma at surgery. Of the 11-gauge vacuum-assisted biopsies of atypical ductal hyperplasia, 11% yield carcinoma at surgery.⁵⁷ These data, although not solely based on ultrasound-guided percutaneous biopsy, support the need for surgical excision of lesions yielding the histology of atypical ductal hyperplasia.

Another disadvantage of ultrasound-guided core biopsy is the need for rebiopsy based on histologic findings or sonographic-pathologic discordance. Liberman and colleagues reported a 10% rebiopsy rate when using 14-gauge automated core needles for percutaneous biopsy.⁵⁶ As previously discussed, the histologic diagnosis of atypical ductal hyperplasia warrants rebiopsy based on possible histologic underestimation. Another entity that requires rebiopsy is the phyllodes tumor. Although most of these tumors are benign, a small percentage of malignant forms may be missed owing to sampling error on ultrasound-guided percutaneous biopsy.⁵⁸

Other lesions for which rebiopsy is often suggested, although somewhat controversial, include papillary lesions,³¹ radial sclerosing lesions,⁵⁹ atypical lobular hyperplasia,⁵⁹ and lobular carcinoma in situ.^{59,60}

What is the patient preparation for ultrasound-guided core biopsy?

The patient is asked to discontinue aspirin, nonsteroidal anti-inflammatory agents, and any other medications that

may promote bleeding for the appropriate duration of time before the biopsy. If the patient is taking warfarin sodium (Coumadin), this should be discontinued for at least 4 days, followed by a serum coagulation profile. A pertinent history of adverse drug reactions and allergies is taken. Written and verbal consent is then obtained.

What equipment is necessary for an ultrasound-guided core biopsy?

The necessary equipment includes a tissue acquisition device such as an automated core needle or vacuum-assisted biopsy device. Automated core needle devices use 14-, 16-, or 18-gauge needles. Vacuum-assisted devices use larger-gauge acquisitions. An ultrasound machine using high-frequency transducers ranging from 7 to 15 MHz is essential.

What is the technique used in ultrasound-guided core biopsy?

The patient is positioned on the ultrasound table with the ipsilateral arm raised over her head, at the appropriate obliquity to obtain adequate visualization, and with optimal accessibility of the target lesion.

The area is prepared and draped in a sterile fashion. Superficial and deep local anesthetic is administered under real-time sonographic guidance in the region of the target lesion. Depending on the tissue acquisition device and gauge of needle chosen, a small skin incision made with a scalpel may be necessary. The needle is then inserted under ultrasound guidance, with the needle position in relation to the lesion confirmed in real time. Multiple samples are obtained at varying needle positions to acquire adequate sampling. Hard-copy images are then obtained documenting accurate needle position through the lesion at each pass (Fig. 16–50).

Ultrasound-guided vacuum-assisted breast biopsy is performed by inserting the device through a small skin incision. Under ultrasound guidance, the probe chamber is advanced posterior to the target lesion. The collection chamber of the probe is then opened toward the lesion, away from the chest wall. Using vacuum assistance, tissue is obtained. If there is no remaining sonographic evidence of the lesion, a localizing metallic clip is placed.

Following all procedures, the areas are cleansed and compressed manually to adequate hemostasis. A sterile dressing is applied. At the completion of the procedure, the patient is given postbiopsy instructions.

What is ultrasound-guided fine-needle aspiration and what are its indications?

Ultrasound-guided fine needle aspiration is a technique used to obtain cells for cytologic evaluation.

The primary indication for ultrasound-guided fine-needle aspiration currently in breast image-guided interventions is for cytologic evaluation of complex cysts. These are defined as cysts that do not meet sonographic criteria for simple benign

A

B

C

Figure 16–50 A, Sonographic image demonstrating a spiculated, irregular highly suspicious mass warranting biopsy. B, The core needle is advanced under ultrasound guidance proximal to the mass in the prefire position. C, Image depicting the core needle through the center of the mass in the postfire position. Histology revealed poorly differentiated infiltrating duct carcinoma.

cysts. Other indications include aspiration of simple cysts for symptomatic relief or to determine mammographic-sonographic correlation for indeterminate masses found on mammography.⁶¹

With the widespread acceptance, ease, and accuracy of ultrasound-guided core biopsy for tissue diagnosis of solid masses, the practice of ultrasound-guided needle aspiration biopsy for solid masses has somewhat declined. It is often used for patients with coagulopathies or patients who are unable to discontinue anticoagulation when confirmation of benignity or malignancy is needed.

What are the advantages and disadvantages of ultrasound-guided fine-needle aspiration biopsies?

The technical advantages are similar to those for ultrasound-guided core biopsy.

A major disadvantage of fine-needle aspiration is the poor sensitivity and specificity of the procedure compared with other available procedures. Pisano and associates reported the

sensitivity of fine-needle aspiration biopsy to range from 85% to 88%, with a specificity ranging from 55.6% to 90.5%.⁶² For example, ultrasound-guided fine-needle aspiration of a sonographically suspicious mass may yield malignant cytology, thus confirming a carcinoma. However, ultrasound-guided core biopsy of the same lesion may yield the histology of an infiltrating ductal carcinoma. This specific diagnosis gives the surgeon the vital information of “invasion.” The surgeon may then plan to sample axillary lymph nodes at the time of surgery. Pisano and associates also reported that although fine-needle aspiration biopsy was more accurate under ultrasound than stereotaxis, the overall accuracy of the procedure ranged from 62.2% to 89.2%, far lower than the reported accuracy of ultrasound-guided core biopsy.⁶²

Other disadvantages include insufficient sampling, often leading to rebiopsy. Pisano and associates reported insufficient sampling of up to 35.4%, requiring additional histopathologic sampling. This, of course, leads to decreased cost-effectiveness of ultrasound-guided fine-needle aspiration biopsy because the patient requires additional procedures.⁶² Having an on-site cytopathologist to evaluate immediately for insufficient sampling at the time of biopsy often decreases this possibility.

What equipment is necessary for ultrasound-guided fine-needle aspiration and biopsy?

Needles of various gauges, ranging from 18 to 25 gauge, and standard syringes may be used, depending on the lesion and the desired result. In the diagnosis and drainage of a small breast abscess, an 18-gauge needle may be used. To obtain cytology of a mass, a smaller-gauge needle would likely be employed. An ultrasound machine with a high-frequency transducer (7 to 14 MHz) is needed.

What is the technique for ultrasound-guided fine-needle aspiration and biopsy?

As in ultrasound-guided core needle biopsy, the patient is positioned with the ipsilateral arm over the head and in an obliquity that allows the target lesion to be accessed safely and easily. The patient is prepared and draped in a sterile fashion. Local anesthesia is optional, although recommended.

The needle is advanced to the lesion under real-time sonographic guidance. For cyst or fluid collection aspiration, the needle tip position within the center of the fluid collection is confirmed sonographically. The radiologist draws back on the plunger, creating negative pressure within the needle and syringe. This allows evacuation of the fluid. The fluid may be sent for cytologic analysis, Gram stain, or culture, depending on the sonographic appearance of the lesion, the appearance of the fluid, and the clinical scenario (Fig. 16–51).

To obtain cytology of solid masses, cellular material is obtained by advancing and withdrawing the needle rapidly at different sites in the mass under ultrasound guidance. The samples obtained are then smeared on glass slides and analyzed by a cytopathologist.⁶¹

When and why do we use ultrasound-guided needle localization?

Preoperative needle localization can be performed under ultrasound guidance. It may be performed for lesions best visualized or only visualized sonographically. If the lesions can be seen both mammographically and sonographically, the radiologist may choose localization under ultrasound guidance because it often is faster, with decreased patient discomfort and lack of ionizing radiation. Ultrasound-guided needle localization may also be performed for lesions that are located

A

B

C

Figure 16–51 A, Sonographic image showing a cyst with internal debris (complex cyst), warranting cytologic analysis. B, The fine needle is advanced under ultrasound guidance to the center of the cyst. C, Image depicting evacuation of the cyst contents and complete sonographic resolution of the lesion. This yielded benign cytology.

in regions of the breast that are difficult to access with the alphanumeric grid necessary for mammographically guided needle localization. These regions include proximity to the chest wall and axillary regions.⁶³

What is the technique for ultrasound-guided needle localization?

Patient preparation and positioning are identical to those of ultrasound-guided core biopsy. Again, informed consent is obtained.

After positioning the patient, the target lesion is localized under ultrasound guidance. The overlying skin is prepared and draped in a sterile fashion. Local anesthesia is administered.

Then, using real-time ultrasonography, the localizing wire-needle device is advanced through the center of the lesion, maintaining a position parallel to the chest wall, preferably advancing the needle tip about 1 cm distal to the lesion. Once accurate positioning of the needle and needle tip is confirmed sonographically, the needle is removed, leaving the localizing wire in place. The accurate position of the wire is again confirmed sonographically. A measurement is obtained from the skin surface to the center of the lesion and wire. This depth measurement is conveyed to the surgeon in the dictated procedural report. A mark is placed on the overlying skin in ink, demarcating the position of the center of the lesion.⁶³

Whether the lesion is mammographically apparent or not, mammographic images of the breast with the wire in place are obtained and sent with the patient to the surgical suite.

Accurate excision of mammographically apparent lesions after preoperative needle localization is confirmed at the time of excision using specimen radiography. For lesions that are only sonographically apparent, specimen sonography may be performed to confirm lesion removal.⁶⁴

Needle Biopsy Diagnosis of Breast Cancer

Madeline F. Vazquez

Needle biopsy is a less invasive alternative to surgical biopsy of breast abnormalities. Fine-needle aspiration biopsy (FNAB) is ideal for the triage of a palpable mass and, in experienced hands, may provide a definitive diagnosis. Because of the high insufficiency and false-negative rates for FNAB, however, core needle biopsy (CNB) has become the preferred needle biopsy method for sampling breast lesions, especially under mammographic guidance. Recently, improvements in ultrasound and transducer technology have led to the increased use of ultrasound for the evaluation of dense breast parenchyma; consequently, there has been a resurgence in the number of FNABs of the breast performed under ultrasound guidance, especially of cystic lesions. This chapter answers some practical questions about the performance and interpretation of needle biopsy of the breast. Additionally, the management of malignant and nonmalignant breast lesions diagnosed by needle biopsy is addressed.

FINE-NEEDLE ASPIRATION BIOPSY

What is the diagnostic accuracy of fine-needle aspiration biopsy of the breast for palpable breast masses?

FNAB is an inexpensive and reliable method to triage breast masses, with few complications. In a summary of 18 reported studies from expert laboratories, Grant and colleagues calculated a sensitivity of 92.5%, a specificity of 99.8%, and an accuracy of 96.5% for FNAB of the breast.¹ Zarbo and associates analyzed the results of FNAB procedures in 294 institutions by 988 pathologists and found comparable results: a sensitivity of 97% and a specificity of 97%.² Of significance, the mean frequency of unsatisfactory aspirates obtained by nonpathologists was more than double the unsatisfactory aspirates obtained by pathologists (18% vs. 7.2%). In a series of 13 studies with 500 or more cases by Kline and coworkers, the false-negative rate ranged from 2% to 11%.³ Layfield reported a false-negative rate in the range of 3% to 5% and a false-positive rate of 0.1% to 0.5% for FNAB in experienced hands.⁴

The literature indicates a marked improvement in diagnostic accuracy when the FNAB results are correlated with the

clinical and imaging characteristics of the breast mass.^{5,6} Proponents of the triple-test method of breast mass evaluation, which includes physical examination, mammogram, and FNAB, recommend excision of all nodules with discordant test results and conservative management of all lesions with concordant negative tests.^{5,6} The triple-test method, whereby the results of clinical examination, mammography, and FNAB are combined for diagnosis, increases the accuracy of FNAB to almost 100%.⁷ One study showed that FNAB was the most reliable diagnostic component of the triple-test method.⁶ Unfortunately, there persists a high insufficiency rate with FNAB. The insufficiency rate can be minimized by increasing the sample size or by performing immediate microscopic assessment of specimen adequacy. In most breast care centers, however, a cytopathologist is not available for on-site evaluation of the specimen while the procedure is being performed.

What is the comparable accuracy of fine-needle aspiration biopsy and core needle biopsy for palpable masses?

One study comparing FNAB of palpable lumps, performed by experienced aspirators and interpreted by experienced cytopathologists, with CNB showed a specificity of 100% for both procedures.⁸ Interestingly, the sensitivity for detection of cancer was higher with FNAB than with CNB (99% vs. 92%; $P < .004$). In contrast, the diagnostic accuracy of CNB for the detection of breast cancer under mammographic guidance (stereotactic core needle biopsy [SCNB]) and ultrasound guidance is higher than the diagnostic accuracy of FNAB and stereotactic fine-needle aspiration biopsy (SFNAB).⁹ With CNB, experienced operators can obtain sufficient breast tissue for histology in nearly all cases; therefore, there are rarely nondiagnostic samples. Another advantage of CNB is that the pathologist can distinguish invasive ductal breast cancer from ductal carcinoma in situ (DCIS), and invasive lobular cancer from lobular carcinoma in situ (LCIS).^{9,10} This distinction cannot be made by aspiration biopsy cytology. Also, specific benign diagnoses can be made more frequently by CNB than by FNAB (Figs. 17-1 and 17-2).

FNAB is an invaluable technique for the detection of breast cancer in nonsuspicious lesions. In one review, FNAB allowed the detection of three unsuspected cancers in 222 screened

Figure 17-1 Core needle biopsy of microcalcifications (arrow) associated with sclerosing adenosis.

Figure 17-2 Fourteen-gauge core needle biopsy of microcalcifications (arrows) associated with microcysts in mild columnar cell hyperplasia (without atypia). Note the columnar cells with apocrine snouts lining the cysts.

patients and of eight unsuspected cancers in 2248 consecutive symptomatic women with palpable masses and normal mammograms.¹⁰ It is also the most cost-effective procedure for the initial evaluation of clinically benign breast lumps.⁷ The procedure is performed on an ambulatory basis and requires minimal patient preparation, and the cost of the tools needed for the procedure (a disposable syringe, a needle, a few glass slides, and a few reagents) is minimal.¹¹ Additionally, the processing in the laboratory is inexpensive, when compared with tissue biopsy by core needle or surgical excision. A study by Layfield and colleagues examined the cost-effectiveness of substituting FNAB for open biopsy in patients with benign clinical and mammographic findings.⁷ The outcomes assessed included stage-specific life expectancy, 10-year survival, and total cost. In this study, 92.8% of the patients had benign cytologic results, 4.9% had indeterminate results, and 2.3% had malignant FNAB findings. The authors calculated a savings of more than \$700 for the diagnosis of a palpable breast lump at the cost of 0.1% decrease in 10-year overall survival when the following protocol is used: (1) excisional biopsy of all suspicious lesions, (2) mammographic and clinical follow-up of all benign FNAB findings, and (3) one-stage operative management of breast masses with malignant FNAB findings.

What is the proper aspiration technique for palpable lesions?

To perform FNAB properly on a palpable mass requires a needle (usually 25 gauge, $\frac{1}{2}$ inch, with a clear hub) and a syringe (usually 10 mL) attached to the Cameco Syringe Pistol (Precision Dynamics, San Fernando, CA). The skin over the lesion is swabbed with an alcohol pad (local anesthesia is not required). The mass is immobilized between the index and middle fingers of the nondominant hand. Breast cancer is generally firm and fixed by palpation. Benign neoplasms, such as fibroadenomas, are firm and mobile, and cysts are generally mobile and doughy when large but can be quite firm when tiny. The needle is inserted into the target lesion, and the piston of the syringe is retracted to create suction. The needle should be moved back and forth inside the mass using rapid, short excursions. The piston is released before the needle is withdrawn from the mass to prevent the entry of cells and tissue fragments into the barrel of the syringe, where they may be irretrievable. The needle is removed from the syringe, the piston is retracted, the needle is once again attached to the syringe, and the material is expelled onto a glass slide. A modified technique for FNAB described by Kim and coworkers eliminates needle manipulation and reduces the risk for needle-stick injury.¹² In this technique, the FNAB is initiated with 1 to 1.5 mL of air in the syringe; after aspiration, the residual air is used to expel the material from the needle. It is also possible to obtain good specimens by fine-needle sampling without aspiration.¹³ In a series of 635 benign and malignant breast lesions sampled with only a needle, a cellular yield comparable to the classic technique was obtained, with an insufficiency rate of 5.5%. This technique reduces the amount of blood and allows for a better perception of tumor consistency, necessary for small lesions.¹³

Fluid should be extracted from cysts until they completely collapse. If there is a residual mass, another aspiration should be performed. For solid lesions, the aim is to keep the cellular sample in the needle; thus, if blood or cellular material is seen in the needle hub, the aspiration should be discontinued. The ideal number of aspirations will depend on the size and nature of the lesion. Sneige and colleagues have stated that the reliability of aspiration cytology depends on a uniform approach to breast sampling and reporting.¹⁴ They standardize the number of aspirations per lesion to three or four.

How are breast samples obtained by fine-needle aspiration biopsy prepared?

All aspirates are prepared as direct smears and stained with both the Diff-Quik method (Baxter Healthcare Corp., Miami, FL) and Papanicolaou method. Adequate specimens are defined as aspirates that contain at least four to six well-preserved cell groups. To prepare an ideal smear, a drop of cellular material should be expressed onto a glass slide, near the label. The slide should be held stationary and firmly in the nondominant hand (Fig. 17-3). A second slide is placed at an angle (of about 45 degrees), with its long edge resting on the specimen slide. It is rotated (dropped slowly without pressure) onto the specimen and spread to the opposite end, again

Figure 17-3 Smearing technique. The slide with the specimen is held stationary in the nondominant hand. A second slide is placed with its long edge resting on the specimen slide. It is rotated without pressure onto the specimen and spread to the opposite end, again without additional pressure. The “dab” (arrow) technique allows one to make several smears from an overly cellular fine-needle aspiration biopsy.

without additional pressure. In this manner, the smear is oval in shape, thick at the leading edge, and feathered at the tail. This type of smear is the ideal for cytologic analysis of FNAB specimens. The thick portion of the smear is excellent for pattern recognition, and the thin portion allows evaluation of cellular detail. Air-dried smears can be examined immediately using the Diff-Quik method, and slides are placed in 95% alcohol for the Papanicolaou or hematoxylin and eosin stains (which provide better nuclear definition). A rapid Papanicolaou technique using air-dried smears combines some of the advantages of the air-dried smears and Papanicolaou staining.¹⁵

The “dab” technique is used to make several smears from an overly cellular FNAB sample. In this method of multiple slide preparation, the specimen is lightly touched (“dabbed”) and then smeared on multiple slides (see Fig. 17-3). Ancillary stains for organisms, mucin, hormone receptors, and other immunohistochemical stains and image analysis can be done on the additional smears. Material from FNABs can be submitted in culture medium for microbiology, in sterile collection fluid for flow cytometry, in formalin for a cell block, and in glutaraldehyde for electron microscopy.

The Cytospin method of specimen preparation involves flushing the aspirate into 10 mL of special fluid for transport to the laboratory, where cells are sprayed onto one or more special glass slides by centrifugation. It may be convenient in an outpatient setting, in which one physician obtains the specimen and another interprets it. The Cytospin method of processing material aspirated from breasts is equal in sensitivity and specificity to skillful preparation of direct smears¹⁶; however, it is more expensive and time-consuming. The aspirated material from either a solid mass or a cyst can also be expelled directly in Cytolyt solution (Cytyc Corp., Marlborough, MA) for a Papanicolaou-stained monolayered cell preparation (ThinPrep, Cyte Corp., Marlborough, MA).

Should cyst contents obtained by fine-needle aspiration biopsy be evaluated microscopically?

Benign cysts yield fluid and should collapse when aspirated. Simple cysts have a thin lining and yield fluid with a few foam cells. Complex cysts can have a papillary lining and tend to yield turbid fluid that is more cellular and contains mostly apocrine (metaplastic) cells. Clear or milky fluid is often acellular and may be discarded.

Routine cytologic examination of all breast cyst fluids is not recommended as a cost-effective procedure. Ciatto and colleagues reviewed the cytologic results of 6782 consecutive breast cyst fluids and found only five (0.1%) clinically and mammographically inapparent intracystic papillomas.¹⁷ All of the intracystic papillomas yielded bloody fluid, yet the cytologic diagnoses for these five lesions were not reliable: two papillomas were correctly identified, two were not recognized, and one was falsely diagnosed as malignant. The authors nonetheless concluded that cytologic evaluation of cyst fluids should be done when blood-stained fluid is obtained. The indiscriminate evaluation of all other fluids in their series did not affect the rate of detection of intracystic lesions and is not recommended.

Few cysts contain cancer; 0.5% to 1.0% was reported in one series.¹⁸ The FNAB of a malignant cyst generally yields bloody fluid and may leave a residual mass. There is a high false-negative rate in these cases owing to sparse cellularity and nuclear degeneration of the cells that are present within the bloody fluid. However, an aspiration of the residual mass can increase the accuracy of detecting intracystic cancers. These aspirates may be very bloody. If a clot forms, it can be submitted in 10% formalin for preparation of a cell block.

Apocrine cells represent metaplasia of lobular epithelium and can be abundant in some cysts. They can be found in papillary aggregates, in large monolayered sheets, and also dispersed singly. The cytoplasm of the apocrine cell is usually abundant and finely granular and can show squamous features. The nuclei are central and round and can vary in size. They have smooth nuclear membranes, finely granular chromatin, and a single prominent nucleolus. Occasionally, there is prominent nuclear variability (in size and shape), especially with squamous metaplasia (Fig. 17-4). The cellular atypia is most pronounced when there is inflammation of the cyst. With inflammation, there may be a residual mass following aspiration owing to a thick capsule. This mimics cancer, but inflamed cysts are usually not bloody, and intracystic or cystic cancers are usually not inflamed.

Can fine-needle aspiration biopsy confirm a benign impression of fibrocystic change?

Aspiration biopsy of the breast can confirm a benign clinical or radiographic diagnosis. All specimens that are not clearly benign or clearly malignant are followed clinically, undergo surgical biopsy, or undergo repeat needle biopsy. The main challenge, therefore, with FNAB is the detection of breast cancer with a high sensitivity while reducing the number of benign lesions requiring surgical biopsy.¹⁹ To evaluate the accuracy of benign diagnoses by FNAB, Zemba-Palko and

Figure 17-4 Squamous metaplasia in the capsule of a cyst on fine-needle aspiration biopsy. Intact tissue fragments were obtained with a 25-gauge needle by aspirating the cyst capsule following evacuation of its contents. Note the nuclear variability and the spindle-shaped cytoplasm of the cells.

associates conducted a 20-year retrospective study of 1518 cytologically benign aspirates from palpable solid breast lesions.²⁰ Each FNAB was followed by surgical excision within 2 years. The aspirates were taken by clinicians, chiefly surgeons. There were 99 false-negative specimens (99 of 1518; 6.5%) for a sensitivity of 93%. There were 52 specimens available for review. Ten cases had no change in diagnosis, 16 were reclassified as unsatisfactory (fewer than three to six well-preserved epithelial cell groups), and 26 as atypical (cellular dyshesion, nuclear enlargement, or irregularity).

In fibrocystic change, there is a mixture of cysts, fibrosis, and epithelial proliferation. Areas of proliferation are highly cellular, areas of fibrosis are rubbery and yield few cells, and cysts yield fluid.²¹ Small regular ductal cells are seen in monolayered sheets with apocrine cells and bare stromal and myoepithelial nuclei. There may be thin proteinaceous fluid coating the slide. The nuclei of the benign ductal cells are generally 1.5 to 2 times the diameter of red blood cells as compared with malignant nuclei, which tend to be larger. Benign epithelial nuclei have smooth nuclear membranes, fine and even chromatin, and inconspicuous nucleoli (Table 17-1). The hallmark of a benign FNAB is the presence of bipolar myoepithelial or stromal nuclei. Although their presence does not exclude malignancy, it warrants caution in making the diagnosis. Myoepithelial nuclei are oval, the chromatin is evenly distributed, the nuclear membrane is smooth, and the nuclei are devoid of nucleoli.

In fibrocystic change, as in cysts, intact apocrine cells may be dispersed singly and must be differentiated from cancer. Important clues to their benign origin are the uniformity of the nuclei and cytoplasm and the low nuclear-to-cytoplasmic ratio. These cells usually are admixed with fluid, foam cells, and benign cell clusters. Many benign diseases of the breast are similar cytologically, but even if a specific benign diagnosis beyond fibrocystic change cannot be rendered by FNAB, the amount of epithelial proliferation and presence of epithelial atypia can be evaluated.²²⁻²⁴ This distinction is significant because several studies have indicated an increased risk for subsequent breast cancer associated with increasing levels of hyperplasia and atypia.^{25,26} Dupont and Page have reported a

Table 17-1 Smear Characteristics of Benign vs. Malignant Breast Fine-Needle Aspiration Biopsy (FNAB)

	Benign Pattern	Malignant Pattern
Bare myoepithelial nuclei	Present	Usually absent
Cellularity	Low to high*	Usually high
Cohesion	Strong	Poor
Epithelial cell arrangement	Even and flat Few single cells	Marked molding Many single cells
Nuclear size	<2 RBCs	>2 RBCs
Nuclear membranes	Smooth	Irregular
Chromatin	Fine and even	Coarse and irregular
Nucleoli	Inconspicuous	Mostly conspicuous
Intracytoplasmic lumina	Absent	Often present
Apocrine cells	Usually present	Absent
Background	Usually clean	Often necrotic

RBCs, red blood cells.

*The cellularity of a benign FNAB is relative to the degree of epithelial hyperplasia.

1.5 to 2 times increased risk for cancer associated with proliferative breast disease without atypia and a 5 times increased risk with proliferative breast disease with atypia.²⁵ Bodian and coworkers reported a modest increase in risk, of 2.1, 2.3, and 3.0, for proliferative changes with no atypia, mild atypia, and moderate to severe atypia, respectively.²⁶ Rosen has suggested caution in making precise risk estimates owing to a lack of reproducibility of the criteria for borderline proliferative breast lesions.²⁷

Nonproliferative fibrocystic change is not associated with any increase in risk for developing breast cancer over subsequent years. The aspirates of nonproliferative lesions usually are scanty and hypocellular, containing a few bare bipolar nuclei, pieces of fibroadipose and fibrous tissue, dispersed fat, and rare small round or oval sheets of small regular ductal cells. If microscopic cysts are present, foam and apocrine cells may also be seen.

Proliferative fibrocystic change, which is associated with a mild increased risk for subsequent breast cancer, includes lesions such as sclerosing adenosis, some fibroadenomas, and radial sclerosing lesions. The aspirates generally are more cellular than with nonproliferative change, and the epithelial sheets may be small and round or large and branched, depending on the lesion (Fig. 17-5). The sheets of cells appear regular with sharply defined margins. The shedding of single, intact epithelial cells or small clusters of two to four cells is not commonly observed. Nuclear crowding and pleomorphism are mild but are more commonly present than in the nonproliferative lesion. Numerous bare myoepithelial nuclei are dispersed in the background.

In proliferative fibrocystic change with atypia, the epithelial hyperplasia is accompanied by a loss of nuclear polarity and regularity. There is a mixture of normal and abnormal cells within a group of cells, and the atypical cells are pleomorphic, hyperchromatic, disorganized, and crowded (Fig. 17-6). Proliferative fibrocystic change with atypia is associated with

Figure 17-5 Proliferative fibrocystic change on fine-needle aspiration biopsy. There are numerous groups of epithelial cells. They are seen in cohesive clusters and branched fronds. Also note the numerous benign oval myoepithelial nuclei in the background. These features suggest that the lesion is a fibroadenoma. However, the identical cytologic features are observed in proliferative fibrocystic change.

Figure 17-6 Proliferative fibrocystic change with atypia on fine-needle aspiration biopsy. The epithelial groups in these cellular aspirates show nuclear pleomorphism, cellular disorganization, and crowding. Fragments of calcium are also seen in the smear (arrow). This case proved to be atypical ductal hyperplasia and focal ductal carcinoma in situ of the solid subtype on histology.

a definite risk for developing subsequent breast cancer and includes such lesions as atypical lobular and ductal hyperplasia. Many lesions diagnosed by FNAB as proliferative fibrocystic change with atypia prove to be DCIS on histology.

In summary, therefore, FNAB does allow an accurate assessment of the degree of proliferation in fibrocystic change, although frequently, specific benign diagnoses cannot be made. When a specific benign pathologic diagnosis is necessary to account for a mammographic or ultrasound finding, a core biopsy or excisional biopsy may be preferable. If a diagnosis of atypia is made by FNAB, excision of the lesion is necessary. In older women, a mass or region of microcalcifications with a high degree of proliferation by FNAB should be excised, even in the absence of cytologic atypia, given the high incidence of carcinoma found on histology when these lesions undergo surgical biopsy.^{20,21}

Does a diagnosis of atypia by fine-needle aspiration biopsy accurately reflect a diagnosis of atypical hyperplasia by histology?

A diagnosis of atypia by FNAB correlates poorly with the presence of a prognostically significant proliferation of ductal epithelium on subsequent histology.²⁸ Instead, atypia by FNAB represents cytologic uncertainty rather than a specific diagnosis of atypical hyperplasia. Some epithelial cells may show some nuclear enlargement or irregularity, or there may be cell dispersal. In some series that analyzed atypical cytologic diagnoses, more than 50% of atypical cases proved malignant by histology.^{29,30} In a series by Mulford and Dawson, 134 of 3798 cases, or 3.5%, were diagnosed as atypical.³¹ Of these, 72 proved benign (54%), and 62 were malignant (46%). The most common benign diagnoses were fibroadenoma and fibrocystic change, accounting for 46% of the benign cases classified as atypical cytologically. The features responsible for a designation of atypia in benign cases were increased cellularity, single epithelial cells, and reactive nuclear atypia: finely granular, uniform chromatin, and small prominent nucleoli.⁴ In general, the diagnosis of atypia suspicious of carcinoma by cytology corresponds to cases with malignant cytologic features but without sufficient cells to evaluate, and to cases of low-grade carcinoma admixed with benign ductal elements.¹⁴

In a review of 2197 FNAB cases, Al-Kaisi found 39 cases (2%) that represented a “gray zone” of breast cytology where the cytologic features of benign or premalignant breast lesions overlap with those of malignant lesions.³² Fibroadenomas accounted for 17 of the cases (44%). These tended to be cellular fibroadenomas with some cellular dyshesion, manifested by isolated epithelial cells with intact cytoplasm. Other breast lesions in the gray zone include papillary neoplasms, apocrine carcinoma, and intraductal and atypical hyperplasia.³² For SFNAB of nonpalpable lesions, there is a higher proportion of atypical or inconclusive diagnoses than for FNAB of palpable lesions.¹⁹ This is related to an increased proportion of DCIS lesions as well as smaller sample size and increased number of bloody smears for SFNAB as compared with FNAB of palpable lesions. Because a diagnosis of atypia by FNAB does not accurately reflect a diagnosis of atypical hyperplasia by histology, a diagnosis of atypia by FNAB should be followed by surgical biopsy.

Can a specific benign diagnosis ever be made by fine-needle aspiration biopsy?

Many benign breast lesions yield cytologic features that allow their subclassification when sampled sufficiently by FNAB. Maygarden and colleagues analyzed the cytology and histology of 265 benign breast masses to determine the ability of FNAB to accurately subclassify benign breast lesions.³³ A non-specific descriptive diagnosis was given in 135 cases (51%). A specific benign diagnosis was made in 130 cases (49%). Overall, the specific diagnosis was correct in 80% of cases. The distinction between proliferative and nonproliferative fibrocystic change was not highly reliable.³³ Lesions that could be specifically diagnosed with a high reliability included fibroadenoma, papillary lesions, inflammatory lesions, fat necrosis, gynecomastia, and lactational change.

Figure 17-7 Fibroadenoma on fine-needle aspiration biopsy. This highly proliferative fibroadenoma shows folded monolayered sheets of cohesive epithelial cells, bare oval nuclei, and stroma (arrow).

Fibroadenoma

The FNABs of fibroadenomas are quite variable. In middle-aged and elderly patients, degenerate (fibrotic) fibroadenomas may have little cellularity and resemble nonproliferative fibrocystic change. In general, typical fibroadenomas are highly cellular and show numerous epithelial cells, bare myoepithelial nuclei, and stromal fragments (Fig. 17-7). Epithelial cells are present in monolayered sheets and branched fronds. Bare oval nuclei are present in abundance and represent myoepithelial and stromal cells.²¹ Stromal fragments appear as dense fibromyxoid material with spindle-shaped cells. There may be marked myxoid degeneration of the stroma, and this mimics mucin of colloid carcinoma cytologically. However, there are many bare bipolar nuclei within the strands of myxoid stroma in fibroadenoma, and these are absent in colloid carcinoma. Also, neoplastic epithelial cells are not observed in fibroadenomas. Giant cells, foam cells, and apocrine cells may be seen in fibroadenomas. Some fibroadenomas have high cellularity, nuclear atypia, mitotic figures, and many intact single cells, features mimicking adenocarcinoma.^{28,31,34} In one series, intact single atypical cells were seen in 27% of benign fibroadenomas.³⁴ Generally, the atypical features in fibroadenoma do not dominate the smear and are accompanied by clearcut microscopic markers of benign disease.

A fibroadenoma must be distinguished from a phyllodes tumor. High stromal cellularity, mitotic figures, and single, intact mesenchymal cells that have plump nuclei and a long and wavy cytoplasm favor a diagnosis of phyllodes tumor. Also, phyllodes tumor may show squamous metaplasia, which is rarely seen in fibroadenoma.³⁵ Phyllodes tumor with atypia must be differentiated from a stromal sarcoma, which lacks the glandular component.

Papillary Lesions

Papillary lesions include florid papillomatosis, papillomas, and papillary adenocarcinoma; it is difficult or impossible to differentiate these lesions cytologically. Three-dimensional papillary clusters with fibrovascular or collagenous cores are the hallmark of papillary neoplasms. Both marked cellularity

Figure 17-8 Papilloma on fine-needle aspiration biopsy. This low-power magnification of a papilloma shows marked cellularity and dyshesion. The presence of the three-dimensional papillary cluster warrants caution in making a diagnosis of carcinoma. The excised specimen proved to be a highly proliferative papilloma.

Figure 17-9 Papilloma on fine-needle aspiration biopsy. This high-power magnification of the papilloma in Figure 17-8 shows cellular features that mimic breast cancer. The cells are monotonous and singly dispersed. They show stratification, are tall and columnar with square tops, and have elongated nuclei. In this case, a false-positive diagnosis of adenocarcinoma, papillary type, low nuclear grade was made by stereotactic fine-needle aspiration biopsy. Owing to the small size of the lesion (4 mm) and the good prognosis associated with the presumed carcinoma's subtype and nuclear grade, a lumpectomy without axillary dissection was performed.

and cellular dissociation can be seen in papillomas (Fig. 17-8), and only marked cellular atypia favors malignancy.³⁶ Mostly, however, papillary adenocarcinomas are composed of monotonous, bland cells. The malignant cells show stratification, are tall and columnar with square tops, and have enlarged, elongated nuclei (Fig. 17-9). When a papilloma is suspected and the FNAB shows marked cellular dissociation and no definitive papillary structures, a CNB can aid in making a more specific diagnosis and ensure that adenocarcinoma is not falsely diagnosed (Fig. 17-10). More commonly, a variation in cell types is actually an important clue to a benign diagnosis in papillomas.^{36,37} Regardless of the cytologic features, a cytologic diagnosis of a papillary lesion requires confirmation by open biopsy, and even then the diagnosis may

Figure 17-10 Papilloma on core needle biopsy. The papilloma is easily diagnosed by core needle biopsy (14-gauge). Small nests of epithelial cells are seen in collagenized stroma with a myofibroblastic proliferation. Calcifications were seen in the sclerotic portion of the papilloma (*arrow*) and on the mammogram.

be controversial. Resection of all these papillary lesions is recommended.

Inflammation

When purulent-appearing material is obtained by FNAB, it should be cultured. This occurs in acute mastitis during lactation and in a subareolar abscess that is due to keratin plugging, squamous metaplasia, and rupture of a lactiferous duct or sinus. Subareolar abscess can mimic cancer clinically by its firmness and can be seen in association with nipple invasion and peau d'orange in nearby skin. The aspirate contains inflammatory cells, cellular debris, and a giant cell reaction to keratin. Superficial squamous cells are abundant.

Fat Necrosis

Needle biopsy of the breast is useful in differentiating cancer from postsurgical or trauma-induced fat necrosis. Fat necrosis is firm and fixed when palpable, gritty by needle sensation, and spiculated with calcifications when seen on the mammogram. Therefore, fat necrosis mimics breast cancer clinically, mammographically, and by needle sensation. The smears show multinucleated giant cell lipophages and siderophages (Fig. 17-11). Blood pigment is sometimes present. Fat necrosis can be associated with breast cancer; hence, its presence does not exclude malignancy completely. Multinucleated giant cells are also seen in suture granuloma and, in patients with implants, in silicone granuloma.

Gynecomastia

Gynecomastia presents as a firm, rubbery, subareolar mass that is resistant to the needle excursions during needle biopsy. The FNAB can be quite painful. The cellularity is variable but often scanty. There can be conspicuous cytologic atypia in gynecomastia, including increased cellularity, pleomorphism, and decreased cohesion. Mitotic figures are also frequently seen. The clue to the benign diagnosis is the bare myoepithelial nuclei.

Lactational Change

The aspirates of the lactating breast yield milky fluid with an abundance of acinar cells, are very cellular, and mimic

Figure 17-11 Fat necrosis on fine-needle aspiration biopsy. Abundant lipophages are seen, many of which are multinucleated.

Figure 17-12 Adenocarcinoma, grade II (on fine-needle aspiration biopsy), showing a homogeneous population of noncohesive epithelial cells with enlarged and hyperchromatic nuclei. Note the absence of bare myoepithelial nuclei.

adenocarcinoma. The cells have enlarged, hyperchromatic nuclei, with prominent nucleoli and dense chromatin. Because the cytoplasm is fragile, dispersed bare nuclei are numerous in the background of vacuolated proteinaceous fluid (milk). These nuclear features may suggest cancer, but when breast cancer is seen in the lactating breast, it usually shows frank malignant features.³⁸

Can a definitive diagnosis of breast cancer be made by fine-needle aspiration biopsy?

By FNAB, the diagnosis of breast cancer can be suspected almost immediately by its gritty sensation. A bloody aspirate or a pasty cream-colored or pink aspirate with granules strongly suggests cancer. The diagnosis can be confirmed immediately by examination of a Diff-Quik smear. The smear shows a homogeneous population of atypical epithelial cells in poorly cohesive groups. Most mammary carcinomas have abundant single intact cells with enlarged nuclei but lack bare bipolar nuclei (Fig. 17-12) and can be rapidly and confidently identified by an experienced cytopathologist.

Figure 17-13 Adenocarcinoma, grade III, on fine-needle aspiration biopsy. The nuclei are pleomorphic, with coarse chromatin and abnormal mitotic figures (*arrows*).

Some subtypes of breast cancer can be identified by FNAB based on the cellularity, degree of nuclear atypia, and background pattern of the smears; the major task, however, is to provide a reliable diagnosis of cancer. There are four patterns of cellularity and atypia in aspirates of breast cancer:²¹ (1) high cellularity and conspicuous atypia, (2) low cellularity and conspicuous atypia, (3) high cellularity and minimal atypia, and (4) low cellularity and minimal atypia.

Breast Cancer: High Cellularity and Conspicuous Atypia

This is the most diagnostic pattern of breast cancer. The cells are in poorly cohesive groups, many cells are intact and singly dispersed, and the nuclei have conspicuous malignant features: enlargement, pleomorphism, coarse chromatin, prominent nucleoli, and abnormal mitotic figures (Fig. 17-13). The cytoplasm is commonly eccentric and may have intracytoplasmic lumina with inspissated mucin.

The FNAB smears of medullary carcinoma are highly cellular and composed of large, pleomorphic cells with delicate syncytial cytoplasm. There is a prominent infiltrate of lymphocytes and plasma cells. Because the cytoplasm is fragile, many bare distorted nuclei are noted. The differential diagnosis includes metastases of a high-grade breast carcinoma to an intramammary lymph node. The prognosis for medullary carcinoma is good, despite its high nuclear grade. It can be distinguished from the prognostically unfavorable cancers by the background of lymphocytes and plasma cells. Medullary carcinoma presents clinically as a soft round mass and must also be differentiated from metastatic cancer.

Papillary carcinomas can be easy to identify if there are markedly atypical cells in three-dimensional papillary clusters, sometimes with distinct fibrovascular cores.

Breast Cancer: Low Cellularity and Conspicuous Atypia

This pattern can be seen in scirrhous carcinomas that have been poorly sampled. In general, more cells can be harvested if multiple samples are obtained from the periphery of the mass and if a finer needle is used (25 to 27 gauge). Multiple samplings and immediate interpretation may reduce inadequate samples.^{27,39} Comedo DCIS can be low in cellularity, but

Figure 17-14 Colloid carcinoma on fine-needle aspiration biopsy, showing single intact cells and small clusters of low-grade tumor cells against a background of mucin. The mucinous background may be very vascular (*arrow*).

usually there are highly atypical pleomorphic cells in a background of necrosis, with or without dystrophic calcifications.

Not all atypical cells are malignant, and this pattern of breast cancer, low cellularity and conspicuous atypia, can be seen in fat necrosis and its subsequent repair and resolution. In the irradiated breast, the epithelial cells show variation in cell size (anisocytosis), but the nuclear-to-cytoplasmic ratio is normal.⁴⁰ When trying to distinguish radiation changes from recurrent breast cancer in the conservatively treated patient, it may be helpful to perform core biopsies.

Breast Cancer: High Cellularity and Minimal Atypia

A specific breast cancer diagnosis can be made by FNAB, even in cases of low-grade cancers, when certain characteristic features are present. Colloid carcinoma has single intact cells and small clusters of tumor cells in a “sea” of mucin, which is metachromatic on Diff-Quik stain (Fig. 17-14) and pink on Papanicolaou stain. The differential diagnosis includes fibroadenoma with mucoid degeneration of the stroma. Adenoid cystic carcinoma has noncohesive basaloid cells arranged around balls and cylinders of homogeneous material, which is intensely metachromatic on Diff-Quik staining. Tubular carcinoma, a well-differentiated ductal adenocarcinoma, presents as a small spiculated mass that is frequently aspirated under mammographic guidance. The malignant cells have bland, uniform nuclei. However, there should be a high suspicion of cancer owing to the mammographic finding and the gritty sensation of the mass during the aspiration procedure. Additionally, the bland, cohesive malignant cells are found in characteristic patterns, which include rigid open tubules (like a garden hose) and angular arrowhead glands⁴¹ (Fig. 17-15).

Breast Cancer: Low Cellularity and Minimal Atypia

This is the typical pattern of benign breast aspirates, but it can also be seen in breast cancer, most commonly in invasive lobular carcinoma. The aspirates of invasive lobular carcinoma may be of sparse cellularity and yield only small, bland cells. Single-file arrangements and intracytoplasmic lumina may

Figure 17-15 Tubular carcinoma on fine-needle aspiration biopsy. The bland, cohesive malignant cells are found in rigid tubules (*arrows*) and angular arrowhead glands (*arrowheads*).

Figure 17-16 Lobular carcinoma on fine-needle aspiration biopsy (FNAB). The FNAB of invasive lobular carcinoma may yield sparse cellularity. However, intracytoplasmic lumina are suggestive of lobular carcinoma (*arrows*).

suggest lobular carcinoma (Fig. 17-16). A core biopsy can be performed to confirm this impression histologically (Fig. 17-17).

CORE NEEDLE BIOPSY

What is the role of core needle biopsy in diagnosing palpable breast lumps?

Many benign diseases of the breast are cytologically similar, making specific diagnosis of breast masses a problem.³³ Also, there is an overlap in the cytologic features of some proliferative or premalignant breast lesions and those of malignant lesions in aspirates by FNAB. This gray zone of FNAB represents the cases in which an unequivocal diagnosis cannot be rendered cytologically (about 2% of FNABs).³² These lesions include papillary neoplasms, cellular fibroadenomas, and some breast carcinomas with small cells (lobular, tubular, cribriform, and noncomedo DCIS). CNB of the breast may be

Figure 17-17 Core needle biopsy of an invasive lobular carcinoma. Single files of small, bland epithelial cells are seen infiltrating dense fibrous tissue.

Figure 17-18 Core needle biopsy of low-grade ductal carcinoma in situ, solid subtype.

Figure 17-19 Core needle biopsy of a low-grade invasive tubular carcinoma. The carcinoma is composed of more than 75% well-formed glands.

extremely useful in minimizing the size of the gray zone. CNBs provide samples of breast tissue for histology that are easier to interpret than FNAB. Markedly scirrhous carcinomas may need to be sampled by CNB because of the scanty cellularity of the FNAB. The determination of invasion by ductal or lobular adenocarcinoma can be made by CNB (Figs. 17-18 and 17-19; see also Fig. 17-17).

In essence, patients with an equivocal diagnosis by FNAB may benefit from CNB.^{42,43} FNAB is less reliable than CNB in the diagnosis of malignancy when there is an invasive lobular carcinoma. In one series by Sadler and colleagues, the FNAB failed to demonstrate malignant cells in 27 of 56 cases (48%) of invasive lobular carcinoma.⁴³ Ten additional cases of invasive lobular carcinoma were diagnosed by CNB when the FNAB was not diagnostic. Fibrosis and calcifications secondary to surgery or radiation can best be diagnosed by CNB because the aspirates tend to be low in cellularity. But, in general, FNAB is the most efficient, cost-effective, reliable procedure for the diagnosis of palpable breast carcinoma. Ballo and Sneige compared the sensitivity and specificity of CNB and FNAB cytology in detecting breast carcinoma in 124 patients who presented to the University of Texas M. D. Anderson Cancer Center for evaluation of a palpable breast mass.⁸ The patients underwent an average of three needle passes and concurrently had a CNB using the 18-gauge Bard Monopty device (C. R. Bard, Inc., Covington, GA). All of the patients had histologic confirmation of their neoplasms. The specificity was 100% for both FNAB and CNB. However, the sensitivity was higher for FNAB than for CNB (97.5% vs. 90%; $P < .004$) and was not dependent on tumor type, size, or differentiation. The addition of CNB to a negative FNAB failed to increase the sensitivity in the detection of breast cancer.

In summary, FNAB is more cost-effective and requires less time and effort than CNB in the diagnosis of palpable lesions. The FNAB procedure allows for greater tactile sensitivity and ease of immobilization. Additionally, FNAB allows for multidirectional passes through the mass. These factors reduce the probability of sampling errors with FNAB compared with CNB for palpable breast masses. When there is discordance with the cytology and imaging findings, a CNB can contribute to a more definitive diagnosis.

What is the optimal number of core biopsy specimens?

Stereotactic and ultrasound-guided percutaneous large core biopsy are now commonly used for the initial histologic diagnosis of nonpalpable breast lesions. A CNB is a sampling procedure; hence, the main concern in the diagnosis of most breast lesions is establishing that the histologic findings on CNB provide an accurate assessment of the mammographically or ultrasound detected target lesion. The first-generation CNB instruments used an automated spring-loaded biopsy gun with a large-core cutting needle (usually 14 gauge) for the procurement of tissue from a target lesion. Second-generation vacuum-assisted CNB devices, such as the Mammotome (Biopsy Medical Instruments, Inc., San Juan Capistrano, CA), use larger-caliber needles (usually 11 gauge) and allow for multiple contiguous specimens to be obtained with a single needle insertion. These vacuum-assisted CNB devices have become a practical alternative to open surgical biopsy for the evaluation of mammographic microcalcifications. They allow for procurement of larger tissue samples, higher retrieval of microcalcifications, sampling of smaller clusters of microcalcifications, and consequently, a reduction in the need for rebiopsy.

If a cytopathologist is not available to determine specimen adequacy of an SFNAB or a touch preparation of a core

biopsy, it is accepted by most radiologists that a minimum of 5 core biopsies be performed for nodules and spiculated densities and that a minimum of 10 core biopsies be performed in cases of microcalcifications.⁴⁴ In one series of 145 stereotactic core biopsies using 14-gauge needles, diagnostic material was obtained with one, two, three, four, five, and six core specimens in 102 (70%), 117 (81%), 129 (89%), 132 (91%), 137 (94%), and 140 (97%) of the 145 lesions, respectively.⁴⁵ A diagnostic yield of 99% was obtained with five specimens for masses and 87% for calcifications. Obtaining six specimens increased the diagnostic yield to 92% for calcifications but did not improve the yield on masses.⁴⁵

Cancers that elude definitive diagnosis are more often associated with microcalcifications than present as masses. When microcalcifications are the target of stereotactic needle biopsy, increased sampling and specimen radiography documentation are necessary.⁴⁶ Automated Tru-Cut biopsy devices are inefficient at sampling small foci of microcalcifications. In one center, a minimum of 12 cores are obtained for microcalcifications.⁴⁷ The procedure can take up to 1 hour. A definitive surgical excision may be preferable in cases of high suspicion for malignancy, but the issue remains unresolved at this time.⁴⁸

The Mammotome was developed in 1994 by a radiologist, Fred Burbank, and a medical device engineer, Mark Ritchart, to address the drawbacks of the automated core biopsy devices. These drawbacks included the need for pinpoint accuracy in targeting the lesion and the need for multiple insertions to obtain the requisite number of cores: 5 for masses and 10 for microcalcifications. The Mammotome is a specialized breast biopsy instrument with a probe at its distal end with a piercing tip to penetrate breast tissue. Proximal to the piercing tip of the probe is an aperture into which tissue is drawn by means of a vacuum into a sampling chamber. Tissue in the sampling chamber is cut away from the breast by a coaxial cutter and pulled back into a standard pathology tissue cassette located in a specimen retrieval chamber⁴⁹ (Fig. 17-20). The Mammotome can routinely excise an entire cluster of microcalcifications, measuring up to 5×5 mm, in less than 10 minutes.^{47,50} The procedure is referred to as stereotactic "mammotomy." With the use of the Mammotome, a breast lesion can be excised quickly and completely because it remains in the breast while the vacuum helps to pull tissue through the probe. The time necessitated for the performance of the CNB procedure is half that needed with the automated CNB devices because of the ability to obtain contiguous sampling of the lesion with one insertion. Another advantage of

Figure 17-20 Mammotome probe.

the Mammotome vacuum is that there is less accumulation of blood at the biopsy site, and less ecchymosis.^{9,51}

Most radiologists now use the Mammotome exclusively for the performance of SCNB. The likelihood of completely removing microcalcifications is higher with the Mammotome when compared with the automated biopsy gun. Liberman and coauthors reported calcification retrieval in 95% of cases with the 11-gauge Mammotome.⁵² In one study, the likelihood of completely removing the mammographic lesion with the 14-gauge automated biopsy gun and the 14-gauge and 11-gauge Mammotome was reviewed.⁵³ Calcified lesions were completely removed in 7%, 26%, and 69% of cases with the 14-gauge automated biopsy gun and the 14-gauge and 11-gauge Mammotome, respectively.⁵³ Another advantage is that the minimum diameter of microcalcification clusters that can be sampled is 3 mm with the automated gun versus 5 mm with the Mammotome.⁵⁴ Consequently, the number of excisions performed following Mammotome biopsy is lower (9% versus 14.9%), the rate of sample insufficiency is lower (1.7% versus 4.4%), and the discrepancy rate between the mammographic findings and CNB diagnosis is lower (0.8% versus 3.4%) than with the automated biopsy gun.⁵⁵ Of note, Jackman and associates found that the underestimation of DCIS on SCNB was 1.9 times more frequent with masses than with microcalcifications, 1.8 times more frequent with automated CNB devices than with vacuum-assisted devices, and 1.5 times more frequent with 10 or fewer specimens than with more than 10 specimens per lesion.⁵⁶

A tiny titanium clip for delivery through the Mammotome has been developed to permanently mark the biopsy site.⁴⁷ The clip can be deployed to mark the area should re-excision following wire localization be necessary. The contiguous sampling by the Mammotome creates a small air-filled cavity. The clip marks the cavity wall. In one series, 111 cases of CNB with clip deployment were reviewed.⁵⁷ The authors showed that 31 (28%) clips were more than 1 cm from the target on at least one postbiopsy image. Postbiopsy mammography in two orthogonal views is therefore necessary to document clip position relative to the biopsy cavity. The radiologist must be aware of the possibility of clip migration.⁵⁸ In one rare case, repeat postbiopsy mammograms showed displacement of targeted microcalcifications adjacent to the misplaced clip.⁵⁹

What type of stereotactic needle biopsy equipment is available?

There are two major types of stereotactic breast biopsy apparatuses: upright units that are added to existing mammography machines, and dedicated prone stereotactic biopsy devices. There are two major advantages of the upright, add-on units: low cost and flexibility of use. When the unit is not being used for needle guidance, the mammography unit can be used for screening. The disadvantages of the add-on units are that patient motion is common, there are more episodes of vagal reactions than with the prone unit, and there is limited working space for the physician performing the procedure. All of these factors adversely affect the accuracy of needle guidance and lengthen the time of the procedure. The dedicated prone units (Mammotest, Fischer Imaging, Denver, CO; and Lorad StereoGuide, Hologic Corp., Bedford, MA) (Fig. 17–21) minimize patient movement and vagal reactions and have

Figure 17–21 Lorad StereoGuide. This stereotactic system minimizes patient movement and vagal reactions and provides ample working space for the operator. (Courtesy of Hologic Corp., Bedford, MA.)

ample working space under the table. The disadvantages of the prone needle guidance systems are the expense and size of the unit. Additionally, the prone units do not allow for versatile use; their sole purpose is to guide needles.⁴⁹ It is recommended that another standard mammography unit or breast ultrasound unit (or both) be placed in the same room so that the room does not stand idle when stereotactic needling procedures are not being performed.⁹

How are the stereotactic images obtained and processed?

Stereotactic images can be obtained with conventional film-screen technique or with the digital technique. Direct digital imaging charge-coupled device (CCD) technology is available on both of the prone units and on many of the add-on stereotactic units. The film–screen technique is less costly, and there is no restriction of the field of view. However, there is poor contrast resolution, higher radiation dose, and lengthy film processing time when compared with the digital technique. Digital imaging allows for almost instantaneous image acquisition and display (about 5 seconds). Additionally, there is more contrast resolution, and the operator can postprocess the image by adjusting the image contrast, brightness, and magnification. The digital video display can be reversed to black on white instead of white on black, which can be especially useful in identifying microcalcifications. Edge enhancement algorithms can be applied to evaluate the margins of a nodule.⁵¹

Parker and coworkers reported a multicenter experience totaling 4744 stereotactic breast core biopsies, using 14-gauge needles. Tissue diagnosis by stereotactic breast core biopsy was found to be accurate and reproducible at 20 sites.⁴⁴ The complication rate was 0.2% and included three hematomas and three infections. The breast cancer miss rate was 1.3%. In comparison, surgical biopsy following needle localization may

not be successful. Failure rate of 5% was reported even when the technique was performed by those experienced with the procedure.⁶⁰

SCNB is not associated with lasting postbiopsy changes on follow-up mammography.^{61,62} Complications include patient motion, vasovagal reactions (up to 7% using upright localization units), bleeding, and, rarely, pneumothorax.^{62,63} Needle track seeding of malignant cells occurs in less than 0.01% of cases.⁶⁴ The surgical excision can be directed to excise the needle track if there is concern.⁶⁵

How is a stereotactic needle biopsy performed?

Stereotactic localization uses parallax shift principles, apparent movement of the breast lesion, to calculate the position of the lesion in the breast. The three-dimensional coordinates of the mass are calculated from two radiographs taken at an angle of ± 15 degrees from a central beam.⁶⁶ The needle is inserted into the calculated position and can be positioned within 1 to 2 mm of the target lesion (Fig. 17–22). A second pair of radiographs is obtained to confirm the position of the needle. In SFNAB, 25-gauge spinal needles are generally used. As with palpable lesions, the sensation of the mass provides a clue that the mass has been hit. Multiple specimens from different sites of the target lesion are obtained to minimize inadequate samples.

Variation in the size of the core needle used for SCNB with an automated gun ranges from 14 to 20 gauge, but the best results are obtained using an automated gun with a long throw (2.2 to 2.5 cm) and a 14-gauge needle with a 1.5- to 1.9-cm sample notch.⁶¹ Local anesthesia is used and a small 4- to 5-mm nick is made with an 11-blade scalpel. The small incision is unnecessary with 18- or 20-gauge core needles. The biopsy needle is then manually advanced so that the needle tip alignment is at the front edge of the lesion to be sampled. The

proper alignment of the needle with respect to the lesion is confirmed by a set of prefire stereoscopic images. The automated gun is fired, and the proper postfire position of the needle tip is documented by another set of images (Fig. 17–23). The breast is manually compressed to achieve hemostasis, and a Steri-Strip or simple bandage is used to close the skin incision. SFNAB may be preferable to SCNB in women with small breasts because the long throw of the automated gun may hit the backplate of the apparatus, although with experience, this can be avoided by using a side approach to the target.⁴⁷ Digital stereotactic imaging provides almost instantaneous image reconstruction with better contrast resolution than film-screen imaging and has eliminated the need for prefire and postfire stereoscopic images; therefore, the patient is subjected to fewer exposures. Additionally, recent software improvements allow for targeting of the lesion orthogonal to the plane of compression. Stereotactic needle biopsy, coupled with stereotactic localization for laser ablation, thermal ablation, or cryotherapy, has been tested on small breast cancers,⁶⁷ and excision of the entire breast mass under stereotactic guidance has also been evaluated.⁶⁸

When is an ultrasound-detected lesion diagnosed by needle biopsy?

Many breast surgeons and radiologists are now evaluating nonpalpable breast masses by ultrasound. Up to 90% of mammographically detected nonpalpable breast masses can be identified by ultrasound.⁶⁹ Ultrasound-guided biopsy is faster and less expensive than stereotactic biopsy, with no compromise in accuracy.^{69,70} Ultrasound offers many other advantages, including no radiation exposure, shorter route to the target, real-time image of the needling procedure, and ability to sample the lesion multidirectionally.^{71,72} High-frequency (7.5- to 13-mHz) linear array transducers with a large sole are optimal for use in ultrasound of the breast.⁷³

Figure 17–22 Mammographic localization. The needle is inserted into the calculated position, and stereoscopic images are taken to confirm the position of the needle.

Figure 17-23 Postfire stereotactic images. The needle tip is documented in its proper position with respect to the lesion of concern.

When a complex cyst or an indeterminate lesion is identified by ultrasound, ultrasound-guided needle aspiration can be performed. If the lesion is a cyst, it is managed based on the appearance of the fluid and the degree of cyst resolution; clear colorless fluid can be discarded, but bloody fluid must be analyzed. If the lesion is solid, FNAB or CNB under ultrasound guidance can be done in the same setting. In 1999, a new handheld version of the Mammotome was developed for use under ultrasound guidance.⁵¹ In one series of 71 ultrasound-guided breast biopsies, the device proved to be accurate with a slightly higher risk for bleeding owing to lack of compression of the breast when compared with CNB performed with stereotactic guidance.⁷⁴ However, the relative value of sonographically guided Mammotome biopsy compared with stereotactically guided Mammotome biopsy for solid masses remains to be determined.

How is the ultrasound needle biopsy performed?

The ultrasound-guided breast biopsy is performed with the patient in the supine position. The skin is cleansed, and sterile acoustic gel is placed on the breast. For core biopsy, the needle pathway is anesthetized. The needle is introduced in a direction longitudinal to the long axis of the transducer, which allows for continuous visualization of the hyperechoic (whiter) needle. This orientation is easier to maintain with the aid of biopsy guide attachments for the transducer.⁷³ Cysts can be evacuated by placing the needle into the center of the mass and then aspirating the fluid. When a core biopsy is performed for solid lesions, the needle is aligned at the edge of the mass, and the automated gun is fired under real-time visualization (Fig. 17-24).

A breast and biopsy device-stabilizing apparatus has been developed for performing three-dimensional ultrasound-guided needle procedures with the patient in the upright position (Sonopsy, NeoVision Corp., Seattle, WA). Four advantages of this method over conventional ultrasound

Figure 17-24 Ultrasound-guided core needle biopsy.

needle techniques are as follows: (1) there is good immobilization of the lesion with breast compression, (2) there is better visualization of the lesion by three-dimensional ultrasound imaging, (3) there is optimal chest wall access and elimination of the risk for pneumothorax, and (4) it is easy to correlate the ultrasound and radiographic images. All of these factors increase the speed and accuracy of performing the ultrasound-guided needle biopsy procedure.

Should a mammogram be performed following a core biopsy procedure?

Hann and coworkers performed mammograms in 86 cases immediately after stereotactic core biopsy using 14-gauge needles to determine whether mammography should be done routinely to diagnose hematoma, confirm sampling of microcalcifications, and establish a new baseline for future mammograms.⁷⁵ The authors found that 57 of 58 hematomas

were clinically occult. Postprocedural mammograms showed a decrease in a number of calcifications in 26 of 54 cases (48%), as compared with specimen radiographs, which showed calcium in 50 of 54 cases (93%). Three masses and one cluster of microcalcifications disappeared after biopsy. Hematomas obscured residual microcalcifications at the biopsy site in three cases. The authors concluded that mammography was not necessary immediately after core biopsy for the diagnosis of hematoma and is inferior to specimen radiography for verifying sampling of microcalcifications. The frequent finding of hematoma makes mammograms after core biopsy suboptimal for the establishment of a new baseline.

What are the practical considerations in the reporting of the pathologic diagnosis on core needle biopsy?

The most important consideration in the reporting of the pathologic diagnosis on CNB is to address the specific pathology of the target lesion. For example, for SCNB performed for microcalcifications, the specific diagnosis for the targeted focus of microcalcifications should be noted as the primary finding along with documentation as to whether the microcalcifications on histology correspond to those in the CNB specimen radiograph. Ideally, a SCNB performed for microcalcifications should be submitted in two parts; the first part should include the tissue cores containing mammographic microcalcifications, and the second part (which may constitute most of the specimen volume) should include the additional tissue. A maximum of five intact cores should be submitted in each cassette. Therefore, although a small focus of clustered microcalcifications may be seen in a microscopic fibroadenoma in 1 or 2 of more than 20 tissue cores, the primary diagnosis should be denoted as “fibroadenoma with clustered microcalcifications; *corresponding to those in the CNB specimen radiograph*,” and any additional findings should be delineated separately with attention to the presence of any high-risk lesions.

In cases of fibrocystic change, microcysts and foci of papillary apocrine hyperplasia may be associated with crystals of calcium oxalate. These may be difficult to identify without polarization. Commonly, sclerosing adenosis (see Fig. 17-1) and columnar cell hyperplasia (CCH) (see Fig. 17-2) may present as suspicious clustered microcalcifications, occasionally of the ossifying type. When multiple sites of microcalcifications are present in one breast, sampling of one can reliably predict the pathology of another.⁴⁸

A diagnosis of atypical ductal hyperplasia (ADH) is rendered when there is hyperplasia and cytologic atypia as well as structural rigidity of the ductal epithelium, but the proliferation is not limited to a monotonous population of cells with distinct cell borders as in DCIS (Fig. 17-25). In most instances in which DCIS is found on CNB, it can be subtyped by its architectural pattern (solid, cribriform, micropapillary, papillary), presence or absence of necrosis, and nuclear grade. The presence of an extensive intraductal component and of microinvasion should be noted to ensure that adequate margins are taken at the time of excisional biopsy. A suspicion of microinvasion can be confirmed or refuted by immunohistochemical staining for basement membrane (collagen IV and

Figure 17-25 Core needle biopsy of atypical ductal hyperplasia (ADH). There is hyperplasia and cytologic atypia of the epithelium as well as structural rigidity of the ducts, but the proliferation is not limited to a monotonous population of cells with distinct cell borders (as in ductal carcinoma in situ [DCIS]). The surgically excised specimen showed DCIS and ADH.

laminin) and myoepithelial cells (smooth muscle actin, CD10, and heavy-chain myosin).⁷⁶

The reporting of the pathology of invasive breast cancer on CNB should include any prognostically relevant findings. A CNB does not permit reliable measurement of tumor size, although a microscopic carcinoma completely incorporated within a tissue core can be very accurately measured by ocular micrometry. Most other prognostic features pertinent to a T1N0 breast carcinoma can be determined on CNB.⁷⁷ Grading of the ductal carcinoma by Scarf-Bloom-Richardson scoring (which includes evaluation of gland formation, nuclear grade, and mitotic index) can be done on CNB material. Certain histologic subtypes of invasive carcinoma with favorable outcomes can be identified on CNB, including adenoid cystic carcinoma, which is composed of nests of basaloid cells with a cylindromatous pattern, tubular carcinoma with greater than 75% well-formed glands (see Fig. 17-19), colloid carcinoma characterized by an abundance of extracellular mucin and lack of desmoplastic response, and medullary carcinoma, which is characterized by high-grade nuclear morphology and a syncytial growth pattern accompanied by an infiltrate of lymphocytes and plasma cells.

Invasive lobular carcinoma of the classic variant shows small neoplastic cells infiltrating dense fibrous tissue as linear aggregates, sometimes with prominence of signet-ring cells (see Fig. 17-17). Other variants (alveolar, solid, histiocytoid, or pleomorphic) may need to be confirmed with immunostaining for E-cadherin, a transmembrane glycoprotein involved in the formation of the intercellular junctional complex.⁷⁶ E-cadherin immunostaining is typically absent or markedly diminished in mammary carcinoma of the lobular phenotype, as opposed to the intense cytoplasmic membrane staining seen in normal, hyperplastic, and neoplastic ductal epithelial cells. An E-cadherin stain can be useful in distinguishing solid DCIS from LCIS as well. In addition to E-cadherin for diagnostic subtyping of invasive carcinoma, immunohistochemical stains can be performed on CNB specimens for prognostic markers, including estrogen and progesterone receptors and *HER-2/neu*. Feulgen-stained sections of

the CNB can be used for determination of ploidy and S-phase fraction with image cytometry. In general, these stains are performed on CNB specimens when the targeted lesion is a small invasive carcinoma that has been completely excised by the needle procedure or when preoperative chemotherapy is to be given.

Evaluation of the CNB for peritumoral lymphatic invasion (PLI) should be done. The lymphatic space should have endothelial cells because artifacts of fixation can cause separation of epithelial cells from the duct wall, mimicking PLI. In CNB material, intraobserver reproducibility for PLI is low.⁷⁷

What is the significance of a diagnosis of atypical ductal hyperplasia by core needle biopsy?

The finding of ADH at SCNB is an indication for surgical biopsy because of the prevalence of carcinoma in the lesions. In one series, ADH was found in 25 of 264 lesions (9%), including 21 of 105 sites of calcification (20%), and 4 of 159 masses (3%).⁷⁸ Surgical biopsy was recommended in all 25 instances and was performed in 21. The histopathology of these 21 cases was benign without atypia in 4 (19%), ADH in 6 (29%), and ductal carcinoma in 11 (52%), including 8 cases of DCIS and 3 invasive ductal carcinomas.

Histologic findings of core biopsy and surgical biopsy specimens were concordant in 5 and discordant in 11 cases of ADH diagnosed by core biopsy in a series by Jackman and colleagues.⁷⁹ The authors concluded that a diagnosis of ADH by core biopsy is inaccurate and that excisional biopsy is necessary. Also, an unequivocal diagnosis of ADH on a CNB does not preclude the presence of DCIS in the immediate vicinity of the target lesion. It is notable that studies that compare CNB with automated and vacuum-assisted devices show a marked reduction in the underestimation rate for ADH using the 11-gauge Mammotome. In a comprehensive review of the literature, Reynolds and coauthors noted that the underdiagnosis rate for ADH was 41% with the use of the automated biopsy gun, as compared with 15% with the 11-gauge Mammotome.⁸⁰ In another review, several subsets of patients with a diagnosis of ADH on CNB with a high likelihood of DCIS in subsequent surgical excisions were identified.⁸¹ These included patients in whom the CNB was diagnosed as ADH bordering on DCIS and patients with a diagnosis of ADH with papillary features, with a 63% and 36% likelihood of DCIS in subsequent surgical biopsies, respectively. The number of atypical foci in CNB and the mammographic span of the microcalcifications, greater than four foci and greater than 2 cm, also correlated with an increased likelihood of DCIS on excision.⁸¹

What is the accuracy of predicting invasion by stereotactic core biopsy?

Stereotactic core biopsy of breast carcinoma can accurately predict invasion, although absence of invasion is not definitive when only DCIS is found. Liberman and associates correlated the histopathologic findings of stereotactic core biopsy and

surgery of 63 breast carcinomas and found concordance in 58 (92%), yielding invasive carcinoma in 46 cases and DCIS in 12 cases.⁸² The results were discordant in five cases (8%), including three cases in which the stereotactic core biopsy showed DCIS and surgery showed invasive ductal carcinoma. There was one false-positive case by CNB in which the core biopsies revealed intraductal carcinoma cells displaced in fibroadipose tissue by the needle procedure. The CNB was falsely diagnosed as invasive ductal adenocarcinoma. This case illustrates a potential interpretive pitfall. There is no evidence that the displaced cells are biologically relevant.

There is a high rate of underdiagnosis of invasion by CNB. In a series reported by Jackman and colleagues, there were 8 of 43 (19%) instances in which DCIS diagnosed by CNB proved to be invasive carcinoma by surgical excision.⁷⁹ Also, in a multi-institutional study, Parker and associates reported that 33% of the lesions that were diagnosed as low-grade DCIS or ADH and 11% of those diagnosed as high-grade DCIS were underdiagnosed cases of invasive carcinoma.⁴⁴ Lee and associates found that SCNB with the 11-gauge Mammotome was as reliable as open surgical excision for diagnosing DCIS without invasion.⁸³ Nonetheless, in the latter series, DCIS without invasion was diagnosed by CNB in 59 patients, and on excision, 17 (29%) had invasive disease. Despite the high incidence of underdiagnosis by CNB, when a diagnosis of invasive breast cancer is made, CNB is highly reliable and allows for a decision regarding axillary lymph node sampling at the time of mastectomy or segmental excision. The presence of an extensive intraductal component (EIC) on CNB should be reported because in one retrospective review of DCIS in breast CNB with invasive cancer, the authors showed that the presence of an EIC correlated significantly with close or positive margins on subsequent excision.⁸⁴

Is there displacement of carcinomatous epithelium in surgical breast specimens following stereotactic core biopsy?

The attribution of carcinomatous displacement in surgical breast specimens solely by core biopsy is complicated by the fact that these specimens are subjected to other needle procedures. These include local anesthetic injection, needle localization, suture placement, and FNAB. Youngson and coworkers found displaced carcinomatous fragments outside the main tumor mass in 12 of 43 (28%) consecutive cases of breast carcinoma that were initially diagnosed by stereotactic core biopsy using 14-gauge needles.⁸⁵ In 18 of these surgical breast specimens, the only needle procedure other than core biopsy was local anesthetic injection by 25-gauge needle. Displaced cancer fragments were seen in 7 of these 18 cases (39%). The authors suggested that the core biopsy was the more likely cause of tumor fragment displacement because they previously documented only one case in which a 25-gauge needle was associated with epithelial displacement.⁸⁶ The displaced epithelial fragments may mimic stromal invasion and represent a potential source of misdiagnosis (Fig. 17-26). The biologic and clinical significance of epithelial displacement has not yet been ascertained. As noted previously, there is one reported case of repeat postbiopsy mammograms that showed displacement of targeted microcalcifications adjacent to the misplaced clip.⁵⁹

Figure 17-26 Core needle biopsy (CNB) of a displaced epithelial fragment. This displaced fragment of a papilloma can mimic stromal invasion in a CNB specimen.

What has been the effect of a selective core biopsy program on the yield of breast cancer at needle localization biopsy of nonpalpable breast lesions?

Before the introduction of core biopsy, the yield of breast cancer at needle localization biopsy was in the range of 21% to 35%, as evaluated in a selective core biopsy program.⁸⁷ After implementation of core biopsy, the yield increased to 55%. Kaufman and colleagues compared a series of 47 patients with suspicious mammographic lesions diagnosed by wire-localized breast biopsy with 66 consecutive patients diagnosed by SCNB.⁸⁸ The use of SCNB was associated with breast excisions of larger volume, negative margins, and decreased need for re-excision.

What is the impact of stereotactic core biopsy on the cost of diagnosis?

In one study by Liberman and colleagues, stereotactic core biopsy replaced surgical biopsy in 140 of 182 patients, with an estimated reduction in cost of more than 50%.⁸⁹ The mean adjusted direct savings in cost was \$893 for Medicare patients and \$1491 for all other patients (based on Relative Value for Physicians [RVP] reimbursement data). Stereotactic core biopsy decreased the cost of diagnosing nonpalpable breast lesions by 52% (RVP) or 55% (Medicare).⁸⁹ In another analysis, the cost of biopsy per cancer detected decreased from \$11,555 to \$8356 when stereotactic core biopsy was performed for lesions that were strongly suggestive of cancer but not clearly malignant.⁹⁰

What nonmalignant lesions (other than ADH) on core needle biopsy require excision?

The management of patients following a diagnosis of invasive and in situ ductal carcinoma and for most benign

breast lesions on CNB is well established. A diagnosis of ADH by CNB requires surgical excision. However, the subsequent management of certain nonmalignant proliferative breast lesions diagnosed on CNB poses a continuing dilemma. Jacobs and coauthors reviewed the available data regarding subsequent surgical biopsy findings for lesions diagnosed on CNB as lobular neoplasia, papillary lesions, radial scars, fibroepithelial lesions, and columnar cell lesions in an attempt to make management recommendations when these lesions are encountered in CNB specimens.⁹¹

Lobular Neoplasia

LCIS is a relatively uncommon lesion, with an incidence of less than 2% in most core biopsy series.⁹¹

Most of these studies are flawed by selection bias because they are retrospective reviews of small numbers of patients. In one series by Liberman, 16 of 1315 lesions that underwent stereotactically guided biopsy using either a 14-gauge automated biopsy gun or Mammotome had LCIS.⁹² A surgical excision was performed for 14 of these 16 cases, and carcinoma was found in three. Five of the excised cases showed LCIS and an additional high-risk lesion, including radial scar in three and ADH in two. In five cases in which LCIS was the only finding on CNB, there was no carcinoma on excision. Liberman and colleagues concluded that if LCIS is present on CNB, a surgical excision is warranted if another high-risk lesion is present. Additionally, if the LCIS lesion shows histologic overlap with DCIS; for example, if the LCIS presents as a cluster of microcalcifications with necrosis, excision is also warranted.⁹² Finally, if there is radiologic-pathologic discordance—for example, LCIS presenting as a mass—excision is warranted. Burak and associates found one patient with DCIS in a series of six excisional biopsies for ADH.⁹³ Of 14 patients with a primary diagnosis of LCIS on CNB reviewed by Shin and Rosen, 3 (31%) had DCIS or invasive carcinoma on excisional biopsy.⁹⁴ Among six patients with ALH on CNB in the same series, one had invasive lobular carcinoma and LCIS, and two had LCIS on excision.⁹⁴ Based on the available data, a surgical biopsy is generally recommended for a diagnosis of LCIS on CNB, especially if the LCIS is associated with another high-risk lesion. The small number of ALH cases does not allow for definitive conclusions about managing these patients.

Papillary Lesion

The diagnosis of papillary lesion on SCNB is rarely made. In one review, Reynolds found an incidence of 0.16% (29 in 18,542 CNB specimens) for a diagnosis of papillary lesion on CNB.⁹⁵ The reported incidence of papillary lesion on CNB was 0.65% (7 in 1077 CNB specimens), 1.3% (16 of 1236 CNB specimens), and 1.6% (12 of 734 CNB specimens) by Liberman and colleagues,⁹⁶ Philpotts and associates,⁹⁷ and Mercado and coworkers, respectively.⁹⁸ A combined total of 38 papillary lesions were excised in these three series, 16 with a diagnosis of benign papilloma on CNB and 22 with a diagnosis of atypical papilloma on CNB. Of the 16 cases of benign papilloma on CNB, subsequent excisional biopsy revealed benign papilloma in 15 and 1 case of papilloma with DCIS. Of the 22 cases of atypical papilloma on CNB, 10 were benign, 6 had ADH, and 6 were DCIS on excisional biopsy. Although limited data are available, papillary lesions should be excised based on the small but definite chance of atypia or cancer on excision.⁹¹

Radial Sclerosing Lesion

Cawson and colleagues found the sensitivity of SCNB for the identification of radial sclerosing lesion (radial scar) to be 85%.⁹⁹ In this series, 4 of 63 patients with radial scar sampled by SCNB had DCIS on excisional biopsy. The SCNB showed either ADH (3 cases) or DCIS (1 case). There were 29 of 42 excised radial scars with coexisting ADH that had an SCNB, and ADH was identified in 21 (72%).⁹⁹ Philpotts and associates found no malignancies at excision of 9 radial scars diagnosed by SCNB and suggested that surgical removal of these lesions following SCNB may not be necessary.⁹⁷ Based on a study of 157 excisional biopsies of nonpalpable lesions diagnosed as radial scar at CNB, Brenner and coworkers also concluded that surgical excision may not be required if there is no associated carcinoma or ADH, the biopsy includes at least 12 core specimens, and the histology correlates with the mammographic target lesion.¹⁰⁰

Fibroepithelial Lesion

Lesions classified as fibroadenoma by CNB need not be excised if the imaging findings are concordant with the diagnosis. Some fibroadenomas have cellular stroma, and their distinction from phyllodes tumor is not possible on CNB. Phyllodes tumors have ill-defined borders, stromal cells with vesicular nuclei, occasional mitoses, marked epithelial hyperplasia, and focal squamous metaplasia. The differential between a fibroadenoma and a benign and malignant phyllodes tumor is based on stromal overgrowth, stromal cellularity, stromal cell mitoses, and cytologic atypia. In short, a diagnosis of fibroepithelial lesion on CNB requires excision of the lesion to exclude a phyllodes tumor.⁷⁶

Columnar Cell Lesion

Columnar cell lesions are encountered with increased frequency in CNB procedures performed for microcalcifications (see Fig. 17–2). They are characterized by columnar epithelial cells lining the terminal duct lobular units and have been termed *columnar alteration with prominent snouts and secretions* (CAPSS) by Fraser and colleagues.¹⁰¹ In their series of excisional biopsies, the authors found that DCIS was twice as likely to be associated with CAPSS with atypia than with CAPSS without atypia. The DCIS is most commonly of low nuclear grade and of the cribriform-micropapillary architectural pattern. Furthermore, an association of CAPSS with LCIS and tubular carcinoma has been reported.¹⁰² However, the appropriate management of columnar cell lesions on CNB, in the absence of atypia, is still uncertain. In a review by Brogi and Tan, 23 columnar cell lesions on CNB underwent surgical biopsy.¹⁰³ There were 7 cases (30%) of carcinoma on excision; 4 were DCIS and 3 invasive carcinoma. None of the cases of columnar cell hyperplasia without atypia on CNB showed cancer on excisional biopsy. Based on these limited data, excision of columnar cell lesions without atypia on CNB is not recommended.

What are the potential pitfalls in the needle biopsy diagnosis of breast masses?

Potential errors in the use of diagnostic needle biopsy are numerous (Table 17–2). False-negative results in fine-needle breast biopsy range from 5% to 20%, which compares with

Table 17–2 Breast Fine-Needle Aspiration Biopsy: Cytologic Diagnoses

<i>Nondiagnostic:</i> Insufficient or poorly preserved cells
<i>Fibrocystic change:</i> Small cohesive ductal cells, apocrine cells, and myoepithelial nuclei Without proliferation With proliferation With proliferation and atypia
<i>Specific benign diagnoses</i> Fibroadenoma Papillary lesion Inflammatory lesion Fat necrosis
<i>Atypical:</i> Nuclear atypia in an otherwise benign pattern
<i>Suspicious:</i> Scanty cells with malignant nuclear features
<i>Malignant:</i> Monotonous population of enlarged, noncohesive ductal cells

the range of surgically missed localized lesions.¹⁰⁴ Breast cancer of low nuclear grade accounts for most false-negative diagnoses. This can be avoided in specific tumor types with characteristic features such as colloid carcinoma. Low-grade ductal cancers may be cytologically indistinguishable from lobular cancer, which tends to be of even lower cellularity. A core biopsy can confirm the diagnosis with certainty. Even one 18-gauge core biopsy may be sufficient to make a diagnosis of invasive carcinoma if a touch preparation of the tissue can be done and stained with Diff-Quik to ensure that a diagnosis of malignancy is made. The suspicious tissue is white and dense, and the core biopsy of a breast cancer tends to sink in the formalin container.

Noncomedo DCIS is composed of a uniform population of cells with small, uniform nuclei having small nucleoli. The cells are seen in tight three-dimensional clusters, occasionally admixed with some bare myoepithelial nuclei and benign cells. Unlike with comedo DCIS, which shows necrosis and atypia by FNAB, a diagnosis of cancer is difficult to make in instances of noncomedo DCIS, which mimics proliferative fibrocystic change by FNAB.

Failure to sample the lesion because of geographic miscalculation is the most common reason for false-negative FNAB samples. Because breast cancers are often deeper than they appear by palpation, some investigators have even proposed that all palpable masses be aspirated under ultrasound guidance.^{9,70} Sampling errors can occur with very small lesions and, paradoxically, with large masses. Tumors with extensive fibrosis can be of low cellularity and account for false-negative results. In cases of large scirrhous cancers, the needle biopsy should be taken from the periphery of the tumor, which is often the most cellular component. Also, using 27-gauge needles may yield more cells in scirrhous tumors. Multiple needle biopsy passes may reduce the number of false-negative breast needle biopsies. For FNAB, three passes are optimal; because of hemorrhage, there is no gain with additional passes.¹⁰⁵ In most cases, one or two well-performed aspirates will yield the diagnosis, especially when a specific diagnosis is rendered.

It is important to determine specimen adequacy to reduce the false-negative rate of breast fine-needle biopsy procedures. Insufficient samples are defined as those with less than seven clusters in the most cellular smears.⁴ Most unsatisfactory

specimens come from benign lesions.¹⁰⁶ Fewer passes may be needed to support a benign diagnosis in premenopausal women than in postmenopausal women, in whom epithelial atrophy accounts for few diagnostic cells. Zemba-Palko and coauthors undertook a 20-year retrospective review of 52 false-negative diagnoses among 1518 benign breast aspirates followed by surgery.²⁰ The authors found that among false-negative specimens aspirated from postmenopausal women, 20 or more epithelial cell groups per slide were seen. These findings suggest that among postmenopausal women, high cellularity alone may warrant an excisional biopsy. If the clinical-mammographic-cytologic diagnostic triplet is negative, the false-negative rate can be reduced from an average of 10% to less than 1%.¹⁰⁶ More specific diagnoses can be rendered with a core biopsy.^{48,50,61,65,70}

In experienced hands, the false-positive rate of fine-needle biopsy is less than 1%, comparable to intraoperative frozen section.¹⁰⁷ The false-positive rate can be reduced to less than 0.2% with judicious use of the triple-test method.¹⁰⁶ To minimize false-positive diagnoses, DeMay suggested that an unequivocal diagnosis of breast cancer should not be made in these instances: (1) in a poorly cellular aspirate; (2) in the absence of single, intact cells; (3) in the presence of bare bipolar nuclei; and (4) in the absence or paucity of atypia.²¹ Most false-positive diagnoses are due to interpretive errors. Many benign breast diseases mimic the patterns of cellularity and atypia of breast cancer. For example, cellular fibroadenoma, proliferative fibrocystic change with atypia, lactational change, and phyllodes tumor are of high cellularity and have conspicuous atypia. There can also be significant cellular atypia following radiation or in fat necrosis, and in the male, gynecomastia. In general, however, these smears are of low cellularity.

By FNAB, papillomas can show a monotonous population of dyshesive, columnar cells that occasionally, in the absence of myoepithelial nuclei, mimic cancer.¹⁰⁸ Therefore, cancer should not be definitively diagnosed in a neoplasm with a papillary pattern unless there is marked cytologic atypia. Even then, excisional biopsy must be done to confirm a diagnosis of papillary carcinoma.

Needle biopsy of a radial scar with adenosis can lead to a false-positive diagnosis. The gritty sensation of the mass, its suspicious spiculated appearance mammographically, and the aspirate are suggestive of tubular carcinoma. The FNAB may show small, angular, and tubular clusters like tubular carcinoma, although it tends to be less cellular, with more bare nuclei.¹⁰⁹ Sclerosing and microglandular adenosis, fibroadenomas, and lactational changes show microacinar structures that may be overinterpreted as carcinoma.

Overdiagnosis and underdiagnosis of cancer may occasionally be due to smearing and drying artifacts in FNAB specimens, and this is even more common in cases in which there is overlap of the cytologic features of benign and malignant lesions (i.e., the gray zone of breast cytology).³² Therefore, proper preparation of FNAB smears is imperative for accurate diagnoses to be made. When proper smearing techniques cannot be ensured, because of inexperience or a bloody sample, the Cytospin¹⁶ or ThinPrep methods of processing of the FNAB material should be employed.

Difficulty in SCNB interpretation occurs because of fragmentation, hemorrhage, and artifactual distortion of the tissue.¹¹⁰ These problems can lead to false-positive diagnoses in

some benign pseudoinvasive lesions such as florid sclerosing adenosis and radial scar. Distortion of ducts with DCIS may lead to a false impression of invasive cancer. A false-negative SCNB is most commonly due to sampling error. CNB is an invaluable method of determining invasion of a breast cancer preoperatively, although CNB can nonetheless underdiagnose invasive disease.

Histologically, there is significant interobserver variability in the diagnosis of proliferative breast lesions (including epithelial hyperplasia, atypical hyperplasia, and noncomedo DCIS) using standardized criteria.¹¹¹⁻¹¹³ SCNB is further limited in the diagnosis of these borderline epithelial lesions by its small sample size as well as by the distortion of the core tissue secondary to the procedure.¹¹⁰ However, a study by Collins and colleagues showed that there is a high level of diagnostic agreement (90% confidence interval) among pathologists in interpretation of CNB, comparable to that seen for open surgical biopsy.¹¹⁴

SUMMARY

No single test can diagnose all breast cancers.¹¹⁵ The accuracy of diagnosing breast cancer is 90% to 99% by FNAB, 85% to 90% by mammography, and 70% to 90% by physical examination.¹¹⁶ The diagnostic accuracy of physical examination, mammography, and FNAB together approaches 100% for palpable lesions,¹⁰¹ as does needle biopsy under stereotactic guidance¹¹⁷ and under ultrasound guidance for nonpalpable breast masses.⁷⁰

Ideally, needle biopsy procedures will be performed in specialized centers by physicians experienced in the multidisciplinary approach to ambulatory breast care. Symptomatic patients with palpable masses (referred or self-referred) should be treated systematically. A clinical assessment of the breast lesion and of the likelihood that the patient will return for follow-up should be made. If, in the opinion of the clinician, the patient is unlikely to return for follow-up, a mammogram or ultrasound, or both, should be performed and an excisional biopsy scheduled at the initial visit. If, in the opinion of the clinician, the patient is likely to return for follow-up, a mammogram or ultrasound, or both, should be performed, followed by needle aspiration or core needle biopsy. If the lesion is cystic, the procedure will be therapeutic. Malignant, suspicious, and atypical lesions should be excised surgically. If the radiologic, clinical, and cytologic impressions are benign and concordant, a follow-up visit should be scheduled. Discordant results will also require surgical excision.

For the diagnosis of nonpalpable breast lesions that are likely to be benign, ultrasound-guided or stereotactic-guided breast needle biopsies may be performed. Ideally, an aspiration biopsy can be done first, and core needle biopsy can then be performed on all lesions not shown to be cysts. Breast parenchyma with microcalcifications is best sampled stereotactically using the Mammotome core biopsy device. It should be emphasized that a negative needle breast biopsy cannot definitely exclude cancer. It is therefore imperative to follow all palpable and nonpalpable breast masses that are not surgically excised. If a malignant, atypical, or equivocal diagnosis is rendered by CNB, an excisional biopsy is required. Using these

clinical measures, breast cancer is rarely missed, whereas the number of open biopsies can be reduced by half.

Advanced Technology and Diagnostic Strategy for Breast Cancer

Elisa Rush Port and Elizabeth A. Morris

MAGNETIC RESONANCE IMAGING

What is the role of magnetic resonance imaging in breast cancer screening?

Breast cancer screening with modalities other than mammography is not condoned by any professional organizations or societies at this time. There are, however, emerging data that screening with magnetic resonance imaging (MRI) may benefit some high-risk patients.^{1–6} Most of these studies are composed of small groups of patients; nevertheless, MRI screening has been shown to demonstrate a 2% to 4% detection rate of cancers that are not seen on mammography. Most patients with MRI-detected cancers have small cancers, less than 2 cm, and negative axillary nodes (Fig. 18–1). Use of surrogate end points for survival, such as tumor size and nodal status, demonstrates that early cancers can be detected with MRI. It is uncertain, however, whether the detection of small cancers in a high-risk population will positively affect patient mortality because no randomized study has been performed to date. In general, when MRI screening is performed in high-risk populations, 20% to 30% of patients will require biopsy based on MRI findings, and 15% to 65% of patients who undergo biopsy will be found to have breast cancer.

Patient populations that are considered at high risk in the MRI screening trials have differed as well (Table 18–1). Some trials have performed screening on patients with high suspicion for harboring or proven *BRCA1* and *BRCA2* mutations. Other trials have examined patients with a broader range of risk factors, including those with a history of a previous breast cancer, a previous biopsy demonstrating lobular carcinoma in situ or atypical ductal hyperplasia, or a strong family history. Additional studies have used risk-assessment models, such as the Gail model, to determine high risk and have set entry criteria at varying levels. Despite these variations in patient selection for MRI screening, there is a surprising consistency of the data from multiple sites in different countries with different imaging techniques.

What is not consistent in these trials is the ability of MRI to detect ductal carcinoma in situ (DCIS); this may have to do

with imaging protocols, patient populations, and radiologic interpretation. Because DCIS is the earliest form of breast carcinoma, a screening test that detects this process is critical (Fig. 18–2). The detection of invasive carcinomas after cells have had access to the breast lymphatics and blood vessels may be too late to positively affect patient survival. Detection of DCIS on mammography has been shown to decrease mortality from breast cancer. It is assumed that DCIS detection by MRI will have a similar impact on mortality. The histologic grade and type of DCIS detected by MRI do not appear to differ from those for DCIS detected mammographically; therefore, it is entirely possible that the MRI-detected DCIS is just as important as that detected mammographically. In addition, the detection of DCIS is one of the advantages that MRI holds over ultrasound as an adjunct screening modality. Whereas ultrasound does not usually detect mammographic occult DCIS unless it presents as a mass, MRI is able to detect ductal enhancement or “clumped enhancement,” and the DCIS lesion does not need to manifest as a mass (Fig. 18–3).

Because of the significant rate of false positivity associated with MRI screening, patient selection should be judicious and individualized. A variety of factors should be incorporated in decision making, including risk assessment, breast density on mammography, patient age and menopausal status, and patient overall health.

The role of MRI screening in patients at increased risk for breast cancer remains to be fully defined, and MRI is typically not used for screening in the general population but may be a useful adjunct to further evaluate abnormalities identified on mammography and sonography.

What are the criteria for diagnosing a suspicious lesion?

MRI of the breast uses intravenous contrast to identify areas of increased blood flow; areas on MRI that are suspicious for malignancy will show increased contrast uptake. Although this increased blood flow is often due to increased angiogenesis, other factors are also probably at play because areas of DCIS that have not incited angiogenesis also display increased

Figure 18-1 This 51-year-old woman underwent right mastectomy 4 years ago for multifocal mixed invasive ductal and lobular carcinoma. Screening MRI was performed of the left breast. Fat-suppressed sagittal three-dimensional fast spoiled gradient-echo pulse sequence image (this and all subsequent images) following contrast administration demonstrates a 5-mm irregular heterogeneously enhancing mass (*arrow*) in the posterior breast. This finding was not seen on mammography or a directed ultrasound examination following MRI. MRI-guided needle localization yielded 5-mm invasive ductal carcinoma with negative sentinel node.

Figure 18-2 A 29-year-old woman with strong family history and prior benign biopsy yielding lobular carcinoma in situ (LCIS). Mammography demonstrated an extremely dense breast with no suspicious findings. Screening MRI examination following contrast injection demonstrates an irregular enhancing mass (*arrow*). Directed ultrasound to this region was negative, and the patient underwent MRI-guided needle localization yielding low-grade cribriform ductal carcinoma in situ (DCIS) and abundant LCIS.

Table 18-1 Summary of Magnetic Resonance Imaging Screening Studies Performed to Date

Studies	Institute	n	Mean Age (yr)	Risk*	No. of Biopsies (%)	PPV (%)	No. of Cancers Detected by MRI Only (%)	No. of DCIS Cases (%)
Kuhl et al. (2000) ¹	U Bonn	192	39	Gene carriers	14 (7%)	9/14 (64)	6/192 (3)	1/6 (17)

Leach (2002) ⁴⁵	UK	1236	<50	High risk	NS	NS	15/1236 (1)	NS
Podo (2002) ⁴⁶	Italy	105	46	Gene carriers	8 (8%)	7/8 (88)	7/105 (7)	3/7 (43)

*Risk factor for entrance into the screening study.

DCIS, ductal carcinoma in situ; MSKCC, Memorial Sloan-Kettering Cancer Center; NS, not studied; PPV, positive predictive value.

Figure 18-3 A 66-year-old woman with *BRCA1* gene underwent MRI that demonstrated clumped enhancement (*thin arrow*) adjacent to a previous lumpectomy site that is marked with a vitamin E capsule (*thick arrow*). Mammography demonstrated several calcifications that were initially not interpreted as suspicious. Because of the MRI findings, the calcifications were resected under stereotactic guidance, yielding high-grade micropapillary DCIS compatible with recurrent carcinoma. The patient subsequently underwent mastectomy.

Figure 18-4 A 44-year-old woman with known invasive lobular carcinoma. Note spiculation of mass.

contrast uptake.⁷⁻¹⁰ In addition, increased uptake alone is not the sole criterion for malignancy because both benign and malignant processes will exhibit increased contrast uptake. Thus, any lesion or condition that results in increased blood flow, such as hormonal stimulation, will generate increased uptake.¹¹

An international group of experts in breast MRI has developed a lexicon for interpretation to assist the radiologist in identifying features that may differentiate suspicious-appearing from benign-appearing lesions.¹²⁻¹⁴ These guidelines have been published by the American College of Radiology. The lexicon describes both morphologic and kinetic features of lesions. The morphology describes how the lesion “looks,” and kinetic analysis evaluates how the contrast is taken up and washed out by the lesion. In general, if the lesion morphology is suspicious, the lesion should undergo biopsy regardless of the kinetic information. The kinetic information is useful if a lesion is not clearly suspicious morphologically. In these cases, the addition of the kinetic information can prompt biopsy rather than close-interval follow-up. Therefore, both the morphology and the kinetics of a particular lesion can be used to facilitate decision making and provide complementary information about a lesion.

Morphologic features that are considered suspicious are spiculated margins (Fig. 18-4) and rim enhancement (Figs. 18-5 and 18-6). Clumped linear enhancement (Fig. 18-7) is suspicious for DCIS, particularly if in a segmental distribution, but can also be seen with benign histology. However, because the descriptor is suspicious, biopsy needs to be

Figure 18-5 A 28-year-old woman with palpable invasive ductal carcinoma demonstrating peripheral rim enhancement, a suspicious sign for malignancy.

performed. Interestingly, kinetic analysis appears not to be reliable in DCIS.

Irregular masses with heterogeneous internal enhancement can also be suspicious and warrant biopsy; however, the positive biopsy rate for these lesions is lower than that for masses without rim enhancement (Figs. 18-8 and 18-9). Well-circumscribed masses with nonenhancing internal septations are considered benign and characteristic of fibroadenoma (Fig. 18-10).

Figure 18-6 A 39-year-old woman with a palpable lump. MRI demonstrated central enhancement, a sign suspicious for malignancy. Pathology yielded invasive ductal carcinoma.

Figure 18-8 A 55-year-old woman with biopsy-proven invasive ductal carcinoma underwent preoperative MRI for extent of disease evaluation. MRI demonstrated an irregular heterogeneously enhancing mass.

Figure 18-7 A 67-year-old woman treated 2 years ago in the contralateral breast for invasive lobular carcinoma underwent screening breast MRI examination, which demonstrated segmental clumped enhancement along the 6-o'clock axis. Subsequent mammogram and ultrasound were negative. MRI-guided needle localization was performed, yielding high-grade extensive ductal carcinoma in situ, solid and cribriform types.

Figure 18-9 A 35-year-old woman with strong family history of breast cancer and a new palpable finding. MRI demonstrated an irregular mass with heterogeneous internal enhancement. Pathology yielded fibroadenoma.

Kinetic features that are suspicious for malignancy are rapid uptake and washout (Fig. 18-11). Because rapid uptake occurs in the first 2 minutes, imaging of the breast should be performed in less than 2 minutes. Washout of the contrast material occurs owing to arteriovenous

shunting, which is characteristic of malignant lesions. The problem is that most kinetic MRI features are not highly specific; benign lesions may have some MRI features typically associated with malignancy, and vice versa (Fig. 18-12).

Because overlap exists, it must be expected that there will be false-positive results if biopsies are performed on all lesions

Figure 18-10 A 48-year-old woman with palpable finding. MRI demonstrated a lobulated mass with homogeneous enhancement and nonenhancing internal septations. Subsequent ultrasound demonstrated the mass, and ultrasound core biopsy was performed, yielding fibroadenoma.

B

Figure 18-12 A 42-year-old woman with known right breast carcinoma presented for staging MRI examinations. *A*, In the contralateral left breast, a suspicious enhancing lesion was identified (arrow). Region of interest is manually placed over the enhancement. *B*, Curve is generated at three time points following contrast injection. Note the malignant features of the curve. Biopsy was performed that yielded radial scar, concordant with the imaging features. This demonstrates that although morphology and kinetic analysis are important in deciding which lesions are suspicious, there will be false-positive findings.

that demonstrate some suspicious characteristics on MRI. In many reported studies, the positive predictive value (PPV) of MRI biopsy is about 40%. Therefore, most findings prove to be benign. It should be noted that this value of 40% is found in a high-risk population of women—not a general

population. Therefore, if MRI were performed on the general population, it would be likely to result in a much lower and unacceptable PPV, one of the many reasons why MRI is not recommended for patients who are not at increased risk for breast cancer.

What is the procedure for biopsy of a suspicious lesion?

If a lesion is identified on MRI and is considered suspicious, a directed ultrasound over the area is often performed. The lesion's location may seem different when viewed with MRI than with ultrasound because MRI is performed with the patient in the prone position and ultrasound with the patient in the supine position. Thus, ultrasound should evaluate the suspected area widely. If ultrasound shows an abnormality corresponding to the MRI finding, ultrasound-guided biopsy can be performed easily. If no ultrasound correlate is found, the patient may need to undergo MRI-guided core biopsy or MRI-guided localization with surgical excision. The position of the lesion in the breast often dictates how biopsy will be performed. Deep, posterior, or subareolar lesions are not optimal candidates for MRI core biopsy, and thus localization with surgical excision is usually necessary.

If an abnormality for which biopsy is recommended is seen only on MRI (and not with ultrasound or mammography), the patient will be required to undergo a second MRI for localization at the time of biopsy. In addition, because currently there is no MRI equivalent of a "specimen radiograph," which is often obtained at the time of needle localization of mammographic findings to verify retrieval of the abnormality in question, a third, "postexcision" MRI may be indicated after surgery to verify that the abnormality has, in fact, been excised. When indicated, this is commonly performed as soon as possible following surgery. From a practical standpoint, the thorough evaluation and ultimate biopsy of an MRI lesion may become quite laborious and stressful, and the patient must fully understand the potential outcomes of having an MRI for breast cancer screening before one is obtained.

What is the role of magnetic resonance imaging in the evaluation of a patient with known breast cancer to evaluate the extent of disease?

MRI has been demonstrated in numerous studies to be the preferred method for detecting disease extent in the breast before surgery.¹⁵⁻²² MRI can detect additional unsuspected carcinoma in up to 33% of patients. This is particularly true in young patients, patients with dense breasts (Fig. 18-13), and patients with breasts that are difficult to examine. In specific cancer histologies such as invasive lobular carcinoma and invasive ductal carcinomas with an extensive intraductal component, MRI has been shown to provide additional information regarding extent of disease. For example, in one study from our institution, selected patients with newly diagnosed invasive lobular carcinoma, a tumor that is notoriously mammographically occult, underwent MRI screening to determine whether additional unsuspected disease could be detected. The findings demonstrated that 11 of 51 (22%) patients had an additional focus of cancer on the ipsilateral side, and 5 of 53 (9%) had a contralateral cancer not seen on mammography.²³ Interestingly, the MRI data appear to mimic known pathologic data, which have documented that most patients with suspected unifocal disease on clinical examination are found to have residual disease (usually multifocal and less

Figure 18-13 A 50-year-old woman with prior history of lobular carcinoma in situ underwent screening bilateral breast MRI. Mammography was negative, demonstrating dense breast tissue. MRI demonstrated two adjacent irregular masses in the superior breast that proved to represent several foci of invasive ductal carcinoma, pure tubular type, ranging in size from 0.2 to 0.7 cm.

likely multicentric). For this and other reasons, postoperative radiation is a mainstay of treatment.²⁴⁻²⁶

Because local failure rates of breast-conservation therapy from the pre-MRI era are much lower than the incidence of detection of additional disease seen on MRI, it is unclear whether the detection and excision of residual disease detected by MRI will actually affect recurrence rates (Fig. 18-14A and B). There may be considerable surgical overtreatment when MRI is used in the staging of breast cancer because these additional areas of carcinoma are now detected and are surgically excised, whereas, previously undetected, they would have been left in the breast and treated with radiation (Fig. 18-15A and B). The use of MRI for determining extent of disease may lead to an increase in the mastectomy rate in some areas of the country because the standard of care is surgical removal of all known or detected disease (Fig. 18-16).

Breast MRI can offer important information in the immediate postoperative period in patients with positive margins following an initial attempt at breast conservation.²⁷ It is particularly helpful in patients with carcinomas that were difficult to diagnose mammographically or tumors without abundant associated calcifications. The postoperative mammogram is excellent for diagnosing residual calcifications but fares poorly when trying to assess residual mass or residual uncalcified DCIS. In these settings, MRI is able to give information regarding the presence of bulky residual disease at the margin of resection or the presence of additional disease elsewhere in the breast, which may preclude an additional attempt at conservation.

The edges of a postoperative seroma cavity will enhance on MRI because of the presence of granulation tissue that begins to form once the breast parenchyma is cut. The thin rim of enhancement that occurs around the cavity happens

Figure 18-14 A 33-year-old woman presented with a palpable mass. *A*, Staging MRI examination demonstrated a palpable mass that is irregular and heterogeneous enhancement, compatible with invasive ductal carcinoma. *B*, Elsewhere in the breast in a separate quadrant, there was suspicious enhancement that represented a separate focus of invasive ductal carcinoma measuring less than 4 mm (*arrow*). The patient was treated with mastectomy, whereas without the MRI results she would have undergone conservation therapy and post-operative radiation therapy.

Figure 18-15 A 61-year-old woman with core biopsy–proven right breast invasive lobular cancer. *A*, Mammography demonstrated a spiculated mass in the 10-o'clock axis of the breast confirmed on MRI examination (*thin arrow*). *B*, Elsewhere in the breast on MRI examination in a separate quadrant is a small focus of enhancement (*thick arrow*) that represents multicentric carcinoma. This patient underwent mastectomy, and tumor was located throughout the lower outer quadrant.

uniformly in the postoperative state and is distinguishable from nodular or mass enhancement at the margin of resection, which represents significant and extensive residual disease (Fig. 18-17). The role of MRI, however, is not to assess for microscopic residual disease in those patients known to have positive margins and for whom additional surgery is planned.

What is the accuracy of magnetic resonance imaging?

To understand the sensitivity and specificity of MRI, one must appreciate what he or she is looking at on the MRI. All MRI examinations of the breast parenchyma use intravenous

Figure 18-16 A 48-year-old woman with extremely dense breasts underwent excision of calcifications, yielding ductal carcinoma in situ (DCIS) with positive margins. Postexcision mammogram failed to disclose any residual calcifications. MRI was performed 1 week after excision and demonstrated the seroma cavity with thin rim enhancement compatible with postoperative granulation tissue. MRI also demonstrated clumped enhancement surrounding the cavity (*thin arrow*) compatible with residual DCIS. In the lower aspect of the breast, additional clumped enhancement (*thick arrow*) was identified compatible with multicentric DCIS. Following confirmation of this impression, patient received mastectomy.

contrast agent (gadolinium chelate) to assess the inherent vascularity of lesions.²⁸ Therefore, we can accurately identify invasive carcinomas that have recruited blood vessels and that have greater microvessel density, leaky capillaries, and arteriovenous shunts. For this reason, the sensitivity for invasive carcinomas on MRI is extremely high. Invasive lobular carcinoma, which has a unique growth pattern as well as a less reliable production of vascular endothelial growth factor (VEGF), may rarely be undetectable on MRI. Well-differentiated or slowly growing tumors may not have as robust a vascular supply and therefore may not take up the contrast agent as avidly.

Benign lesions can also have increased vessel density but usually do not have the leaky capillaries or arteriovenous shunting seen with malignant lesions; thus, contrast does not usually “wash out” of benign lesions, as is usually seen in malignancy. Even benign breast parenchyma can enhance, particularly at certain phases of the menstrual cycle, because estrogen has been shown to increase capillary leakiness (Fig. 18-18). Thus, the optimal time for obtaining an MRI in a menstruating woman is during the most quiescent phase of the menstrual cycle, between days 7 and 14 after the last menstrual period (Fig. 18-19).

Enhancement alone is not the only criterion for suspicion; other features of benign and malignant lesions can help discriminate them. A model based on the American College of Radiology Breast Imaging Reporting and Data System (BI-RADS) lexicon is available for MRI. In numerous studies, the positive biopsy rate for MRI is no worse than and is usually even better than the positive biopsy rate for mammography. In general, positive biopsy rates range from 25% to 65%. The accepted positive biopsy rate for mammography is in the range of 25% to 35%.²⁹⁻³¹

A

B

Figure 18-17 Rim enhancement from recent surgery is typically distinguishable from significant amount of residual disease. **A**, A 50-year-old woman with large palpable breast mass status post surgery with positive margins. MRI demonstrated thin enhancement around the postoperative cavity (*arrows*). **B**, A 42-year-old woman underwent an excisional biopsy yielding invasive lobular carcinoma extending to the margins, and MRI was performed to assess residual disease. A large postoperative seroma cavity with an air-fluid level is seen, compatible with the postoperative state. In addition, residual mass is noted along the posterior margin of the biopsy cavity and extends inferiorly toward the nipple (*arrows*). Mastectomy confirmed the presence of extensive residual invasive lobular carcinoma.

The sensitivity of DCIS detection on MRI has been controversial in the past. When using low-resolution techniques, DCIS detection was low. However, with improvements in the hardware and software used to perform MRI, the resolution has improved over time, and it has become abundantly clear that MRI is able to detect DCIS. The sensitivity of detection is again variable when multiple series are examined. However, it has been demonstrated that with high-resolution techniques, sensitivity can approach 85%. MRI does not replace

mammography because some lesions, particularly DCIS, are calcified and are not detected on MRI.³²

What is the clinical approach to magnetic resonance imaging findings?

Given the multiple and emerging applications of MRI technology, clinical decision making that incorporates MRI findings can be complex (Fig. 18–20).

Patients often indicate that undergoing different screenings for high-risk breast cancer at different intervals (i.e., mammogram every year, staggered with sonography or MRI at alternate 6-month periods) provides an added sense of security and reassurance that they are getting “checked” in some way at least every 6 months. At Memorial Sloan-Kettering Cancer Center, however, our experience has been that different imaging modalities complement each other and that information is most useful when tests are performed synchronously. Thus, if high-risk screening with MRI is performed, we most often recommend that it be done within about 1 month of the yearly mammogram. This way, if a new finding is identified on the MRI, it can be compared with the recent mammogram; the physician would most likely want to obtain a new mammogram if it had been done 6 months earlier.

Findings identified on MRI can vary from minimal and scattered areas of nonspecific enhancement to a highly suspicious mass, and follow-up of MRI findings can thus range from performing a follow-up examination to a recommendation for biopsy. Because MRI contrast enhancement is related to breast tissue blood flow, MRI can vary with the menstrual cycle in premenopausal women. When obtaining a breast MRI, timing the examination with the most quiescent phase of the menstrual cycle, 7 to 14 days after the last period, can reduce the risk for false-positive findings related to hormonal stimulation.

When a suspicious lesion is seen on MRI but a recent mammogram shows no findings, often a targeted sonogram is

Figure 18–18 A 50-year-old woman with strong family history underwent screening MRI examination. Patchy enhancement in the superior breast was noted and thought to represent benign hormonal enhancement, which was confirmed at follow-up MRI examination.

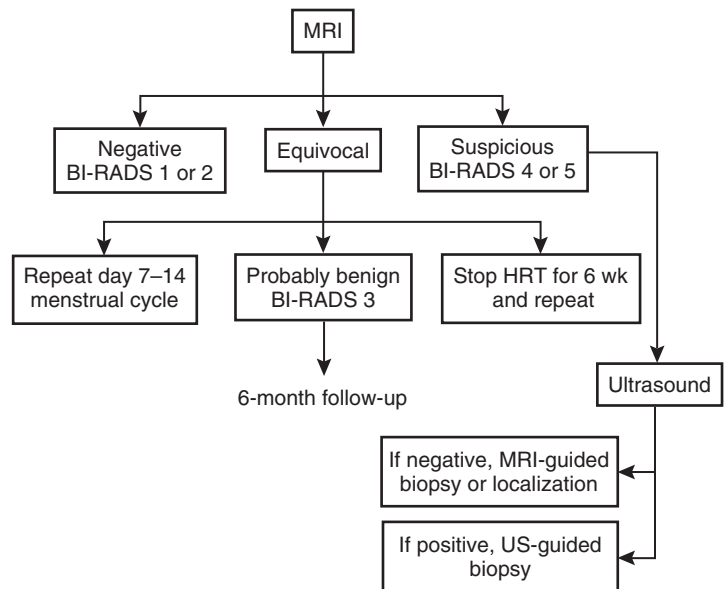

A

B

Figure 18–19 A 43-year-old woman with a history of stage II breast cancer underwent screening MRI examination. *A*, Patchy enhancement was noted in the superior breast (*arrow*). *B*, This disappeared on the subsequent follow-up examination, probably owing to hormonal changes.

Figure 18–20 Algorithm for clinical decision making based on MRI results. BI-RADS, American College of Radiology Breast Imaging Reporting and Data System; HRT, hormone replacement therapy.

obtained. In our experience, sonography will visualize 24% of abnormalities first identified by screening MRI. If the lesion is visualized by sonography, the patient can undergo the more expeditious procedure of either sonogram-guided core biopsy or surgical excision with ultrasound-guided localization. If the sonogram fails to demonstrate the MRI abnormality, biopsy is typically still pursued and is performed using MRI as a guide. Both MRI-guided core biopsy and MRI localization with surgical excision are feasible options for MRI abnormalities. If multiple abnormalities or one widespread area is identified, often surgical excision with localization is recommended because surgery provides a better opportunity for more extensive sampling.

In our study of MRI screening in 367 women at high risk for developing breast cancer, 59 (15%) underwent biopsy for a suspicious lesion. Of these 59 patients, 50 (85%) had MRI-guided localization, whereas 9 (15%) had sonographically guided biopsies. A total of 14 of the 59 women (24%) who underwent biopsy were found to have cancer. The likelihood of finding cancer when a sonographic correlate was identified (2 of 9 patients; 22%) did not differ significantly from when the lesion was seen only on MRI (12 of 59 patients; 24%).⁶

Performing MRI-guided needle localization requires the patient to undergo another MRI on the day of surgery so that the lesion can be visualized and localized. One or more wires made of titanium, and thus magnetically inert, are inserted by the radiologist into the area or areas in question. A standard mammogram is obtained so that the surgeon can estimate the path and depth of the wire within the breast. Surgical excision is performed in the standard fashion, targeting the area marked by the wire. Because MRI abnormalities are identified by blood flow, once surgical excision is performed and blood flow is severed, the lesion within the removed specimen can no longer be identified. Thus, there is no method for performing a specimen radiograph using MRI. Rather, if a question exists regarding adequate sampling, a postexcision MRI can be performed on the operated breast to verify removal of the area in question.

When MRI is performed for contralateral screening in a patient with a known diagnosis of cancer (Figs. 18–21 and

18–22), identified contralateral abnormalities can undergo biopsy at the time of surgery for the known cancer, using the same localizing techniques. Alternatively, patients can undergo either ultrasound- or MRI-guided core biopsy preoperatively if amenable.

Often, MRI is performed to evaluate the extent of disease or multicentricity in a breast with a known cancer. Importantly, as with other imaging modalities, the decision to perform a mastectomy should not be based on MRI findings alone because false-positive findings are common.

POSITRON EMISSION TOMOGRAPHY

What is the role of positron emission tomography scanning in the detection of breast cancer?

Positron emission tomography (PET) is one of the most promising imaging modalities. In October 2002, the Center for Medicare and Medicaid Services approved expanded coverage for the use of PET scanning in patients with breast cancer; however, appropriate applications relating to breast cancer have yet to be fully defined. PET scanning is most commonly performed using ¹⁸F-fluorodeoxyglucose (FDG), a radiolabeled glucose analogue, and is based on the finding that cells with high metabolic rates, such as tumor cells, consume more glucose. Thus, ¹⁸F-FDG uptake is more avid than in normal tissue.³³ In addition, FDG is metabolized differently from glucose, getting trapped in cells after it is consumed. Therefore, tumor cells preferentially usurp FDG, which is then trapped within the cell, thereby facilitating imaging of tumor foci with nuclear medicine imaging techniques. The ability of PET scanning to identify primary breast cancer lesions has been extensively studied and documented.^{34,35} Although PET scanning can clearly differentiate breast tumors from normal tissue with high levels of specificity, its ability to detect smaller lesions is limited. In one study investigating breast

Figure 18-21 A 53-year-old woman with history of lobular carcinoma in situ had new calcifications in the right breast that were excised, yielding ductal carcinoma in situ. MRI was performed for ipsilateral staging and contralateral screening. *A*, Residual clumped enhancement was noted surrounding the clip (seen as signal void) that was placed following right breast stereotactic biopsy for calcifications (*thin arrow*). *B*, Contralateral screening demonstrated a spiculated mass (*thick arrow*) in the left breast that proved to represent an invasive ductal carcinoma, not detected on mammography.

Figure 18-22 A 52-year-old woman with new spiculated mass in the right breast on mammography. Ultrasound-guided core biopsy yielded invasive lobular carcinoma. MRI was performed for ipsilateral staging and contralateral screening. *A*, In the right breast, a unifocal spiculated mass compatible with the known diagnosis of invasive lobular carcinoma was seen. *B*, In the left breast, clumped enhancement in the central breast was proved to represent extensive ductal carcinoma in situ.

imaging with PET, sensitivity for primary tumor detection was 92% for T2 lesions but only 68% for T1 lesions.³⁶ Given that mammography and MRI can consistently identify lesions that are microscopic, PET scanning pales in terms of its limit of resolution based on size criteria, and thus PET technology, as it exists currently, is not useful as a screening modality for the detection of primary breast cancer lesions. In addition to the possibility of not detecting breast tumors that are small, there is evidence that some histologic types of breast cancer, such as invasive lobular cancers, may be less FDG avid, making them more likely to go undetected by PET scanning.^{36,37}

For these reasons, PET scanning is not a standard modality for breast cancer screening.

What is the role of positron emission tomography scanning in the evaluation of a patient with breast cancer?

PET scanning is being investigated as a modality to determine extent of disease in patients with known breast cancer or those suspected of harboring a recurrence. Studies have analyzed

Figure 18–23 Fluorodeoxyglucose positron emission tomography (FDG-PET) scan demonstrating uptake by breast cancer and ipsilateral axillary nodes representing metastatic disease.

the accuracy of PET scanning in demonstrating the presence of lymph node metastases with the goal of obviating removal of negative nodes and the associated morbidity (Fig. 18–23). Although PET scanning has shown high specificity for lymph node metastases, the detection of lymph node metastases with PET seems to be a function of size and amount of tumor burden in lymph nodes, as is seen with primary lesions. Thus, micrometastatic disease in lymph nodes is not detectable by PET imaging. Sentinel lymph node biopsy, in which even isolated tumor cells can be detected pathologically in lymph nodes, is a new standard of care in breast cancer surgery. Because PET scanning currently has no ability to detect such microscopic amounts of disease, the role of PET scanning in staging the axilla is quite limited.^{38,39}

PET scanning has been demonstrated to effectively image internal mammary nodal disease in breast cancer as well as other tumor types. PET provides increased specificity over computed tomography (CT) scanning for imaging nodal disease because CT relies only on size estimates to define suspicious nodes, with less than 1 cm being the generally accepted cutoff point for normal size. PET can provide more specific metabolic information that can distinguish benign from malignant adenopathy with a high degree of reliability. However, the assessment of internal mammary nodes is typically not part of standard treatment because previous work has demonstrated that extended radical mastectomy, which incorporates dissection of the internal mammary node chain, does not confer survival benefit over standard modified radical mastectomy. Yet, the detection of metastatic disease in internal mammary nodes could affect adjuvant treatment decisions by resulting in the addition of either chemotherapy or widened radiation fields, particularly if axillary lymph nodes are negative and a patient would not have received adjuvant treatment otherwise. To date, the role of PET scanning to investigate internal mammary node status should be considered exploratory.

There is no standard practice or set of recommendations for evaluating extent of systemic disease in patients with breast cancer. Practice patterns can vary widely, with

physicians having different thresholds for obtaining different imaging studies. The yield of discovering foci of metastatic disease is quite low in patients with small primary tumors and clinically negative nodes who are asymptomatic (<1%). However, the yield will be higher in any patient with new symptoms possibly related to the development of metastatic disease, palpable adenopathy, or larger tumors (20% to 30%). In such patients, imaging tests, including PET scanning, may be helpful in determining whether identifiable metastatic disease is present. Definitive findings of metastatic spread could substantially affect the decision to perform surgery and other factors related to patient management.

Because the most likely sites of development of systemic disease include bone, brain, lung, and liver, an extent of disease evaluation may include a CT scan of the chest, abdomen, and pelvis and a bone scan. PET scanning has been shown to be useful in identifying abnormalities in bone as well as viscera and may be complementary to standard imaging modalities.⁴⁰ PET may also be more useful in specific clinical scenarios such as when recurrence is suspected. Scar tissue and radiation changes can be difficult to image, and the information that PET scanning provides regarding the presence of hypermetabolic foci may raise or lower the suspicion for the presence of disease. As with other imaging modalities, it should be noted that a variety of different scenarios can lead to either false-positive or false-negative results on PET. The presence of infection or autoimmune disease can cause increased FDG uptake and thus lead to false-positive results. Conversely, PET can miss small foci of disease and cannot be relied on to consistently pick up areas with minimal disease. Thus, as with all imaging modalities, definitive treatment decisions should not be based on PET scan results alone.

What are novel tracers?

The use of fluorodeoxyglucose in detecting tumor is based on the premise that glucose uptake by neoplastic lesions is greater than in surrounding normal tissue. Although the detection of tumor deposits makes PET useful for many reasons, the metabolic property that makes tumors glucose avid is nonspecific relative to tumor type. As a result, much current work is being devoted to identifying novel tracers that are receptor specific and thus have applications for specific tumor types. The development of such technology holds promise for detection, assessment of response to systemic therapy, and even treatment because a radiolabeled ligand that is tumor specific could be developed not only to identify and visualize tumor but also to destroy it.

Some studies have demonstrated the ability of radiolabeled estrogen molecules to image estrogen receptor–positive tumors, and serial scanning after tamoxifen treatment may be useful in assessing response to treatment.⁴¹ At this time the use of tumor-specific ligands in combination with PET scanning is investigational only, but it holds promise for future applications.

What is fusion imaging?

Fusion imaging technology is based on the concept that combining and superimposing two different imaging

modalities with different strengths provides better information. Currently, PET/CT is performed at our institution. Although PET provides important biologic and metabolic information, often lesions seen on PET cannot be localized to the specific organ or site of involvement. Superimposing CT images allows foci of uptake on PET to be localized to the site of interest. Currently a biopsy cannot be performed based on PET images alone, but a suspicious site seen on PET and localized with CT can then undergo percutaneous needle biopsy.

Other types of fusion imaging, combining MRI with PET, for example, hold promise for potential future applications but are not used as part of the current standard of care.

Evaluating and Staging the Patient with Breast Cancer

Tara L. Huston and Michael P. Osborne

Why stage breast cancer?

Breast cancer, similar to other malignancies, is staged in order to classify groups of patients with similar outcomes and delineate treatment approaches based on the extent of disease. Using a uniform system ensures accuracy and consistency and provides a basis for clinical as well as basic science research. Patient outcomes in studies both nationally and internationally can then be effectively compared. With separate strata of disease defined by the staging system, the efficiency of specific treatments can be analyzed as well.

How did the current staging system develop?

One of the earliest widely used staging systems for breast cancer patients was the Manchester classification, first presented in 1940. It consisted of four stages and was based on the local extent of the primary tumor in conjunction with the presence, absence, and mobility of involved axillary lymph nodes. This system could only be used preoperatively and afforded prognostic survival information.¹ In 1943, Haagensen and Stout published another set of criteria, the Columbia staging system, which defined whether a patient was appropriate for surgery. Tumor size was not a factor in their system, but other grave signs of breast cancer, including skin ulceration, edema, and tumor fixation, were important.² The Columbia clinical classification of breast cancer was a precursor for the current staging system.

The TNM classification system, shorthand for primary tumor (T), regional nodes (N), and distant metastasis (M), was first introduced in 1958 by the International Union against Cancer (UICC). Until this time, all staging was performed on a clinical basis; thus, TNM was the first system for breast cancer staging based on histopathologic grounds. Independent from the UICC, the American Joint Committee on Cancer (AJCC) published a similar series of site-specific staging systems between 1962 and 1974. The AJCC published the first edition of their manual for the staging of cancer in 1977 based on the existing state of knowledge about clinical outcomes of breast cancer. Every few years since that time, the

AJCC has released an updated version of the manual.^{3,4} It was not until the late 1980s that the two bodies agreed on a single staging system.^{5,6}

Significant changes in the understanding of patients with breast cancer have furthered the development of the TNM system. The most current system, published in 2002, is found in the sixth edition of the *AJCC Cancer Staging Manual*.⁷ It relies strongly on pathologic evaluation of the patient, rather than clinical evaluation, more precisely stratifying the patient and providing improved prognostic information. With each upgrade the TNM classification has become more complicated. Its accuracy, however, has increased as well, ideally preventing both undertreatment and overtreatment.

What are the components of the TNM staging system?

Evaluation of the primary tumor and the regional lymph nodes and a search for distant metastases is prerequisite to staging a patient. Therefore, surgical resection of the primary tumor, sampling of the axillary nodes, and knowledge of metastatic disease are needed before beginning treatment.

How is tumor size evaluated and recorded?

When assessing the size of the primary tumor, only the invasive component is considered.⁸ Determination either by palpation or by imaging using mammography, ultrasonography, or magnetic resonance imaging (MRI) is considered clinical classification. Determination surgically by evaluation of the resected specimen is considered pathologic classification. The maximum diameter of the primary tumor has always been an integral part of staging, even in the earliest classification systems, and has been shown to correlate with the risk for lymph node metastasis as well as with prognosis.⁹⁻¹¹ A positive correlation has been documented between increasing size of the primary tumor and the greater likelihood of disease in the ipsilateral axillary lymph nodes.¹²

With the increased incidence of cancers found on screening mammography, the average size of breast cancer at the time of

diagnosis has decreased.¹³ Some of these small cancers could be effectively treated with minimal local therapy; certain cancers, however, are inherently more malignant. The varied outcomes among this group of small cancers created a need for an enhanced system of delineation at the lower levels of the staging system.⁴

The current staging system for primary tumor size, as published in the *AJCC Cancer Staging Manual*, 6th edition, is shown in Table 19–1.⁷ If the primary tumor either cannot be assessed or involves the resection margin, it is designated TX. If the patient has presented with axillary lymph node metastases and there is no evidence of a primary tumor, it is designated T0. Carcinoma in situ now holds a place, with ductal carcinoma in situ referred to as Tis (DCIS) and lobular carcinoma in situ as Tis (LCIS). Paget's disease of the nipple without an underlying tumor is designated Tis (Paget). Paget's disease of the nipple with an underlying tumor falls in the category size of that tumor. T1 tumors are less than 2 cm in their maximum diameter. A T1 mic tumor demonstrates microinvasion of 0.1 cm or less. T1 tumors are further subdivided into T1a if between 0.1 cm and 0.5 cm, T1b if greater than 0.5 cm up to 1.0 cm, and T1c if greater

than 1 cm but less than 2 cm. T2 tumors encompass a group of malignancies whose maximum diameter is greater than 2 cm yet less than 5 cm. T3 lesions are greater than 5 cm in their maximum diameter. Any tumor directly extending to the chest wall or skin is categorized as T4. T4 is further classified into T4a if the mass extends to the chest wall, not including the pectoralis muscle; or T4b if there is edema (including peau d'orange), ulceration of the breast skin, or satellite nodules confined to the same breast. A combination of T4a and T4b is considered T4c. Finally, inflammatory breast carcinoma is automatically T4d. If a tumor is staged pathologically, as opposed to clinically, the letter *p* precedes the T designation.

In some cases, the tumor size must be determined by consensus. If a patient has synchronous lesions in the same breast, then the T stage is based on the larger of the two. Multifocal cancers have a higher likelihood of lymph node metastases, owing to a greater tumor burden; thus, it is important to recognize this multifocality when assigning a single stage in one breast even when there are two lesions.¹² Finally, if synchronous, bilateral lesions are present, each breast is staged independently.¹⁴

Table 19–1 American Joint Committee on Cancer Staging System for Patients with Breast Cancer

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma <i>in situ</i>
	Tis (DCIS) Ductal carcinoma <i>in situ</i>
	Tis (LCIS) Lobular carcinoma <i>in situ</i>
	Tis (Paget's) Paget's disease of the nipple with no tumor
T1	Tumor 2 cm or less in greatest dimension
	T1mic Microinvasion 0.1 cm or less in greatest dimension
	T1a 0.1 to 0.5 cm
	T1b >0.5 to 1 cm
	T1c >1 to 2 cm
T2	Tumor >2 to 5 cm in greatest dimension
T3	Tumor >5 cm in greatest dimension
T4	Tumor of any size with direct extension to chest wall or skin
	T4a Extension to chest wall, not including pectoralis muscle
	T4b Edema (including peau d'orange) or ulceration of the skin of the breast, or satellite skin nodules confined to the same breast
	T4c T4a and T4b
	T4d Inflammatory carcinoma
Regional Nodes (N)	
NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastasis
N1	Metastasis in movable ipsilateral axillary lymph nodes
N2	Metastasis in ipsilateral axillary lymph nodes fixed or matted, or in clinically apparent ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
	N2a Metastasis in ipsilateral axillary lymph nodes fixed to one another or to other structures
	N2b Metastasis only in clinically apparent ipsilateral internal mammary nodes and in the absence of clinically evident axillary lymph node metastasis
N3	Metastasis in ipsilateral infraclavicular lymph node(s) with or without axillary lymph node involvement, or in clinically apparent ipsilateral internal mammary node(s) nodes in the presence of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
	N3a Metastasis in ipsilateral infraclavicular lymph node(s) and axillary lymph node(s)
	N3b Metastasis in ipsilateral internal mammary lymph node(s) nodes and axillary lymph node(s)
	N3c Metastasis in ipsilateral supraclavicular lymph node(s)
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

How is the lymph node status evaluated and documented?

The presence or absence of malignant disease in the axilla has long been recognized as one of the most significant prognostic indicators for patients with breast cancer.^{15,16} To assess the axillary lymph nodes accurately, they must be surgically resected and examined pathologically. This can be performed either by sentinel lymph node (SLN) biopsy or by full axillary dissection.

SLN biopsy has replaced the traditional axillary dissection for assessment of axillary nodal disease in most patients with breast cancer. Axillary dissection is costly, carries a significant morbidity in terms of lymphedema and nerve damage, and is no longer necessary solely to provide staging information. It is generally reserved for patients with documented axillary disease.

The concept of the SLN was introduced in 1994 when Giuliano and colleagues published a landmark paper demonstrating that intraoperative lymphatic mapping could accurately identify the sentinel node, the lymph node most likely to contain breast cancer metastases, and that this technique could improve staging accuracy.¹⁷ The breast drains primarily through sentinel nodes before spreading to other nodes; therefore, detecting, removing, and sampling of these nodes reflects the status of the axilla in more than 95% of cases.¹⁸ Because the pathologist has less tissue to examine, it is also possible to spend more time carefully studying the sentinel nodes in order to identify metastases.¹⁹ Analysis of multiple sections, use of immunohistochemical (IHC) staining,

and molecular biologic detection of sentinel nodes increases the accuracy of axillary staging and identifies significantly more patients with lymph nodes metastases, especially micrometastases.²⁰ The rise in popularity of the SLN biopsy has led to the more frequent detection of minute foci of tumor, the clinical significance of which foci remains largely unknown.⁴

Two of the major revisions in the 2002 staging guidelines are related to the detection and description of lymph node micrometastases and to the location and number of lymph node metastases. Micrometastases are now differentiated from isolated tumor cells on the basis of size. Metastatic lesions smaller than 0.2 mm are now classified as isolated tumor cells, whereas a micrometastasis is defined as a tumor deposit of greater than 0.2 mm but less than 2.0 mm. Metastatic cells seen with hematoxylin and eosin staining are considered to be of equal importance to those discovered using IHC because it is generally accepted that the size of a lesion is more closely related to its clinical significance than is the way in which it was detected.⁴

Identifiers are used to document the use of SLN biopsy versus axillary dissection as well as the employment of IHC or molecular techniques. The classification is followed by i(+) if the lesion was detected by IHC or by i(-) if it was not detected by IHC; and by mol(+) if the pathologist is using reverse transcriptase polymerase chain reaction (RT-PCR) or by mol(-) if the lesion is undetectable by RT-PCR. If the staging classification is based on SLN biopsy and not axillary dissection, the N is followed by (sn), which stands for sentinel node.⁷ See Table 19-2 for a detailed description of the regional pathologic lymph node status.

Table 19-2 Pathologic Classification of Breast Cancer

Primary Tumor (pT)	
See clinical classification in Table 19-1	
Regional Nodes (pN)	
pNX	Regional lymph nodes cannot be assessed (not removed or previously removed)
pN0	No regional lymph node metastasis histologically, no additional information for isolated tumor cells
pN0(i-)	No regional lymph node metastasis histologically, negative IHC
pN0(i+)	No regional lymph node metastasis histologically, positive IHC, no IHC cluster >0.2 mm
pN0(mol-)	No regional lymph node metastasis histologically, negative molecular findings (RT-PCR)
pN0(mol+)	No regional lymph node metastasis histologically, positive molecular findings (RT-PCR)
pN1	Metastasis in 1 to 3 axillary lymph nodes and/or internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent
pN1mi	Micrometastasis >0.2 mm to 2 mm
pN1a	Metastasis in 1 to 3 axillary lymph nodes
pN1b	Metastasis in internal mammary nodes detected by sentinel lymph node dissection but not clinically apparent
pN1c	Metastasis in 1 to 3 axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent
pN2	Metastasis in 4 to 9 axillary lymph nodes, or in clinically apparent internal mammary lymph nodes in the <i>absence</i> of axillary lymph node metastasis
pN2a	Metastasis in 4 to 9 axillary lymph nodes (at least one tumor deposit >2.0mm)
pN2b	Metastasis in clinically apparent internal mammary lymph nodes in the <i>absence</i> of axillary lymph node metastasis
pN3	Metastasis in 10 or more axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically apparent ipsilateral internal mammary lymph nodes in the <i>presence</i> of 1 or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral supraclavicular lymph nodes
pN3a	Metastasis in 10 or more axillary lymph nodes (at least one tumor deposit >2.0 mm), or metastasis to the infraclavicular lymph nodes
pN3b	Metastasis in clinically apparent ipsilateral internal mammary lymph nodes in the presence of 1 or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent
pN3c	Metastasis in ipsilateral supraclavicular lymph nodes

The number as well as the location of lymph nodes is critical to accurate staging. A high number of involved lymph nodes is a strong negative prognostic factor.²¹ Patients with 1 to 3 positive axillary lymph nodes are classified as pN1a, patients with 4 to 9 positive axillary nodes are considered pN2a, and patients with 10 or more positive axillary nodes are considered pN3a. Metastasis to the infraclavicular lymph nodes is a significant adverse prognostic feature; thus, these nodes are also considered N3a.²²

How are the internal mammary lymph nodes classified?

There is a synergistic effect on survival between the internal mammary (IM) and axillary lymph nodes, with disease to both nodal basins portending a poor prognosis. Additionally, the size of the metastatic deposit within the node is associated with survival.²³ IM nodes are classified based on how they were detected—SLN biopsy versus clinical exam or imaging—as well as on the number of positive axillary nodes. In a patient without axillary disease, IM lesions found with IHC are considered pN1b, whereas those detected clinically or radiographically are pN2b. In a patient with one to three involved axillary lymph nodes, IM lesions found with IHC are considered pN1c, whereas those detected clinically or radiographically are pN3b. Finally, all IM lesions associated with four or more involved axillary lymph nodes are considered pN3b.

How are the supraclavicular lymph nodes classified?

Historically, a dismal prognosis has been associated with disease in the supraclavicular lymph nodes (SCLNs). This has resulted in the M1 classification for these involved nodes in the past. However, recent data suggest that women with locally advanced breast cancer (LABC) and positive ipsilateral SCLN, but no other metastatic disease, have survival rates comparable to those seen in LABC patients without metastatic disease, and considerably better than those with stage IV disease who have metastases at distant sites.²⁴ Therefore, SCLN metastases have been reclassified as N3c or pN3c and are now placed in stage IIIC.

What are the five stages created with the TNM groupings?

Stage 0, defined as TisN0M0, affords a 10-year survival rate of 95%. Stage I is T1N0M0 and has an approximately 88% 5-year survival rate. Stage IIA is T0N1M0, T1N1M0, or T2N0M0 and has an overall survival rate of 81% at 10 years. Stage IIB can consist of T2N1M0 or T3N0M0 and has an overall survival rate of 70% at 10 years. Stage IIIA contains many permutations, including T0N2M0, T1N2M0, T2N2M0, T3N1M0, and T3N2M0, averaging a 59% 10-year overall survival rate. Stage IIIB encompasses all T4 tumors with N1 or N2 status that have not yet metastasized and demonstrates a 36% 10-year overall survival rate. Stage IIIC is any T stage combined with N3 status and also gives about a 36% 10-year overall survival

Table 19–3 Stage Groupings for Patients with Breast Cancer According to the TNM Classification

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIA	T0	N1	M0
	T1	N1	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T0	N2	M0
	T1	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
Stage IIIB	T4	N0	M0
	T4	N1	M0
	T4	N2	M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any N	M1

rate. Evidence of distant metastases indicates stage IV and has an approximately 18% 10-year overall survival rate.^{7,25} Table 19–3 lists the stages as determined by the TNM groupings.

Why is histologic grade not a factor in staging?

Even though the morphologic appearance of breast cancer and its degree of malignancy are likely to be related, histologic grading remains very subjective, and developing a uniform system to incorporate into staging has not been possible. Unfortunately, the available studies that link histologic grade to outcome in early breast cancers are both difficult to assess and variable in results. At this time, sufficient data are lacking to include this factor in a uniform staging system.⁴

Although histologic grade is not factored into the staging, all invasive breast carcinomas should be graded. The Nottingham combined histologic grade (Elston and Ellis modification of the Bloom-Richardson grading system) is the most commonly used.²⁶ Histologic grade is determined by assessing the tumor's morphologic features, including tubule formation, nuclear pleomorphism, and mitotic count. Each factor is then rated between favorable (1 point) and unfavorable (3 points). The scores for all three categories are added. Grade 1 is a combined score of three to five, grade 2 is a score of six or seven, and grade 3 is a score of eight or nine.⁷

Do all patients need to undergo a complete workup for distant disease?

The prevalence of detectable metastases at initial diagnosis is very low in the early stages of breast cancer. Nevertheless, their presence does significantly alter the course of treatment. Thus, it is important to distinguish patients with early distant disease. Unfortunately, widespread use of the entire gamut of

Table 19–4 Sensitivity, Specificity, and Positive Predictive Value of Radiologic Staging Tests in Evaluating Asymptomatic Patients with Breast Cancer

	Sensitivity	Specificity	Positive Predictive Value
Chest radiograph	0.31	0.996	0.44
Bone radiograph	0.35	0.986	0.32
Bone scan	0.48	0.995	0.15
Liver ultrasound	0.29	0.995	0.33

From Ciatto S, Pacini P, Azzini V, et al. Preoperative staging of primary breast cancer: A multicentric study. *Cancer* 1988;61(5):1040.

staging tests is inaccurate, expensive, time-consuming, and anxiety provoking. Ideally, the subset of patients most likely to develop distant disease needs to be identified, allowing exhaustive workups to be performed appropriately. Patients with stage III disease merit a comprehensive workup.

The three most common sites of breast cancer metastases are the bone, lung, and liver, in that order. A large study encompassing more than 3600 women with breast cancer who underwent preoperative metastatic workup with chest radiography, bone radiography or scintigraphy, and liver echography or scintigraphy revealed an abysmally low detection rate. It was concluded that this pattern of testing should not be recommended for asymptomatic women because of poor sensitivity and an extremely low detection rate of distant disease, as shown in Table 19–4.²⁷

Who should be evaluated for bone metastases, and how should it be done?

Bone is the most frequent site of distant breast cancer spread, with about 25% of metastatic disease presenting at this site. Up to 70% of women who die from breast cancer will eventually have disease in the bony skeleton. The bones most commonly affected, in declining order, are the spine, ribs, pelvis, skull, and long bones of the extremities. Evaluation should commence with a history and physical examination aimed at eliciting osseous involvement. The patient should be questioned about bone pain, history of fractures, and possible symptoms of spinal cord compression such as lower extremity weakness with bowel or bladder dysfunction. If there is any suspicion of bony involvement, a workup may include measurement of serum alkaline phosphatase and serum calcium levels, technetium bone scan, computed tomography (CT), MRI, positron emission tomography (PET), or biopsy as appropriate.

The aforementioned multicenter review of more than 3600 patients demonstrated that preoperative evaluation of the skeleton, in the absence of symptoms, is not warranted because of low sensitivity and specificity. In this group, of 2450 stages I and II patients, only 22 (<1%) had a true-positive bone scan, whereas 125 had false-positive results. Further, there were no positive scans in patients without symptoms and with normal levels of alkaline phosphatase.²⁷ This supports the practice of performing radiologic or nuclear medicine studies only on patients with specific complaints or elevation of serum alkaline phosphatase.

More recently, PET scanning has been used to evaluate the entire body for metastatic tumor deposits. A study comparing whole-body PET scanning with traditional bone scintigraphy was performed on 51 women with breast cancer. With a specificity of 98%, PET scanning was superior to bone scintigraphy, which displayed only 81% specificity.²⁸ Additionally, compared with bone scintigraphy, MRI had a higher rate of skeletal metastases detection for the spine, pelvis, limb bones, sternum, scapula, and clavicle but a lower rate in the ribs and skull.²⁹

Who should be evaluated for lung metastases, and how should it be done?

Up to 25% of patients with metastatic disease develop pulmonary metastases, with only a small percentage of these present at the initial breast cancer diagnosis. About two thirds of women who eventually die from breast cancer have evidence of disease in the lung. The initial evaluation for all breast cancer patients should begin with a history and physical examination directed at signs of pulmonary involvement, including fatigue, dyspnea, dry cough, and chest pain or a feeling of heaviness in the chest, even though most patients are asymptomatic. If there is suggestion of pulmonary involvement, the lungs may then be further studied with chest radiograph, CT, fluorodeoxyglucose (FDG)-PET scan, or bronchoscopy.

In a study of 3627 breast cancer patients undergoing preoperative staging by chest radiography, the detection rate of preclinical lung metastases was found to be 0.3%, with a sensitivity of 0.31 and positive predictive value of 0.44.²⁷ Clearly, the routine use of preoperative chest radiography for the detection of pulmonary involvement is neither clinically useful nor cost-effective because the false-positive results would necessitate further unnecessary testing. However, because of the age bracket of the women undergoing surgery for breast cancer, a preoperative chest radiograph is often required at many institutions. If there is an abnormal finding on the chest radiograph, a CT scan may help to delineate nodules as well as detect mediastinal disease. The presence of calcium in lung nodules indicates benign pathology.

To assess the utility of chest radiography in the long-term management of patients with breast cancer, 1161 chest radiographs of 141 patients were examined. Of the chest radiographs, 15% were clinically indicated, and the remaining 85% were undertaken as part of “routine” follow-up. Fewer than 0.4% of the routine chest radiographs demonstrated previously undiagnosed pulmonary disease. Thus, the use of routine chest radiography is not a viable method of monitoring asymptomatic breast cancer patients.³⁰ Finally, when FDG-PET was retrospectively compared with chest radiography for detection of metastatic disease, FDG-PET was found to be superior in the identification of pulmonary and lymph node metastases.³¹

Who should be evaluated for liver metastases, and how should it be done?

The liver is the third most common site of distant breast cancer metastases. Two thirds of patients with stage IV disease

will eventually sustain hepatic involvement. The initial evaluation for all breast cancer patients should begin with a history and physical examination directed at eliciting the presence of right upper quadrant pain or fullness, jaundice, weight loss, or hepatomegaly. It is exceedingly uncommon for women with early breast cancer to present with findings of advanced liver disease, such as portal hypertension or jaundice. If there is any suggestion of hepatic involvement, the liver should be studied with liver function tests and, possibly, radiographically.

Liver function testing includes measurement of the enzymes alkaline phosphatase (AP), aspartate aminotransferase (AST), alanine aminotransferase (ALT), and lactate dehydrogenase (LDH). The performance of these tests on all patients with breast cancer at the time of diagnosis results in a very low yield. A study of 227 stages I, II, and III breast cancer patients identified elevated liver enzymes in 33.³² In 27 of the 33, only one enzyme was elevated, most commonly LDH. Overall, the specificity of liver enzymes is too low to reliably detect hepatic metastases at the time of breast cancer diagnosis. Including liver enzymes without any clinical suspicion of metastatic disease inevitably leads to unnecessary, expensive, and extensive evaluation, which does not even accurately predict who will develop distant disease. It is the recommendation of most that only patients with elevations of multiple liver enzymes or hepatomegaly should undergo further radiographic evaluation of the liver.

Options for radiographic evaluation include radionuclide liver scan, CT, ultrasound, MRI, and PET. ^{99m}Tc-sulfur colloid scans cannot detect lesions smaller than 2 cm and are therefore not very sensitive. A study of 3627 breast cancer patients revealed that screening liver ultrasound and liver scan have very low rates for detecting preclinical asymptomatic metastases, with positive predictive values of 0.33 and 0.08, respectively.²⁷ A study using a smaller series of 33 patients concluded that preoperative ultrasound may be efficacious in a subgroup of patients with markedly abnormal liver function tests or a physical examination suggestive of hepatic involvement, but not as a general screening tool.²⁸ In a study at Memorial Sloan-Kettering Cancer Center of 76 cancer patients in whom 124 indeterminate liver lesions were found on CT, hepatic ultrasound was a useful adjunct for patients with average body habitus in order to characterize small (0.6- to 1.5-cm) lesions.³³ CT and MRI are superior to ultrasound and technetium scanning for the identification of small metastatic foci in the liver; however, neither is more useful for screening asymptomatic patients.³⁴ Finally, when FDG-PET was retrospectively compared with chest radiography, bone scintigraphy, and ultrasonography of the abdomen for detection of metastatic disease, it was found to be superior in the identification of pulmonary and lymph node metastases in comparison with chest radiography, but its sensitivity in the detection of bone and liver metastases was comparable to that of bone scintigraphy and liver ultrasonography.³¹

In summary, because the percentage of patients with liver involvement at initial breast cancer diagnosis is so low and the screening tests are very nonspecific, it is not necessary to perform routine screening in asymptomatic patients. In patients with right upper quadrant pain or fullness, jaundice, weight loss, or hepatomegaly, liver function tests and possibly imaging studies are indicated.

Once hepatic involvement is present, the median survival is between 1 and 14 months. Factors that adversely affect

prognosis include advanced age, jaundice, deranged liver function tests (elevated bilirubin, low serum albumin), ascites, palpable hepatomegaly, and poor liver performance status. Patients with a single focus of disease in the liver fare better than those with multiple confluent and distant metastases. The interval between initial presentation and metastatic disease does not seem to be a significant factor. The tumor marker CA-15-3 is usually elevated in patients who perform poorly secondary to hepatic involvement; however, it is not an independent predictor of survival. Marked elevation of carcinoembryonic antigen (CEA) (>1000 ng/mL) may be used to predict poor outcome on an individual patient basis, but the level of elevation cannot be used to predict survival.³⁵

Who should be evaluated for central nervous system metastases, and how should it be done?

The central nervous system consists of the brain, cranial nerves, spinal cord, leptomeninges, and eyes. Central nervous system involvement will eventually affect up to 20% of breast cancer patients. Breast cancer is the second most common type of cancer metastatic to the brain, second only to primary lung cancer. The most common presenting symptoms are motor deficit and gait disturbance (24%), seizures (23%), headaches (16%), cognitive dysfunction (14%), nausea and vomiting (11%), cranial nerve dysfunction (10%), cerebellar symptoms (2%), and speech disturbances (2%).³⁶ The most common presentation of spinal cord involvement is pain, which can mimic the pain of bony metastases. The diagnosis of brain involvement is made on the basis of clinical suspicion and then confirmed by CT or MRI of the brain. MRI is the most sensitive method for detecting brain metastases.³⁷

Who should be evaluated for bone marrow micrometastases, and how should it be done?

The occult spread of tumor cells in patients with operable breast cancer may be a determinant of the risk for future metastases. Unfortunately, occult spread is overlooked with conventional tumor staging. The status of the axillary lymph nodes has historically been the most important indicator of prognosis in breast cancer patients. However, up to one third of women with negative lymph nodes have recurrence with systemic disease. Monoclonal antibodies against cytokeratins found specifically in epithelial cells are used to identify metastatic cells in breast cancer patients. The detection of bone marrow micrometastasis (BMM) is of potential clinical significance because it may help to predict prognosis and disease course and to guide adjuvant therapies.³⁷

Bone marrow aspiration at the time of initial surgical resection of invasive breast cancer is a brief and simple process performed by the primary surgeon. Once the patient is comfortably sedated by the anesthesiologist for her upcoming surgery, approximately 2 mL of marrow is drawn from each anterosuperior iliac crest using local anesthesia. This aspirate is then studied using an anticytokeratin monoclonal antibody immunocytochemical technique. The techniques employed for the detection of micrometastatic cells in the

marrow include immunocytochemistry (ICC), PCR, and flow cytometry.³⁸

Numerous studies have evaluated the clinical implications of BMM. A correlation has been identified between increasing breast cancer stage and a higher number of BMM cells detected.³⁹ BMM has also been shown to correlate with the size and grade of the primary tumor. BMM was identified in 30%, 42%, 62%, and 75% of T1, T2, T3, and T4 carcinomas, respectively.⁴⁰ In grade I and II cancers, one study showed that 39% of the patients had BMM, whereas in the grade III tumors, 52% had BMM.⁴⁰ There does not appear to be a direct relationship between BMM and axillary lymph node metastases.⁴¹ BMM and axillary lymph node metastases may actually represent independent routes of cancer dissemination.³⁸

Multiple studies have identified a strong correlation between the presence of BMM and distant recurrence as well as decreased survival. In the first study to demonstrate this correlation, Cote and colleagues showed that the 2-year distant recurrence rate for bone marrow–negative patients was 3%, compared with 33% in patients with BMM.³⁷ The absolute number of malignant cells in the bone marrow has also been shown to predict early recurrence and decreased survival.³⁷ In a study by Diel and associates of 727 patients with primary operable breast cancer, 76% of the patients who developed distant recurrence had BMM at presentation, and 83% of those who died of their disease had BMM at the time of initial diagnosis.⁴⁰ Braun and coworkers, studying 552 women with stage I through III breast cancer, also found that the presence of BMM was an independent indicator of death from breast cancer.³⁹

From the data available, it is evident that the knowledge of a breast cancer patient's bone marrow status may complement knowledge about the axillary lymph node status. Further research is necessary, however, to clarify the impact of bone marrow status on outcome.

Are hormone receptors significant even though they are not included in the staging system?

Since the mid-1970s, estrogen receptor (ER) and progesterone receptor (PR) status have been used in the clinical management of breast cancer. They have served both as markers of endocrine responsiveness and as harbingers for increased recurrence. Even though the hormone receptors are clinically useful, their absolute prognostic power is limited, and therefore they are not included in the staging system.

ER positivity is known to be a favorable prognostic indicator, whereas PR positivity alone is a weak favorable prognostic indicator. Overall, about 58% of breast tumors are ER and PR positive. The next most frequently occurring combination is ER positive, PR negative, which accounts for 23% of breast cancers. The least common group, ER negative, PR positive, accounts for only 4% of all cancers. Finally, about 15% of cancers show no hormone receptors and are ER negative, PR negative.⁴²

ER-positive breast tumors have been shown to afford patients longer disease-free as well as overall survival. A trial of 1392 patients with early breast cancer was undertaken to determine whether hormone receptor determination gives independent prognostic information for long-term survival.

The 10-year overall survival rate for ER-positive patients was 66%, compared with 56% in the ER-negative group. Additionally, higher percentages of ER-positive cancers were found in white women as well as in postmenopausal patients.⁴³ Thus, the presence of the ER may provide prognostic information in addition to that provided by the tumor size and nodal status.

The ER status may identify subgroups of patients who would benefit from specific treatments. A meta-analysis encompassing more than 37,000 patients from 55 studies demonstrated that in women with ER-positive cancers, a 5-year course of tamoxifen significantly reduces the odds of breast cancer recurrence and death. This strong correlation was not seen with ER-negative tumors. The benefit was directly proportional to the level of ER in a tumor, with patients with the highest levels of ER positivity faring best.⁴⁴ Women whose tumors are both ER and PR negative have about a 5% chance of responding to any endocrine therapy, whereas those whose tumors are ER positive, PR positive have a greater than 70% chance of response to endocrine therapies of various types.⁴⁵

A retrospective review encompassing more than 16,000 patients was recently compiled in order to assess the prognostic utility of PR in addition to ER in patients with primary breast cancer who received no systemic adjuvant therapy.⁴⁶ It was determined that women with systemically untreated ER- and PR-positive cancers have better clinical outcomes than women with ER-negative, PR-positive cancers, at least over the first 3 years after diagnosis. Treatment with hormone therapy broadens this effect. Also, there was a trend toward decreased overall survival and disease-free survival for patients with ER-positive, PR-negative tumors when compared with those with ER- and PR-positive tumors. The combined presence of ER and PR positivity may be a stronger marker for the benefit of adjuvant therapy than just ER alone; thus, the addition of PR status to ER status significantly improves the accuracy of predicting the endocrine responsiveness of the primary tumor.⁴⁶ In conclusion, the major value of ER and PR status is as predictive factors for the utility of hormone-based therapy.

Why are the cell kinetics of individual breast cancers tested?

Markers of tumor cell proliferation are a valuable adjunct in the determination of short-term survival. S-phase fraction is related to the ploidy status of the tumor. Increased incidence of aneuploidy and higher S-phase fractions have been correlated with tumors that are ER and PR negative, are greater than 2 cm in diameter, have spread to the axillary lymph nodes, and occur more often in patients younger than 35 years. An elevated S-phase fraction and abnormal DNA ploidy, in combination with the above associated factors, are predictors of early distant relapse.⁴⁷

An elevated thymidine labeling index (TLI) is associated with a highly proliferative tumor cell population and has also been correlated with a greater probability of relapse and death. A prospective study of 286 node-negative breast cancer patients who underwent locoregional treatment alone was performed to determine the prognostic significance of numerous biologic markers. After 5 years of follow-up, only the tumor size and the TLI proved to be significant

independent prognostic indicators of relapse-free survival.⁴⁸ However, since TLI must be performed on a fresh specimen, it is too labor intensive for incorporation into routine use.

Why are proto-oncogenes important in the diagnosis of breast cancer?

Cellular oncogenes are known factors in the pathogenesis of malignancy. One of the most well known, *HER-2/neu*, occurs in about 25% of all breast cancers. *HER-2/neu* is an oncogene derived from the *c-erbB* proto-oncogene, which encodes for a transmembrane glycoprotein receptor structurally similar to epidermal growth factor receptor. It has been thoroughly studied as a prognostic indicator, a predictor of response to systemic treatment, and a target of biologic therapy. Overexpression of the *HER-2/neu* receptor implies that thousands of *HER-2/neu* receptor molecules are present on the tumor cell surface and that a proliferative signal is continuously being transduced to the nucleus. In a retrospective review of 529 patients, when high proliferative activity was associated with *HER-2/neu* overexpression, the risk for relapse was approximately doubled when compared with rapidly proliferating but *HER-2/neu* weakly expressing tumors.⁴⁹ Additionally, *HER-2/neu* overexpression may be an independent prognostic variable for patient survival. When immunostaining for erbB-2 protein is combined with evaluation of nuclear grade, it may be possible to use immunostaining for erbB-2 protein to identify patients at increased risk from within a relatively low-risk group.⁵⁰ Also, the presence of *HER-2/neu* overexpression is a predictive factor that may indicate success with the use of trastuzumab (Herceptin).⁴⁹

The *p53* gene, located on the short arm of chromosome 17, encodes a nuclear protein that is found in small amounts in normal tissue but in elevated amounts in tumor tissue. A review of 192 patients with infiltrating ductal carcinoma identified a correlation between *p53* expression and shorter overall and disease-free survival.⁵¹ However, present data are insufficient to recommend *p53* measurements for the management of patients with breast cancer.

Finally, cellular proliferation has also been assessed using Ki-67 monoclonal antibodies. The cellular target for Ki-67 antibodies is a cell cycle-specific nuclear antigen present in proliferating cells but absent in the G0 resting phase. Positive staining with the Ki-67 antibody has been correlated with abnormal ploidy, high S-phase percentage, negative ER status, and decreased survival.¹⁴

Why are growth factors sometimes measured in breast cancers?

The absence of a cellular response to estrogen in a breast cancer cell indicates that estrogen has been replaced by alternative growth-regulatory substances. The growth factors may be autocrine; that is, the growth control process acts locally and is limited to the tumor cells alone. Alternatively, the mediators may be paracrine; that is, they may be involved near the tumor with roles including hyperplasia of the cancer stroma, known as desmoplasia, or angiogenesis.⁵²

Some of the growth factors recognized in breast cancer include transforming growth factor- α (TGF- α), insulin-like

growth factor-1 (IGF-1), epidermal growth factor (EGF), and platelet-derived growth factor (PDGF).⁵³ The growth hormone-IGF-1 axis is understood to play a fundamental role in the development of breast cancer. The IGF-1 receptor correlates directly with the presence of the ER. The maintenance of normal breast tissue architecture is assisted by its effect on proliferation, differentiation, and apoptosis. Although there are conflicting data regarding its ability to predict outcome, the IGF-1 receptor has been shown to be involved in the development of resistance to tamoxifen and trastuzumab (Herceptin), an anti-*HER2/neu* receptor monoclonal antibody that inhibits growth of erbB-2-overexpressing breast cancer.⁵⁴

When is restaging appropriate?

There exist a number of reasons for restaging, or thoroughly re-evaluating, a breast cancer patient. Restaging is defined as the repeated application of the TNM system.

The first and most common reason for restaging is to monitor a patient in the immediate post-treatment course because most recurrences occur within the first 2 years of initial diagnosis. The American Society of Clinical Oncology (ASCO) has a published set of guidelines for recommended follow-up. ASCO recommends a monthly breast self-examination as well as physician visits for updated history and physical examination every 3 to 6 months for the first 3 years after treatment, then every 6 to 12 months for the following 2 years, and annually once the fifth anniversary from treatment is reached. Worrisome symptoms that would prompt further radiographic or laboratory examination include chronic bone pain or tenderness; rashes, redness, or swelling on the skin of the breast; new breast or chest wall masses; chest pain or shortness of breath; persistent abdominal pain; or sudden changes in weight, especially weight loss. Mammograms of the ipsilateral breast are recommended every 6 months for 2 years following the completion of radiation therapy for lumpectomy patients and every year in the contralateral breast for those who have undergone mastectomy. From that point, yearly mammograms are acceptable for nearly all patients. All women taking tamoxifen should undergo pelvic examination on a yearly basis; however, there is no need for routine endometrial biopsies. ASCO does not recommend the use of blood tests or radiographic studies (beyond the mammogram stated earlier) as follow-up care for patients in good physical condition in the absence of symptoms. These additional tests have not been shown to affect survival, may miss cancer when it does exist or falsely indicate its presence, and are costly.⁵⁵

At the time of an event, such as a recurrence or development of a second primary malignancy, a thorough workup should be performed. The knowledge of a patient's current breast cancer status is critical in making treatment decisions for other diseases.

Finally, it is wise to perform retreatment staging when additional or new treatments are being given for breast cancer in order to determine the current extent of the disease. A change in stage may make a woman eligible for a new treatment or may protect her by making her ineligible. Because the staging guidelines change every few years, it is very possible that a patient's stage may change even if she has no additional evidence of breast cancer.

Genetic Counseling for Patients with Breast Cancer and Their Families

Elsa Reich and Harry Ostrer

Breast cancer is the most common gender-specific malignancy among women.^{1,2} It is estimated that in 2005 over 211,000 women will have been diagnosed with breast cancer in the United States and that more than 40,000 will die of the disease. It is estimated that an additional 58,490 women will be diagnosed with ductal carcinoma in situ (DCIS). One of eight, or 12.6%, of all women can expect to develop breast cancer at some time during their lifetime, and for 1 in 30 women, breast cancer will be the cause of death. Although breast cancer may also affect men, the frequency among men is quite small, approximately 1% of the total number of breast cancers. However, the risk for developing disease varies among individuals.

Recent advances in understanding the genetic basis of susceptibility to breast cancer have led to risk estimates based on family history, age at onset, and specific genetic tests. Because of the growing public awareness of the predisposing genes, both affected individuals and their unaffected relatives often request risk assessment for themselves or their close relatives. This chapter reviews the current general information about the risk for developing breast cancer based on the family history of breast or ovarian cancer; the role of genetic testing for modifying that risk; the potential benefits, drawbacks, and limitations of testing; and specific recommendations for follow-up care for people who are identified as high risk.

Is there a hereditary predisposition to breast cancer?

Most cases of breast cancer occur sporadically in the absence of other affected family members, but because breast cancer is a common disease, about 20% of individuals with breast cancer have a positive family history.³ For more than 100 years, it has been observed that some families have multiple relatives affected with breast cancer, sometimes coexisting with ovarian cancer.⁴ Careful analysis suggested that the cancer predisposition in these families was transmitted as an autosomal dominant trait.⁵ Many of these women develop disease on the basis of inheritance of a predisposition gene. If a woman inherits this gene, her likelihood of developing disease is high.⁶

Predisposition mutations in the genes *BRCA1* and *BRCA2* are relatively common. It is estimated that the frequency of carriers of *BRCA1* in a multiethnic population is about 1 in 800 and that the frequency of *BRCA2* in this population is slightly greater.⁷ There is a significantly higher frequency in selected populations; however, these numbers cannot be extrapolated to describe all populations. Such genes account for 5% to 10% of all breast and ovarian cancers.⁸ This implies that between 11,000 and 22,000 of the women who will be diagnosed in 2005 in the United States will have a heritable form of breast cancer and that more than 700,000 individuals in the United States are carriers of a mutant allele.

Environmental and other factors also influence the probability that a woman will develop breast cancer. These include older age, nulliparity, early age at menarche, late age at menopause, previous history of breast cancer or benign breast disease, obesity, one or more close relatives affected with breast cancer, and a personal or family history of ovarian cancer. Use of exogenous estrogens and increased alcohol consumption and the duration of these exposures also increase risks.⁹

Knowledge about genes that predispose to the development of breast cancer has exploded in recent years, but there is clearly much still to be learned. Although information about the number and frequency of these genes remains unclear, and the probability that carriers will develop breast cancer is incompletely defined, risk assessment can still be provided for and may contribute to decisions about medical care for the patient and family members. Molecular analysis of genes predisposing to breast cancer is an option that may provide further risk modification in selected families and individuals. Genetic testing and risk assessment should be carried out within the framework of a recommended genetic counseling protocol to ensure informed and autonomous patient decision making.

Although new developments in molecular genetics enhance our ability to perform risk analysis, the task is complicated by the discovery of an extensive number of different mutations causing common hereditary cancers; incomplete ascertainment of all predisposing genes and mutations; a high frequency of variants of uncertain significance; incomplete

knowledge of genotype–phenotype correlations, including penetrance estimates; cost; and the inconsistent willingness of third-party payers, including Medicaid and Medicare, to pay for the testing. A patient’s decision to undergo genetic testing is sometimes complicated by fear of the potential misuse of genetic information by insurers.

What are the genes predisposing to breast and ovarian cancer?

Mutations in *BRCA1* and *BRCA2* are known to be major causes of hereditary predisposition to breast cancer. The *BRCA1* gene was mapped in 1990 to 17q12 and cloned in 1994.^{10,11} The *BRCA2* gene was mapped to chromosome 13q12–13 in 1994 and cloned in 1995.^{12,13} Among the high-risk families selected for mapping studies and subsequently used for mutation analysis, these genes were thought to account for about 90% of all hereditary breast cancer. *BRCA1* accounted for 40% to 50% of hereditary breast cancer, and *BRCA2* for about 35% to 45%. More recent studies have shown that these contributions may have been overestimated.^{14–20} The distribution and frequency of mutations vary in diverse ethnic populations.

Several hundred mutations distributed throughout both genes have been identified. Readily available sources of information about mutations include the Breast Cancer Information Consortium (<http://research.nhgri.nih.gov/bic/>) and Myriad Genetics (<http://www.myriad.com>). Mutations are interpreted as deleterious if they prematurely terminate or truncate the protein product of *BRCA1* at least 10 amino acids from the C-terminal or the protein product of *BRCA2* at least 110 amino acids from the C-terminal.²¹ Specific missense and noncoding intron mutations are interpreted as deleterious on the basis of linkage analysis of high-risk families, functional analysis, biochemical analysis, or demonstration of abnormal RNA processing. Genetic variants that do not fulfill these criteria are reported as being of unknown significance.

An inherited predisposition to the development of breast cancer is also associated with germline mutations in *p53* and may be seen in families with Li-Fraumeni syndrome, characterized by an aggregation of soft tissue tumors and hematologic tumors.^{22,23} Likewise, breast (and thyroid) cancers are features of Cowden disease, an aggregation of hamartomatous tumors that arise from mutations in the *PTEN* gene.²⁴ Heterozygotes for the mutant allele causing ataxia-telangiectasia, a recessively inherited syndrome predisposing to cancer, have an increased risk for breast cancer, but these genes contribute only marginally to the total number of cases.^{25,26} More recently, the variant 1100delC in *CHEK2*, a cell cycle–checkpoint kinase, has been identified as a risk factor for breast cancer.²⁷ In rare cases of male breast cancer, mutations in the androgen receptor gene may be contributory.²⁸ An interesting recent finding is that biallelic mutations in *BRCA2* contribute to the Fanconi anemia phenotype. As expected, affected individuals have a familial aggregation of breast cancer.²⁹ All of these genes contribute only marginally to the total number of cases with a hereditary predisposition; thus, an unknown number of other predisposition genes have yet to be identified.

What is the pattern of inheritance by which mutations in *BRCA1* and *BRCA2* are transmitted?

BRCA1 and *BRCA2* are transmitted as autosomal dominant traits. Any carrier, female or male, has a 50% chance of transmitting the mutation to her or his offspring. The phenotype of the carrier is gender dependent and variable, and penetrance for both breast and ovarian tumors is less than 100%.

What is the penetrance of predisposition genes?

Having a dominantly inherited breast cancer predisposition gene is not sufficient to cause the development of breast cancer. Data obtained from the original families recruited for the mapping studies demonstrated that the penetrance of breast and ovarian cancer among mutation carriers of *BRCA1* and *BRCA2* was high. These families were specifically selected because they were large and had multiple affected family members; thus, there was considerable bias of ascertainment. Penetrance of breast cancer in *BRCA1* carriers in these high-risk families was 51% by age 50 years and 85% by age 80 years.⁶ The penetrance of ovarian cancer in these same families was lower, 23% by age 50 years and 63% by age 70 years. Comparable risks applied to the occurrence of a second tumor in the same individual. Penetrance estimates for breast cancer among *BRCA2* carriers was equally high (87%), but the penetrance of ovarian cancer was considerably lower, about 6% to 10%. The penetrance of breast cancer in male carriers of *BRCA2* mutations was as high as 14%.³⁰

Further studies in these high-risk families have confirmed the high penetrance estimates and have also demonstrated that the median age of onset of breast cancer in carriers of *BRCA2* mutations is higher than that in *BRCA1* carriers.¹⁸ *BRCA2* is believed to confer about a 6% risk for breast cancer to male carriers, and male carriers of *BRCA1* mutations are also believed to be at increased risk for developing both prostate cancer and breast cancer, but the exact risks have not yet been determined.³¹ Prostate cancer, pancreatic cancer, and melanoma show increased frequency in carriers of *BRCA2* mutations.³¹ The frequency of other malignancies remains to be defined. Recent studies have failed to identify an increased frequency of colon cancer among carriers of mutations in either of these genes.³²

From the outset, investigators cautioned clinicians about applying the penetrance values obtained from the high-risk families to all carriers. Studies that were based on recall of family history have demonstrated that penetrance of breast and ovarian cancer among carriers may be significantly lower in some families. However, a recent study based on genetic analysis of the relatives of mutation carriers demonstrated that the age-related penetrance by age 80 years was 82% for breast cancer and 54% for ovarian cancer for *BRCA1* mutation carriers and 85% for breast cancer and 23% for ovarian cancer for *BRCA2* mutation carriers.³³ A major determinant of penetrance was birth year, with mutation carriers born after 1940 being at significantly higher risk for developing breast cancer than mutation carriers born before 1940. This study also showed that low prevalence within a family did not equal

low penetrance. Rather, the low-prevalence families could be explained on the basis of small family size or transmission through the paternal germline. This study was carried out exclusively among Ashkenazi Jews harboring one of the three founder mutations (discussed later), and it is unclear whether these penetrance values apply to other populations and mutations.

Have the same mutations been observed more than once?

Both *BRCA1* and *BRCA2* are large genes, and multiple mutations have been demonstrated in each gene, many of which occur in single affected families. Some mutations have been seen repeatedly, particularly among certain ethnic groups, indicating a historical progenitor or “founder.” For example, among individuals of Ashkenazi Jewish origin, there are three recurrent common mutations: 185delAG and 5382insC in *BRCA1*, and 6174delT in *BRCA2*.^{34,35} The 5382insC is common in other Eastern European groups, and the 185delAG mutation has been observed in Iraqi Jews, suggesting ancient origin.³⁶ The *BRCA1* 185delAG mutation has also been observed in groups that may have had historical Jewish links.³⁷ These three mutations account for more than 95% of all detectable mutations among Ashkenazi Jews. The frequency of nonfounder mutations detected among Ashkenazi families with a heritable predisposition is low, 2% to 4%.³⁸

The prevalence of founder mutations is high in the unaffected Ashkenazi Jewish population. Among control populations, the frequency of 185delAG was about 1%, the frequency of 5382insC was 0.11%, and that of 6174delT was 1.36%.^{15,34,39,40} Thus, 2.4% of all Ashkenazi Jews are carriers for at least one of these mutations, a rate at least eightfold greater than that in other populations. The cases that arise from the inherited mutations are thought to account for the excess of breast cancer among Ashkenazi Jewish women.⁴¹ The founder mutations in this population group have provided the basis for many prevalence and penetrance studies.

There are multiple other populations in which founder mutations occur. In Iceland, a single *BRCA2* mutation, 999del5, accounts for all heritable cancer in the country.⁴² The same mutation occurs in Finland. Founder mutations have been identified in other countries, regions, or ethnic groups, including those from Russia, Belarus, Poland, Norway, Sweden, Finland, the Netherlands, Belgium, France, Germany, England, Scotland, Wales, Northern Ireland, Spain, Italy, Sardinia, Hungary, Czech Republic, Slovenia, Greece, Turkey, Pakistan, India, Thailand, China, Mongolia, Japan, and the Philippines as well as African Americans and French Canadians (<http://research.nhgri.nih.gov/bic/>). Awareness of these founder mutations may facilitate testing because targeted mutation analysis may provide a more efficient approach to testing for a given individual with a known ethnic origin.

Is there a correlation between genotype and phenotype?

The clinical presentation depends on whether the patient is a *BRCA1* or *BRCA2* carrier. The frequency of mutations is

inversely related to the age of onset, with a lower than expected contribution of *BRCA2* mutations in early-onset breast cancer.¹⁴ The median age of onset of breast cancer among *BRCA1* carriers is 41 years, whereas that of *BRCA2* carriers is 45 years.³⁴ Mutations in *BRCA1* appear to be the major etiologic factor in breast-ovarian and site-specific ovarian cancer families.^{17,43} Likewise, families in which there is an individual with both breast and ovarian cancer are far more likely to harbor mutations in *BRCA1*.¹⁶ Mutations in *BRCA2* contribute to an increased risk for breast cancer in men and may account for almost 15% of the total cases of male breast cancers.³⁰ Some studies have suggested that there is a correlation between the presence of specific mutations and the risk for developing ovarian cancer. Some investigators have demonstrated that individuals carrying mutations in the first two thirds of the gene have a higher frequency of ovarian cancer than those carrying mutations in the terminal one third.^{44,45} They have also reported that the occurrence of ovarian cancer is increased in *BRCA2* carriers in whom the mutation is found in exon 11.⁴⁶ Others have found no correlation.¹⁶

Who is at increased risk for developing breast cancer?

Women who present for breast cancer risk assessment may generally be divided into two groups, those at moderate risk and those at high risk.⁴⁷ Women at moderate risk have fewer affected family members, absence of a family history of ovarian cancer, and an older age at the time of diagnosis. The molecular basis of disease among such women may *not* be the result of inheritance of a single dominant susceptibility gene.

In contrast, women at high risk usually have multiple cases of breast cancer in close relatives or early age at diagnosis. The age of onset of disease tends to be one to two decades earlier than in the general population (frequently, ≤ 45 years of age). The affected relatives are often closely related, with one or more affected first-degree relatives, especially in succeeding generations, some with more than one primary tumor (i.e., bilateral breast cancer or breast and ovarian cancer). One or more affected individuals may have developed cancer before the age of 50 years, and some have a very early age of onset (< 40 years of age). The earlier the age of onset, the more likely it is that a mutation will be identified. There may be one or more affected men in the family. The presence of a woman with ovarian cancer in a family of women with breast cancer or a woman with both breast and ovarian cancer significantly increases the risk for a familial predisposition mutation. The presence of any second primary tumor also supports the suspicion of an inherited predisposition mutation.⁴⁸ Any woman younger than 40 years, even in the absence of a family history, particularly if she comes from a high-risk group, should be considered to have a significant probability of being a mutation carrier. For women at moderate risk for developing breast cancer, the likelihood of developing disease has been determined empirically, based on observations from large numbers of individuals.

What are the statistical models used by genetic counselors and oncologists to estimate the probability that an individual will develop cancer?

Models of developing breast cancer used most frequently by risk assessment counselors on behalf of unaffected women are the Gail model and the Claus model (Table 20–1). These models of risk prediction were developed before genetic testing was available but are still useful for women who have not undergone genetic testing. Each of the models was based on a different study design and uses different factors for calculating risks. Hence, the estimates that are provided by each of these models may differ.

Gail Model

The Gail model is still used for unaffected individuals with a limited family history. Gail and colleagues based their model on data in the Breast Cancer Detection and Demonstration Project (BCDDP) of 2852 cases and 3146 matched controls.⁴⁹ Five variables were used to calculate risk ratios. These included current age, age at first live birth, age at menarche, number of first-degree relatives with breast cancer, and number of prior biopsies. The Gail model predicts cumulative risks from age 20 to 80 years and corrects for other causes of mortality. This model does not take into consideration the age at diagnosis of the relative's breast cancer, nor does it consider the occurrence of breast cancer in second-degree relatives, thereby overlooking the contribution of genetic mutations from the maternal grandparental generation as well from paternal relatives. Both tables and a computer program are available for estimating individual age-specific risks, based on this model.

Table 20–1 Parameters Included in Models for Estimating Risks of Developing Breast Cancer

Parameter	Gail	Claus	Tyrer-Cuzick
Personal Information			
Age	Yes	Yes	Yes
Body mass index	No	No	Yes

Ovarian cancer	No	No	Yes
Male breast cancer	No	No	Yes
Genetic Testing			
Proband or relative had genetic testing	No	No	Unknown

Claus Model

The second model commonly used for unaffected women was derived by Claus and colleagues from data collected in the Cancer and Steroid Hormone (CASH) study on 4370 breast cancer cases in patients aged 20 through 54 years and 4688 controls.⁵ This study provides age-related risks for breast cancer dependent on the presence of one or two affected first- or second-degree relatives together with their age at onset. These data were compiled to create lifetime risk tables based on family history of breast cancer (see Table 20–1).

Neither the Gail model nor the Claus model takes into consideration the carrier status of the proband or her affected relatives, the presence of affected men, or the occurrence of either bilateral breast cancer or ovarian cancer in family members. The lifetime estimate derived from these models for the proband remains the same, regardless of whether the proband or her relatives have been tested.

What are the statistical models used by genetic counselors and oncologists to estimate the probability that an individual will be a carrier?

BRCAPRO Model

Models have also been developed to estimate the likelihood that a woman carries a mutation in *BRCA1* or *BRCA2* (Table 20–2). BRCAPRO is a bayesian-based model that takes into account the prevalence of mutations in the population and the penetrance estimates that allows genetic counselors and oncologists to predict the likelihood that a given individual is a carrier of a *BRCA1* or *BRCA2* mutation⁵⁰ (see Table 20–2). It takes into account the affected or unaffected state of the proband,

Table 20–2 Parameters Included in Models for Estimating Risks for Carrying a *BRCA1* or *BRCA2* Mutation

Parameter	BRCAPRO	Frank ²¹
Personal Information		
Age	Yes	Yes

Genetic Testing		
Proband or relative had genetic testing	Yes	No

whether she has unilateral or bilateral disease, and the presence or absence of breast and ovarian cancer and certain other cancers in all of her first- and second-degree relatives. Third-degree relatives are not included in this estimate, nor are men affected with breast cancer. The program provided by the developers of this model includes estimates from the Claus and the Gail models and from four other models. BRCAPRO is widely used by risk assessment counselors and, when compared with the estimates of experienced genetic counselors, was found to be slightly more sensitive in identifying carriers than were the counselors. Of note, 16% of carriers were not identified by this model when the cutoff for testing was set arbitrarily at 10% risk for harboring a mutation.

Many counselors use empirical data from Myriad Genetic Laboratories that reported their experience in identifying mutations in *BRCA1* or *BRCA2* in individuals submitting samples to their laboratory.²¹ The patients were classified by their affected or unaffected status and by the presence of early-onset breast cancer or ovarian cancer in first- and second-degree relatives. The researchers divided their population of patients into 2233 Ashkenazi Jewish individuals and 4716 non-Ashkenazi Jewish individuals, because of the well-recognized greater frequency of founder mutations among Ashkenazi Jews. They took into consideration the type of tumor (breast, ovarian, or both), the age of onset, and the number of affected first- and second-degree relatives. These data did not recognize the presence of an affected male in the pedigree or the presence of bilateral breast cancer in either the proband or her relatives. In none of these models (Gail, Claus, or BRCAPRO) are third-degree relatives included. Estimates derived from these data may underestimate the a priori risk to be a carrier because male breast cancer was not included as a risk factor and all affected relatives older than 50 years were omitted from this model. In addition, the family history was derived from laboratory requisition forms and not confirmed independently. Some of these deficiencies have been addressed on Myriad's web-based compilation of data, but a drawback of the web-based data and the original study data is that the carrier status of affected relatives is not included in the calculations. Because some probands included in the web-based data came from families in which there was a known mutation, the estimates may be biased upward.

An important point of consideration is that all of these studies consider "affected" individuals to be only those with an invasive lesion. A limited study of probands affected by DCIS compared risk estimates for a small number of Ashkenazi women younger than 50 years with DCIS and those with invasive lesions. Further studies are required to elucidate these risks more fully. Another model includes women with DCIS but routinely adds 10 years to the age at diagnosis; for example, a woman diagnosed with DCIS at 45 years of age would be included as an affected subject diagnosed at 55 years of age.⁵¹ This model has been weighted to include the possibility that DCIS may not always progress to an invasive lesion.

Tyrer-Cuzick Model

Lastly, a newer model, not presently available in a computerized version, includes many additional personal characteristics, including the presence of LCIS, height, weight, and body mass index (BMI).⁵²

For clinical counseling, it is useful to calculate risks derived from several models and to offer these to patients as a range.

The experience and judgment of the genetic counselor are invaluable in applying the risk assessment models in the most appropriate way and in helping patients to understand their risks. The American Society of Clinical Oncology guidelines for genetic testing emphasize the importance of the clinical judgment in estimating these risks.⁵³

Who should have genetic counseling for heritable risk for breast or ovarian cancer, and how is it undertaken?

Genetic counseling is appropriate for individuals who perceive themselves or their relatives to be at increased risk for breast or ovarian cancer (see Table 20–1). Generally, such perception is based on family history, although some individuals with early-onset or multiorgan disease perceive that *they and their family members* are also at risk for other malignancies. A genetic evaluation is a multistep procedure that may result in modifying risk. Because it is intended to be a service for each person who participates and because the implications of a positive test result can have profound ramifications for that person and the family, participation is always voluntary.

A detailed protocol that is used for counseling patients in the Human Genetics Program at New York University School of Medicine is presented in the appendix at the end of this chapter. An initial telephone contact by the genetic counselor will provide the patient with details about the overall consultation, and the counselor will obtain a preliminary family history. Some centers request that patients complete a written family history form before making an appointment. The counselor may suggest that more than one individual be involved in the counseling process, particularly if a relative is better suited to be tested initially. Arrangements are made to obtain relevant medical records and pathology reports. The patient will learn about the basic elements of the consultation, including the educational aspects of the genetic counseling session, the number of sessions to expect, and the way in which results will be communicated (almost always in person). Of considerable importance is communicating to the patient the nondirective stance of the counselor so that the patient is free, without coercion, to make a considered decision about whether to undergo genetic testing.

The first session lasts about 2 hours, during which the counselor obtains a detailed medical history and at least a three-generation family history with special attention to the history of cancer in the relatives. In addition, general medical and genetics histories are obtained to learn about other conditions about which the patient may be concerned. Based on this information, the genetic counselor or medical geneticist will identify the gene or genes most likely to account for the malignancies in the family or individual.

The educational aspects of the discussion include in-depth information about the testing protocol. This includes a discussion about the contribution of *BRCA1* and *BRCA2* (or other genes, if appropriate) to a hereditary predisposition to breast cancer, the genetics of cancer, an approximate estimate of the likelihood that the patient is a carrier, the likelihood of detecting a mutation, the frequency of variants of uncertain significance, the implications of both positive and negative results, the recommendations for surveillance and cancer prevention following testing, and the benefits and drawbacks of

testing.⁵⁴ If the patient is part of a family group being tested, an opportunity is provided for each person to meet individually with the counselor or physician during this time.

The major reasons that individuals choose to be tested are (1) the results may modify medical care; (2) the results of testing may benefit relatives, especially daughters; and (3) just “to know.” In conjunction with the first reason, there is considerable discussion about the options for medical care, which include (a) doing nothing differently because the patient is already following appropriate surveillance recommendations; (b) initiating more intensified surveillance, surgical intervention, or chemoprevention with referrals to appropriate specialists or a high-risk prevention clinic; or (c) reverting to surveillance appropriate for the general population because the patient has learned that she is not at high risk. With respect to the second reason, it is common that women seeking testing have not discussed the testing with their relatives, especially their daughters, with the intention of telling them the results after the testing has been completed. We routinely recommend that a woman inform her relatives of her intention to have genetic testing before undergoing the testing to learn whether those relatives want to learn the results. We encourage them to consider the rights of their relatives to make the same independent and autonomous decisions as they themselves have made.

At the conclusion of the first session, the patient has the choice of having blood drawn for testing, declining testing permanently, or deferring the decision about testing until a later time. Some patients defer testing until we can ascertain whether their testing will be covered by third-party payers. Others defer so that they can discuss the implications of testing with other family members and learn whether their family members want to have the information. Some defer because they determine that the information will not be useful to them personally. Still others feel so emotionally overburdened at the end of the session that they prefer to have their testing at a later time when they feel more comfortable.

Wherever possible, we make an effort to obtain pathology reports that document the malignancies in the patient and family members. This is particularly important with respect to gynecologic cancers. In a woman who has had endometrial or cervical cancer and not ovarian cancer, there is a significantly lower probability that she or a member of her family is a *BRCA1* or *BRCA2* carrier, compared with a woman who has had ovarian cancer. In addition, a woman who has had an in situ lesion has a lower probability of harboring a deleterious mutation.²¹ If testing has been carried out in one or more family members, we request those results because they may allow us to interpret our patient’s results with greater certainty or to estimate her risks to be a carrier with greater accuracy. When there is a question about the diagnosis, we may obtain slides for review by an in-house pathologist.

At the time that blood is drawn for testing, an appointment is made for the patient to return to learn the results in person. The results may be provided solely to the patient or in the presence of a relative or friend designated by the patient. If more than one member of a family is receiving results at the same session, we determine in advance whether they wish to receive their results separately or together. We have provided some anticipatory guidance about potential difficulties that may arise when one turns out to be a carrier and the other a noncarrier and in some instances have recommended

that they may wish to receive their results at individualized sessions.

An essential component of genetic counseling is a concern about the psychosocial issues surrounding illness, especially heritable disease. For the patient diagnosed with cancer or coming from a cancer-prone family, there may be a significant affective component. It is quite common that an individual coming for genetic counseling and testing has other stress-inducing events in her life that become even more burdensome in the context of dealing with cancer and its hereditary nature. She may be quite depressed or anxious.

Providing the patient with emotional support is a vital aspect of genetic counseling. One important element of this process is encouraging the patient to “tell her story,” that is, to describe her experiences leading up to and following her diagnosis, to describe her support system and her response to her treatment, to provide her own evaluation of her emotional status, and to evaluate the impact of her disease on other family members such as her children, partner, and parents. There are many patients for whom recalling their experiences within a family with multiple affected members may be quite depressing and anxiety provoking. Many patients have not had an opportunity to discuss their experiences with a professional, and they express their appreciation at being given the opportunity to do so. Although it is ultimately beneficial to a patient to engage in this recollection, it can be emotionally exhausting, and the patient may not feel prepared to go ahead with the testing at that time. She may prefer to return to have her blood drawn.

The counselor or physician needs to be prepared not only for anger or depression among those who learn about an increased risk but also for paradoxical or perhaps unexpected responses. Patients who are told of positive results may express a sense of relief because the uncertainty with which they have lived has now been resolved. Patients who are told of negative results may experience a sense of “survivor’s guilt,” especially if other family members are told of positive results. Patients may be quite depressed and require a referral to a psychotherapist for psychotherapy or short-term use of antidepressants. Acute depressive reactions have been observed only rarely under such circumstances, although the physician or counselor should have made prior arrangements to obtain emergency psychiatric consultation, should this be required.

The indications and timing of surveillance by self-examination, physician examination, diagnostic imaging including digitized mammography, breast and pelvic sonography, magnetic resonance imaging (MRI), and tumor markers are reviewed. Use of risk-reducing surgery is an important subject for discussion, as is the potential role for chemoprevention.

How is genetic testing for *BRCA1* and *BRCA2* carried out?

Mutations in *BRCA1* and *BRCA2* can be detected with molecular techniques that use polymerase chain reaction, including direct DNA sequencing and single-stranded conformational polymorphism analysis together with targeted sequencing. Other methods are under development. For the individual being tested, only a small blood sample is required. Ideally, an individual in the family who is most likely to be a carrier

should be tested first; that is, the youngest affected individual or an individual with multiple tumors. If a mutation is identified in this affected person, other family members wanting to know their carrier status may be tested. Any unaffected relative who does not have the family mutation is counseled that her chance of developing breast or ovarian cancer is no different from that of anyone else in the population. There may be exceptions to this in a given family, but this would be subject to a complete family and individual assessment.

If an affected individual from a high-risk family tests negative in the initial mutation analysis, it may be prudent to test another affected member because the first individual may constitute a sporadic case within a hereditary breast family. The estimate of risk for that first individual should be based on an assessment of the probability that breast cancer is heritable in the individual or family, together with an assessment of the sensitivity and specificity of the test.

What are the recommendations to people who are at high risk for developing breast cancer?

Although the complete implications of inheriting a mutation in either *BRCA1* or *BRCA2* are uncertain, it is still possible to provide some risk assessment to carriers. This should be individualized, taking into account the personal medical history of the patient, the family constellation of cancer, the ethnic origin, and the specific mutation. The care provider should investigate the latest studies and extrapolate from them information that is most relevant. He or she should provide a range of risks derived from multiple studies with an explanation of the limitations of these results with respect to the given individual. Patients should be educated about surveillance and about the possibility of reducing risk for disease by up to 95% by prophylactic mastectomy and oophorectomy.⁵⁵⁻⁵⁷ These recommendations are applicable to patients who remain at high risk, even in the absence of a detectable mutation. In addition, risk assessment or testing and recommendations for screening may be applicable to other family members and should be offered.

Affected women with *BRCA1* mutations should be advised of their increased risk for a second primary tumor, either breast or ovarian, and referred for appropriate monitoring, as outlined below. Unaffected women who are carriers of the mutation should understand the range of risks to which they are subject, as discussed previously in the section on penetrance. Men carrying a *BRCA1* mutation should be monitored for prostate cancer and breast cancer, although it has not been demonstrated that there is an early age of onset.

Affected and unaffected women carrying the *BRCA2* mutation should be advised similarly as for *BRCA1* carriers, with the caveat that the probability of ovarian cancer, although higher than for the general population, is lower than for *BRCA1* carriers. Men who are carriers should also be examined regularly by their internists for signs of breast cancer. The benefit of mammography in men at high risk is unknown. Men and women should be screened for signs of melanoma and monitored for symptoms of pancreatic cancer (i.e., unexplained abdominal pain). Currently, there are no recommended screening tests for pancreatic cancer outside of an

investigational protocol. In addition, men who are carriers should be monitored for signs of prostate cancer.

Breast Cancer

The major recommendations for increased surveillance for prevention of breast cancer are breast self-examination and mammography.⁵⁸ Monthly breast self-examination should begin in early adult life. The young woman should familiarize herself with the characteristics of normal breast tissue and should be instructed to palpate for lumps and to observe for unusual discharges or skin retraction. This should be supplemented by semiannual or annual clinical examination beginning at age 25 to 35 years. Up to 10% of breast cancers can be detected by clinical examination alone.⁵⁹

Mammography, ultrasonography, and MRI are useful for identifying early cancers that may not be palpable by physical examination. For women who are at moderate or high risk, annual mammography is recommended beginning at age 25 to 35 years.⁶⁰ Whenever possible, the mammograms and sonograms should be performed at the same institution and with prior films and images available for comparison. Studies on the risks and benefits of mammography have been based on women with average risk; hence, the risks and benefits of mammography before age 50 years have not been established.⁶⁰ Although not proven, the estimated 20-fold increase in risk for developing breast cancer for *BRCA1* and *BRCA2* mutation carriers suggests that mammography and ultrasonography screening may be of benefit.

Two major concerns with early use of mammography have been expressed.^{62,63} First, early and frequent exposure to radiation may, in fact, increase the risk for breast cancer, as discussed in Chapter 15. Second, mammography is less useful for identifying small masses in younger women, whose breasts are more dense than those of older women. Furthermore, clinical trials have provided preliminary reports of cases of breast cancer in women with increased genetic risk that were identified by MRI, but not by ultrasonography or mammography.^{64,65} For carriers of mutations in these genes, because the risk for other malignancies is also increased, surveillance for carriers should include monitoring for ovarian and prostate cancer.

Ovarian Cancer

Two major screening methods are available for detection of early-stage ovarian cancer in *BRCA1* mutation carriers: vaginal ultrasound and measurement of the serum marker CA-125. Vaginal ultrasound can detect masses as small as 2 mm in diameter, that is, at a stage at which they may not be palpated during physical examination.^{66,67} Two analytic methods have been applied to improve the discrimination between malignant and benign lesions: (1) application of a morphology index based on ovarian volume, cyst wall thickness, and septal structure; and (2) use of color-flow Doppler, which can reliably distinguish the lower impedance to blood flow of ovarian neoplasms.^{68,69}

CA-125 is a glycoprotein that is shed into the blood by malignant cells, most commonly of ovarian epithelial origin.⁷⁰ After a baseline is established, elevation on a subsequent measurement may be indicative of the development of an ovarian cancer.⁷¹ Unfortunately, both false-positive and false-negative results occur with a measurable frequency, suggesting that CA-125 is not a stand-alone technique to screen for early-stage ovarian cancer. In addition, clinical trials assessing a

variety of techniques for early diagnosis of ovarian cancer are underway.

Risk-Reducing Surgery

Some individuals who are at increased genetic risk may choose to have risk-reducing surgery for prevention of breast and ovarian cancer. Bilateral salpingo-oophorectomy reduces the risk for ovarian cancer by 95% and for breast cancer by about 50%.⁵⁶ Bilateral prophylactic mastectomy reduces the risk for breast cancer by about 90%.^{55,57} Residual breast or ovarian tissue following these operations provides the remaining risk.^{72,73} For maximal reduction of risk, women might choose prophylactic oophorectomy and mastectomy. However, the single procedure that maximally reduces risk is prophylactic salpingo-oophorectomy.

Prostate Cancer

Screening for prostate cancer is endorsed by some professional groups but not by others.⁷⁴ The American Urological Association recommends that prostate-specific antigen (PSA) screening and digital rectal examination start at age 50 years in the general population and at age 40 years for men in high-risk groups (men with a positive family history and African American men).⁷⁵ The American Cancer Society similarly recommends that screening start at age 50 years for men in the general population, at 45 years for African American men and for men with one affected first-degree relative, and at 40 years for men at higher risk.⁷⁶ However, the American College of Physicians and the American College of Preventative Medicine recommend against the use of routine screening.^{77,78} Those who are proponents of screening argue that since the widespread use of PSA testing there has been a migration to lower stages of disease at diagnosis, which would ultimately lead to an overall reduced cause-specific mortality rate.

What other social and psychological issues should be addressed with the patient?

Many individuals who are at high risk for hereditary cancer choose not to have such testing. Some may cite a desire “not to know,” whereas others express concerns about potential misuse by third parties, including insurers and employers.⁷⁹ Given the sensitive nature of this information, there are several steps that the health care provider can take. First, he or she can provide the patient with a promise of confidentiality in compliance with federal and state regulations. These statutes include maintenance of the patient’s record in a locked cabinet or within an electronic medical record that is not accessible to others. The patient’s clinical information and test results can be disclosed to others only with the patient’s written consent. The inpatient hospital record can be written so that only information necessary to the patient’s care is provided. For example, it may be irrelevant to note that a patient is a *BRCA1* mutation carrier if she is being admitted for a routine pregnancy delivery. Obviously, the guarantee of confidentiality is waived by the patient when she signs a request directing her information to a third party.

Second, the provider can advise patients that several forms of legal protection exist on both the federal and state levels.⁸⁰ The major federal laws are the Health Insurance Portability and Accountability Act (HIPAA) of 1996 and the Americans

with Disabilities Act (ADA) of 1990. HIPAA provides patients with the right to access their personal health information and to direct who else may have access. The Act also specifies the physical, procedural, and technologic security protections that health care providers must make to ensure the confidentiality of patients’ medical information. The ADA provides a broad definition of disabilities, so that being perceived as having a disability is the same as actually having such a condition. This confers certain protections to employees or prospective employees with disabilities. For health care, the guiding principle is that employers cannot treat their disabled employees differently from other employees. Any requirements for pre-employment testing must be extended to all. Likewise, any limitations on health care benefits must be extended to all. In recent years, certain states have enacted protective legislation that limits the use of genetic testing by insurers and employers.⁸⁰ Nonetheless, individuals may still be coerced into having genetic testing.

Third, providers can anticipate adverse psychological interactions of family members. Although individuals may report no change of psychological state or may report resolution of anxiety, even when they learn about an adverse outcome, a few individuals may experience an acute depression. Learning of a favorable test outcome may trigger an adverse psychological response, including survivor’s guilt, depression, or a manic attack. Before undertaking genetic testing, it is advisable to review how the patient may handle the results and to arrange for psychiatric support should an adverse psychological outcome occur.

The identification of genetic risks for development of breast and ovarian cancer has the potential to be a public health benefit by leading the identification of those at risk before the development of disease. Judiciously applied preventive strategies could have a major impact for those at highest risk. Significant changes are likely to occur with testing strategies and prediction of risks. Development in these areas is likely to occur during the next several years, and it may be necessary for health care providers to consult sources beyond this chapter.

Appendix: Genetic Counseling Protocol

TELEPHONE INTAKE

1. Ascertain the problem and concerns of the patient and source of referral.
2. Determine the affected or unaffected status of the patient and other family members by taking a brief family history.
3. Provide a short description of the evaluation process, to include
 - a. The number and length of the sessions
 - b. The elements of the evaluation
 - c. The type of information that is to be obtained and given
 - d. Who will accompany the patient to the meeting (partner, close friend, other relative, other)
4. Discuss fees and potential insurance issues.

5. Advise the patient about additional information or records that may be required.
6. Send release forms if necessary.

FIRST SESSION

1. Ascertain the motivation of the patient and others in seeking information and testing.
2. Determine the patient's understanding of what is to be learned and the patient's perception and that of others of the probability that cancer is heritable in the family or that the patient will develop cancer or have a recurrence.
3. Learn from the patient how the information is likely to be useful both personally and by other family members.
4. Learn whether the patient definitely wants testing, does not want it, or is uncertain, and learn what the factors that influence that opinion are.
5. Describe the elements of the consultation:
 - a. The number of sessions (usually at least two)
 - b. The content of the sessions
 - c. Review of records and slides for confirmation of the diagnosis
 - d. The time frame for the receipt of information and completion of testing
 - e. How the patient will receive results (in person only, with occasional exceptions)
 - f. The availability of other specialists (e.g., surgical, medical, and gynecologic oncologists, radiologists, other medical specialists, psychotherapists)
6. Obtain a detailed medical history, including the affected or unaffected status of the patient. If the proband is affected, find out the date and age of diagnosis; how the patient came to be diagnosed; the physicians providing care at each step of the diagnostic process; the treatment received, both surgical and medical; reproductive history; other medical history; exogenous hormone exposure; smoking history; alcohol consumption; dietary fat consumption; dietary supplements; and physical activity.
7. Obtain a detailed three-generation family history to include
 - a. History of all maternal and paternal relatives, with information about as many relatives as possible from at least two antecedent generations (parental and grandparental) and relatives from all descendant generations (i.e., children, grandchildren, nieces, nephews)
 - b. Ages of affected and unaffected relatives
 - c. History of all malignancies in all recorded relatives and their ages at diagnosis and death
 - d. Other genetic conditions in the family
8. Identify family members from whom confirmatory diagnostic information will be required and make arrangements to obtain records, slides, and other test results if possible.
9. Discuss a potential diagnosis and provide an estimate in qualitative and quantitative terms of the probability that there is a heritable cancer syndrome in the family and the probability that the patient and other family members are carriers. In discussing these issues, elicit whether the

patient has discussed testing with other family members and whether they want to receive results. Encourage the patient to inform relatives of the testing before it occurs, or at least before results are received.

10. Explain what testing or counseling may be applicable or appropriate to define the condition more precisely (this may not be possible until additional information and records are obtained).

If Family or Individual Wants to Consider Testing

1. Discuss the contribution of major genes to a hereditary predisposition to breast and ovarian cancer and describe the genetics of the applicable hereditary predisposition. Explain which gene or genes may be appropriate to test in the given family.
2. Give a full explanation of the testing procedures, including the identification of the individual within the family who may be most appropriate to test first (i.e., the youngest affected individual if possible).
3. Emphasize and quantify the accuracy and limitations of the diagnosis, including the sensitivity and the specificity of the testing.
4. Explain the implications of both positive and negative results.
5. Advise the patient that a specific diagnosis may not be possible.
6. Indicate whether the test is investigational and whether the laboratory is a research laboratory, is approved by the Clinical Laboratories Improvement Act, or is state licensed.
7. Indicate, before testing, the importance of obtaining medical records or other documentation of the diagnosis in relevant family members, with your understanding that it may not always be possible.
8. Discuss the emotional and psychological aspects of testing versus not testing.
9. Discuss the benefits and drawbacks of testing versus not testing for both affected and unaffected family members.
 - a. Benefits of testing
 - (1) Allows the patient to plan medical care
 - (2) May be useful for other family members who want to learn their carrier status and risks and modify their health care
 - (3) Allows unaffected family members to learn that they are not at increased risk or are at lower risk than anticipated
 - (4) Alleviates the anxiety of not knowing
 - (5) May improve family relationships
 - b. Drawbacks of testing
 - (1) May heighten anxiety in carriers
 - (2) May interfere with family relationships
 - (3) May produce guilt in parents who transmit the gene
 - (4) May engender resentment among relatives, some of whom will learn they are carriers whereas others are noncarriers
 - (5) Individuals choosing testing and carriers may encounter employment or insurance discrimination
- (6) Individuals choosing testing may, in the process, learn genetic information about relatives who choose not to be tested
- (7) Patient may encounter uncertainty because of the unknown efficacy of surveillance
10. Discuss issues of confidentiality; that is, results will be shared only with individuals identified by the patient, and the patient must provide written permission from these individuals to share the results with them
11. Discuss fees and insurance reimbursement; potential for insurance or employment discrimination.
12. Emphasize that testing will be limited to individuals who are of age to consent unless medical management is affected.
13. Remind the patient that testing is elective.
14. Tell the patient that he or she will receive the results in person only and may wish to be accompanied by a partner, relative, or friend.
15. Discuss the pros and cons of having individuals hear their results with other members of their family or separately.
16. If family members are being counseled as a group, provide adequate time for all individuals to meet privately with the counselor or physician.
17. Provide recommendations for surveillance and risk-reducing surgery following testing.
18. Provide to the patient a written summary of the content of the session summarizing the medical content of the session.
19. Draw blood for testing, sign consent form, complete insurance forms, or make arrangements for a second appointment.

If the Family Is Not a Candidate for Testing or Individuals Choose Not to Be Tested

1. Provide an estimate of the risks for recurrence or occurrence in affected and unaffected family members based on the family history, personal medical history, and data from current medical literature and risk assessment tools.
2. Offer DNA banking (tumor, lymphocytes, tumor block) for appropriate family members if indicated.
3. Discuss scheduling additional sessions if needed or indicated.
4. Provide the patient with a written summary and promise a copy of the letter to the physician.

A patient may return to have blood drawn for testing at another time.

INTERIM

1. Collect medical records, pathology specimens.
2. Review the medical records, including review by the pathologist.
3. Update the literature search.
4. Conduct a multidisciplinary management conference.
5. Provide the referring physician with a summary of the evaluation to the patient and any other designated individual (written consent is required).

SECOND SESSION

1. Give results.
 - a. Ascertain who is to be in the room (may be done before the appointment).
 - b. Review the implications of diagnosis, giving individuals the opportunity not to learn their results, or to defer learning results.
 - c. Provide results.
 - d. Provide emotional support, especially for those learning of their at-risk status, or alleviate guilt for those not at risk, if appropriate.
 - e. Reiterate the degree of accuracy and the limitations of the test.
 - f. Review or explain how the risks were calculated.
 - g. Discuss the patient's perception of the results and the alternatives.
 - h. Discuss in greater detail preventive measures and surveillance and state that there is no clear evidence that surveillance improves outcome in breast cancer.
 - i. Refer to other medical specialists, if indicated, including psychiatrist or psychotherapist.
 - j. Discuss the availability of clinical trials.
 - k. Discuss implications for other at-risk individuals in the family and offer testing if appropriate. If preventive measures should be performed before the legal age of consent, testing should be offered to children.
- l. After this session, write a letter to the patient summarizing the results of testing and risk assessment and include recommendations for surveillance. Provide a copy of the test report and obtain written consent to report results to any third party, including the physician.

Development of Modern Breast Cancer Treatment

Daniel F. Roses

Breast cancer therapy has evolved through most of its long history without any verifiable understanding of the behavior of the disease, little technical means by which it could be studied, and limited diagnostic and therapeutic resources. By contrast, our present modern era of breast cancer treatment, beginning in the closing decades of the last century, has developed with increasing rapidity through the efforts of an extremely broad spectrum of basic research scientists and clinical investigators who have redefined our standards for developing, evaluating, and applying meaningful therapeutic strategies. Historically, the most important development in breast cancer treatment was the rise of modern surgery, which made careful and thorough ablation of local disease technically feasible and demonstrated to a skeptical medical world that breast cancer is a treatable disease. Paradoxically, this advance also made clear the limitations of therapy that was exclusively directed at the breast and its regional nodal drainage sites. As other therapeutic modalities were developed, the possibility of curing an ever-greater population of patients became a reality. At the same time, advances in radiographic and pathologic diagnosis also made clear the inappropriateness of overzealous and uniformly rigid efforts to extirpate local disease. As we enter into a new century, the intensity with which modern diagnostic and therapeutic strategies are assessed, and with which the molecular mechanisms of disease are being defined, carries the hope that we are on the threshold of a new era in which it will become possible to translate an enhanced understanding of oncogenesis and growth into universally effective treatment and even prevention.

Has breast cancer always been a major health problem?

Cases of breast cancer have been recorded in medical writings for more than 5000 years. In documents from the ancient world, they appear with perhaps greater frequency than any other form of cancer. This suggests that the incidence of breast cancer was significant, particularly considering that life expectancy in the ancient world was probably no more than 40 years. The first written evidence possibly indicating a breast cancer is from ancient Egypt and is found in the Edwin Smith Surgical Papyrus, a compendium of surgical cases and therapeutic recommendations, dating back from 3000 to 2500 B.C.E.¹ Although the patients referred to are to men, case 45

concerns a “bulging” tumor of the breast. Ancient Egyptian physicians are instructed to do nothing to such bulging tumors if they are hard and cool when touched—likely indicative of cancer. This is in contrast to case 39, a tumor that had “spread with pus over his breast” and had “produced redness, while it is very hot therein”—certainly indicative of an abscess. The recommended treatment here is incision with an instrument known as a “fire drill.”

How did physicians in the ancient world view the etiology of cancer?

In ancient Greece, Hippocrates (circa 460–377 B.C.E.) set forth a humoral concept of cancer’s origin, extending his belief that diseases were caused by imbalances in the four basic humors—blood, phlegm, and yellow and black bile—cancer being due to an excess of black bile. Before this, breast cancer was likely thought to be of supernatural origin. Clay models of breast tumors found in the remains of Greek temples suggest that remedies were sought through supernatural intervention.² Hippocrates wrote of “carcinoma apertus,” which was a malignant ulcer, and “carcinoma oclusus,” which was a nonulcerated, deep-seated tumor. Of the latter, he stated that it was better to omit treatment altogether, for, “if treated, the patients die quickly; but if not treated they hold out for a long time.”³ In the first century C.E., the teachings of the Roman scholar Celsus did suggest that efforts to extirpate malignant lesions early in their development might offer some hope of success, whereas treatment when the disease became more advanced might hasten its progression.⁴

Aglacon, by the second century C.E., embellished the humoral concept, teaching that when the temperature of the liver increased, it began to generate decomposed, thick blood,⁵ which the spleen forced to various sites in the body. If this thick blood were to stagnate in an organ such as the breast, cancer would be produced. His student Galen, whose writings were destined to become the most authoritative therapeutic directive for centuries, expounded on such humoral theories of disease, also promoting the Hippocratic view that breast cancer, among other neoplasms, was due to an excess of black bile. The Greek surgeon and physician Paul of Aegina (625–690) again promoted the belief that cancer arose from thick overheated bile, which commonly affected the breast “due to its laxity which admitted humours.”⁶

How was cancer treated in the ancient world?

The basic component of cancer therapy, according to Galen, was the use of purgatives, although he did recognize surgery as a form of therapy for accessible lesions. If surgery were resorted to, he advised that it be done “from the root,” by which he meant encompassing the veins “full of the malignant matter.”⁷ Recorded clinical observations of progressive axillary nodal involvement, as well as descriptions of partial mastectomies by the Greek physician Leonides in the second century C.E., suggest that there existed a tension between the authoritative promotion of theories of humoralism on the one hand and the recognition that surgery, then a violent therapeutic intervention, might be required for a disease that so obviously did not respond to purgatives, bleeding, caustics, cauterization, or dietary manipulation.⁸

During the period from the fall of the Roman Empire to the Renaissance, medical progress remained stagnant as Christianity and Islam limited anatomic dissection and, in turn, surgical practice. The teachings of Galen were elevated to official doctrine, and efforts to question his dictates were viewed as heretical. Despite edicts to restrict the performance of surgery, eminent surgeons, such as Henri de Mondeville (1260–1320) and Guy de Chauliac (1300–1368), advocated surgery for breast cancers that could be completely excised. William of Salicet (1210–1277) and Lanfranc of Milan (?–1315) advocated extending surgery to complete removal of the breast. William of Salicet, in a synthesis of surgical and humoral thinking, stated that

*the disease cannot be truly cured except by the amputation of the part, as I have said above, for its roots are imbedded in the veins which course about it, and which are full of melancholy blood [containing black bile]; and that it is necessary for the perfect cure that the veins be cut and the roots extracted in some fashion. This cannot be done except by removing the part in its entirety, and the disease cannot be cured by any other means. It appears to me that it is neither good, nor useful, nor honest for the physician to interfere with this cure. It would be better, to be sure, and I advise you, my friend, to decline.*⁹

Medieval surgeons empirically recognized that inadequate excision was futile. It is understandable, therefore, that breast cancer, a disease that was likely to be locally advanced upon presentation to surgeons, was for the most part treated by attempts at local palliation using caustics. What was required to free breast cancer treatment conceptually, if not practically, from the dominance of folk wisdom and ancient medical dogma was anatomic observation and study.

When did anatomic concepts of breast cancer development appear?

Anatomic paradigms for breast cancer arose with the Renaissance and the renewed study of anatomy. The critical figure in the development of scientific anatomy based on observation and dissection was Andreas Vesalius (1514–1564). Vesalius was also a surgeon who is recorded as having operated for cancer of the breast, excising the lesion widely and achieving hemostasis by ligating blood vessels rather than by the brutal cauterization in common use during this era.¹⁰ His

contemporary, Ambrose Paré (1510–1590), the most famous surgeon of the 16th century, described the swelling of axillary lymph nodes that he observed in patients with breast cancer.¹¹ Although he is recorded as having excised superficial lesions, for most patients he would compress the base of the breast between lead plates, the resulting ischemia hopefully arresting the progression of the disease.⁸

Several other surgeons of the 16th century described more surgically aggressive approaches to breast cancer, including Johannes Scultetus (1595–1645), who with great speed excised the breast after traction had been applied by heavy leather thongs threaded through its base, hemostasis being provided by a hot iron applied to the chest wall¹² (Fig. 21–1). Another surgeon, Wilhelm Fabry von Hilden of Germany (1560–1624), also developed a rapid technique using an instrument that lifted the breast away from the chest wall, its base then constricted with an iron ring, following which it was amputated. Guillaume de Houpperville incorporated the subjacent pectoralis major muscle in his mastectomies, and Marcus Aurelius Severino (1560–1634) first removed enlarged axillary lymph nodes.¹³ Fabry von Hilden, however, observed that excising axillary tumors was difficult and dangerous because

*the breast veins come together in that spot, bleeding from which must be controlled. Furthermore, also through contraction of such tumors, the breast muscles which aid in breathing might be injured, and for this reason there is danger of suffocation. Therefore it is necessary to proceed slowly, humbly, and gently with such parts.*¹⁴

He recognized the futility of incomplete resection of fixed lesions, noting,

Above all things, one must inform himself carefully whether the tumor weaves about or moves from one place to another, or whether it can be removed from its base, including its roots. For all would be for naught if a part of the tumor, be it ever

Figure 21–1 Mastectomy (breast amputation) for cancer. (From Johannes Scultetus *Armamentarium Chirurgicum*, Amsterdam, 1741.)

*so small, even a bit of membrane with which such tumors are generally surrounded, were to remain behind. Then it flames up again and becomes worse than ever before.*¹⁴

Not surprisingly, he deferred treating ulcerating lesions and, believing cauterization incited further malignant growth, proposed the topical application of a distillate of suckling puppies boiled in wine.

Surgeons of the Renaissance were obviously frustrated by an inability to translate their new anatomic knowledge and more critical clinical observations into therapeutic progress. Despite their intentions, the extremes of disease continued to be managed by bizarre topical concoctions, such as those of Fabry von Hilden, and even by the application of animal feces to the tumor, excreta being frequently used medicinally during this era. Nevertheless, progress was clearly being made toward establishing an anatomic concept of the disease upon which a consistent therapeutic strategy could be constructed.

When was a local theory of breast cancer introduced?

The 18th century brought a new focus by surgeons on anatomic and experimental pathology. In France during this Age of Enlightenment, the ancient humoral theory of oncogenesis was discarded most forcefully by Henri François Le Dran (1685–1773) (Fig. 21–2). In a memoir published in 1757, he reasoned that because axillary nodal involvement in a patient with cancer of the breast was indicative of a worse prognosis, the disease must spread through the lymphatics to these lymph nodes and then into the general circulation after its

Rights were not granted to include this figure in electronic media.
Please refer to the printed publication.

origin in the breast. At its earliest phase of development, therefore, it was a local disease and might well be eliminated by surgery. If “cancer lymph” passed beyond the adjacent lymph nodes, the entire lymphatic system would become contaminated.¹⁵ New theories on the lymphatic origins of cancer arose. At the University of Halle, Friedrich Hoffman (1660–1742) and Georg Ernst Stahl (1660–1734) espoused the view that cancer was composed of fermenting and degenerating lymph, a concept that was also proposed by John Hunter (1728–1793).¹⁶

When did a unified surgical approach to breast cancer arise?

The surgical application of Le Dran’s conceptualization of breast cancer as a local disease found its most forceful advocate in Jean Louis Petit (1674–1750) of Paris (Fig. 21–3), a leading founder of the French Academy of Surgery. In Petit’s book, *Traits des Maladies, Chirurgicales et des Operations*, published posthumously, he outlined a concept of ablative surgery that required excising the breast, palpable axillary lymph nodes, and underlying pectoralis major muscle if attached to the tumor. As he noted,

*. . . the roots of cancer were the enlarged lymphatic glands; that the glands should be looked for and removed and that the pectoral fascia and even some fibers of the muscle itself should be dissected away rather than leave any doubtful tissue. The mammary gland too should not be cut into during the operation. . . . Where the integuments are also affected and strictly joined to the cancer there is little hope to expect a perfect cure if they are not both clearly extirpated together.*¹⁷

Figure 21–2 Henri François Le Dran (1685–1773), who developed a local theory of breast cancer. (Courtesy of New York Academy of Medicine.)

Although Petit did not always encompass the nipple and areola in his procedures, he did clearly promote the concept of en bloc resection of cancer. Petit attracted students from many European surgical centers and certainly influenced the course of breast cancer surgery through the 18th and 19th centuries. Lorenz Heister (1683–1758) of Germany advocated mastectomy with the attached pectoralis major muscle and axillary nodes if necessary. However, his vivid description of a mastectomy performed in 1720 leaves no doubt as to the brutality of surgery at that time and the near impossibility of translating any detailed surgical concept into clinical reality.¹⁸ Heister was able to report the surgical removal of cancers “bigger than one’s fist” and one that weighed 12 pounds, reflecting the expanded advocacy of surgery as a therapeutic option.¹⁸ Bernard Peyrilhe (1735–1804) in 1773 envisioned surgery that encompassed the entire breast, axillary nodes, and pectoralis major muscle.¹⁹ Samuel Sharpe in England and Benjamin Bell (1749–1806) in Scotland also promoted mastectomy and the excision of palpable axillary lymph nodes. However, the limitations on surgery in the preanesthetic and preantiseptic era clearly continued to inhibit timely intervention and restrict its use except as a treatment of desperation. As a result, extreme pessimism regarding the curability of breast cancer persisted.

Did a local theory of breast cancer development result in any major change in treatment?

Despite the acceptance of Le Dran’s local concept of breast cancer, surgery was still considered worse than the disease, and little advance in treatment resulted. A vivid account of a mastectomy performed on September 30, 1811, makes this clear. The patient, the novelist Fanny Burney, best known for her letters and diaries, was married to a French aristocrat, Alexander D’Ablay, and living in France when, in 1811, she noticed a lump in her breast. Cancer was diagnosed, and surgery was performed by the illustrious surgeon to Napoleon, Baron Dominique-Jean Larrey (1766–1842). In a letter to her sister on the ordeal, she wrote that she was given very little notice of her operation, only being informed that it would take place on the very morning of the day of the procedure. To gather up the necessary resolve, she was able to delay its commencement for several hours, at which time Larrey arrived with six assistants. After being prepared with wine she was laid down on a bedstead. A handkerchief was spread over her face to block her view, but it was thin, and she could make out what was about to take place. When the procedure commenced, she let out a scream, which, she wrote, “lasted uninterruptedly during the whole time of the incision,” and when the instrument was withdrawn, the pain was undiminished. She recalled the “knife rackling against the breastbone—scraping it!” The operation lasted 20 minutes, during which time she fainted twice, and when the handkerchief was removed from her eyes, she “saw my good doctor Larrey, pale nearly as myself, his face streaked with blood, and its expression depicting grief, apprehension, and almost horror.”²⁰ Madame D’Ablay lived another 30 years, which has even called into question the accuracy of the diagnosis. More typical of the results following surgery was the experience of 46-year-old Abigail Adams Smith, daughter of the second president of the United States. In the same year that Fanny Burney discovered

her tumor, she also felt a mass in her right breast and was advised by Dr. Benjamin Rush that the only remedy was “the knife.” He wrote,

From her account of the moving state of the tumor, it is now in a proper situation for the operation. Should she wait until it superates or even inflames much, it may be too late. . . . I repeat again, let there be no delay. . . . Her time of life calls for expedition in this business, for tumors such as hers tend much more rapidly to cancer after 45 than more early in life.²¹

On October 8, 1811, in a bedroom next to that of John and Abigail Adams, a 25-minute mastectomy was performed by four surgeons. She recovered but died of her disease 2 years later. Even more typical of treatment during this era is a poignant account of an indigent patient having surgery for breast cancer that took place in a crowded amphitheater in Edinburgh in 1830, as recorded by an onlooking medical student, Dr. John Brown. The patient was brought into the amphitheater in her street clothes, accompanied by her husband and her dog, where she stoically withstood the painful procedure only to die of sepsis a few days later.²²

Given the desperation of such therapy, it is no wonder that in the same year as the operations on Fanny Burney and Abigail Smith, the English surgeon Samuel Young again described treating breast cancer by compression, as had Paré 250 years earlier.¹⁷ This technique was to prove no more successful than it had been when originally introduced. The problem of this era was best summarized by Henry Fearon (1750–1825), who noted that although surgery for breast cancer at an early time represented the most favorable opportunity for effecting a cure, it was unlikely that patients whose disease was creating few or any symptoms could be convinced of undergoing such painful and dangerous therapy.²³ In 1792, a cancer charity ward was established for the first time at Middlesex Hospital in London, where patients could be cared for and studied in an attempt to arrive at some new understanding of the natural history of a disease that so eluded comprehension and possible methods of treatment. In 1803, the first patient with breast cancer was admitted there for study.

Was breast cancer viewed as a curable disease at the beginning of the 19th century?

Such eminent English surgeons as James Syme (1799–1878), Sir James Paget (1814–1899), and Robert Liston (1794–1847) all wrote with skepticism on the possibility of effecting a cure for breast cancer through surgery.^{24–26} Paget, who in 1874 was to describe one of the more favorable forms of carcinoma of the breast with which his name is attached, actually believed that women with what was described as “scirrhous carcinoma”—a generic category that encompassed any lesion with painless growth and a hard consistency—were less likely to have a prolonged survival if surgery were attempted rather than if the disease were allowed to progress unimpeded. In 1853, Paget wrote that “in deciding for or against the removal of a cancerous growth, in any single case, we may, I think, dismiss all hope that the operation will be a final remedy for the disease.”²⁴ In 1856, citing his failure to have a disease-free survivor beyond 8 years among 235 patients on whom he had operated, he again wrote, “We have to ask ourselves whether

it is probable that the operation will add to the length and comfort of life enough to justify incurring the risk for its own consequences.²⁵ In the United States, D. Hayes Agnew (1818–1892), ironically memorialized in the famous painting by Thomas Eakins depicting his supervision of a breast procedure at the University of Pennsylvania, wrote skeptically, “I do not despair of carcinoma being cured somewhat in the future, but this blessed event will never be wrought by the knife of the surgeon.”²⁷

What was the impact of microscopic pathology on breast cancer treatment?

The rise of microscopic pathology in the first half of the 19th century provided evidence for a verifiable and rational explanation on the natural history of breast cancer. Following the development of the achromatic microscope in 1830 by Joseph Jackson Lister (1786–1869), which enabled clear microscopic images to be studied without blurring, Johannes Müller (1801–1858) in 1838 was able to demonstrate the cellular structure of malignant growths, whereas Joseph Recamier (1774–1852) in 1829 first described “metastasis” as well as local infiltration of malignant tumors into surrounding tissues and veins.^{28,29} Tumors were now clearly defined as lesions evolving from cells that could infiltrate and invade lymphatic and vascular structures. With the establishment of cellular pathology by Müller’s student Rudolf Virchow (1821–1902) (Fig. 21–4), cancer was now viewed as evolving from normal cells.

The development of metastases, however, eluded pathologic observation and understanding. Virchow, for one, felt that metastatic spread occurred “by means of certain fluids, and these possessed the power of producing an infection which disposes different parts to a reproduction of a mass of the same nature as the one which originally existed.”³⁰ Regional nodal metastases were viewed by Virchow as representing a temporary barrier to distant dissemination. Of axillary nodal metastases, Virchow stated in 1858,

*When an axillary gland becomes cancerous, after previous cancerous disease of the mamma, and when during a long period only the axillary gland remains diseased without the group of glands next in succession or any other organs becoming affected with cancer, we can account for this upon no other supposition than that the gland collects hurtful ingredients absorbed from the breast and thereby for a time affords protection to the body, but at length proves insufficient, nay, perhaps at a later period itself becomes a new source of independent infection to the body, inasmuch as a further propagation of the poisonous matter may take place from the diseased parts of the gland.*³¹

Karl Thiersch (1822–1893) and Wilhelm Waldeyer (1837–1921), by studying serial sections of cutaneous and gastrointestinal neoplasms, further established the epithelial origins of malignant growth. They believed that migration of cells, not the suffusion of “hurtful ingredients,” through the lymphatic and circulatory system, led to metastases, agreeing that the regional lymph nodes served as a protective filter.²⁹ Virchow, like Paget before him, believed that cancer required a hereditary or constitutional predisposition. Both believed some inciting mechanism was required. For Virchow, the mechanism was chronic irritation; for Paget, it had been a

humoral material that was spread throughout the vascular system.³²

By the second half of the 19th century, therefore, the establishment of the cellular origins of disease and the local pattern of cancer’s progression had provided a more rational framework on which to structure surgical treatment. If tumors expanded and infiltrated before spreading to other sites, then operations to encompass the disease widely, as originally proposed by Le Dran and Petit, were justified. Despite this rethinking, the constraints on surgical practice compelled surgeons in the mid-19th century to sympathize with even such a famously bold surgeon as Robert Liston of London, who wrote

*Recourse may be had to the knife in some cases but the circumstances must be very favorable indeed to induce a surgeon to recommend or warrant him in undertaking any operation for removal of malignant disease of the breast. When the disease has been of some standing there is a considerable risk of the axillary glands having become contaminated. No one could now be found so rash or so cruel as to attempt the removal of glands thus affected whether primarily or secondarily.*²⁶

How did surgeons adapt the advances in cellular pathology to treatment?

The cellular basis of disease now began to permeate medical thought and emboldened many surgeons to advocate more thorough extirpation of the local origins of breast cancer. Joseph Pancoast (1805–1882) in the United States again advocated removal of the breast in continuity with involved

axillary lymph nodes.³³ Writing in 1844, 2 years before the introduction of general anesthesia, he did urge careful selection of appropriate cases, noting the great likelihood of local recurrence “if it has involved the chain of axillary glands, and especially if it has become adherent to the pectoral muscles, or has formed an open ulcer,” urging a candid discussion of such a risk with the patient.³³

With the introduction of general anesthesia in 1846, a new window was opened on what might be attempted in the local extirpation of breast cancer. In 1869, Richard Sweeting in England advocated removing the lower portion of the pectoralis major muscle as well as a generous margin of skin, noting that if the cancer cells lie in the fascia, they are likely to embed themselves in the lower part of the pectoralis major muscle, “certainly not a vital organ that cannot safely be removed. The lower two-thirds of the muscle is more than occupied by the base of a large cancer.”³⁴ Most influential was Charles H. Moore (1821–1870) (Fig. 21–5), a surgeon at the Middlesex Hospital, who in an 1867 article titled “On the Influence of Inadequate Operations on the Theory of Cancer” criticized the frequency with which the breast was only partly removed by other surgeons. He noted the tendency for cancer to recur centrifugally from the scar owing to inadequate removal. He stated that

*local recurrence of cancer after operations is due to the continuous growth of fragments of the principal tumor. Such recurrences may take place also in a residual part of the organ respecting which it cannot be asserted that it is cancerous at the time of operation. . . .*³⁵

He urged wide resection around the tumor to avoid cutting through malignant tissue and directed surgeons to remove the entire breast as well as adjacent diseased tissue, including

Figure 21–5 Charles H. Moore (1821–1870), who asserted that breast cancer evolved centrifugally and required wide resection en bloc with contiguous structures. (Courtesy of National Library of Medicine, Washington, DC.)

generous margins of skin and axillary lymph nodes to avoid “dividing the intervening lymphatics,” a crucial concept in the development of surgical thinking.³⁵ This approach was supported by W. Mitchell Banks in London and in the United States by Samuel W. Gross (1837–1889), both of whom advocated the elective inclusion of an axillary dissection with the mastectomy.^{36,37} Joseph Lister (1827–1912) detached the origins of both pectoral muscles to enhance his ability to dissect the axillary nodal contents. As he noted in an 1870 report on antiseptic surgery,

*I have at present a patient about to leave the infirmary three weeks after the removal of the entire mamma for scirrhus, all the axillary glands having been at the same time cleaned out after division of both the pectoral muscles, so as to permit the shoulder to be thrown back and the axilla freely exposed, as is done in the dissecting room—a practice which I have for some years adopted where the lymphatic glands are affected in that disease.*³⁸

The surgical revolution brought about by general anesthesia, and then by antiseptic practice, proposed by Lister in 1867, led to an escalated effort to surgically treat breast cancer. In Germany, Ernst Küster (1838–1922) championed axillary dissection as a routine component of mastectomy, reporting on his experience in 1883.³⁹ Richard von Volkmann (1830–1889) (Fig. 21–6), writing in 1875, concluded that the fascia of the pectoralis major muscle could be infiltrated, and introduced a procedure to remove it along with the breast and axillary lymph nodes. As he explained,

Figure 21–6 Richard von Volkmann (1830–1889), who advocated removal of the pectoralis major fascia along with the breast and axillary lymph nodes. (Courtesy of National Library of Medicine, Washington, DC.)

*I was led to adopt this procedure because, on microscopical examination, I repeatedly found when I had not expected it that the fascia was already carcinomatous whereas the muscle was certainly not involved.*⁴⁰

Lothar Heidenheim (1860–1940) provided support to Volkmann, reporting on the frequency of lymphatic metastases between the breast and pectoralis major muscle. In 1889, he reported on his experience of including not only the pectoralis major fascia but also a superficial layer of muscle or even the entire muscle for those instances in which the tumor was fixed to the underlying muscle.⁴¹ The greater availability of surgical specimens enabled further detailed pathologic anatomic studies of breast cancer, many supporting a radiating pattern of lymphatic permeation.^{42,43} A consolidation of the advances in surgery and the new conceptualization of breast pathophysiology into a dominant therapeutic doctrine was about to take place.

Why was Halsted so influential in the treatment of breast cancer?

William Stewart Halsted (1852–1922) (Fig. 21–7) had been raised in New York City and received his medical education and spent his early surgical career there. Like many well-to-do graduates of American medical schools, he had gone to Europe to immerse himself in the scientific medicine that was emerging in the great centers of European learning, particularly in Germany and Austria. Between 1878 and 1880, he traveled to Vienna, Berlin, Hamburg, Leipzig, Kiel, Halle, and Würzburg, where he was exposed to the modern advances in clinical investigation, antisepsis, microscopic anatomy, and pathology as well as to the great leaders of European surgery

such as Theodor Billroth (1824–1887), von Volkmann, and Karl Thiersch (1822–1895).⁴⁴ His move to the new Johns Hopkins School of Medicine in 1888 and his subsequent appointment in 1889 as surgeon-in-chief to the outpatient clinic and appointment 2 years later as Professor of Surgery and Surgeon-in-Chief to the Johns Hopkins Hospital led to the establishment of a modern American school of scientific surgery and a surgical training system, greatly influenced by his European experience, that became the model for all those that were to follow in the United States. This position of influence contributed significantly to his impact on the treatment of cancer of the breast.

What was Halsted's contribution to breast cancer treatment?

Halsted extended the operation devised by von Volkmann. He believed that the Volkmann mastectomy was “obviously incomplete” because it failed to encompass fully the surrounding structures.⁴⁵ Halsted noted that von Volkmann’s results, along with the results of his contemporaries, were dismal. Billroth, perhaps the most eminent surgeon of the era, had reported an operative mortality rate of 18.5% and an 82% local recurrence rate after only 3 years from treatment. Only 4.7% of Billroth’s patients had survived more than 3 years. Halsted decided to include the entire pectoralis major muscle. Gross infiltration of the pectoralis major muscle was not uncommon, given the advanced presentations of many of the patients on whom Halsted operated.⁴⁶ This is clearly reflected by one hospital summary from 1905 in which Halsted describes an 8-cm cancer as “small” (Fig. 21–8).

In his first published reference to his operative approach to cancer of the breast in 1891, Halsted stated his reason for excising the pectoralis major muscle:

About eight years ago, I began not only to typically clean out the axilla in all cases of cancer of the breast but also to excise in almost every case the pectoralis major muscle, or at least a generous piece of it, and to give the tumor on all sides an exceedingly wide berth. It is impossible to determine with the naked eye whether or not the disease has extended into the pectoral muscle.

*From the careful microscopical examination of many very small cancers of the breast, I am convinced that the pectoralis major muscle is usually, at the time of the operation, involved in the new growth. Strange to say, no authorities (to my knowledge) suggest the advisability of always removing the pectoralis major muscle or a portion of it in operations for the cure of cancer of the breast; and still stranger there are many surgeons of the first rank—surgeons in favor of methodically cleaning out the axilla—who instead of recommending the excision of the muscle advise the removal of the fascia only from the pectoral muscle. König, for example, in the fourth edition of his Surgery says: “When the fascia over the pectoralis major muscle is diseased, it [the fascia] must be removed.” Surely it is absurd not to remove the muscle when its fascia is, even to the naked eye, diseased.*⁴⁷

The en bloc removal of the breast and pectoralis major muscle with wide resection of the skin and axillary nodes became known as the Halsted mastectomy.

DEAD

S.N. Miss Catherine V. F.W.S Aet 50 Wd C
 17505 Sykesville, Md.
 20926
 22012 I Adm: March 22/05. Disch: May 1/05.
 Operation: Apr. 3/05: Dr. Halsted. Excision left breast,
 axillary and cervical glands. Ext. jugular vein "li-
 gated and excised." "Skin closed with subcutaneous silver"
 Thiersch graft.

Tumor: Small infiltrating scirrhus, metastases to axilla; in upper outer quadrant, 2 x 7 cm. in diameter.
Incision: Circular; over shoulder; to clavicle.
Closure: Small drains in neck and axilla. Arm N.I.
Post Op: Apr 13: Grafts practically all taken. Neck incision healed p.p. No puffiness, no filling up. Axillary fold well preserved. Arm N.I.

Adm II: June 21/07. Disch: July 15/07.
 June 22/07: Cauterization (Pacquelin cautery) of local recurrence, left breast.
 Note on admission states that there was no swelling of arm after the operation of Apr 3/05.
 Post Op: No infection.

(over)

Figure 21-8 A summary report of a patient treated by Halsted in 1905 describing an 8-cm cancer as "small." (From Lewison EF, Montague AC [eds]. Current Concepts: Diagnosis and Treatment of Breast Cancer. Baltimore, Williams & Wilkins, 1981, p 7.)

Why was the Halsted mastectomy viewed as an advance in breast cancer treatment?

At first, the Halsted operation was called the complete operation, then the radical mastectomy. The original Halsted mastectomy consisted of en bloc removal of the entire breast and wide excision of the overlying skin, full dissection of the axilla, and resection of the pectoralis major muscle. In 1894, he wrote in the Johns Hopkins Hospital Reports,

The pectoralis major muscle, entire or all except its clavicular portion, should be excised in every case of cancer of the breast, because the operator is enabled thereby to remove in one piece all of the suspected tissues.

The suspected tissue should be removed in one piece, 1) lest the wound become infected by the division of tissues invaded by the disease or of lymphatic vessels containing cancer cells, and 2) because shreds or pieces of cancerous tissue might readily be overlooked in the piecemeal extirpation.⁴⁶

In his 1894 paper, Halsted was able to report dramatic results with 50 patients who had been treated by his mastectomy since 1889. He maintained that "the efficiency of an operation is measured truer in terms of local recurrence than of ultimate cure."⁴⁶ Halsted compared the local recurrence rate in his patients with the results achieved by surgeons in Europe who were performing the von Volkmann mastectomy. In the European experience, local recurrence rates ranged from 51% to 82%, whereas Halsted was able to report an incidence of only 6% (Fig. 21-9).

Halsted's 6% local recurrence rate was particularly striking in light of his patients' advanced stages of disease. "The prognosis at the time of the operation was recorded as hopeless or unfavorable in 27 of the 50 cases of complete operation," he wrote. "In every one of the 50 cases, some or all of the axillary glands were cancerous."⁴⁶

Local Recurrence Rates

Surgeon	Time Period	No. of Cases	Rate
Bergmann	1882-1887	114	51%-60%
Billroth	1867-1876	170	82%
Czerny	1877-1886	102	62%
Fischer	1871-1878	147	75%
Gussenbauer	1878-1886	151	64%
Halsted	1889-1894	50	6%
König	1875-1885	152	58%-62%
Küster	1871-1885	228	60%
Lücke	1881-1890	110	66%
Von Volkmann	1874-1878	131	60%

Figure 21-9 Halsted's report of his surgical experience compared with those of his European contemporaries. (Data from Halsted WS. The results of operations for the cure of cancer of the breast performed at the Johns Hopkins Hospital from June, 1889, to January, 1894. Johns Hopkins Hosp Rep 1894-1895;4:297-350.)

Halsted, in his analysis of the results, followed von Volkmann's definition of cure, which required patients to be disease free after 3 years. Halsted noted, "As to ultimate results, permanent cures effected by the operation—we again look to [von] Volkmann [who stated:] 'I unhesitatingly make this statement for all cancers, that when a whole year has passed and the most careful examination can detect neither a local recurrence nor swollen glands, nor any symptoms of internal disease, one may begin to hope that a permanent cure may be effected; but after two years, and after three years without exception, one may feel sure of the result.'"⁴⁵

In 1898, Halsted reported to the American Surgical Association the results of 133 breast cancer operations performed at the Johns Hopkins Hospital over a 9-year period (1889-1898). Of the 133 patients, 13 (9%) had local

Figure 21–10 Willy Meyer (1858–1932), who reported on a radical mastectomy in 1894, the same year as Halsted. (From Walsh JJ. *History of Medicine in New York*, vol 4. New York, National Americana Society, 1919.)

recurrences, and 22 (16%) had cervical or internal mammary regional recurrences. Of 76 patients who were operated on 3 or more years previously, 40 (52%) lived without signs of local recurrences or regional metastases for more than 3 years.⁴⁸ By contrast, the comparable disease-free survival statistics reported by Halsted from the European review of operations performed before the introduction of the radical mastectomy ranged from a low of 4.7% (Billroth) to a high of 30.2% (Bergmann).

Were there other surgeons proposing operations similar to Halsted's?

On September 19, 1894, the same year that Halsted reported on his initial 50 patients at the Johns Hopkins Hospital, Willy Meyer (1858–1932) (Fig. 21–10) of the New York Post-Graduate Medical School (now part of the New York University Medical Center) described a similar operation for breast cancer. Meyer, who had been born and educated in Germany before coming to the United States in 1884, developed his procedure independently of Halsted. It differed from Halsted's in certain details. First, Meyer made a diagonal incision (Fig. 21–11) in the breast rather than the teardrop incision preferred by Halsted (Fig. 21–12). Second, Meyer excised

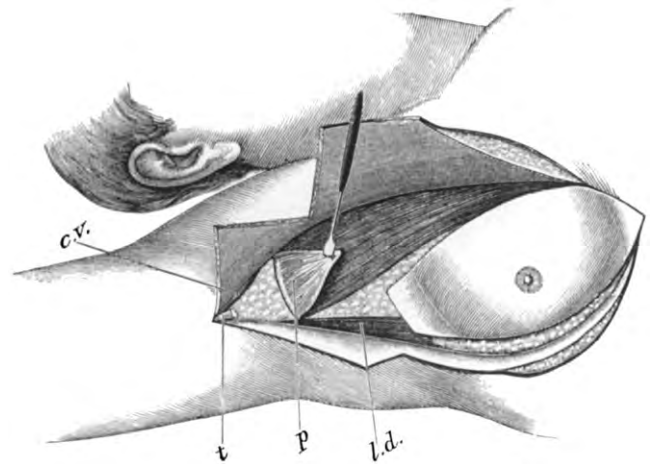

Figure 21–11 The mastectomy incision of Meyer.

Rights were not granted to include this figure in electronic media. Please refer to the printed publication.

Figure 21–12 The mastectomy incision of Halsted. (From Halsted WS. *The Surgical Papers*, vol 2. Baltimore, Johns Hopkins Press, 1924.)

the pectoralis minor muscle along with the pectoralis major, whereas Halsted divided the pectoralis minor but did not excise it.⁴⁹ Meyer's diagonal excision eventually came to be used more frequently than the teardrop incision, and Halsted himself later excised the pectoralis minor as well.

Both Halsted and Meyer emphasized the need to excise wide margins of skin and to immediately close the defect with a graft. In his 1898 report, Halsted noted, "We remove rather more skin than we did originally, and in all cases we graft the wound immediately. Grafts are cut from the patient's thighs large as or larger than one's hand. A single one of these large grafts may be enough to cover the raw surface."⁴⁸ Skin grafting, as practiced by Halsted, had originally been developed by 1886 by Thiersch, one of the surgeons whose clinic Halsted had visited on his tour of Germany.

For a time, Halsted extended the radical mastectomy to include routine removal of the ipsilateral supraclavicular nodes, viewing metastases to these nodes as equivalent to those in the axilla. The excision of anterior mediastinal nodes was first performed by one of his residents, Harvey Cushing (1869–1939), in cases of recurrent disease. Eventually, Halsted abandoned the practice of excising the supraclavicular nodes when he was unable to demonstrate an improvement in

outcome. He did not adapt mediastinal node excision as an extension of his operation because it could not be incorporated en bloc by available techniques at that time.

Despite his efforts to extend even further the surgical landmarks of his radical mastectomy, Halsted's emphasis was on early intervention in the evolution of the disease process. In his 1894 paper, he wrote,

*But now we can state positively that cancer of the breast is a curable disease if operated upon properly and in time. I cannot emphasize too strongly the fact that internal metastases occur very early in cancer of the breast, and this is an additional reason for not losing a day in discussing the propriety of an operation.*⁴⁶

Halsted was aware of the limitations of surgery in many instances and also of the importance of classifying breast cancer by stages. He wrote,

*I know of no very successful attempted classifications of cancers of the breast with reference to their relative malignancy, and yet the importance of such a classification, if it were to any extent possible, is so evident that it is unnecessary to emphasize it.*⁴⁸

What was the halstedian view of cancer dissemination?

In a 1907 report,⁵⁰ Halsted wrote that he was in agreement with the permeation theory of cancer metastasis as enunciated by his English contemporary, the London surgeon William Sampson Handley (1872–1962) (Fig. 21–13). Based on

Figure 21–13 William Sampson Handley (1872–1962), who along with Halsted advocated a lymphatic permeation theory of breast cancer dissemination. (From Brickner WH. The story of the Annals. *Ann Surg* 1925;81:392–412.)

autopsy studies, Handley's theory held that cancers arose in one focus and spread in all directions centrifugally away from the center, solely through the lymphatics. Halsted wrote,

*The dissemination probably takes place by way of the lymphatics—not by the blood vessels—and the disease holds together without important interruptions. . . . It permeates to the bone rather than metastasizes to it, and, via the lymphatics, along fascial planes. Much evidence has been adduced by others, and most convincingly by Handley, to indicate that the centrifugal spread of breast cancer takes place primarily in the plane of the deep fascia.*⁵⁰

Even metastases to liver were believed by Halsted to occur by lymphatic permeation. The adherence to this lymphatically oriented view of breast cancer dissemination by such dominant surgical leaders as Halsted and Handley represented a divergence from previous beliefs in tumor dissemination through both the lymphatics and the bloodstream. In 1887, the English surgeon Thomas Bryant had stated the contrary view:

*When a cancer or carcinomatous growth ceases to be a local disease, it spreads in three methods, by continuous or local infection, by lymphatic infection, or by secondary vascular infection. One form may be more marked than another or all forms may coexist together.*⁵¹

Why was Halsted preeminent among his contemporaries in the treatment of breast cancer?

Other surgical contemporaries of Halsted's, not only Meyer, promoted or reported on their experiences with similar operations. As superbly detailed by Frykberg and Bland, these included Arbuthnot Lane in London (who, as reported in *The Lancet*, performed a similar resection in 1893, 1 year before the more substantive reports of Halsted and Willy Meyer), J. Collins Warren in Boston, Jabez N. Jackson in Kansas City, and Alton J. Ochsner in Chicago.²³ Halsted became preeminent not only because of the forcefulness with which he welded his surgery to his conceptualization of cancer dissemination but also because of his promotion of a meticulous operative technique that represented a major advance in surgery in the early anesthetic and antiseptic era. It was summarized well after his death in a 1925 memorial service address by Rudolph Matas (1860–1957), the eminent professor at Tulane University in New Orleans, who contrasted breast cancer surgery before Halsted to what Halsted practiced:

There are many of us who recall “an amputation” of the breast for cancer, as it was classically performed in the late 70's and early 80's. The operation then was a mere mammectomy, performed in 15 or 20 minutes, or less, with a few rapid and sweeping strokes of the knife. It was a quick, “brilliant,” but bloody affair, in which the diseased mamma and underlying fascia were removed, with here and there an obviously diseased axillary gland. There was no effort to remove the breast and tributary areas in block dissection, or systematically to pursue and ferret out the disease and all its known hiding places or routes of travel. The wounds were usually easily closed as there was ample skin left to cover the incision completely without leaving bare surfaces.

No one who has been privileged to see Dr. Halsted at work on a cancer of the breast could fail to recognize the reason for his extraordinary success. Deeply interested in his work and absorbed in all its details, whether operating himself or directing his staff of well-trained and brilliant assistants, his delicate but far-reaching dissections, by which he pursued the disease relentlessly, without regard to aesthetic effect or plastic union; his minute and almost fastidious precautions against infection and hemorrhage, controlling the smallest bleeding point so that the total blood loss throughout the operation was negligible; his skill and nicety in covering large skin defects with autogenic skin grafts in a way that has scarcely been equalled and has never been excelled; and his final dressing of the wound, covering it with silver foil and immobilizing plaster dressing, gave the impression to the onlooker that he was seeing the performance of an artist, close akin to the patient and minute labor of a Venetian or Florentine intaglio or cutter or a master worker in mosaic. Yet this task, which with all its discipline and method often consumed two and three hours, was practically shockless and bloodless and was followed almost invariably by recovery.⁵²

Halsted himself, in his 1898 report, described his efforts:

*Operating for the cure of cancer is a very great labor. We never attempt more breast cancers than one in a day. The operation, including the toilet of the wound and the grafting, requires from two to four hours with highly trained and skilled assistants; it is performed in an absolutely bloodless manner, and the patient, in consequence, suffers not at all from shock.*⁴⁸

Halsted's influential approach to surgery became known as the "surgery of safety," embracing principles of gentle and meticulous technique, and was practiced by generations of surgeons whom he trained and who in turn went on to develop similar residency programs at universities around the country. As Samuel Crowe, who worked with Halsted at Johns Hopkins and had developed the division of otolaryngology, wrote in 1912,

*The operating room technique that Halsted initiated in 1889–1890 was far ahead of that at other large hospitals. He insisted on rigid asepsis, and trained his assistants to handle tissues with the greatest care and gentleness. He taught, by example, that in the operating room brilliance and speed must be subordinated to thoroughness and safety.*⁵³

His technique encompassed a view of cancer that placed the surgeon in a position of potentially doing great harm. As Halsted stated,

*I believe that we should never cut through cancerous tissues, when operating, if it is possible to avoid doing so. The wound might become infected with cancer either by the knife, which has passed through diseased tissue and perhaps carries everywhere the cancer-producing agents, or by the simple liberation of the cancer cells from their alveoli, or from the lymphatic vessels. The division of one lymphatic vessel and the liberation of one cell may be enough to start a new cancer.*⁴⁶

In his 1907 report to the American Surgical Association, Halsted noted that

women are now presenting themselves more promptly for examination, realizing that a cure of breast cancer is not only

*possible, but, if operated upon early, quite probable. Hence the surgeon is seeing smaller and still smaller tumors, cancers which give not one of the cardinal signs.*⁵⁰

Halsted was able to report a 3-year (or more) disease-free survival rate of 42.4% among 210 patients treated by radical mastectomy at the Johns Hopkins Hospital. The postoperative mortality rate in the hospital was 1.7%.⁵⁰ Although the initial data with radical mastectomy were tempered by this more sober appraisal of longer-term survival statistics, the halstedian concept of cancer dissemination, the importance of encompassing the entire local disease effectively, and a more confident espousal of the importance of earlier diagnosis and expeditious surgery became hallmarks of halstedian doctrine that permeated thinking and continue to have a major impact to this day.

When did skepticism about the radical mastectomy arise?

In 1907, Halsted noted that even in instances where there was no microscopic evidence of axillary metastases, 23.4% of patients in his experience died from metastatic disease. He regarded this as evidence of further lymphatic dissemination before surgical intervention occurred. While this did not explain the apparent failure of regional nodes to serve as temporary barriers to the further spread of disease, Halsted believed it unlikely that dissemination might take place in the absence of lymph node metastases, arguing that there must have been pathologically unappreciated disease "in many, if not in most" of the axillae recorded as negative.⁵⁰

It is curious that Halsted's approach was not without criticism in his lifetime. Rudolph Matas, for one, in a discussion of Halsted's 1898 report to the American Surgical Association, reflected a point of view more akin to our contemporary one, stating rather bluntly that the Halsted radical mastectomy "offers no more prospect of cure or chance of escape from internal metastases and secondary recurrence in the neck than that obtained by the older and less mutilating operation."⁵⁴ In 1898, A. Marmaduke Shield in London expressed a similar skepticism on the advisability of radical procedures for locally advanced disease. In his monograph *Diseases of the Breast* he wrote,

*There is now a tendency to operate upon all cases of cancer of the breast, and the more extensive the disease, the larger the operation. I feel here that the greatest care and judgment is needful in estimating the advisability of the performance of these operations. The interest of the patients must always be taken into due account. If extensive operations involving loss of large areas of skin with slow, tardy, and painful convalescence are universally done in these cases, we shall soon have patients preferring the blandishments of the charlatan to the treatment of the surgeon. It has seemed to me that the earlier the cancer the more reason there is for a very complete operation. In widely spread disease, it is as a rule hopeless to try to get beyond the limits of the tumor. After undergoing the mental and bodily distress of a severe operation, the disease returns within six months at most or makes itself apparent in some internal organ where likely enough it had been silently progressing at the very time when an enthusiastic operator was attempting to eradicate its external manifestations by what is termed "heroic surgery."*⁵⁵

When was radiation introduced as a treatment of breast cancer?

In 1896, within one year after Roentgen reported on his discovery of x-rays using a cathode-ray tube, Emile Grubbe treated a woman with breast cancer. As he reported many years later, the patient survived only 1 month.⁵⁶ The biologic effects of radiation at that time were obviously untested. Soon thereafter, Marie and Pierre Curie, who discovered the emission of radiation by uranium crystals in 1896, noted inflammation and the shedding of skin at the ends of their fingers which had held radioactive materials. Henry Becquerel, after carrying in his vest pocket a small tube of radium given to him by the Curies wrapped in paper and a cardboard box for several hours, noted that a burn had developed on the underlying skin, the exact shape of the oblong tube. Subsequently, Pierre Curie observed that after strapping a radium fragment to his forearm for 10 hours, he also developed an area of inflammation which sloughed and subsequently healed. Furthermore, hair did not return to the healed skin. Becquerel and Pierre Curie reported these findings in 1901.⁵⁷ Soon thereafter, a number of investigators began attempting the use of radium in the treatment of benign cutaneous neoplasms. Alexander Graham Bell, for one, suggested in 1903 that radium be placed in a glass tube, which might then be inserted into a cancer.⁵⁸ Carcinoma of the cervix became an appropriate lesion upon which to initiate this new theory, and several dramatic responses were noted.

Breast cancer, an accessible lesion, became a target lesion early on in this effort. In 1906, there was a report from Boston on the use of radiation as primary therapy for breast cancer, and 2 years later a French physician, George Chicotot, attempted radiotherapy for breast cancer in Paris, memorializing his effort in a painting he did of himself and the patient⁵⁹ (Fig. 21–14). Not surprisingly, the often unrealistic expectations that had been generated by early enthusiasts inevitably gave way to pessimism as primitive equipment, the lack of ability to measure dose, and the general ignorance of the other biologic effects of radiation led to the use of massive radiation exposures aimed at eradicating tumors in one treatment. Significant morbidity and even mortality, let alone long-term complications and a high rate of recurrence, undermined the initial enthusiasm for the technique.

In 1919, Claude Regaud promoted the crucial concept of dose fractionation. He argued that malignant tumors mimicked the high cell turnover rate of spermatogenesis in the testes of experimental animals, which he was able to eliminate by sequential daily fractionated doses of radiotherapy. A single massive dose was not able to produce the same effect, while its toxicity to skin was prohibitive.⁶⁰ Similarly fractionated doses applied to cancer would be both more effective and safer. With Henri Coutard, a fellow worker at the Curie Foundation in Paris, efforts were initiated to treat head and neck cancer as well as cancer of the cervix.^{61,62}

Although the treatment of breast cancer by radiotherapy became more common, its acceptance was limited to its use in treating local recurrences after surgery. The first major effort at primary radiation treatment for breast cancer was made by the English surgeon Geoffrey Keynes in 1922 using radium needles. Working at the St. Bartholomew's Hospital in London, he first applied this method without surgery, for

Figure 21–14 Painting by George Chicotot, *The First Trial of X-ray Therapy for Cancer of the Breast* (1908, Musée de l'Assistance Publique, Paris.) The physician pictured is Chicotot himself.

advanced and inoperable cases. In 1932, he was able to report a 77.1% 5-year survival in the absence of palpable nodes and a 33.6% survival with axillary metastases. Keynes extended his use of radiation therapy for more operable lesions, combining it with conservative surgery, having begun with very advanced inoperable tumors.⁶³ By 1937 he was able to report an 83.5% 3-year survival for patients whose lesions were confined to the breast treated by radium implants, and he suggested that the most effective therapy was the surgical excision of clinically obvious disease followed by radiation therapy to destroy any subclinical disease that may have remained.⁶⁴ Keynes proposed this treatment as an alternative to the radical mastectomy while recognizing that radiation was not without complications as a result of scarring and neurologic injury. His efforts were interrupted by the outbreak of World War II, when supplies of radium in London were dispersed because of the danger of air raids and when Keynes himself had joined the Royal Air Force.⁶⁵ In the United States, George E. Pfahler also reported in 1932 on an experience with the use of post-operative radiation, noting an improved survival in patients with axillary metastases.⁶⁶

When was a systemic concept of disease treatment introduced?

Even before the emergence of radiation as a form of cancer therapy, hormonal manipulation had been recognized as

influential in the progress of breast cancer. Sir Astley Cooper as early as 1835 had referred to observations he had made on size variations of tumors in pre- and postmenopausal patients as well as a greater frequency of the disease in nulliparous women.⁶⁷ In 1889, Albert Schinziger (1827-1911) proposed oophorectomy as a form of treatment based on his observation that the prognosis was worse in younger patients and the unlikely premise that this procedure might make women “a little bit older.”⁶⁸ It was George Beatson (1848-1933) of Glasgow, however, who first performed a bilateral salpingo-oophorectomy on a 33-year-old woman with a chest wall metastasis from breast cancer in June of 1895. The dramatic response led him to treat two other similar patients, one of whom again demonstrated a response. He reported his experiences in 1896.⁶⁹ Other surgeons subsequently attempted oophorectomy in young patients with advanced disease. Subsequently, ovarian ablation by radiation was used by some as an alternative to surgical oophorectomy.

How was halstedian surgery extended?

The effort to follow halstedian principles was extended by the adoption of the frozen section technique for tissue preparation and rapid diagnosis by Rutherford in 1871⁷⁰ and promoted initially at the Johns Hopkins Hospital in 1895.⁷¹ Frozen section preparation of biopsy tissue allowed surgery to be performed immediately after histologic diagnosis, a concept fully in keeping with the halstedian hypothesis of rapidly encompassing the disease process without delay or risking its dissemination through any surgical means. Most important, it withdrew any reservations about the histologic verification and study of disease, particularly as more patients were presenting with less advanced and clinically obvious disease. At the same time, halstedian principles were extended anatomically even further as attention was directed to internal mammary metastases. Richard S. Handley (1909–1984), stimulated by the observance of parasternal recurrences after radical mastectomy made by his father, W. S. Handley,⁷² performed internal mammary node biopsies. In R. S. Handley’s initial series of 50 patients, a significant 38% rate of metastases was demonstrated.⁷³ These observations suggested that the radical mastectomy was inadequate because it did not encompass this frequent site of regional metastases. W. S. Handley proposed treating the internal mammary nodes with interstitial radiation, but other surgeons began to develop surgical procedures that would encompass this drainage site en bloc with a radical mastectomy. Such an operation became formalized first by Mario Margottini (1898–1981) in Italy in 1948 and subsequently by Jerome Urban (1914–1991), among others.^{74–76} Erling Dahl-Iversen (1892–1978) in Denmark again adopted Halsted’s initial efforts to excise the supraclavicular as well as the internal mammary nodes as separate procedures at the time of radical mastectomy.⁷⁷ The most radical extension of halstedian doctrine was reported by Prudente in France, who treated advanced cases by a trans-scapulothoracic amputation of the upper extremity en bloc with the mastectomy.⁷⁸ Owen Wangenstein (1898–1981) also developed a “super-radical” mastectomy, which combined a radical mastectomy with resection of the supraclavicular, internal mammary, and mediastinal lymph nodes.⁷⁹ When an improvement in survival could not be demonstrated, and with an operative mortality

Figure 21–15 Extended radical mastectomy of Urban. The sternum has been split, and the chest wall is separated by cutting through the ribs and intercostal soft tissues just lateral to the costochondral junctions of the second through fifth ribs to achieve resection of the internal mammary chain in continuity with the overlying muscles and breast. (From Urban JA, Baker HW. Radical mastectomy in continuity with en bloc resection of the internal mammary lymph node chain. *Cancer* 1952;5:992–1008. Copyright © 1952 American Cancer Society. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

of 12.5%, the procedure was abandoned.⁸⁰ An extended radical mastectomy continued to be advocated by Urban based on the premise that the lymphatic drainage of medial lesions was also to the internal mammary nodes (Fig. 21–15).

As extended radical procedures were attempted, there was a growing recognition of the multicentric evolution of breast cancer in many instances, an observation first made by G. L. Cheatle in England⁸¹ in 1920, as well as the risk for contralateral breast cancer. This provided additional support for the basic concept of mastectomy, although conceptually detached from the lymphatic permeation theories that had been previously embraced, even for lesions far smaller than Halsted had encountered, and led some, such as New York surgeon George Pack (1898–1969), in 1951 to advocate bilateral mastectomies in the treatment of clinically unilateral disease.⁸²

When did the radical mastectomy begin to lose favor?

While efforts were being made to encompass wider zones of local lymphatic permeation, evidence began to accumulate

that lymphatic permeation could not be implicated in the dissemination of disease, as Halsted and Handley had proposed. The concept of en bloc resection was first called into question when J. H. Gray reported, in 1938, that lymphatic permeation was rarely observed through lymphatic channels extending from the primary lesion to the regional lymph nodes.⁸³ An alternative concept of lymphatic embolization was consistent with the concept of metastasis first established by the studies of Thiersch and Waldeyer. There also seemed to be a paucity of lymphatic vessels on or even approaching the deep fascia of the pectoralis major muscle, further undermining a basic premise of halstedian doctrine.

There also emerged the growing recognition of an intraepithelial phase in breast cancer evolution first recognized grossly by Joseph C. Bloodgood (1967–1935), who as an assistant to Halsted commented on the exudation from a clinically benign tumor “many grayish-white granular cylinders, which I called comedos.”⁸⁴ Following further histologic observations by numerous investigators it was termed “in-situ” by Broders in 1932 and was notable for the absence of malignant cell migration beyond the ductal basement membrane⁸⁵ and for the absence of lymphatic permeation and lymph node involvement.⁸⁶ By the end of the 1930s, there began to emerge a reassessment of the concept of lymphatic permeation as a foundation for extensive surgery along with a growing appreciation of more favorable histologic characteristics for many cancers, which differed from those of the tumors for which radical procedures had been devised.

Halsted, as already noted, recognized that as many as 25% of his patients without lymph node metastases died of breast cancer. Furthermore, when his patients were followed for longer than 3 years, it became clear that the success of long-term cure diminished as even more time elapsed from the dates of initial treatment. As patients were followed to 5 and 10 years, there was a progressive decrease in survival, an observation also noted in series from the Massachusetts General Hospital, as reported by Greenough and colleagues in 1907,⁸⁷ and from the Mayo Clinic, as originally reported by Judd and Sistrunk in 1914⁸⁸ and then by Harrington in 1929.⁸⁹ In 1922, the eminent pathologist James Ewing (1866–1943) wrote,

From clinical and pathological studies I have drawn the impression that, in dealing with mammary cancer, surgery meets with more peculiar difficulties and uncertainties than with almost any other form of the disease. The anatomical types of the disease are so numerous, the variations in clinical course so wide, the paths of dissemination so free and diverse, the difficulties of determining the actual conditions so complex, and the sacrifice of tissue so great as to render impossible in a majority of cases a reasonably accurate adjustment of means to ends. The scope of the operative field having apparently reached a limit, the chief hope for a reduction in the mortality from mammary carcinoma lies in its prevention and earlier diagnosis.⁹⁰

When was staging introduced?

As the surgical treatment of breast cancer expanded, Halsted's prophecy that women would present for treatment at earlier stages of disease was fulfilled. The broader spectrum of breast cancer faced by surgeons required appropriate prognostic

criteria to enable meaningful study. The first attempt to establish a staging system based on clinical criteria is credited to Steinthal of Stuttgart⁹¹ in 1905. More widely accepted was the clinical Manchester Staging System introduced in England in 1940⁹² and the Portmann Classification introduced in Cleveland in 1943.⁹³

However, it was Cushman Haagensen, a vigorous exponent of radical mastectomy, and Arthur Purdy Stout in the early 1940s who paradoxically signaled a retreat from the uniform application of the radical mastectomy by identifying those prognostic factors that made the procedure inappropriate. In reviewing more than 568 patients with breast cancer treated by the radical mastectomy at the Columbia-Presbyterian Hospital from 1915 to 1942, Haagensen and Stout defined three features that were associated with 100% mortality at 5 years and a 60% incidence of local recurrence despite treatment by radical mastectomy.^{94,95} These features were edema of the skin that extended over one third of the breast, satellite nodules of cancer within the skin, and erythema and edema over one third of the breast indicative of inflammatory carcinoma. They also defined other features indicative of inoperability, which included internal mammary nodal metastases, supraclavicular nodal metastases, extensive axillary metastases leading to edema of the arm, and, of course, distant metastases. They further identified additional “grave signs,” any two of which also placed the patient in the same inoperable category. These included edema of the skin over less than one third of the breast, skin ulceration, chest wall fixation, axillary lymph nodes greater than 2.5 cm in diameter, and fixation of the axillary lymph nodes to the skin or deep structures of the axilla. More prognostically favorable lesions were categorized by the size of the tumor or the presence or absence of movable axillary lymph nodes. The Columbia Clinical Classification (Table 21–1), dividing patients into stages A, B, C, and D, became the most important early classification system by which to stage patients for surgical treatment and to assess prognosis and long-term survival following treatment.⁹⁶

What advances led to radiotherapy as a primary modality of therapy?

Between 1920 and 1940, kilovoltage therapy was developed. This was first introduced by William David Coolidge (1873–1977), who invented a vacuum x-ray tube that could produce energies as high as 200 kV.⁹⁷ Physicists studying the effects of radiation quantitated the radiation dose by identifying the first physical unit for measurement of radiation, the roentgen, which was replaced by the rad in 1956, as techniques for delivering radiation were refined. The physical dose distribution of 200 kV limited the use of kilovoltage therapy to superficial lesions. Higher beams of energy clearly had to be developed if greater cure rates were to be realized for deeper lesions.⁹⁸ Radioactive cobalt provided by nuclear fission soon after World War II provided a substitute for radium, which was extremely expensive. Concurrently, new electronic devices, such as the betatron and the linear electron accelerator, could provide beams of very high energy. Such megavoltage energies were able to produce their maximal ionization at levels much deeper than the skin, and the limitation of skin tolerance was no longer a major issue.⁹⁹

Table 21–1 Columbia Clinical Classification

<p>Stage A No skin edema, ulceration, or solid fixation of tumor to chest wall; axillary nodes not clinically involved</p>
<p>Stage B No skin edema, ulceration, or solid fixation of tumor to chest wall; clinically involved nodes, but <2.5 cm in transverse diameter and not fixed to overlying skin or deeper structures of axilla</p>
<p>Stage C Any of five grave signs of advanced breast cancer:</p> <ul style="list-style-type: none"> • Edema of skin of limited extent (involving less than one third of the skin over the breast) • Skin ulceration • Solid fixation of tumor to chest wall • Massive involvement of axillary lymph nodes (measuring ≥ 2.5 cm in transverse diameter) • Fixation of the axillary nodes to overlying skin or deeper structures of the axilla
<p>Stage D All other patients with advanced breast cancer, including</p> <ul style="list-style-type: none"> • A combination of any two or more of the five grave signs listed under stage C • Extensive edema of the skin (involving more than one third of the skin over the breast) • Satellite skin nodules • The inflammatory type of carcinoma • Clinically involved supraclavicular lymph nodes • Internal mammary metastases, as evidenced by a parasternal tumor • Edema of the arm • Distant metastases

Adapted from Haagensen CD. *Diseases of the Breast*, 3rd ed. Philadelphia, WB Saunders, 1971, p 630.

These advances made it possible to apply radiation therapy not only as a substitute for surgery for inoperable cases but also as an adjunct to the radical mastectomy for patients at high risk for local recurrence. In the 1930s, François Baclesse (1896–1967) administered radiation to 21 patients before surgery. Of note is the fact that in one third of the patients treated with preoperative radiation therapy, no tumor was found in the mastectomy specimens, with almost all of the others demonstrating marked changes in tumor morphology.¹⁰⁰ With larger series and longer follow-up, however, survival rates seemed the same, and there was a growing consensus that radiation therapy could be reserved for use following mastectomy, if necessary.

More significantly, some investigators began to use radiation as an adjunct to lesser surgical procedures. In 1941, Robert McWhirter (1904–1994) (Fig. 21–16) in Edinburgh began to perform mastectomy alone followed by postoperative irradiation of the axillary, supraclavicular, and internal mammary lymph nodes for patients with operable breast cancer, instead of a radical mastectomy, with comparable 5-year survival rates. For the first time, combining two modalities of therapy in the treatment of operable breast cancer was presented as a viable option.¹⁰¹ In a trial conducted by Sigvaard Kaae and Helge Johansen¹⁰² in Copenhagen between 1951 and 1957, patients were randomized to treatment with either extended radical mastectomy or total mastectomy and postoperative radiation therapy. Survival rates and local recurrence rates were equivalent, further supporting the use of

radiation therapy in the treatment of subclinical disease. This concept was extended to the breast itself by François Baclesse at the Curie Foundation, who began to treat patients with both operable and inoperable disease by radiotherapy, in most cases without excision of the tumor. Dosage was adjusted based on the size of the tumor, and the radiation portals were adjusted as well, based on the findings in the axilla. Although Baclesse concluded that this was not appropriate for all cases, he did suggest that in selected instances and for those who refused mastectomy, radiation was an alternative.¹⁰³ Sakari Mustakallio¹⁰⁴ in Finland initiated an effort to excise favorable lesions followed by radiation to the breast through tangential portals as well as axillary and supraclavicular radiation.

When was the radical mastectomy modified?

David H. Patey (1889–1977) and W. H. Dyson, of the Middlesex Hospital in London, began to question the appropriateness of routine removal of the pectoralis major muscle, particularly in instances in which there was no discernible involvement by the tumor. Because the original halstedian concept was based on large lesions often abutting or affixed to the pectoralis major muscle and the concept of continuous lymphatic tumor extension, removal of the pectoralis major muscle became increasingly questioned. While the pectoralis major was preserved in Patey's procedure, most of the other components of Halsted's procedure were left intact, including removal of the pectoralis minor, a complete axillary dissection, and excisions of wide margins of skin. Patey and Dyson

first reported on their technique in 1948.¹⁰⁵ A subsequent analysis by Handley and Thackray of 143 patients treated with Patey's procedure at the Middlesex Hospital showed survival equivalent to that of radical mastectomy in patients classified as stage A by the Columbia Clinical Classification (see Table 21-1), with no recurrences in the pectoralis major muscle being noted.¹⁰⁶

How did mammography alter therapeutic thinking?

Although efforts to detect breast cancer radiographically were made throughout the century, Jacob Gershon-Cohen in Philadelphia vigorously pursued this diagnostic technique and was able to demonstrate in 1948 the ability to detect nonpalpable carcinoma.¹⁰⁷ The feasibility of diagnosing breast cancer radiographically became increasingly evident through the efforts of Robert Egan¹⁰⁸ and others, and by the 1960s, strategies were proposed for evaluating asymptomatic patients in screening programs.¹⁰⁹ Initial data suggested that mortality could indeed be reduced by such an approach, and despite concern that mammography could itself induce breast cancer if used inappropriately and excessively, a concern largely abated by smaller radiation dosage, mammography became integrated into the diagnostic armamentarium of physicians.¹¹⁰ This led to the detection of an increasing number of clinically occult and prognostically favorable cancers, providing even greater impetus to reducing the extent of surgery. If the radical mastectomy had demonstrated the feasibility of curing breast cancer and had encouraged women to seek treatment earlier, as Halsted had predicted, was it not equally appropriate to propose that a further inducement to earlier diagnosis would be a reduction not only in breast cancer mortality but also in the extent of surgery?

What led to a permanent withdrawal from radical mastectomy?

Increasingly, surgeons began to adopt the modification of the radical mastectomy proposed by Patey and Dyson, essentially the same prehalstedian operation that had been performed by Moore in 1867. In 1953, I. G. Williams and his colleagues¹¹¹ reviewed 1044 cases of breast cancer treated at St. Bartholomew's Hospital in London from 1930 to 1939. They found that the 10-year survival rates of patients treated by radical mastectomy, modified radical mastectomy, or simple mastectomy did not differ, with or without the use of additional radiation therapy. In the United States, the modified radical mastectomy was championed by such surgeons as John L. Madden¹¹² and Hugh Auchincloss.¹¹³ The better cosmetic and functional results following the procedure were emphasized, and survival rates appeared comparable to those following Halsted's radical mastectomy. The extensive removal of skin advocated by Halsted, and even by Patey and Dyson in their modification, became questioned, and primary skin closures were increasingly achieved with reduced skin margins.

By 1972, the frequency with which the radical mastectomy was performed began to decline dramatically. Data developed

by the Commission on Cancer of the American College of Surgeons revealed that between 1972 and 1981, use of the radical mastectomy had plummeted from 47.9% of operations for breast cancer to 3.4%. At the same time, the frequency with which the modified radical mastectomy—an often ill-defined designation—was performed had risen from 27.7% of operations for breast cancer to 73.2%.¹¹⁴ By 1974, the modified radical mastectomy had eclipsed the radical mastectomy as the most widely performed procedure for breast cancer in the United States. During this time, reconstruction of the breast following mastectomy was introduced, first with implant placement techniques,^{115,116} and then with autologous musculocutaneous flaps using the latissimus dorsi¹¹⁷ or rectus abdominis muscles.¹¹⁸

The justification for lesser operative procedures was supported by the relative freedom from recurrence in the pectoralis major muscle following procedures in which it was preserved.⁸³ Evidence presented by Engell¹¹⁹ that there was venous dissemination of cancer cells, not only in breasts but also in other solid tumor models, along with experimental evidence that cancer cells could bypass regional lymph nodes as well as extend from lymphatics to blood vessels, further undermined the concept of contiguous lymphatic permeation and even orderly embolization.^{120,121} George Crile Jr., Oliver Cope, Vera Peters, and Bernard Fisher, among others, began to question not only the appropriateness of mastectomy in all instances but also, most important, the biologic principles used to support ablative surgery of the breast and regional lymph nodes. These questions coincided with the emergence of support for, and reliance on, prospective randomized trials to assess more objectively the comparative efficacy of different therapeutic options, not only surgical but also those directed at the increasingly perceived problem of early systemic dissemination. At the forefront of these efforts to carry out controlled clinical trials, with appropriate statistical power derived from the participation of multiple institutions, was the National Surgical Adjuvant Breast and Bowel Project (NSABP), initially founded as the Surgical Adjuvant Chemotherapy Breast Cancer Group, and directed by Bernard Fisher¹²² (Fig. 21-17). These studies challenged physicians to prove or disprove clinical hypotheses by scientific methodology and to shun retrospective analyses that purported to support what might well be antiquated thinking that served as the biologic underpinning of surgical therapy.

How did multimodality therapy evolve?

Chemotherapy developed with great rapidity after World War II from several programs that dealt with such diverse goals as chemical warfare, nutrition, and research into basic biochemical mechanisms. The rapid development of chemotherapeutic agents and their potential applications to the treatment of solid tumors compelled the National Institutes of Health to organize national controlled studies to assess their efficacy. During this era as well, a renewed interest arose in the endocrine treatment of breast cancer as Charles B. Huggins (1901-1997) at the University of Chicago in 1941 demonstrated the efficacy of castration in the treatment of metastatic prostatic cancer and proposed that oophorectomy, as had originally been attempted in the late years of the 19th century,

Figure 21–17 Bernard Fisher (1918–), whose championship and successful directorship of controlled clinical trials dramatically altered the direction of local and systemic therapy and led to a rethinking of breast cancer biology.

might be efficacious as well in the treatment of breast cancer.^{123,124} The availability of corticosteroids made the prospect of adrenalectomy to further reduce endogenous hormones possible. Both testosterone and synthetic estrogen were used in the treatment of advanced breast cancer, provoking further investigation into the role of hormones in the etiology and promotion of the disease.¹²⁵ The demonstration of the estrogen receptor protein by Elwood V. Jensen and associates¹²⁶ and by Jack Gorski and associates in 1966¹²⁷ and its identification in human breast cancer by William McGuire,¹²⁸ and subsequently, the identification of progesterone receptors,¹²⁹ provided greater predictability to the impact of hormonal manipulation. The development of antiestrogen compounds, first described in 1971, provided another means of treatment for metastatic breast cancer.¹³⁰ Although such advances in chemotherapy and hormonal therapy were directed initially at metastatic disease, they refocused attention, with greater specificity, on the potential for systemic therapy of earlier stages of disease.

By the 1970s, the effectiveness of radiation therapy was becoming well established, and the increasing use of mammography had provided greater impetus toward early diagnosis and a possible reduction in the extent of surgery. The policy of screening populations of normal women with routine periodic mammography received a major impetus from the trial of the Health Insurance Plan (HIP) of Greater New York comparing 62,000 women randomized to have or not have annual mammography. In this trial, annual mammography detected a significant percentage of clinically occult cancers, with an associated 40% reduction in mortality.¹³¹ The progressive realization that any efforts to improve survival might depend on the effective treatment of subclinical local and systemic disease led to a variety of trials initiated to assess the appropriateness of new approaches to local treatment and to assess what might be the impact of systemic drug therapy as

an adjunct to surgery in high-risk patients likely to harbor distant micrometastases.

A randomized trial using thiotepa as an adjuvant to surgical therapy was begun by the NSABP in 1958 under the direction and support of the National Institutes of Health. All patients were treated by a radical mastectomy with chemotherapy delivered at the time of surgery and for 2 days postoperatively so that cells that might have been disseminated at the time of surgery would be destroyed. When compared with patients receiving a placebo, a benefit was suggested for those receiving thiotepa who were premenopausal and had four or more lymph nodes containing metastases.¹³² Subsequently, there were numerous trials of adjuvant chemotherapy based not on the presumption of tumor dissemination at the time of surgery but on the recognition of patients at high risk for harboring systemic micrometastases. Two such studies had a particularly strong impact on forming a consensus that adjuvant chemotherapy was of value, which in turn led to further study of a broader spectrum of patients. Between 1972 and 1975, the NSABP compared 349 patients randomized to receive L-phenylalanine mustard (L-PAM) for 2 years or placebo. All patients had been treated by radical mastectomy and had been demonstrated to have nodal metastases. L-PAM was chosen because of its relative lack of toxicity.¹³³ In another trial begun in 1973 by the Milan Cancer Institute, 386 patients treated with radical mastectomy and proved to have nodal metastases were randomized to receive a regimen of cytoxan, methotrexate, and 5-fluorouracil for 12 cycles given over the course of a year or placebo.¹³⁴ In the NSABP trial, a 9% improvement in recurrence-free survival for the treatment group was demonstrated, and in the Milan trial, a 12% improvement was seen, with subset analyses in both trials demonstrating a particularly significant improvement of 17% for premenopausal women. Such data clearly affected survival, a claim that advocates of differing approaches to local therapy could not make. These studies established the early systemic treatment of breast cancer as the linchpin of multimodality therapy and became the prototype for similar efforts with other solid malignant neoplasms.

When did molecular biology first affect breast cancer treatment?

A modern era of hormonal therapy was launched with the identification of estrogen receptor protein in breast cancer cells.¹³⁵ Subsequently, progesterone receptor assays became available, and it was shown that a high percentage of patients with advanced breast cancer responded to hormonal therapy when both the estrogen receptor and progesterone receptor were present. The level of hormone receptor and the positivity of only one of the two hormone receptors or the absence of both were directly related to the ability to elicit a response from hormonal ablation. Before then, trials of adjuvant oophorectomy, performed either surgically or by radiotherapeutic ablation, initiated in the 1950s and 1960s for premenopausal or early postmenopausal women, were equivocal. The development of antiestrogens, initially proposed as antifertility drugs, led to the use of one agent, tamoxifen, as a primary treatment option when antihormonal therapy was desired, and was applied to the adjuvant setting in several trials beginning in 1975 for both node-positive and

node-negative patients.¹³⁶ The survival benefit to women receiving tamoxifen in the treatment of early breast cancer was supported in meta-analyses of adjuvant trials and, as expected, restricted to those with estrogen receptor–positive tumors.¹³⁷ An additional observation was a decrease in the development of contralateral breast cancer, particularly in those receiving prolonged therapy, prompting the initiation of the first randomized prevention trials using tamoxifen in women at high risk for developing breast cancer.^{138–141} In the NSABP prevention trial (NSABP P-1), tamoxifen reduced breast cancer by 50% in high-risk patients, its effect also being limited to estrogen receptor–positive tumors.¹⁴¹ The development of selective estrogen receptor modulators (SERMs), such as raloxifene, with potential preferential antiosteoporotic effects, but without undesired agonist effects in the uterus, and the development of aromatase inhibitors to selectively block estrogen production have further broadened the spectrum of antihormonal treatment and possible preventive strategies.

In 1997, Dennis Slamon and associates reported on the adverse impact on prognosis that tumor overexpression of *HER-2/neu*, an epidermal growth factor receptor, had in node-positive patients with breast cancer.¹⁴² This led to the development of the monoclonal antibody trastuzumab¹⁴³ (Herceptin, Genentech, Inc., South San Francisco, CA) to interrupt *HER-2/neu* cancer cell growth stimulation.

When was breast conservation established as an alternative to mastectomy?

As prospective randomized adjuvant systemic trials were increasingly applied in the effort to improve survival for high-risk patients, prospective randomized trials became applied as well to assess the efficacy of surgical therapy. Between 1971 and 1974, in 34 institutions participating in the NSABP protocol B-04, 1765 women with primary operable breast cancer and clinically negative axillae were randomized to radical mastectomy, total mastectomy followed by chest wall and regional nodal irradiation, or total mastectomy alone. Delayed axillary dissection was performed for the last group if their nodes became clinically positive. Women with clinically positive axillae were randomized to radical mastectomy or total mastectomy and locoregional radiation.¹⁴⁴ In the node-negative and node-positive groups, there was no difference in disease-free survival or overall survival in any of the treatment arms of the study. This consolidated the inappropriateness of radical mastectomy and provided support for those who viewed skeptically the therapeutic benefit of axillary dissection.

Two additional trials were of particular importance regarding mastectomy, then the foundation stone of surgical therapy. One, conducted by Umberto Veronesi and the National Cancer Institute of Milan between 1973 and 1980, compared 701 patients with lesions 2 cm in diameter or less and clinically negative axillae randomized to either radical mastectomy or quadrantectomy and axillary dissection followed by radiotherapy (QUART). Relapse-free survival and overall survival were the same¹⁴⁵ (Fig. 21–18). Between 1976 and 1984, a second trial begun in the United States by the NSABP (protocol B-06) randomized 1843 patients with lesions up to 4 cm in diameter to total mastectomy or segmental mastectomy (lumpectomy) with or without radiation

Figure 21–18 Actuarial disease-free survival from the National Tumor Institute of Milan trial comparing radical mastectomy with quadrantectomy, axillary dissection, and radiation. (Data from Veronesi U, Saccozzi R, DelVecchio M, et al. Comparing radical mastectomy with quadrantectomy, axillary dissection, and radiotherapy in patients with small cancers of the breast. *N Engl J Med* 1981;305:6–11. Copyright © 1981 Massachusetts Medical Society. All rights reserved.)

therapy.¹⁴⁶ This trial demonstrated that treatment with either total mastectomy or lumpectomy plus radiation was able to achieve equally effective local control of disease and that overall survival was equivalent in all three groups, although lumpectomy alone was significantly inferior to lumpectomy and radiation in achieving disease-free survival in the conserved breast (Fig. 21–19). Twenty-year follow-up of both trials has further confirmed the earlier findings and conclusions.^{147,148}

Subsequent trials have been conducted to confirm and refine the appropriateness of breast-conserving treatment. The increasing use of mammography has led to the application of prospective randomized trials in the assessment of breast conservation for the expanding population of patients with noninvasive disease detected mammographically. When mastectomy is required or judged appropriate, reconstruction has been increasingly used with growing confidence that it does not adversely affect survival or the ability to detect recurrent disease.

The other foundation stone of surgical therapy, axillary dissection, has also been subjected to increased scrutiny because its direct therapeutic impact has remained unproven, whereas the prognostic significance of axillary metastases has been enhanced by effective adjuvant systemic therapy. Cabanas¹⁴⁹ introduced the concept that a specific cutaneous site—in the case he reported, a penile carcinoma—would drain not only to a specific nodal site but also to a specific sentinel node. Donald Morton¹⁵⁰ brought this concept into the operating room with great specificity in the treatment of melanoma using blue dye to map the lymphatic circulation and convincingly demonstrated that identifiable sentinel nodes were the first drainage sites not only of cutaneous lymphatics but also of nodal metastases. Armando Giuliano¹⁵¹ applied this blue dye technique to the treatment of breast cancer to map the lymphatic drainage to the sentinel nodes,

Figure 21-19 Life-table analysis showing disease-free survival, distant disease-free survival, and overall survival of patients treated by the National Surgical Adjuvant Breast and Bowel Project protocol B-06 comparing total mastectomy (TM) vs. segmental mastectomy plus radiation (SM + RTx). (Data from Fisher B, Baver M, Margoles R, et al. Five-year results of a randomized clinical trial comparing total mastectomy and segmental mastectomy with or without radiation in the treatment of breast cancer. *N Engl J Med* 1985;312:666–673.)

a technique augmented by the use of radioisotope using a gamma probe as proposed by David Krag and others.¹⁵² The nodal tumor status could thereby be evaluated by the selective assessment of this node or nodes while limiting the extent of surgery for those without nodal metastases. Sentinel lymphadenectomy has now become the focus of intense study and clinical application and is leading to a further redefinition of surgery for cancer of the breast.

SUMMARY

At the beginning of a new century, breast cancer treatment has shifted from a confident belief in the possibilities of improving survival with aggressive local treatment to a far broader effort to utilize the advances in diagnostic radiology, radiation therapy, and chemohormonal therapy to treat more appropriately both the local disease and the possible, often likely, systemic disease. Conservative and selective surgical approaches to the breast and axilla, once viewed as heretical, have become standard forms of therapy for most patients. Improved survival has been achieved for many patients with improvement in diagnostic imaging, technical advances in radiotherapy, the development of effective chemotherapeutic and pharmacologic hormonal agents, and the progressive ability to assay and develop therapies directed at the molecular components of the disease. This shift in treatment paradoxically reflects the still only vaguely understood origins and evolution of breast cancer. Certainly the advances in molecular biology, most significantly the identification of the susceptibility gene for early-onset breast cancer, *BRCA1*, by Mary-Claire King at the University of Washington,¹⁵³ followed by *BRCA2*, hold great promise for further directing studies to elucidate the basic mechanisms of breast cancer oncogenesis.

The modern advances in breast cancer treatment and basic research on the molecular biology of the disease have cast the often heroic efforts of our surgical ancestors as primitive, and even inhumane. Placed in a historical context, however, their efforts in the late 19th and early 20th centuries were quite the opposite, demonstrating that survival could be improved and, for the first time, providing evidence that breast cancer could be cured. After centuries of therapeutic nihilism that relegated women to an often painful existence and certain death, their

Table 21-2 Milestones in the Development of Modern Breast Cancer Treatment

Local origin of disease proposed (Henri François Le Dran), circa 1750
Principle of en bloc excision of breast and palpable axillary lymph nodes (Jean Louis Petit), circa 1750
Cellular origins of cancer (Johannes Müller), 1838
Axillary nodes barrier to dissemination (Rudolf Virchow), 1858
Centrifugal local dissemination encompassed by wide excision of breast, skin, axillary nodes, and, if necessary, pectoral muscles (Charles H. Moore), 1867
Inclusion of pectoralis major fascia in mastectomy (Richard von Volkmann), 1875
Radical mastectomy (William S. Halsted, Willy Meyer), 1894
Oophorectomy for metastatic breast cancer (George Beatson), 1896
Primary radiation treatment of breast cancer (Geoffrey Keynes), 1922
Total mastectomy and postoperative regional irradiation (Robert McWhirter), 1941
Columbia Clinical Staging (Cushman Haagensen, Arthur Purdy Stout), 1943
Extended (internal mammary dissection) radical mastectomy (Mario Margottini, Jerome Urban), 1948
Mammographic detection of clinically occult breast cancer (Jacob Gershon-Cohen), 1948
Modified radical mastectomy (David H. Patey, W. H. Dyson), 1948
Estrogen receptors (Elwood V. Jensen, Jack Gorski, William McGuire), 1950–1960
Excision and locoregional radiation (François Baclesse, Sakari Mustakallio), 1973
Adjuvant chemotherapy trials (Bernard Fisher, Gianni Bonadonna), 1975–1976
Breast conservation trials (Umberto Veronesi, Bernard Fisher), 1981–1985
Breast cancer susceptibility genes <i>BRCA1</i> and <i>BRCA2</i> (Mary-Claire King), 1990–1996
Sentinel lymphadenectomy (Donald Morton, Armando Giuliano, David Krag), 1991–1998

efforts to effectively ablate local disease, although significantly modified in recent decades, remain a critical component of modern therapy. Most important, their legacy provided the momentum for the present efforts made possible by modern technology, scientific methodology, and molecular biology to further improve survival and even to prevent breast cancer in the near future (Table 21-2).

Multimodality Treatment of Breast Cancer

John E. Niederhuber

Efforts to reduce breast cancer mortality have focused on early diagnosis and improved therapy. These efforts have been facilitated by a greater acceptance and participation by women in active screening programs, by their willingness to participate enthusiastically in clinical research trials, and by the evolution of treatment that has become truly multidisciplinary. The intensity of these changes in the management of breast cancer has transformed what was once a relatively straightforward therapy into one of sometimes overwhelming complexity. Comprehension of the nuances of this complexity is often difficult for both physician and patient. This chapter attempts to clearly explain the process for choosing among multiple options of treatment for patients with stages I and II invasive breast cancer as well as for some patients with stage IIIA disease (i.e., the operable, local regionally advanced breast cancers).

The complexity surrounding the variety of options for breast cancer therapy derives from our inability to predict accurately the natural history of a given patient's cancer. Treatment strategies effective for some patients are less effective or even ineffective for others—presumably because they represent genetically distinct tumors. Some years ago, Bloom and colleagues¹ had an opportunity to observe the course of untreated breast cancer. They concluded that the survival of untreated breast cancer patients presenting at the same clinical stage was quite variable, ranging from months to decades.

During the past 2 decades, results of adjuvant chemotherapy trials and hormonal interventions have suggested the need for a significant rethinking of models for breast cancer growth and progression.² In support of rethinking the model for breast cancer growth and metastasis is the long-standing recognition that the course of the disease is often quite extended—certainly more so for breast than for other common epithelial tumors. Not infrequently, breast cancer patients experience relapse of their disease 20 or more years after the initial diagnosis and surgical treatment. This certainly implies that some breast cancers during specific periods in their natural history are completely dormant.²⁻⁴

Obviously, the relationship of a specific cancer's growth rate to prognosis is critical to decisions regarding appropriate therapy and the sequencing of the various treatment options within an overall plan. Because recurrence of breast cancer is at present invariably associated with death from the disease, our primary goals must be to define the best methods of discovering breast cancer at the earliest possible stage, to identify ways of more precisely defining tumor growth rate, and to

elucidate better prognostic indicators that more accurately calculate the risk for mortality. Discovering the tumor and tumor microenvironment conditions that lead to states of metastatic tumor cell dormancy could provide major therapeutic options.

How do observations regarding breast cancer cell growth and tumor cell dormancy affect treatment?

A discussion of breast cancer cell growth must consider not only the complexities of the primary tumor and the breast tissue microenvironment in which it resides but also the presence of occult or measurable metastatic tumor and the variety of tissues hosting such tumor deposits. Although perhaps only partially understood at present, it appears clear that during the natural history of breast cancer, the interplay (autocrine and paracrine) between cancer cells and host environment and perhaps the interplay between the primary tumor, while it is still present, and secondary tumors affect the growth rate and overall progression of disease. Until recently, discussions of breast cancer cell growth focused on the measures of primary tumor progression and have come mainly from two sources: (1) direct analysis of randomized breast cancer screening trials and (2) indirect measures of tumor cell DNA synthesis and of cell division. Such models failed to include the growth and progression of metastatic disease and the influences of the host on the growth rate of the complete tumor burden.

For example, Gershon-Cohen and colleagues⁵ reported in 1963 on a small series of 18 patients who had two or more mammograms before a biopsy of their tumor. They used these data to calculate a median observed tumor doubling time (DT) of 120 days (range, 23 to 209 days). Their observations led investigators to conclude that the smallest 1- to 2-mm lesion detectable by mammography would have undergone an estimated 20 doublings of cell mass since its initial transformation to a cancer cell, and a 10-mm tumor would require an average of an additional 4 years of growth. Thus, using the median DT of 120 days, it would take a total of 20 years for an initial transformed breast epithelial cell to become a 2-cm cancer.⁶ In another study by Fournier and colleagues,⁷ 147 patients had serial mammograms before definitive treatment. The observation of these breast cancers ranged from

2 months to 11 years (mean, 27 months), and the measured DTs were 44 to 1869 days (mean, 212 days).⁷

The pattern of essentially exponential growth, however, does not fit well with clinical observations. To begin with, there has been a lack of correlation between DT and tumor differentiation. Studies have also shown that DT is much longer for larger, grossly measurable tumors than it is for pre-detection cancers.⁸ As a result, an alternative model based on irregular growth patterns rather than consistent growth was proposed. This model is known as the Gompertzian growth rate because it is based on the 19th-century observations of Gompertz.⁹ This Gompertzian model was specifically developed for breast cancer and predicts a progressive increase in the length of DT with the passage of time and with an increase in tumor volume.

Although the Gompertzian model is incompletely understood, growth-inhibitory influences, such as tumor cell necrosis factor, the process of apoptosis, and immunoregulatory responses by the host, are implicated but remain to be defined. The Gompertzian model has seemed more compatible with actual clinical observations regarding the natural history of breast cancer and has been consistent with the results of adjuvant polychemotherapy trials that presumed log cell-kill.¹⁰⁻¹⁵

In the early 1970s, a method of labeling tumor cell DNA with tritiated thymidine during the S phase of the cell division cycle was introduced into clinical practice.^{16,17} This made it possible, using DNA flow cytometry and image cytometry, to assess the number of cells of a given tumor that were actually in the S phase of the cell cycle.¹⁸ DNA flow cytometry, as well as direct labeling of tumor cells, could determine the proportion of tumor cells actively dividing, the duration of the division cycle, and the DNA ploidy of the tumor. This assessment of the primary tumor was shown to be useful in determining risk and contributed to the overall decision regarding adjuvant therapy. For example, breast cancers with diploid DNA content tend to be of a lower grade and to have a higher estrogen receptor (ER) content, whereas tumors that are aneuploid are more anaplastic and have a low ER content or are ER negative.

Plevritis, writing in *Mathematical Biosciences*,¹⁹ presents a mathematical model that simulates tumor size and growth rate among screen-detected and interval breast cancers. The author notes that the initial set of models^{20,21} was developed before most randomized controlled screening trials had accrued enough follow-up data. With longer follow-up, alternative methods for modeling breast tumor growth have emerged. The Plevritis model¹⁹ differs from previous models because it uses information about tumor size when the tumor is clinically detected in a nonscreened population (control arm) and searches backward in time to determine the earliest the tumor could have been screen-detected under optimal screening conditions. The advantage of this approach is that detection of the tumor in the nonscreened cohort is an observable event, whereas actual time of tumor onset is not. When this algorithm was implemented, it demonstrated that screen-detected tumors are smaller in diameter and slower in growth than interval cancers. Also, the slower-growing screen-detected cancers had a longer lead time.

Thus, the answer to the question regarding the growth rate of stages I and II breast cancer is that these cancers do not always grow at a constant rate. Irregular tumor growth and progression is the result of a balance of progressive

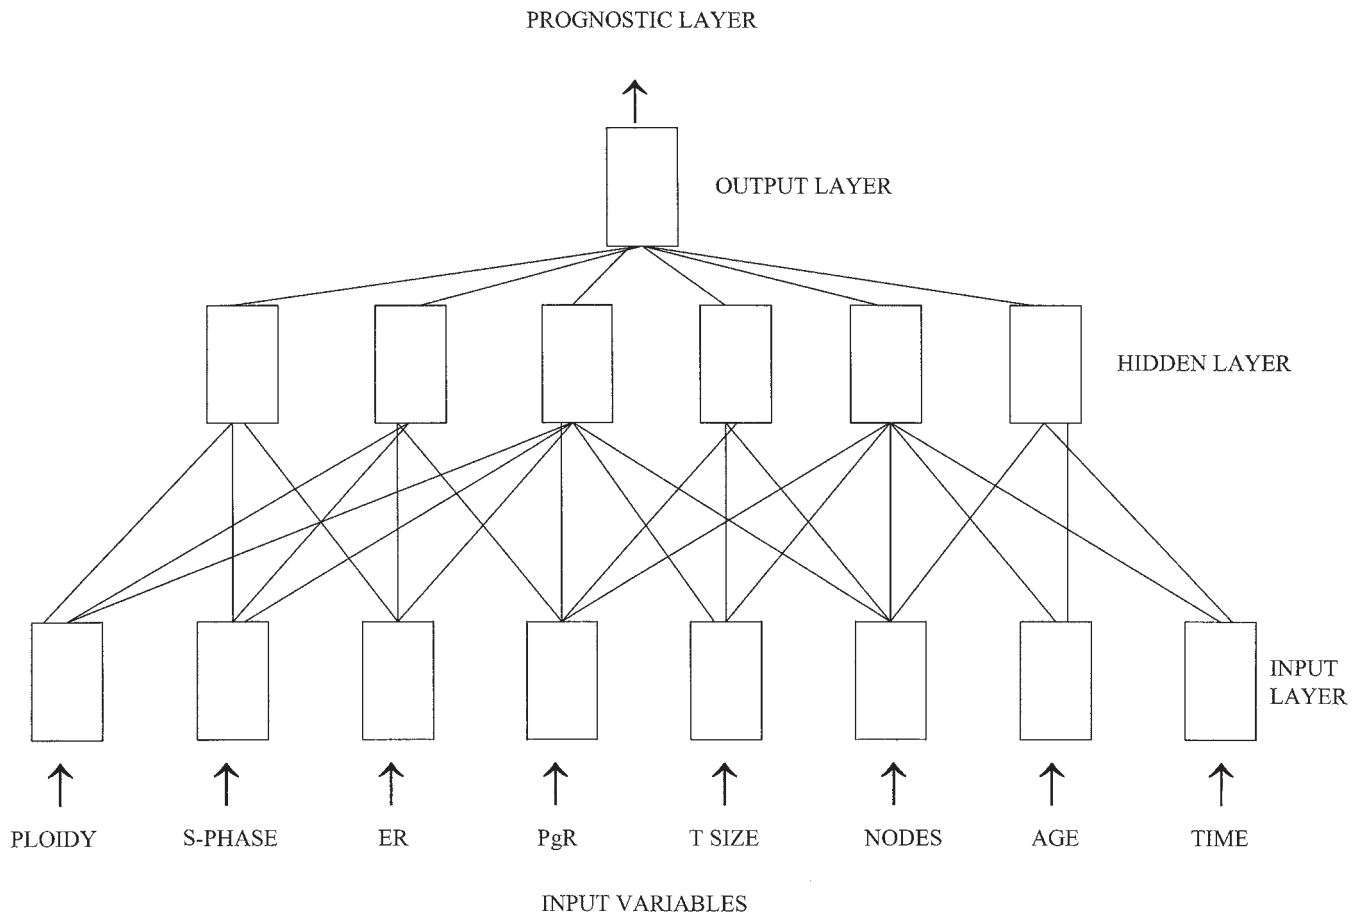

genetic alterations between initiation and detection (predetection phase), genetic events that permit metastasis, hormonal changes within the patient, deceleratory growth patterns (as tumor volume increases), the regulation of tumor angiogenesis, spontaneous tumor cell death (necrosis), genetically programmed cell death (apoptosis), immunologic modulation, and host defenses from adjacent nonmalignant tissues.²² For the most part, it is reasonable to assume that the stepwise genetic changes that take a transformed cell from initiation through to ultimate metastatic growth are changes facilitating growth, invasion, and acceptance in other tissues.

As noted previously, those involved in the long-term follow-up of patients treated for primary stages I and II breast cancer are not surprised when their carefully monitored patient suddenly manifests recurrence of disease after being disease free for 2, 3, and even 4 decades.^{3,4} Thus, although it is important to study and use data concerning the growth rates of primary breast tumors, there are clearly multiple factors at play when projecting the ultimate course of the total disease (primary and metastatic), and primary tumor growth rates more often than not have no relationship to the length of a patient's relapse-free survival and overall survival.²³ This conclusion is supported by several clinical observations:

1. The length of time a patient may experience without evidence of recurrent disease is not a good predictor of the length of survival after relapse.²⁴ These observations, along with others such as the sudden appearance of chest wall metastases, suggest a change in tumor cell growth rates around the time when the recurrent disease is first detected and that the host microenvironment and systemic factors may be significantly involved.^{25,26}
2. There are two peaks of recurrences over time. There is an early sharp peak at 2 to 3 years and a broader peak in the incidence of metastases at 7 to 9 years.²⁷⁻³²
3. Although larger tumors are at greater risk for having involved axillary lymph nodes, it is well established that tumor size and nodal status are independent predictors of outcome.³³ Large tumors are often found to be node negative, and occasionally patients present with an axillary mass and undetectable primary breast cancer.
4. The increasing frequency of tumors being ER and progesterone receptor (PR) negative that occurs with age is seen to plateau abruptly with the onset of menopause.^{34,35}

At issue, therefore, is the extent to which breast cancer is viewed in relative isolation as an autonomous entity of proliferating cells or as an "organ" or "tissue" composed of tumor and its supporting environment. If it is viewed as an autonomous unit, then "killing the last cancer cell" becomes the key to treatment decisions. On the other hand, if breast cancer is seen as cancer cells growing within a dynamic and complex support environment of positive growth facilitators and negative growth regulators, a more sustained therapeutic approach—for example, hormonal manipulation or molecularly targeted approaches—becomes the paradigm of therapy.²³

The increased numbers of methods available to determine these growth variables over the entire course of the disease, as well as other measures of risk, obviously require the computer software capability of handling a diverse data set. These evolving computer programs also include mathematical solutions to the different growth possibilities (i.e., exponential, Gompertzian, linear) to permit the compliance of more

A

Figure 22-1 A, Basic architecture of a neural network for analyzing prognostic variables for breast cancer. ER, estrogen receptor; PgR, progesterone receptor; T, tumor.

complex data sets with earlier clinical observations.³⁶ As a result, computer analysis is becoming extremely useful in identifying risk variables consistently associated with recurrence for node-negative early breast cancer and is becoming essential to designing appropriate therapy and appropriate clinical trials—especially in the adjuvant setting.³⁷⁻³⁹

Often, these computer-based programs are referred to as “neural networks,” a computerized form of artificial intelligence.⁴⁰ Such systems have been applied to oncology patients using a set of data defining a given patient’s prognostic information. The neural network is trained to use the stimulus of this prognostic information to predict patient outcome.⁴¹ This allows the construction of a survival probability curve for an individual patient and the improvements in that curve that can be predicted from specific interventions. This methodology is certainly important in planning the aggressiveness as well as the sequencing of therapy⁴² (Fig. 22-1).

What is the impact of mammographic screening on the stage of disease at detection and on mortality?

In a study by Cady and colleagues,⁴³ patient data from 1969 to 1993 were gathered from the New England Deaconess Hospital and the Mt. Auburn Hospital (both in Boston). The

results clearly demonstrate that invasion, size, and nodal involvement are dramatically decreasing as a result of mammographic screening (Table 22-1). The impact of mammography, in fact, has led to further subdividing T1 lesions into subgroups T1a, T1b, and T1c to accommodate the rising incidence of detection of tumors of reduced dimensions (Table 22-2).

Several other reports also describe an earlier clinical presentation of invasive breast cancer and a higher incidence of noninvasive breast cancer.⁴³⁻⁴⁶ Ductal carcinoma in situ (DCIS), accepted as a precursor of invasive ductal cancer (IDC), is currently diagnosed 90% of the time as clinically occult disease in the presence of an abnormal mammogram.⁴⁶⁻⁴⁸ This documented increase in the percentage of newly diagnosed breast cancers having Tis, T1a, or T1b stage, coupled with recent reports that the number of women who undergo mammographic screening continues to rise, promises to further reduce breast cancer mortality. For example, the percentage of women older than 40 years who undergo mammographic screening increased 200% during the 1980s.⁴⁹ Even with this increase in use of mammography, estimates are that perhaps 25% of women older than 50 years have never had a mammogram.⁵⁰

In an effort to determine the current use of screening mammography, Ostbye and colleagues at Duke University⁵¹ reviewed data obtained by two national longitudinal surveys,

Survival estimates at 10 years

DATA USED

Patient age: 65 years
 Breast cancer–related mortality in 5 years: 18%
 Relative effectiveness of adjuvant therapy: 35%

If this breast cancer had not happened

- 81% Women alive
- 19% Women die (not of this breast cancer)

If no adjuvant therapy is given to this patient

- 57% Women alive
- 27% Women die (of this breast cancer)
- 15% Women die (not of this breast cancer)

If adjuvant therapy is given to this patient

- 65% Women alive
- 8% Women alive because of adjuvant therapy
- 19% Women die (of this breast cancer)
- 16% Women die (not of this breast cancer)

B

Average life expectancy

These estimates are based on many assumptions and are only informed projections.

Average years lost due to cancer 5.2

Average years regained by adjuvant therapy 1.6

Projected survival

Figure 22-1—Cont'd. B, Tables and graphic output from neural network programs showing projections of outcome for a patient who receives adjuvant 35% effectiveness. (A, Data from Ravdin PM, Clark GM. A practical application of neural network analysis for predicting outcome of individual breast cancer patients. *Breast Cancer Res Treat* 1992;22:289. B, Data from Ravdin PM. A computer program to assist in making breast cancer adjuvant therapy decisions. *Semin Oncol* 1996;23[Suppl 2]:47.)

the Health and Retirement Study (HRS)⁵² and the Asset and Health Dynamics among the Oldest Old (AHEAD) survey.⁵³ The HRS involves 5942 women aged 50 to 61 years, whereas the AHEAD survey concerns 4543 women aged 70 years and older. Use of mammographic screening appears to be fairly stable at 70% to 80% among women aged 50 to 64 years.⁵¹ There is a steady decline in use after age 70 years to about 40% among women aged 85 to 90 years.^{51,53} Higher education, being married, higher income, not smoking, no cognitive impairment, perception of health being excellent, and a higher life expectancy were all positively related to participation in screening.⁵¹ The Medicare Current Beneficiary Survey had similar findings, with only 26.7% of women 75 years and older involved in screening.⁵⁴

The increased participation of women in voluntary annual screening mammography programs is accepted as the major reason for a significant decline in deaths from breast cancer. This decreasing mortality, seen between 1989 and 1998, has occurred for every age and racial group.^{46,55} Tabar⁵⁶ recently reported a 63% reduction in breast cancer mortality for women 40 to 69 years of age who were documented to have

participated in annual screening mammography. Some have argued that this observed reduction in mortality is not the result of screening mammography but is primarily due to the tremendous improvements in therapy.^{57,58} This explanation seems highly unlikely because a similar reduction in mortality should have occurred in the control group. Even when corrected for possible selection bias, the reduction in breast cancer mortality was at least 50%. Other randomized breast cancer screening trials have undergone recent long-term follow-up, and they also support a significant reduction in breast cancer stage at diagnosis and in overall mortality.^{59,60}

To further test whether there is an underlying association between mammography use and decreasing late-stage disease, investigators at the Fred Hutchinson Cancer Research Center in Seattle studied the effect of an organized breast cancer screening program.⁵⁰ They used patients enrolled in the Seattle-based Group Health Cooperative. They found that mammography screening increased for the health plan members from 25.9% to 51.2% among women aged 40 to 49 years and from 32.9% to 74.7% of women older than 50 years. More important, they found that enrolling women in organized

Modified from Cady B, Stone MD, Schuler JG, et al. The new era in breast cancer: Invasion, size, and nodal involvement dramatically decreasing as a result of mammographic screening. Arch Surg 1996;131:301–308. Copyright 1996, American Medical Association.

screening and getting a screening mammogram were associated with a 69% reduction in the risk for late-stage disease among the cancer cases. Even more important was the finding of a 61% reduction in the odds ratio for late-stage disease with screening enrollment when determined using the general health plan population (disease-free) controls. This latter comparison provides the least biased estimate of an advantage for enrollment in an organized screening program.

Although the marked reduction in mortality resulting from optimal mammographic screening has been welcome news, there has been a controversy regarding the appropriateness of screening for women between the 40 and 49 years of age.⁶¹ With the continuing debate, the evidence is increasing that

this age group may also benefit. Breast cancer occurs in the 40- to 49-year-old population at the rate of about 1.3 to 1.6 cases per 1000 women per year.⁶² In part, the controversy surrounding screening of younger women derives from the fact that many large-scale trials were not designed to analyze specifically women 40 to 49 years old.⁶³ Point estimates in several trials, however, demonstrate a mortality reduction in this population due to mammographic screening, ranging from 22% to 49%.⁶³ One of the main arguments against screening in the premenopausal years is the higher number of false-positive findings produced by mammography because of differences in breast composition. Nevertheless, there is already a great deal of evidence that mammography for premenopausal women can significantly reduce mortality.^{62–65} In 1996, a

Table 22–2 Staging Classification

Primary Tumor (T)			
Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. The <i>telescoping</i> method of classification can be applied. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, T3). If other measurements, such as mammographic or pathologic, are used, the telescoped subsets of T1 can be used.			
Tx	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis*	Carcinoma in situ: intraductal carcinoma, lobular carcinoma in situ, or Paget's disease of the nipple with no tumor		
T1	Tumor 2 cm or less in greatest dimension		
T1a	0.5 cm or less in greatest dimension		
T1b	More than 0.5 cm but not more than 1 cm in greatest dimension		
T1c	More than 1 cm but not more than 2 cm in greatest dimension		
T2	Tumor more than 2 cm but not more than 5 cm in greatest dimension		
T3	Tumor more than 5 cm in greatest dimension		
T4†	Tumor of any size with direct extension to chest wall or skin		
T4a	Extension to chest wall		
T4b	Edema (including peau d'orange) or ulceration of the skin of the breast or satellite skin nodules confined to the same breast		
T4c	Both (T4a and T4b)		
T4d	Inflammatory carcinoma		
Regional Lymph Nodes (N)			
Nx	Regional lymph nodes cannot be assessed (e.g., previously removed)		
N0	No regional lymph node metastasis		
N1	Metastasis to movable ipsilateral axillary lymph node(s)		
N2	Metastasis to ipsilateral axillary lymph node(s) fixed to one another or other structures		
N3	Metastasis to ipsilateral internal mammary lymph node(s)		
Pathologic Classification (pN)[‡]			
pNx	Regional lymph nodes cannot be assessed (e.g., previously removed or not removed for pathologic study)		
pN0	No regional lymph node metastasis		
pN1	Metastasis to movable ipsilateral axillary lymph node(s)		
pN1a	Only micrometastasis (none larger than 0.2 cm)		
pN1b	Metastasis to lymph node(s), any larger than 0.2 cm		
pN1bi	Metastasis in 1 to 3 lymph nodes, any more than 0.2 cm and all less than 2 cm in greatest dimension		
pN1bii	Metastasis to 4 or more lymph nodes, any more than 0.2 cm and all less than 2 cm in greatest dimension		
pN1biii	Extension of tumor beyond the capsule of a lymph node metastasis less than 2 cm greatest dimension		
pN1biv	Metastasis to a lymph node 2 cm or more in greatest dimension		
pN2	Metastasis to ipsilateral axillary lymph nodes that are fixed to one another or to other structures		
pN3	Metastasis to ipsilateral internal mammary lymph node(s)		
Distant Metastasis (M)			
Mx	Presence of distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis [includes metastasis to ipsilateral supraclavicular lymph node(s)]		
Stage Grouping			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIA	T0	N1	M0
	T1	N1	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T0	N2	M0
	T1	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
Stage IIIB	T4	Any N	M0
	Any T	N3	M0
Stage IV	Any T	Any N	M1

*Paget's disease associated with a tumor is classified according to the size of the tumor.

†Chest wall includes ribs, intercostal muscles, and serratus anterior muscle, but not pectoral muscle.

‡The prognosis of patients with pN1a is similar to that of patients with pN0.

Adapted from Beahrs OH, Henson DE, Hutter RVP, et al. Manual for Staging of Cancer, 6th ed. Philadelphia, American Joint Committee on Cancer, The American Cancer Society. New York, Springer-Verlag, 2002.

meta-analysis of randomized screening trials presented in Sweden^{64,65} demonstrated a 24% reduction in mortality from breast cancer in mammographically screened women aged 40 to 49 years.

The ability of screening mammography to diagnose cancer in the preclinical phase of growth, when a cancer is either noninvasive or just beginning its invasive growth phase, creates a great need for developing additional markers of risk. With these early invasive tumors, the goal is to minimize unnecessary therapy. It is imperative to calculate the risk, as accurately as possible, for the presence of occult micrometastases. Specific markers of risk are vital pieces of prognostic information needed to guide decisions regarding the extent of local tumor treatment, the need for nodal dissection, and the type and duration of systemic therapy.

What is the impact of biologic markers on therapeutic decisions?

At diagnosis, patients present with primary tumor staging that historically has provided information on the risk for developing locoregional and distant site failure, the risk for death from disease, and the probability of response to specific treatments. Such clinical and pathologic staging is enhanced by the identification of molecular markers associated with the tumor process that are of value in determining prognosis and in making decisions regarding therapy. In this new era of rapid scientific discovery, research to identify and characterize specific biomarkers of breast cancer and specific genetically altered cellular pathways not only relates to patient outcome but also is increasingly offering opportunities for targeted therapies. While such research will more accurately define the risk for developing recurrent disease, the ultimate goals are the detection of those women at risk for developing breast cancer and the development of preventive interventions.

Estrogen Receptor and Progesterone Receptor Intracellular Proteins

Intracellular steroid hormone receptors, discovered in 1966, were the initial tumor markers used in predicting risk for recurrence and for making decisions regarding hormone therapy. Some 50% to 85% of breast cancers contain measurable amounts of ER protein (>10 fmol/mg).⁶⁶ The degree to which tumors are ER and PR positive is a reflection of how well differentiated the tumor is; that is, tumors that are ER and PR positive are of low grade. ER and PR are linked in that PR expression depends on transcriptional activation by a normal ER-estrogen complex.

There are two ER subtypes, ER α and ER β , expressed from different genes.⁶⁷ ER α is a more potent transcriptional activator than ER β in standard laboratory assays and has a higher affinity for estrogen response elements.⁶⁸⁻⁷³ ER α and ER β consist of three distinct domains: an N-terminal domain, a DNA-binding domain, and a C-terminal ligand-binding domain. The binding of a specific ligand to the ER produces a distinct conformational change in the receptor protein, enabling it to interact selectively with the coregulatory proteins, coactivators, and corepressors involved in the transcriptional activation of estrogen-regulated genes.⁷⁴

In addition to predicting a more favorable disease-free survival, ER positivity predicts a higher (50% to 60%) response

rate to hormone or endocrine therapy. The response rate is highest when both ER and PR are positive. Perhaps the presence or absence of ER has been most important in making decisions regarding adjuvant therapy in early node-negative breast cancer. ER-negative, node-negative patients have an 8% to 12% worse outcome than those who are ER positive.^{66,75} McGuire and colleagues³⁷ used a multivariate analysis of risk factors in 3000 breast cancer patients and found that the ER status in node-negative patients was more predictive than tumor size. This was not true for node-positive patients. It remains difficult to state that ER functions as an independent marker, however. ER expression is highest when tumors are of favorable histology, have a normal DNA diploid pattern, and have a low number of cells undergoing division.

Selective ER modulators (SERMs) are synthetic chemical compounds that, when bound to ER, produce a tissue-selective biologic activity. Depending on the nature of the bound SERM, the ER subtype, the gene promoter elements, and the cellular levels of coregulatory factors, the response in specific tissues may vary. In tissues such as an ER-positive breast tumor, the biologic activity may be one of blocking estrogen function, whereas in other important selected normal tissues, the biologic effect is one of preserving desired estrogen function.^{76,77}

Tamoxifen was the first SERM developed and approved by the U.S. Food and Drug Administration (FDA) (in 1986) for adjuvant therapy in postmenopausal women with node-positive breast cancer. It was later approved (in 1990) for node-negative breast cancer. In the adjuvant setting, tamoxifen reduces the risk for disease recurrence in ER-positive patients by 47% and reduces overall mortality from breast cancer by 26%. The response rate using tamoxifen for ER- and PR-positive patients with metastatic breast cancer is 60% to 75%, and it is about half that when only one receptor is positive.

DNA Content and S-Phase Fraction

The determination of DNA content and of the number of cells actually synthesizing DNA and proceeding through the cell cycle has been facilitated by automated systems of flow cytometry. These analyses are best performed on fresh-frozen tissue. A diploid content is present in 32% to 51% of breast cancers. A report in 1993 of a consensus conference regarding the value of DNA flow cytometry provides a good summary of its status.⁷⁸ As mentioned earlier, diploid tumors have a favorable prognosis compared with aneuploid tumors; aneuploid breast cancers are larger in size and of higher grade. DNA content has not fared well as an independent marker in multivariate analysis because of its strong association with other more powerful markers of risk. S-phase fraction, on the other hand, has proved to be a more independent predictor but also loses some of its value when compared with tumor grade.

Other measures of cellular proliferation, such as thymidine labeling for image-cytometry (TLI), are more accurate measures of the actual number of cells in the S phase of the cell cycle and have proved to be stronger predictors of risk than the S-phase fraction calculated from flow cytometry. TLI is more difficult to perform and therefore has not been adopted for routine clinical evaluation.

Antibodies reactive with a nuclear antigen present only in cells in G₁, S, G₂, and M phases and not in G₀ cells have also been used to measure the rate of tumor cell proliferation.^{79,80}

High Ki-67 antibody scores (more proliferating cells) are associated with a poor prognosis and have been reported as an independent marker of risk.^{81,82}

Cell Adhesion Molecules

The ability of cancer cells to grow, invade, and metastasize is dependent on the integrity of cell adhesion proteins, proteolytic enzymes, growth factors, and growth factor receptors.⁸³ For cancer cells to metastasize, they must acquire a motile phenotype and be able to penetrate tissues in order to reach the microvasculature and lymphatic channels. The initial step in the metastatic process involves an interaction with the basement membrane and the eventual passage through this membrane into the extracellular matrix.

A major component of the basement membrane is a large family of glycoproteins called the laminins.⁸⁴ Numerous breast cancer cell surface proteins, namely the integrins, constitute cell surface receptors that interact with specific molecular sites on collagen and laminin. Integrins are transmembrane molecules composed of $\alpha\beta$ heterodimers.⁸⁵ Integrins have also been found to interact with growth factors such as parathyroid hormone-related protein (PTHrP), which is involved in normal mammary gland development and function.^{86,87} Overexpression of PTHrP in experimental models increases the expression of $\alpha6$ and $\beta4$ integrin subunits, resulting in increased adhesion, migration, and invasion of MCF-7 breast cancer cells. Dales and colleagues studied the prognostic value of markers of activated endothelial cells, CD105, Tie-2/Tek, and VEGF receptors.⁸⁸ They studied 905 patients with breast cancer and found that overexpression of CD105 and of Tie-2/Tek significantly correlated with a poor outcome. This was not the case in their study of VEGF-R1 and VEGF-R2. Furthermore, CD105, but not Tie-2/Tek, retained its prognostic significance for node-negative low-risk breast cancer. These were independent markers when compared with other risk indicators in a multivariate analysis. Overexpression of CD105, Tie-2/Tek, and VEGF-R1, but not of VEGF-R2, was an independent predictor of greater metastatic risk. Only Tie-2/Tek and VEGF-R1 expression correlated with early local failure in node-negative patients. Thus, these markers may allow selection of those node-negative patients who would benefit from more aggressive therapy, especially from specific antiangiogenic agents.⁸⁹⁻⁹¹

Studies have also implicated the importance of stabilizers of cell-cell and cell-matrix interactions, demonstrating the role of desmosomes and cadherin-containing junctions.⁹² For example, E-cadherin belongs to a large family of proteins responsible for the calcium-dependent cell-cell adhesion and is a normal adhesion molecule expressed in breast ductal epithelial cells but found to be significantly reduced in areas of invasive breast cancer.⁹²⁻⁹⁵ Rimm and associates⁹³ reported that E-cadherin was significantly decreased or absent in 63% of primary breast tumors and that the cytoplasmic portion of the E-cadherin molecule that attaches to the actin cytoskeleton through catenins such as α -catenin was reduced or lost in 18%. Other studies suggest that in high-grade breast cancers, E-cadherin may be replaced by P-cadherin.⁹⁶ P-cadherin is usually expressed only in the luminal cells of the adult breast and in the basal layers during fetal development. Its presence in malignant ductal epithelial cells represents abnormal expression.⁹⁶ In a retrospective study of 222 breast carcinomas, P-cadherin was shown to identify a subgroup of cancers

that were ER negative and that had a higher proliferation index and an aggressive pattern of growth.⁹⁷ This would suggest that E-cadherin and P-cadherin have distinct roles and hormonal relationships in breast cancer growth and progression.

Whether changes in the expression of P-cadherin, E-cadherin, and α -catenin will prove to serve as independent markers for the presence of occult micrometastases remains to be demonstrated. Alterations in the expression as well as in the structure of E-cadherin and the catenins have been linked to tumor cell invasion and metastasis in breast cancer and several other tumors.^{98,99}

Matrix Metalloproteinases

A series of gelatinases (matrix metalloproteinases) secreted by cytoplasmic zymogens and activated by cell membrane proteins are specifically reactive with type IV basement membrane collagen.^{94,100} Two of the metalloproteinases, MMP-8 and MMP-9, have been found to be elevated in invasive breast cancers.¹⁰¹ A current hypothesis is that breast cancer cells stimulate the fibroblasts, causing the stroma around the tumor to produce these gelatinases, which then act to break down the extracellular matrix, facilitating tumor invasion and metastasis.¹⁰²⁻¹⁰⁷ Although MMP-8 and MMP-9 may prove to be useful markers of risk, of even greater interest is the possibility that metalloproteinase inhibitors will be useful therapeutic agents.^{108,109}

Cathepsin D

Cathepsins are proteases with enzymatic activity against matrix proteins. Cathepsin D is estrogen dependent and is overexpressed and secreted in about 22% of invasive breast cancers. Overexpression is associated with a high incidence of nodal metastases and a worse prognosis.¹¹⁰ A study of the prognostic value of cathepsin D in 771 patients with breast cancer found an increase in death rate approaching 70% with a doubling of the level over threshold values.¹¹¹ The strong association of cathepsin D with a positive nodal status, however, may make it less useful in predicting risk, especially in patients with node-negative disease.^{66,112}

Oncogenes and Tumor Suppressor Genes

The most widely studied of the oncogenes is the *erbB-2* (*HER-2/neu*) oncogene. The *erbB-2* oncogene is overexpressed in 15% to 20% of breast cancers, and this overexpression is associated with larger tumors, node positivity, higher S-phase fractions, and ER negativity.¹¹³⁻¹¹⁵ It is associated with an overall worse prognosis and an increased incidence of metastases.^{116,117} It loses some of its value as a prognostic factor because it is associated mainly with node-positive patients who are routinely treated aggressively. Studies have found overexpression of *erbB-2* in less than half of recurrent breast cancers.¹¹⁸ Of recent interest is the observation that *erbB-2* amplification has shown correlation with an increased benefit of doxorubicin-based adjuvant therapy but a lack of equal benefit with cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) therapy.^{119,120} Amplification of *c-myc* has also been reported in about 20% of tumors and is associated with higher-grade tumors and loss of hormone receptors.^{113,121}

Mutations in some tumor suppressor genes, including *p53*, *BRCA1*, *BRCA2*, *PTEN*, and *ATM*, as well as epigenetic inactivation of other suppressor genes, such as *SYK* and *NES1*,

appear to be important to the development and progression of breast cancer. The most widely studied tumor suppressor gene is *p53*. The presence of mutated *p53* (in 40% to 50% of breast cancers) correlates with the usual features of high-risk tumors.^{122,123} Mutant *p53* has been documented in more than 50% of patients having the breast and ovarian cancer syndrome and in all cases of Li-Fraumeni syndrome.¹²⁴ Detection of mutant *p53* has a negative impact on both disease-free survival and overall survival. In one report dealing with node-negative patients, the 6-year disease-free survival rate decreased from 90% (no mutant *p53*) to 60% (mutant *p53*).¹²³ In other reports, the presence of mutant *p53* predicted an even worse disease-free survival.¹²² Once again, the predictive value of *p53* is somewhat weakened by its association with other known predictors of poor outcome. Loss of heterozygosity at a number of other chromosomal loci in breast cancer cells indicates that *p53* is just one of several tumor suppressor genes involved in the progression of breast cancer.^{125,126}

Whether any of the oncogene or tumor suppressor gene abnormalities alone or in a specific pattern will be able to provide highly specific and accurate predictive value where it is most needed, that is, in early breast cancer, remains unknown. In general, these genetic abnormalities have been identified with advanced stages of disease—larger tumors that are actively proliferating, are node positive, have a higher histologic-grade, and are receptor negative—all markers of poor outcome. They are not, at this time, useful as stand-alone markers in making decisions regarding therapy.

Genomics and Proteomics

The relative completion of the Human Genome Sequencing Project heralds a new era in breast cancer research. As a result, genomic hybridization and complementary DNA (cDNA) and RNA expression profiling and proteomic analyses of breast cancer cells, surrounding host tissue, and patient serum hold great promise for determining patients at risk or harboring early predetection breast cancer. These new technologies will eventually provide the true characterization of the patient's tumor and define the highly individualized therapy required.

Considerable work has already been reported using cDNA microarrays to detect differences in gene expression in breast cancer.^{127–130} In one study, 130 genes were identified and clearly defined different tumor types, including breast.¹³¹ For breast cancer, there were 42 genes that appeared to correlate significantly with the overall survival of patients. Examples of genes that were clearly up-regulated and predicted a worse prognosis were *cyclin B1*, *TGF-β3*, *B-Myb*, and *Erg2*. Those genes that were down-regulated included *MIG-6*, *Esp15*, and *CAK*.¹³¹

Workers at the Institute of Proteomics, Harvard Medical School, have developed an automated literature-mining tool, called Med Gene, which they used to analyze the extensive reports of novel microarray gene expression studies comparing breast cancer to normal breast tissue.¹³² This relational database seems to demonstrate that for genes displaying a 5-fold or less change in tumor tissue compared with normal tissue, there is no evidence in the literature of a correlation of altered gene expression and breast cancer phenotype. However, with genes showing a 10-fold change in expression level, there was a strong correlation between the level of expression and disease. This strongly suggests that these are the genes deserving further intense study. It is interesting that

this was true for ER-positive tumors but not ER-negative tumors. Even so, the search found a number of understudied genes in ER-negative tumors with a 10-fold expression that certainly deserve investigation.

It has been shown that comprehensive gene transcriptional profiles can be obtained from single-passage fine-needle aspirations of breast cancers.^{130,133,134} These authors were successful in obtaining good quantity and quality of RNA suitable for successful microarray analysis from 71% of the needle aspirates.¹³⁴ Although these transcriptional profiles have provided significant insight into tumor characterization and have helped define prognosis in node-negative early-stage breast cancer,¹³⁴ expression arrays may not accurately characterize all tumor-associated and functional proteins involved in the cancer process. There are several concerns in this regard: (1) a lack of correlation between level of transcript expression and actual protein level; (2) abnormalities associated with the translocation of the protein in the cancer state; and (3) the possible underidentification of proteins because of restriction on the number of expressed sequence elements on a microchip.

Some of these concerns are now being addressed by proteomic studies that attempt to characterize all proteins encoded by the genome and functionally expressed.^{135–137} Proteomics allows identification of protein-protein interactions and identification of specific proteins associated with a given malignancy, such as breast cancer. Even more important, proteomics will be able to identify specific stages of this disease from premalignant to metastatic. Proteomics may also provide a direct method of monitoring the serum or tissue protein profile before and after administration of systemic therapy as a way to predict response and outcome.¹³⁸

What needs to be done to completely evaluate the patient before initiating treatment?

For the surgeon, the preoperative evaluation of the patient with biopsy-proven breast cancer can be divided into two tasks. First, the surgeon is responsible for providing the patient with a safe operative experience and postoperative recovery. To accomplish this, the surgeon must obtain a comprehensive systems assessment of the patient's current health status and a thorough review of all prior health care. This requires a careful search for any risk factors that might suggest the presence of occult cardiac disease and renal and pulmonary compromise. Unsuspected ischemic heart disease is the most frequent cause of serious surgical complications in postmenopausal women. Pulmonary disorders such as asthma and chronic obstructive pulmonary disease can be a significant source of morbidity when the surgery is extensive and includes reconstruction. The surgeon needs to be aware of the presence of diabetes mellitus, any chronic cutaneous diseases such as collagen-vascular disease, and prior exposures to radiation that might complicate the normal healing of tissues.

Second, the goal of the surgeon as a member of a multidisciplinary breast cancer treatment team is to begin the process of defining the extent of the patient's cancer and the process of assisting the patient, including the patient's family, in developing an understanding of appropriate therapy options based on accurately staged disease.

What are the laboratory tests and imaging needed?

Keeping the two goals mentioned earlier in mind, the surgeon and anesthesiologist will want to obtain a complete blood count (CBC); platelet count; and a general laboratory panel that includes liver function assessment, prothrombin time, serum albumin, blood sugar, calcium, and serum creatinine. A chest radiograph and an electrocardiogram (ECG) (especially important for women in their postmenopausal years) are considered routine. Other tests may be deemed necessary based on careful evaluation of the patient's past medical history and current health status. As discussed later in this chapter, patients who are to receive an anthracycline (doxorubicin) as part of their adjuvant therapy should have a baseline multiple-gated acquisition (MUGA) cardiac scan, Doppler echocardiography, or both before therapy is initiated. These tests are used to monitor cardiac toxicity during systemic treatment.

The surgeon must be satisfied that a good-quality bilateral mammogram exists for the patient. If the diagnosis of invasive cancer was obtained by stereotactic x-ray or ultrasound-guided core needle (14 to 18 gauge) biopsy or by a needle- and wire-localized breast biopsy (the gold standard) of an occult mammographic abnormality, it is important to document clearance of the radiographic findings. The most common example is the mammographic finding of clustered microcalcifications. In this case, it is best to obtain a repeat two-view mammogram of the surgically cleared breast to ensure the removal of all the microcalcifications or, in the case of an occult density, the clearing of the abnormality on the mammogram that led to the original biopsy. This repeat imaging of the breast may be obtained after lumpectomy and before initiation of breast irradiation.^{139,140} This optimizes confidence

that all mammographic abnormalities have been eliminated and histologically evaluated.

It is important that the surgeon personally review the histopathologic findings with the pathologist. Tumor histology, volume, and margins are important factors in planning surgical therapy. There is no substitute for an in-person review of the histopathology in developing a confident plan for local therapy.

A bone scan is indicated only when suspicious skeletal symptoms are present and when the serum alkaline phosphatase is elevated. A computed tomography (CT) scan is obtained only when indicated by patient symptoms or for stage III locally advanced breast cancer patients. An exception is sometimes made when the patient presents with clinical stage II disease. In such instances, CT evaluation of the chest, abdomen, and pelvis provides reassurance that the disease is confined to the axilla, establishes a baseline for future evaluations, and provides information regarding the status of the internal mammary and mediastinal lymph nodes.

Functional imaging using fluorodeoxyglucose positron emission tomography (FDG-PET) is increasingly used in the management of patients with cancer—especially lung, colorectal, and lymphoma cancers.¹⁴¹ As experience increases, it is clear that whole-body PET imaging can detect distant metastases from breast cancer, but it remains to be determined whether its sensitivity and accuracy are equal to or exceed standard CT imaging and whether there will be specific instances in the management of breast cancer in which the ability of PET to detect occult disease will contribute to the treatment decision process.¹⁴²

Magnetic resonance imaging (MRI) of the breast is clearly a valuable new diagnostic tool (Fig. 22–2). In evaluating the breast for the presence of cancer, gadolinium-enhanced scans

Figure 22–2 Magnetic resonance imaging of the breast. *A*, Normal craniocaudal (*left*) and mediolateral oblique (*right*) mammograms of the right breast. *B*, Sagittal view MRI of the same right breast demonstrating an invasive ductal cancer.

Figure 22-3 Magnetic resonance imaging used to follow the response to polychemotherapy treatment of an inflammatory left breast cancer in a young woman. A mastectomy was performed shortly after the July 2004 MRI, and no residual tumor was found by histopathology.

have proved to be exceptionally sensitive (close to 100%).¹⁴³ Cancerous tissue has a more rapid initial enhancement after a bolus of intravenous gadolinium (gadopentetate dimeglumine, 0.1 mmol/kg body weight) than benign tissue. Specificity, however, may be as low as 60%, primarily because of false-positive findings.

Currently, gadolinium-enhanced MRI is used to evaluate the difficult diagnostic problems (e.g., when trying to delineate the extent of the tumor). MRI is better than physical examination, film-screen mammography, and ultrasonography in determining the extent of the cancer before surgery.¹⁴⁴⁻¹⁴⁶ The patient with invasive lobular carcinoma is an excellent candidate for having gadolinium-enhanced MRI of both breasts. It is difficult to correctly assess the extent of invasive lobular cancer within the breast and its potential multifocality using standard imaging (especially when considering breast conservation).¹⁴⁷ The higher incidence of occult contralateral disease for patients with lobular carcinoma also supports the use of MRI.¹⁴⁸

Another indication for MRI is a patient who presents with an axillary metastasis but has a negative physical examination, ultrasound, and mammogram. In this situation, gadolinium-enhanced MRI has become routine. MRI is also indicated and more accurate in following the response of stage III, locally advanced breast cancer, to primary chemotherapy and provides for a more accurate assessment of the extent of residual tumor. This is critical to making a decision regarding the use of further cycles of systemic therapy and for the feasibility of breast preservation in these patients (Fig. 22-3).

There are also a number of women who require regular screening but have glandular dense breasts for which two-view film-screen mammography is not ideal. These women tend to be younger. There are also a number of women with a history of Hodgkin's disease clearly at increased risk for developing breast cancer.^{149,150} Also, young women with a strong family history or *BRCA1* or *BRCA2* gene mutations would be candidates for MRI screening. In a prospective study¹⁵¹ of screening for breast cancer in women with a family history or

genetic predisposition for developing breast cancer, MRI detected 20 cancers (including one DCIS) that were not found on mammography or by clinical exam. Eleven of the 19 invasive cancers were smaller than 10 mm, and only 1 had an associated positive axillary lymph node.

At present, however, gadolinium-enhanced MRI is used primarily in managing the difficult diagnostic problem—especially when attempting to rule out multifocality and to better define the extent of tumor. For such patients, there is increasing evidence that MRI will alter the surgical management of the primary cancer in a significant percentage of women, perhaps as many as 25% to 30%. More study is required to better define this percentage and to identify the characteristics of the patients most likely to benefit. Gadolinium-enhanced MRI is currently more accurate than mammography in defining the extent of disease as it relates to the index tumor and of finding multicentric disease not seen on standard film mammograms when used before excisional biopsy or lumpectomy. Although MRI is somewhat compromised when used in the immediate (<4 to 6 weeks) period after surgical removal of the tumor, it may be helpful in selecting patients in whom the margins of excision remain positive or close (<2 mm), providing information about location and extent of residual tumor requiring further excision.

To date, MRI has not proved to be useful in identifying positive axillary lymph nodes and directing actual node sampling. Some reports suggest that MRI may prove useful in MRI-directed breast cancer ablation procedures.^{152,153}

How do other medical conditions affect therapy decisions?

Cardiac and Pulmonary Disorders

With modern techniques for delivering radiation to the breast and, if indicated, to the regional lymph nodes, there is very little risk to the heart and the lungs. Even so, when there is a history of cardiac disease or underlying lung disease, extra

precautions are warranted, but it is unusual for such conditions to be severe enough to preclude irradiation. When this is the case, a simple complete mastectomy is performed, often using regional and local anesthesia.

The risk to the heart is associated with the treatment of left-sided breast cancer. The left ventricle may receive irradiation from the tangential field, and an increase in left descending coronary artery disease has been reported.¹⁵⁴ The left ventricle is also at risk when the internal mammary chain of lymph nodes is treated. Large prospective randomized trials looking at the role of irradiation following mastectomy and as part of breast-conserving therapy (BCT) have shown a slight increase in the number of cardiac deaths in irradiated patients with left-sided breast cancer.¹⁵⁴ This is almost exclusively in stage I disease. Once these risks became known, changes in the technique of delivering the radiation using CT-directed conformal therapy appear to be eliminating cardiac damage. Endomyocardial injury has been reported when radiation was given while patients were receiving doxorubicin.¹⁵⁵

Some lung tissue almost always receives low amounts of radiation, especially when the treatment plan includes the regional lymph nodes. Using electrons instead of photons, especially in the treatment of the supraclavicular nodes, may reduce the incidence of acute pneumonitis. Pulmonary fibrosis may occur in portions of the lung included in treatment fields because the lung is the most sensitive tissue.¹⁵⁶ This can result in some slight decline in pulmonary function but not enough to cause symptoms in a normal patient. The concern comes when there exists underlying chronic lung disease.

Rheumatologic Disorders

A history of one of the numerous rheumatologic diseases, although affecting only a relatively small number of patients with breast cancer, is not to be overlooked. Often, these diseases are associated with small vessel vasculitis or significant skin changes. The presence of such conditions obviously may complicate the use of radiation and affect the cosmetic results of BCT. Awareness of potential risks was initially noted in a report from the University of Texas M. D. Anderson Cancer Center,¹⁵⁷ where skin complications of moist desquamation, ulceration, and skin necrosis were observed in three patients.

It should be noted, however, that the number of instances of patients with connective tissue disorders reported to have had complications following breast-conserving radiation therapy is quite small.^{158,159} Many of these earlier reports used techniques not used today, and rheumatologic diseases represent a spectrum of disorders that affect the vessels and connective tissues in different ways. Thus, the knowledge that a patient has such a disease should be considered on a case-by-case basis.¹⁶⁰ Recht¹⁶¹ recommended that radiation in these patients be limited to a dose of 45 Gy given in 25 fractions using 6 MV or higher-energy photons. He emphasized that care should be taken to minimize any match-line overlap and not to combine radiation with chemotherapy.¹⁶¹

A number of rheumatologic diseases may be associated with dilated cardiomyopathy, including systemic lupus erythematosus, polyarteritis nodosa, and progressive systemic sclerosis. Heart disease is virtually never the presenting symptom in these patients, and persons with connective tissue disease may have a degree of cardiac involvement overlooked or underestimated when they present with breast cancer.

How does age affect the decision-making process?

Patient age as a factor in planning appropriate breast cancer therapy has been an area of some controversy. The question really concerns two patient groups, the very young (<35 years old) and the older group (>80 years old). In response to this question, one is tempted to state simply that age is not a factor and that patients are managed according to stage of disease, with exceptions in the very elderly based on significant comorbid disease.

This would, however, be an oversimplification, and it is important to review the issues that have been raised concerning the effect of age in the selection of therapies. Most debate has focused on patients younger than 35 years. A number of centers reported that patients younger than 35 years treated with breast conservation appeared to have a higher risk for recurrence of cancer within the treated breast than that observed for older patients.¹⁶²⁻¹⁷² Others have argued that improved patient selection, especially regarding the presence of extensive intraductal component (EIC) (Fig. 22-4), and insistence on good, histologically negative margins eliminated the observed increase in recurrence of cancer within the treated breast.¹⁷³⁻¹⁷⁷ As a result, surgeons and radiation oncologists no longer dissuade young patients from breast conservation but pay careful attention to the histology and uniformly recommend re-excision of the biopsy site.¹⁶¹ The re-excision is done to establish optimal margins and to be sure all EIC, if present, has been excised. Further, even if there is a slight increased risk for local recurrence, it is not at all clear that this would translate into a decrease in overall survival.¹⁶¹

At the other end of the age spectrum (patients in their eighth and ninth decades of life), there has been some sentiment that these elderly patients would not tolerate breast radiation well or that it was not necessary to achieve disease control. Clearly, there is no evidence that such patients cannot tolerate good radiotherapy.^{162,178,179} What is not known is whether all such patients require radiotherapy for control. At this state of our knowledge, it is certainly best to include

Figure 22-4 Patterns of associated intraductal component, including extensive intraductal component. *Wavy lines* indicate the invasive tumor border, and *clusters of dots* show intraductal cancer.

radiation as part of the treatment. When early-stage disease is found in a patient in this advanced age group, a generous wide excision under local anesthesia with good follow-up is probably excellent treatment. Also, good physician–patient communication and solicitation of the patient’s treatment preferences are critical to building a successful partnership with elderly patients. Spending the extra effort to do so will improve the quality of the treatment decisions by the elderly.¹⁸⁰

Are there other medical conditions that affect treatment decisions?

Rarely, patients provide a history of prior high-dose irradiation for other malignancies—most commonly Hodgkin’s lymphoma. It is best to recommend mastectomy for such patients. Low-dose irradiation, given in the past as treatment for infant thymic enlargement, is not considered a contraindication for breast conservation.

Some have argued that a strong family history is a risk factor for local failure if breast conservation is used.¹⁶¹ Others have failed to show this, and in fact there are not enough data collected to provide a confident answer. At this time, the appropriate decision would rest significantly on the strength of the family history coupled with genetic testing, evidence regarding the overall risk for developing contralateral breast cancer, and of course, the patient’s desire. If these factors, taken together, add up to a physician–patient decision to consider prophylactic mastectomy, then perhaps an optimal cosmetic result and overall risk reduction can be best achieved by bilateral mastectomies and transverse rectus abdominis myocutaneous (TRAM) reconstruction.

What about breast cancer occurring in the pregnant patient?

Since 1975, there has been a 60% increase of first full-term pregnancies in women older than 30 years of age.¹⁸¹ As a result, there is an increase in the number of breast cancers diagnosed during pregnancy (about 1 to 3 per 10,000 pregnancies).¹⁸² Mammograms are not routinely used as part of the initial evaluation in pregnant women presenting with breast symptoms, both to avoid radiation risk to the fetus during the first and second trimester and because mammography is less reliable as a diagnostic tool in the dense gestational breast. Ultrasound may be useful in differentiating cystic lesions from solid tumors. In addition, MRI is useful for evaluating the breast during pregnancy and can also be used to look for evidence of metastatic disease, if indicated.¹⁸³

If the diagnosis is made early in pregnancy, a difficult decision must be made regarding a therapeutic abortion. Obviously, this would greatly simplify treatment decisions. However, recent evidence indicates that especially in early nondisseminated disease, there is no benefit to early abortion, survival being the same with or without abortion.¹⁸² Breast cancer cells do not cross the placenta, as occurs with some cancers such as melanoma, lymphosarcoma, or leukemia, and therefore are not a direct threat to the fetus.¹⁸²

Modified radical mastectomy is usually the treatment of choice for such patients. If the patient is in the third trimester,

a decision can be made to seek early induced delivery and to hold the radiation for breast conservation until after delivery. In almost all cases, chemotherapy is not used during pregnancy but delayed until after delivery. The effect of chemotherapy on the fetus is directly related to gestational age and drug dosage. Certainly, cytotoxic therapy has been used after the first trimester without apparent damage to the fetus. Even so, the risk for complications such as sepsis and hemorrhage during unplanned delivery make the risk of chemotherapy during even the last trimester too great to justify its use in an adjuvant setting.^{183,184}

What is meant by the term multimodality therapy?

When a patient is newly diagnosed with stage I or II breast cancer, she and her physician team are faced with a number of treatment decisions. The choices to be made depend heavily on the input of the radiologist evaluating the imaging of the tumor within the breast, the pathologist evaluating the tumor grade and the adequacy of the surgical margins, and the design of an appropriate treatment plan by the surgeon, radiation oncologist, and medical oncologist. When mastectomy is part of the treatment, a plastic surgeon experienced in breast reconstruction is also important to the multidisciplinary approach. It is this team of physicians that is best prepared to determine appropriate local therapy, management of regional nodes, selection of adjuvant therapy, and most important, the best sequencing of available treatment options.

The many decisions that need to be carefully considered and, to a great extent, the continued complexity of these decisions, in light of rapidly advancing new knowledge derived from laboratory investigations of the biology of cancer and from the results of clinical trials research, are the basis for a multidisciplinary team approach to both the diagnosis and the treatment of breast cancer. All members of the team contribute valuable knowledge and critical thinking to the sequencing of the various therapeutic options. This medical team is joined by psychiatrists and psychologists expert in working with cancer patients and their families and by social workers, genetic counselors, and support groups to help the patient through the difficult time of diagnosis and therapy. Providing an expert team is the best way to ensure having a patient prepared to continue a productive high-quality life at the completion of the treatment phase.

Even though the greater use of screening mammography is resulting in the detection of smaller and smaller cancers, the risk for developing a distant recurrence that ultimately leads to death has not been eliminated. As a result, there is an ongoing requirement to include systemic therapy in the management of the primary tumor. Strategies of clinical research that examine drug combinations, doses of drug, new agents, and endocrine therapies are now being applied to the treatment of newly diagnosed, early-stage, node-negative breast cancer as well as locally advanced disease. How these systemic therapies should be integrated with local therapies (surgery and radiation), the intensity of the systemic therapy to be used, and how such systemic treatment may alter local therapy are important questions for future study. Having a multidisciplinary team approach greatly facilitates the selec-

tion of clinical trials research to be made available to the group's patients and encourages physician and patient participation in these trials. Thus, the standard of care is raised to its highest level by the combined input of physicians with different areas of clinical expertise.

In the paragraphs that follow, the surgical, radiotherapeutic, and chemotherapeutic-hormonal options for treatment are examined for their specific indications and their sequencing in the overall plan.

What are the indications for breast conservation?

The 1990 National Cancer Institute Consensus Conference on the treatment of early-stage breast cancer stated that "breast conservation treatment is an appropriate method of primary therapy for most women with stage I and II breast cancer and is preferable because it provides survival rates equivalent to those of total mastectomy and axillary dissection while preserving the breast."¹⁸⁵ Given that BCT is an equivalent therapy when compared with mastectomy, the factors that become important to the patient in making this choice are the risk for local recurrence after BCT (vs. mastectomy) and the ability to achieve the desired cosmetic result. Thus, this question is not really "what are the indications for BCT," but instead "what are the factors, if any, that might be considered contraindications."

For example, the first step is a careful evaluation of preoperative breast images. These may need to be repeated before radiation following lumpectomy (tumorectomy) to ensure clearance of microcalcifications. Film-screen mammography must include magnification views for microcalcifications. These magnification imaging studies define the extent of the tumor and determine the status of the remainder of the involved breast as well as the contralateral breast.

In recent years, the additional images obtained by MRI have also been useful in defining the extent of tumor involvement. As noted earlier, in cases of malignancy, it is important that microcalcifications be surgically cleared from the region of the tumor to eliminate the possibility of multicentricity. The presence of extensive microcalcifications is often an indication of the presence of an EIC. The goals are to ensure, by imaging, that (1) the contralateral breast is clear of any mammographically suspicious areas that would require biopsy; (2) the involved breast has been cleared of all suspicious areas; and (3) if microcalcifications were a feature of the primary tumor, magnification views have documented their extent, and post-surgical films have confirmed that they were cleared.

The second step is a careful pathologic evaluation of the breast tissue removed. There is no substitute for a direct review of the gross specimen and histology by the surgeon sitting in consultation with the pathologist. The surgeon must be responsible for correct specimen orientation so that all sides can be inked using different colors. Gross tumor measurements are performed by the pathologist only after the gross intact specimen has been oriented and appropriately inked. Although inking is the preferred method for assessing margins, there are some problems with this technique that the surgeon should be aware of. For example, during the excision of the specimen and subsequent initial handling, some of the fatty tissue may be rubbed off the exterior surface. In addition,

the ink may seep into crevices in the margin surface, causing some microscopic confusion regarding the actual margin depth.

This discussion regarding specimen orientation and inking of margins underscores the importance of obtaining adequate tumor-free margins in determining the risk for local recurrence.¹⁸⁶ The best data and most frequently quoted studies are those of the National Surgical Adjuvant Breast and Bowel Project (NSABP) and the Joint Center for Radiation Therapy (JCRT).^{178,187,188} In the JCRT study of 340 patients treated with 60 Gy, patients with EIC-negative tumors had a 5-year local recurrence rate of 1% if margins were negative and 2% if margins were negative but the carcinoma was within 1 mm of the ink but not at the ink.¹⁸⁸ If there was focal margin involvement (i.e., three or fewer low-power fields were positive), the risk for recurrence increased to 9%. When margins were more than focally involved, the risk was 19%. For patients with EIC-positive tumors, the risk for local recurrence in the JCRT patients with negative margins was 8%. This risk increased to 27% when EIC-positive tumors demonstrated histologically positive margins.^{178,188}

In practice, it is best to obtain generous negative margins, especially when there is a significant EIC. Although the definition of a negative margin may differ among institutions, most breast cancer surgeons strive to achieve a margin of a minimum of 1 to 3 mm of normal tissue. In other institutions, the standard is a margin of 1 cm or greater.¹⁸⁹ When concerned about adequacy of margins, it is in the patient's best interest to re-excite the original biopsy site.

As suggested, the presence of EIC must be carefully considered. A re-excision of the tumor bed should be performed in all EIC-positive tumors to ensure the absence of multicentricity (skip areas of DCIS scattered among normal breast tissue in the areas around the primary tumor). If the re-excision specimen exhibits multiple areas of residual cancer, mastectomy is the preferred treatment (Table 22-3).

Table 22-3 Management of Patients with an Extensive Intraductal Component

Definition	Ductal carcinoma in situ (DCIS) inside <i>and</i> outside the index lesion <i>or</i> DCIS with minimal amounts of invasion.
Workup	Pay careful attention to the mammogram. EIC patients frequently have microcalcifications. Make sure all suspicious-looking microcalcifications are excised.
Primary excision	Should be wide; negative pathologic margins should be the goal.
Re-excision	Use liberally, especially if margin is positive or if residual microcalcifications are present.
Treatment	If margins are negative on first excision or re-excision shows minimal tumor with negative margins, treat with lumpectomy plus radiation. If new margins are positive, especially with widespread DCIS in the re-excision specimen, treat with mastectomy.

Modified from Abeloff MD, Lichter AS, Niederhuber JE, et al. Breast. In Abeloff MD, Armifage JO, Lichter AS, et al. (eds). *Clinical Oncology*. New York, Churchill Livingstone, 1995, p 1617.

What seems to be clear from all reports is the conclusion that the greater the extent of resection, the lower the risk for local failure. Thus, even when EIC is present, patients undergoing quadrantectomy have an acceptable failure rate, and those with EIC-negative tumors drop below a 1% risk.¹⁹⁰ The surgeon and the patient are faced with balancing the extent of breast resection with a desire for a favorable cosmetic outcome. The greater the resection, as in quadrantectomy, the worse the cosmetic result and the less the indication for breast preservation. The cosmetic result of a reconstructed breast may actually be preferred.

Smitt and colleagues¹⁸⁶ at Stanford University evaluated the impact of surgical margins on long-term local control. They found that truly negative margins (greater than 2 mm) resulted in 90% local control at 10 years, in contrast to 82% for patients with positive and close margins. Re-excision to a negative margin was important, providing a 97% 10-year local control rate. When tumors were EIC positive, the re-excision specimen demonstrated residual cancer 82% of the time, compared with only 31% for EIC-negative tumors.

In another report examining re-excision for EIC-positive tumors, residual DCIS was noted a minimum of 2 cm from the primary in at least 30% of EIC-positive tumor re-excision specimens. This finding confirmed that a wide excision such as segmentectomy or quadrantectomy is necessary to provide the lowest risk for local failure.¹⁹¹ Younger patients (<40 years old) and those with comedo-type DCIS histology are reported to demonstrate a greater distance of spread within the adjacent ductal systems, perhaps accounting for the increased difficulty of truly clearing these lesions and the greater risk for local failure observed in EIC-positive tumors for young women and comedo histology.¹⁹² Although the presence of EIC is not considered in itself a contraindication to breast preservation, it clearly demands an exacting approach to ensuring clear margins through a resection of greater volume. The importance of re-excision cannot be overemphasized.

Perez recently reported the experience of treating T1 and T2 breast cancer by breast preservation and radiation at Washington University School of Medicine in St. Louis.¹⁹³ He analyzed the records of 1347 patients treated with breast preservation between 1970 and 1997 at their institution. The 10-year incidence of local failure was 7% for T1 tumors and 11% for T2 tumors. It is important to note that Dr. Perez also found that patients younger than 40 years who had EIC had a greater risk for local relapse (17%) compared with a similar EIC-positive group of postmenopausal women, who had a relapse rate of 10%.

Although most invasive breast cancers are adenocarcinomas arising from the terminal ducts (about 80%), there are several less common histologic findings that have a better overall prognosis. The better prognosis of these tumors (mucinous, medullary, papillary, tubular, and adenoid cystic) is best seen in node-negative patients.¹⁹⁴ Other pathologic features, such as vascular-lymphatic invasion, inflammatory response, and degree of intratumor necrosis, have been less helpful in predicting risk. Eventually, genomic and proteomic profiling will provide more specific prognostic information.

The final determinant in selecting a woman for BCT has to do with the patient's desires and expectations. It requires a certain commitment of a surgeon's time to listen carefully to what the patient is saying and to ask appropriate nonleading questions that give an insight into the patient's wishes

regarding cosmetic outcome. The size of the required breast resection compared with the breast size and the expected changes in the breast secondary to the radiation must be carefully evaluated to provide reasonable expectations of what the final cosmetic outcome might be.

From a technical standpoint, placement of the incision is important to the cosmetic outcome. It is best placed in a circumareolar position or in a line that runs parallel to the margin of the areola. It is essential to obtain optimal hemostasis of the cavity and to avoid closure of the deep tissues, letting the cavity fill with a small seroma that will gradually be reabsorbed during the healing process. Drains in the breast should be avoided. The placement of small titanium clips in the walls of the cavity will assist the localization of the radiation boost. Every effort is made to keep the site of the lumpectomy entirely separate from the site of the axillary surgery.

What are the contraindications to breast-conserving therapy?

Perhaps an easier way to approach the question of selecting patients for BCT is to review the absolute and relative contraindications or the reasons for choosing mastectomy. The Joint Committee of the American College of Surgeons, the American College of Radiology, the College of American Pathologists, and the Society of Surgical Oncology attempted to provide a consensus of standards, which was published in 1992.¹⁹⁵ Absolute contraindications to BCT are well established (Table 22–4). They include (1) prior therapeutic radiation to the involved breast, (2) a patient in the first or second trimester of pregnancy, (3) the presence of two or more distinct tumors present in different quadrants of the breast, and (4) the presence of diffuse, suspicious microcalcifications involving more than one quadrant of the breast.

Relative contraindications are, by their nature, somewhat controversial. They include (1) a large tumor volume-to-breast volume ratio precluding an acceptable cosmetic outcome; (2) a very large breast, which may present unacceptable difficulty in delivering a uniform radiation dose to the breast following tumorectomy; and (3) a history of collagen-vascular disease and primary lung disease.

The intensity of the skin reaction and fibrosis in patients with a collagen-vascular disorder such as scleroderma, cutaneous lupus, and active collagen disease may be related to

Table 22–4 Contraindications to Breast-Conserving Therapy

Absolute Contraindications

- Prior therapeutic radiation to the involved breast
- When the patient is in the first or second trimester of pregnancy
- The presence of 2 or more distinct tumors involving different quadrants of the breast
- The presence of diffuse, suspicious microcalcifications involving more than 1 quadrant of the breast

Relative Contraindications

- Large tumor volume-to-breast volume ratio precluding an acceptable cosmetic outcome
- Very large breast, which may present unacceptable difficulty in delivering a uniform radiation dose to the breast
- History of collagen-vascular disease and primary lung disease

how much their skin and subcutaneous tissues are clinically involved. This must be carefully evaluated before making a decision regarding radiation therapy. Although prior radiation to the chest wall is generally a contraindication to BCT, it is important to have the radiation oncologist assess the previous port sites, the dosage received, and the time lapse from prior treatment before arbitrarily excluding the patient. The issue of the large breast is not often a deterrent if methods are devised to immobilize the breast to ensure a homogeneous radiation dose. The problem with the very large, essentially fatty breast is not the ability to deliver the appropriate radiotherapy but the risk of the breast's developing marked fibrosis and retraction following radiotherapy. These patients often are better served by mastectomy and reconstruction with a TRAM flap accompanied by a significant reduction mastopexy of the contralateral breast.

In the past, patients with tumors located beneath the nipple–areolar complex were not considered good candidates for BCT. The concern was that such patients had a more extensive spread of tumor along the various branching ducts that would not be adequately excised by lumpectomy.¹⁹⁶ The extent to which such lesions should be resected (i.e., whether the nipple–areolar complex is excised) remains a contentious subject. Recent data suggest the nipple-areola may be left in place as long as an acceptable negative tumor margin is achieved. Even if one includes the nipple–areolar complex as part of the resection, the cosmetic result is actually quite acceptable, leaving a good breast mound with normal skin sensation and texture. There is no evidence that the incidence of local recurrence is higher when central lesions are treated by the same criteria used elsewhere in the breast.^{197–199}

What is the current status of sentinel lymph node mapping and axillary node dissection?

The size of the primary tumor and the status of the axillary lymph nodes, although independent predictors, are additive and still remain the strongest prognostic factors in determining survival from breast cancer. Of these two staging features, physicians have, by tradition, placed a greater weight on the presence of tumor cells in axillary nodes as the more accurate predictor of systemic occult metastases. Thus, there are three important reasons to consider axillary dissection. The first is to determine whether the axillary nodes are positive or negative and to what extent they are involved. This knowledge provides essential information for the process of making sound therapeutic decisions. The second reason, although controversial, concerns the fact that positive nodes left untreated may later cause the patient to have significant local problems such as pain, impaired motion, ulceration with infection, and limb edema. The third reason is also controversial and concerns the risk that nodal disease may, in itself, be the source of distant spread. Although these three concepts have provided the rationale for node dissection, they must be considered, to some extent, the historical basis for this procedure.

To my best knowledge, Sir Charles Moore was the first, in 1867, to record a dissection of the axillary content when removing a cancerous breast.²⁰⁰ Eventually, this concept led, in the United States, to the widely accepted Halsted radical mastectomy, which persisted as the primary treatment of breast cancer until appropriately tested by the surgeons of

the NSABP in their B-04 trial.^{201,202} This trial, which began in 1971, clearly demonstrated that breast cancer patients with clinically determined stage II disease had equal long-term outcome whether treated by radical mastectomy or by total mastectomy (without axillary node dissection) plus radiation to nodal areas.

For clinically determined stage I patients, the survival results were identical whether the patient had a radical mastectomy, total mastectomy plus nodal radiation, or total mastectomy with delayed nodal dissection when and if nodal disease developed. In the last group, only 20% of patients with clinical stage I disease went on to develop involved nodes despite the 40% rate of detecting positive nodes in the radical mastectomy group. This extremely important trial began to place in question the role of axillary dissection and most certainly began to eliminate arguments for even more radical surgery such as dissection of the internal mammary nodes and the supraclavicular nodes. The B-04 trial was followed by B-06, designed to evaluate the efficacy of breast-preserving surgery.²⁰³ Like B-04, long-term follow-up of patients enrolled in B-06 has continued to add to our understanding of the role of axillary dissection.

Two factors have had a significant impact on the evolution of the approach to the axillary nodes. The first event was the introduction some 30 years ago of the concept of adjuvant chemotherapy.^{204,205} The use of either chemotherapy or hormonal therapy has been shown to provide statistically significant benefits to most women with breast cancer. The decision to offer adjuvant therapy, as indicated earlier, initially was primarily based on nodal status. This fact accounts to a great extent for the ongoing practice of including axillary nodal dissection. What remains unclear is the impact of adjuvant therapy on occult nodal disease.

The second significant change has been the impact of screening and routine mammography on the stage of detected disease. As a result, today it is estimated that 80% of newly detected breast cancers each year represent early-stage disease.¹⁸⁵ Thus, when we answer the question implied in the title of this chapter, that is, “What is meant by the term *multimodality therapy*?” we do so today in the context of a very different set of parameters, which include more patients with noninvasive disease, smaller invasive cancers, more favorable histologic findings, and the increasing frequency of finding only microscopic minimal involvement of one or two axillary nodes.

Nevertheless, we are still left with a desire to know whether this extremely important prognostic indicator is positive or negative. One factor in the equation has been well documented over the years and demonstrated again in recent studies. This factor is the knowledge that we are not very successful at clinically assessing the axilla. In an analysis of 377 breast cancers of stage T1 to T4 tumors undergoing axillary dissection, 44% of those judged to have clinically negative axilla were actually pathologically positive, and 34% judged preoperatively as clinically positive proved at pathologic review to be negative.²⁰⁶ In this study, the authors confirmed two other commonly held principles: (1) the rate of detecting involved nodes correlates with the risk for finding axillary metastases, and (2) there is only a 2% incidence of skipped metastases to level III nodes when levels I and II are negative. This latter finding supports the perception that resecting level I and II lymph nodes provides adequate staging.

Over the years, surgeons have noted that patients with palpable breast cancers were more likely to have positive axillary nodes. Silverstein and his colleagues²⁰⁷ found evidence to support this axiom when they reviewed their practice experience. They compared the predictive value of using T stage in combination with the physical findings of either a palpable or nonpalpable tumor compared with using only the T stage to predict axillary stage. Their conclusions were based on 1554 axillary node dissections in which 551 (35.5%) were node positive. They found that even in early T-stage cancers (T1b, T1c, and T2), if the lesion could be palpated on breast examination, there was a significantly greater risk ($P < .002$) of finding involved axillary nodes than when the tumor was nonpalpable for the same T stage.

It is important to remember that multiple studies have reported axillary node involvement in 12% to 37% of patients whose tumors were 1 cm or smaller.²⁰⁸ These numbers concerning the risk for axillary metastasis, however, may overstate the problem because of the dramatic downward slope of the maximum tumor diameter today. Cady,²⁰⁹ in a review of cases at the New England Deaconess Hospital from 1989 to 1993, found 29% of all invasive cancers to be only T1a or T1b (1 cm or smaller). If this trend continues, the median diameter will be less than 1 cm within this decade. This clearly requires changes in the standard approach to surgical therapy.

Certainly there is no argument with the fact that surgical clearing of the axillary nodes provides excellent local control of the disease. The issues behind the controversy of providing such treatment for all patients are the increasing numbers of patients presenting with early-stage, nonpalpable cancers and the decreasing use of nodal status in deciding whether adjuvant therapy is to be used.²¹⁰ Couple these facts with the associated morbidity of axillary dissection arm edema, paresthesias, loss of shoulder mobility, and pain and the possibility that adjuvant therapy in itself may be adequate therapy for micrometastatic nodal disease, and one has the basis for the dilemma facing surgeon and patient. Is there a way to select patients who really need axillary staging?

Sentinel Lymph Node Mapping

The answer has come in a somewhat unexpected way—not through discovery of a prognostic marker^{211–215} but through the development of a new surgical technique termed *sentinel lymph node (SLN) mapping*. SLN mapping has taken on the role of being the best current method for selecting clinical stage I patients for axillary dissection. The concept of SLN mapping dates back to work by Cabanas in 1977 describing the first draining lymph node in squamous cell carcinoma of the penis.²¹⁶ Morton and colleagues²¹⁷ applied this concept to melanoma staging, and in 1993, Krag²¹⁸ reported identification of the SLN in the axilla of breast cancer patients using radioisotope localization. This was almost simultaneously followed by a report by Giuliano and colleagues using the blue dye technique established by his colleague Morton for melanoma SLN mapping.^{219,220} Giuliano and coworkers²²¹ were able to find a sentinel node in 114 of 174 lymphadenectomies and demonstrated that the sentinel node accurately predicted the status of the axillary nodes in 96% of the dissections.

This technique involved the injection of 3 to 5 mL of 1% isosulfan blue vital dye into the breast tumor and surrounding breast tissue or into the wall of the previous biopsy site. A

small incision was placed in the low axilla, and the lymphatic channels stained by the blue dye were carefully identified and followed to the blue-stained sentinel node. In the hands of Giuliano and associates, a careful analysis of the sentinel node was more accurate in predicting a positive axilla than a standard level I and II dissection with routine histopathology of the identified nodes. It is important to note that in their investigation, T1 tumors had a somewhat higher-than-expected incidence of positive nodes, 20%. Other investigators have used ^{99m}Tc-labeled antimony sulfur colloid injected into the breast lumpectomy (biopsy) site to identify lymphatic drainage and a sentinel node.²²²

During the years since these initial reports, many technical advances have simplified the SLN mapping procedure and have resulted in even greater accuracy of SLN identification (now generally accepted to be >95%).²²³ For example, anatomic studies demonstrated that lymphatic drainage in the breast occurs in a nonrandom fashion to the axillary SLN.²²⁴ In addition, many studies showed that injecting the tracer into the dermis or subdermal skin and in a subareolar location was equal to or perhaps slightly better than peritumoral injection. Compared with the breast parenchyma, the skin around the areola has a much denser lymphatic network. Hand-held gamma probes have been specifically designed for SLN identification. They have a smaller probe head of 14 mm and more internal shielding to improve accuracy.

SLN mapping is a minimally invasive procedure and as such has rapidly gained popularity and acceptance by both surgeons and patients. In multiple nonrandomized studies, SLN mapping accuracy for predicting the status of the axillary nodes has been quite high, with an apparent false-negative rate of 2% to 3%. Thus, although not as yet confirmed by a randomized trial, SLN mapping has been widely adopted, and patients with a negative SLN are not subjected to an axillary dissection. It remains unclear whether patients with an SLN positive for microscopic disease need a completion axillary dissection. Several studies suggest that micrometastases detected only by immunohistochemistry in the SLN of patients with T1 tumors have a very low incidence of involvement of additional axillary nodes.

The important questions to validate SLN mapping are being addressed by two large phase III trials. The NSABP B-32 trial opened in 1999 randomizes clinically node-negative patients with T1-3 breast cancers to SLN mapping followed by axillary dissection or SLN biopsy alone. In the SLN biopsy alone group, if the SLN is positive, the patients go on to axillary dissection. All negative SLN patients are further assayed using immunohistochemistry (www.nsabp.pitt.edu). The second major trial is being conducted by the American College of Surgeons Oncology Group (ACOSOG) as protocols Z0010 and Z0011. Z0010 is attempting to determine whether SLN biopsy in T1-2, N0, M0 patients, including immunohistochemical assessment, is equal to or better than bone marrow aspiration for determining prognosis. The B-32 trial and Z0010 have reached accrual and await maturity. Z0011 randomizes SLN-positive patients (excluding those positive only by immunohistochemistry) to completion axillary dissection or to no immediate axillary dissection or axillary radiation (www.acosog.org).

Some surgeons recommend SLN mapping for patients with high-grade or extensive DCIS, where it is possible that occult microinvasion exists or has been documented but no clinical

data exist to support SLN mapping in these cases. When, however, the DCIS is so extensive as to require mastectomy, SLN mapping can be used to avoid unnecessary axillary dissection.

There are several contraindications at present for doing SLN mapping and proceeding directly to axillary dissection. These include the clinically suspicious axilla and tumors located in the tail of the breast (tail of Spence). In addition, if the surgeon fails to identify with confidence an SLN, axillary dissection is required. Some debate continues about whether SLN mapping should be performed before beginning patients on neoadjuvant or induction chemotherapy, but the results of the NSABP B-27 trial indicate that SLN biopsy is a reliable staging procedure following chemotherapy.²²⁵ There is a significant learning phase for surgeons, and initially an axillary dissection should be performed with the SLN mapping until confidence is established in the ability to identify the SLN accurately. It is not uncommon to find two and sometimes three nodes that qualify as the SLN, and interestingly, there is evidence that those with multiple negative SLNs have a better prognosis.²²⁶

Technical Aspects of Level I and II Node Dissection

The extent of axillary node dissection needed to accurately stage and treat the breast cancer patient has also been the subject of debate. From past experience, it is clear that when levels I and II are negative, it is rare that there will be skip metastasis to level III, the highest axillary nodes. The best estimate of the risk for such an occurrence is generally cited to be about 2%.²⁰⁶ In recent years, this has led most surgeons to do at least a level I dissection and to include level II when the tumor size predicted a greater risk. By limiting the node dissection to only levels I and II (i.e., dissecting only to the medial border of the pectoralis minor muscle), the risk for associated long-term morbidity is virtually eliminated. A level I and II node dissection is associated with the lowest risk for subsequent axillary recurrence. Care is taken to preserve the lymphatic channels along the anterior surface of the axillary vein and overlying the brachial plexus. The lateral and medial pectoral nerves are avoided, as are the long thoracic nerve and the thoracodorsal nerve. Preserving the upper branches of the costobrachial sensory nerve avoids the dense and bothersome numbness along the upper inner arm.

Because screening has resulted in discovery of smaller and smaller tumors, the number of women being subjected to unnecessary node dissection is a concern. When no nodes were removed from the axilla, the Danish Breast Cancer Group recorded a 19% recurrence in the axilla in 5 years.²¹⁵ This contrasted with a 5-year risk of 5% when more than five negative nodes were resected.²¹⁵

From this discussion, it seems safe to conclude that, based on present knowledge, axillary dissection of at least level I and II nodes is indicated for patients undergoing mastectomy (this also ensures removing all of the tail of the breast), patients for whom therapy would be changed by identifying whether the axilla was positive or negative and to what extent positive (i.e., number of nodes positive), and patients involved in clinical trials.

The essential question, which requires further testing, is whether the presence of micrometastases in axillary nodes requires primary resection in the setting of multimodality

therapy.²²⁷ It is certainly possible that careful sentinel node analysis may provide the necessary prognostic information, but current trial results must be awaited. The approach to sentinel node evaluation may be further aided by use of reverse transcriptase polymerase chain reaction (RT-PCR) to detect the presence of tumor cell DNA in otherwise histologically negative sentinel nodes.²²⁸ Proof of the efficacy of sentinel node staging should eliminate the need to evaluate the entire axilla and permit managing the axilla expectantly following adjuvant chemotherapy. Eventually, T1 tumors may all be managed expectantly for development of axillary metastases without even the sentinel node testing.

Which mastectomy patients benefit from radiation therapy?

Historically, postmastectomy radiation therapy was common practice in the management of breast cancer. The more advanced stage of disease at diagnosis and the high rate of development of local skin flap and chest wall recurrent disease accounted for this approach. The first trial to test this question was the Manchester, England, study of immediate compared with delayed postmastectomy chest wall radiation. This trial began in 1948, and in the intervening years, a number of randomized prospective trials were completed.^{229–236} Although none of these early trials found a clear survival benefit, we now know that there is a significant decrease in chest wall relapse, approaching 5%, when postoperative irradiation is used.^{237,238}

With the passage of time, an interesting conclusion from the analysis of the many adjuvant chemotherapy trials began to emerge. This conclusion indicated that chemotherapy failed to lower the risk for chest wall recurrence.^{239–241} This was even true when high-dose polychemotherapy was used.²⁴² These perhaps surprising results have led to a re-evaluation of the indications for postmastectomy chest wall irradiation (Table 22–5). For example, the Danish Cooperative Breast Group published a report that in premenopausal women treated with mastectomy and CMF (cyclophosphamide, methotrexate, and 5-fluorouracil) adjuvant chemotherapy, the addition of chest wall irradiation not only improved disease-free survival but also improved overall survival when node-positive, premenopausal patients were analyzed.^{243,244} These observations, plus the introduction of aggressive polydrug adjuvant chemotherapy for node-positive patients, led to the use of postmastectomy chest wall

Table 22–5 Indications for Postmastectomy Chest Wall Irradiation

Indicated
<ul style="list-style-type: none"> • Positive or close (1–2 mm) margins following mastectomy • T3 tumors (especially stages T3, N1) • All T4 tumors • High-dose chemotherapy for cure in patients with extensive nodal involvement • Extracapsular nodal disease
Considered
<ul style="list-style-type: none"> • ≥4 positive nodes, especially premenopausal

irradiation only in selected patients with stage II tumors having evidence or risk of internal mammary node involvement and/or local extension close to or into the chest wall.

Often, the question is raised concerning extending the irradiation to the axilla in breast conservation and in mastectomy patients. In node-positive patients, the incidence of recurrence in the axilla is less than 1% when a careful axillary dissection has been performed. Currently, radiation to the axilla is advised when there is extracapsular extension of the tumor in the involved nodes or when there are four or more involved nodes.

Who should receive adjuvant chemotherapy?

Even though the first randomized prospective clinical trials designed to determine the benefits of adjuvant chemotherapy began more than 30 years ago, questions persist regarding the choice of therapy, the intensity, and the duration of therapy. In addition, there has been great concern that every effort be made to identify risk factors that would better select patients for such treatment. The debate has focused on a real concern that many women were receiving potentially dangerous therapy unnecessarily. To address these issues, the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) undertook a meta-analysis of all randomized trials conducted before 1985.²¹⁰ This analysis included 133 randomized prospective trials involving some 75,000 women.²¹⁰ This group convened again in 1995 and 2000 to update their analysis.^{245–247} As a result, the EBCTCG overview analyses provide excellent support for several sound conclusions regarding the use of adjuvant therapy. These are as follows:

1. There is a significant survival benefit for women receiving polychemotherapy.
2. The survival advantages have been demonstrated in all age groups, but the magnitude of the benefit appears to be less in older women.
3. Polychemotherapy has been shown to be of greater benefit than single-agent chemotherapy.
4. Administering adjuvant chemotherapy for more than 6 months has not generally been of great benefit.
5. Adjuvant tamoxifen is of some benefit in all patient groups but appears to have a greater benefit in women older than 50 years.
6. Several years of tamoxifen treatment provides greater benefit than a single year.
7. The analysis appears to support the conclusion that combined chemoendocrine therapy is superior to either chemotherapy or endocrine therapy alone (the benefit appears greater in older women than younger).
8. Perhaps the most important and somewhat unexpected result of the analysis was evidence that gains in survival from adjuvant treatment were larger at 15 years than at 5 years.

Translating results of the EBCTCG meta-analysis into terms that are understandable for the patient is never easy. A woman with a T1 or T2 tumor that is node negative has a 10% to 20% risk for dying of breast cancer. The smaller the tumor and the more favorable the histology, the closer the risk is to 10% or even less (5%). Given the standard adjuvant treatment, she can expect an approximate benefit of 4% (a decrease of four

deaths for 100 women treated). This translates to a persistent annual reduction in the odds of death of 30%. For node-positive patients, the benefit is 12%, with a reduction in annual risk for death of 15%. This is summarized in Table 22–6.

The benefit of adjuvant chemotherapy is certainly real, and because of the very large number of women affected by cancer worldwide, it is extremely valuable. The benefit, however, is only a modest change, and women at significant risk for developing recurrent disease continue to do so whether or not they have been treated with polychemotherapy with or without tamoxifen. Of great significance is the observation that the long-term (15-year) follow-up of these trials by the EBCTCG never shows a plateau in the curve, suggesting instead a prolongation in time to relapse rather than a true elimination of occult disease.²⁴⁷ As a result, current interest has focused on dose intensity, scheduling of drug administration, sequencing of therapies (primary chemotherapy), and, of course, new agents.

Addressing the issue of dose intensity, Cancer and Leukemia Group B (CALGB) members reported a clinical breast trial comparing three dose levels of CAF—cyclophosphamide (Cytoxan), doxorubicin (Adriamycin), and 5-fluorouracil—for node-positive patients.²⁴⁸ The two higher-dose arms had significantly better relapse-free and overall survival results than the low-dose arm. The highest-dose arm, however, was essentially what is commonly used in standard practice. This is consistent with the EBCTCG analyses^{244,246} that found anthracycline-containing regimens to be better than standard CMF.

The Southwest Oncology Group (SWOG) reported in 2001 the results of comparing tamoxifen alone to CAF plus tamoxifen (CAFT) therapy in postmenopausal, node-positive, receptor-positive patients. The 5-year disease-free survival rate was 76% for CAFT and 67% for tamoxifen alone.²⁴⁹ The NSABP B-20 trial showed that both premenopausal and postmenopausal women who were node negative but had hormonally dependent tumors benefited from the addition of

Table 22–6 Improvement in 10-Year Survival from Treatment of 100 Women with Stage II Breast Cancer

Treatment	Proportional Reduction in Annual Mortality Percentage (SD)	Absolute Reduction in 10-Year Mortality/100 Women Treated (SD)
Age <50 yr		
Polychemotherapy	25 (5)	10 (3)
Ovarian ablation	28 (9)	11 (4)

Age >50 yr		
Polychemotherapy	12 (4)	5 (2)
Tamoxifen	20 (2)	8 (1)
Polychemotherapy + tamoxifen	30 (5)	12 (2)

Adapted from Early Breast Cancer Trialists' Collaborative Group. Systemic treatment of early breast cancer by hormonal, cytotoxic or immune therapy: 133 randomised trials involving 31,000 recurrences and 24,000 deaths among 75,000 women. *Lancet* 1992;339:71–85. © by The Lancet Ltd.

tamoxifen to their adjuvant chemotherapy.²⁵⁰ The results of these trials suggest that receptor-negative tumors may be more responsive to chemotherapy.

Of the new drugs introduced in recent years, certainly the taxanes have been the most interesting.^{251–254} These drugs act to disrupt microtubules. Other drugs include those that interfere with epidermal growth factor receptors on cancer cells, known as the *epidermal growth factor receptor inhibitors* (gefitinib, erlotinib, lapatinib), or agents that interfere with the capacity of cancer cells to invade (matrix metalloproteinase inhibitors), and inhibitors of angiogenesis. In a study of paclitaxel in an adjuvant setting, the CALGB conducted a trial that randomized women with node-positive breast cancer to four cycles of CA (Cytoxan [cyclophosphamide] and Adriamycin [doxorubicin]) given every 3 weeks with or without four additional cycles of paclitaxel given every 3 weeks.²⁵⁵ The sequential treatment using paclitaxel resulted in an improved 5-year disease-free survival (65% without paclitaxel vs. 70% with) and an improved overall survival (77% without paclitaxel vs. 80% with). Of interest is the observation that the benefit of the additional paclitaxel was confined to women with ER-negative tumors. Similar results were found in the NSABP B-28 trial of similar design.^{256,257}

The benefits of adjuvant chemotherapy and adjuvant hormonal therapy have also been shown to improve disease-free survival and overall survival in low-risk, node-negative patients. Because node-positive patients obviously suffer from a greater risk for treatment failure, the benefit, as expected, is not as great in the node-negative patients. As a result, there is considerable interest at present in searching for prognostic and predictive indicators that would better select node-negative patients for adjuvant therapy. Ideally, these markers of disease risk would also aid in selecting the type of adjuvant therapy most likely to be beneficial.

Many studies have been conducted to evaluate the value of *p53* as a prognostic indicator in node-negative patients. These studies in general have failed to document that *p53* expression has a predictive value.²⁵⁸ About one fourth to one third of breast cancer specimens stain positive for *p53*.^{258,259} It is possible that actual cDNA sequencing to identify *p53* gene mutations may identify a higher-risk group and be better than immunohistochemical identification of *p53*. Other markers being studied include those of microvessel density (angiogenesis), tumor invasion (urokinase plasminogen activator inhibitor-2), the presence or absence of telomerase activity, and expression of cathepsin, *erbB-2*, and *mdr-1*. Obviously, whether these or other markers prove useful will require considerably more study. The design of such studies is difficult because of their complexity.

For today's patient, with a low-risk, node-negative tumor, the risk markers of age, tumor size, hormone receptor level, and degree of tumor differentiation must still be used to decide whether adjuvant therapy is indicated and what therapy should be recommended. For a tumor that is 1 cm or less in diameter, a 95% to 99% relapse-free survival rate can be expected unless the histologic findings show a poor nuclear grade and lymphatic invasion. If this is the case, the relapse-free survival drops to 67%, similar to that of a node-positive tumor, and adjuvant therapy is certainly indicated.^{260–262} Patients with node involvement or node-negative patients with tumors greater than 1 cm in diameter (T1c) are appro-

priate candidates for adjuvant chemoendocrine therapy. Patients with T1c-staged tumors that are node negative but ER negative receive CA. If they are younger than 50 years, such patients are also given tamoxifen if they are ER positive. Patients with T1c tumors who are ER positive and older than 50 years are treated with tamoxifen unless they are node positive, in which case they have an option for CA followed by tamoxifen.

Who should receive adjuvant hormonal therapy?

Clinical trials data, epidemiologic studies, and now molecular research support the role of estrogen in the initiation and development of hormonally dependent breast cancer.^{263–268} As a result, antagonizing estrogen is a prime target to reduce the risk for recurrence of breast cancer following treatment of the primary tumor and for prevention of second breast cancers.^{269,270} Receptors for estrogen were discovered in 1966, and within a few years, it became obvious that patients whose tumors lacked ER rarely responded to endocrine ablative surgery or hormonal therapy. The first SERM developed was the nonsteroidal tamoxifen.²⁷¹ Tamoxifen was approved by the FDA in 1986 for adjuvant treatment of postmenopausal women with node-positive disease and in 1990 for node-negative disease. Postmenopausal women have breast cancer that usually expresses ER and PR, and in such women, there are multiple sources of endogenous estrogen such as the skin, fat, muscle, and breast stromal cells. Breast cancer cells also can be shown to produce estrogen.²⁷⁰

Tamoxifen has been shown to reduce the development of recurrent disease by some 47% and overall mortality by 26% in ER-positive breast cancer patients.²⁷² Five phase III randomized trials comparing tamoxifen to placebo have been performed in women at risk for developing breast cancer. All trials were positive for tamoxifen, showing a 38% to 48% reduction in ER-positive breast cancers but no effect for preventing ER-negative cancers.²⁷³ As a result, tamoxifen became the drug of choice for hormonal therapy of women with ER- or PR-positive tumors.

The EBCTCG reported a recent meta-analysis that provides an overview of the use of tamoxifen as adjuvant therapy either alone or in combination with chemotherapy.^{210,273,274} In these trials, tamoxifen reduced the incidence of breast cancer by 38%. Although the incidence of breast cancer was reduced in all age groups, it was only the incidence of receptor-positive tumors that was reduced. Both this meta-analysis and a similar review of the NSABP prevention trials confirmed the risks associated with daily tamoxifen use.²⁷⁵ These included endometrial cancer and thromboembolic occurrences as the most serious complications of therapy. Although serious and potentially life threatening, both were rare and almost never occurred in women younger than 50 years. Vasomotor symptoms and genitourinary effects were the most common toxicities—especially in women in their perimenopausal years.

Tamoxifen, however, is not the perfect SERM and exhibits partial estrogen-like actions as well. These are amply demonstrated by its toxicities, such as the development of endometrial polyps or cancer and the occurrence of thromboembolic disease. In addition, tamoxifen has an estrogen-like positive

effect on reducing osteoporosis and the incidence of osteoporotic fractures.²⁷⁶ In efforts to identify and synthesize more efficacious drugs for antagonizing estrogen, investigators have focused on the estrogen synthetase enzyme (aromatase), which is the rate-limiting enzyme catalyzing the conversion of androgens to estrogens. Highly specific aromatase inhibitors (AIs) that block total body estrogen production by more than 99% have been developed. When AIs have been compared with tamoxifen in direct comparison trials, they have appeared superior. As a result, efforts are now underway to compare third-generation AIs. There are two classes of AIs: steroidal (class I) and nonsteroidal (class II). The third-generation AIs are more effective and less toxic. Anastrozole (1 mg daily) is completely absorbed from the gastrointestinal tract and has a half-life of about 50 hours with steady-state serum concentrations achieved at about 7 days. Letrozole (2.5 mg daily) is also completely absorbed by the gastrointestinal tract and has a half-life of 2 to 4 days. Steady state is achieved at 2 to 6 weeks. Both are nonsteroidal AIs. Exemestane (25 mg daily) is a steroidal AI with nonreversible enzyme binding and, unlike the others, appears to also prevent bone loss. It is also readily absorbed and is about 90% protein bound. Exemestane reduces estrogen levels to a greater degree than anastrozole.²⁷⁷

The largest trial to evaluate the AIs for adjuvant treatment of breast cancer is the anastrozole (Arimidex), tamoxifen alone or in combination (ATAC) trial. The drugs are given for 5 years to 9366 postmenopausal women. The first analysis at 33.3 months (median) follow-up showed anastrozole to have a significantly better disease-free survival than tamoxifen (reduced by 17%; $P = .006$). There did not appear to be a benefit from combining the drugs at this early date of analysis.²⁷⁸

Thus, adjuvant treatment of postmenopausal women with invasive breast cancer with tamoxifen or an AI is indicated for all T1-3, N0, ER-positive, PR-positive tumors with unfavorable histology or associated risk factors such as angiolymphatic invasion, high nuclear grade, and *HER-2* overexpression. For those patients who are perimenopausal (<60 years of age) with ER- or PR-positive tumors, adjuvant chemotherapy followed by 5 years of tamoxifen or AI is indicated for the additive effects. Of the available AIs, anastrozole continues to be the preferred agent, but there is increasing interest in exemestane because it is slightly more active and because it appears to prevent bone loss. Whenever possible, the AIs should be administered as part of a clinical trial. Of importance is the evidence that indicates that the steroidal AIs do not show cross-resistance with the nonsteroidal AIs, and vice versa. A single study (MA17 Intergroup) compared 5 years of letrozole versus placebo in postmenopausal women with hormone receptor-positive breast cancer who, after receiving 4.5 to 6 years of adjuvant tamoxifen, were still disease free.²⁷⁹ The early results of this trial are strongly supportive of the continuation of endocrine therapy using an effective AI in sequence with the 5 years of tamoxifen. The estimated 4-year disease-free survival rate is 93%, compared with 87% for the placebo group ($P < .001$).

For premenopausal women, there is increasing evidence that ovarian ablation or suppression using luteinizing hormone-releasing hormone plus tamoxifen is equivalent to adjuvant chemotherapy.²³ Further research is needed to

document this and to explore the potential benefit of timing the oophorectomy to occur during the luteal phase of the cycle.

How can the quality of life of breast cancer survivors be improved?

Patients who have been successfully treated for breast cancer make up the largest group of long-term cancer survivors. It is important to recognize that at least one fourth of these are women younger than 50 years. As a result, issues of quality of life (QOL) are an extremely important component of overall outcome assessment. The term QOL defines the physical, psychological, social, and spiritual aspects of everyday living—measured during active anti-cancer therapy or as a survivor without known disease. Studies of QOL in such patients are important to identify the specific needs of patients that could be addressed by medication, psychosocial intervention, and physical therapy and exercise.

Only a few studies have compared breast cancer survivors with noncancerous healthy women.^{280,281} Arndt and colleagues in Germany reported the results of a study designed to describe the QOL of patients with breast cancer 1 year after diagnosis and compared them to women in the general population.²⁸² They concluded that overall the QOL, general health, and physical functioning of breast cancer survivors 1 year after diagnosis was comparable to that of women in the general population. This was not the case, however, when they evaluated the emotional, social, role, and cognitive functions. These assessed measures of QOL showed persistent deficits and were more likely to be found in young women. Bloom and colleagues at the University of California, Berkeley, conducted in-person interviews with 185 women younger than 50 years at diagnosis who were cancer free for 5 years.²⁸³ They compared QOL in the physical, psychological, social, and spiritual aspects of daily living at 5 years with an assessment performed a few months after the diagnosis. They found that about 75% were now menopausal with an improved QOL. They did not find any significant changes in employment status, marital or partner status, sexual activity, sexual problems, self-esteem, and attendance at religious services or frequency of prayer. Greater improvement in their physical QOL was associated with having fewer chronic health conditions, being employed, and having been treated with chemotherapy.

One of the more bothersome problems for younger women who have been treated for breast cancer is the symptoms associated with therapy-induced menopause.²⁸⁴ As a result, the surgeon is frequently consulted by such patients regarding estrogen replacement therapy. The safety of using hormone replacement therapy (HRT) in women with a history of breast cancer has always been questioned because of the possibility that these hormones would stimulate the growth of micro-metastases or induce the development of new primary tumors. A retrospective analysis from the Royal Hospital for Women in Australia found that women given HRT following the diagnosis and treatment of breast cancer had 16 new or recurrent incidents of breast cancer, compared with 31 incidents in a matching group of breast cancer patients not given HRT.²⁸⁵ It is highly likely that any differences in increased risk for patients receiving HRT would be small if risks do exist, and therefore large numbers of patients would need to be

randomized to establish a clear answer. A National Cancer Institute workshop concluded that HRT users could be predicted to have survival decreases greater than 2 years. This decrease does not appear to be as great when progestin is used in combination with tamoxifen to alleviate unwanted symptoms. Users of tamoxifen plus progestin are projected to live more than 0.5 year longer than users of tamoxifen alone.²⁸⁶

There are other options for managing concerns regarding osteoporosis, such as alendronate (Fosamax), an aminobisphosphonate that acts as a specific inhibitor of osteoclast-mediated bone resorption. The bisphosphonates inhibit the recruitment function of osteoblasts to produce an inhibitor of osteoclast formation. Clinical trials involving postmenopausal women treated with alendronate showed a 9% increase in lumbar spine density over a 3-year span as well as a significant increase in hip, forearm, and total-body bone density.²⁸⁷ This resulted in a 50% reduction in fractures.^{288,289}

The ability of the bisphosphonates to increase bone density and their lack of significant risk have positioned them as the first alternative to HRT in dealing with postmenopausal osteoporosis. Evidence has suggested that they may be useful in delaying the development of bone metastases. This promises to be an important new area of investigation in the management of breast cancer.^{290,291}

There has also been increased interest in the role of physical exercise as an intervention that could improve QOL in cancer patients. One of the difficulties has been in determining the type of exercise— aerobic versus strength training— and there is little information regarding the frequency, duration, and timing of exercise interventions. In a review of 12 published randomized trials, the authors found a positive effect of exercise on overall QOL in three studies, a positive benefit in terms of decreasing fatigue in three studies, an improvement in physical function in one study, and an improvement in physical capacity, muscular strength, or both, during and after cancer treatment in six studies.²⁹² It certainly appears that exercise can be an extremely important part of the therapy regimen, but almost certainly such interventions need to be specifically designed and in fact tailored to the individual. The program needs to be adjusted to meet specific needs of the individual patient during different phases of active anti-cancer therapy.

How should patients with stages I and II breast cancer be followed?

The standards for follow-up and surveillance of breast cancer patients whose primary tumors have been successfully treated for cure are well established.²⁹³ Initially, patients are seen by a member of the treatment team for interview and examination every 4 months for the first 2 years. This frequency is chosen in part not so much for the risk for early recurrence as for the positive effect physician–patient interactions have on addressing psychological as well as physiologic issues that determine post-therapy QOL. The visits are scheduled every 6 months for the remainder of the first 5 years and then conducted on an annual basis. At the time of the visit, a CBC, platelet count, and general laboratory chemistries, including a liver function panel and prothrombin time, are drawn. Some reports suggest that routine laboratory testing is not justified and that a carefully conducted patient interview and physical examination is

sufficient for the early discovery of recurrent disease.²⁹⁴ A chest film and mammogram are obtained every 12 months. For patients treated by breast conservation, the first follow-up mammogram should be obtained 6 months after completion of the breast radiotherapy.

Women taking tamoxifen require close follow-up regarding the risk for endometrial carcinoma. A yearly pelvic examination is mandatory. Controversy exists regarding the value of yearly uterine ultrasound, but certainly any change in ultrasound pattern of the uterine lining or vaginal bleeding is indication for uterine lining biopsy. It must be remembered that women with a history of breast cancer are also at risk for developing second malignancies and that colon surveillance every 3 to 5 years is as important as yearly pelvic examination for ovarian cancer and endometrial cancer.

Signs and symptoms obtained by careful interview or laboratory findings suggestive of recurrent disease require immediate restaging. This is accomplished by obtaining a bone scan and CT imaging of the chest, abdomen, and pelvis. MRI is generally equivalent to CT imaging unless there are specific indications for MRI's use. For example, MRI is preferred for evaluation of the central nervous system and spine. Biopsy of accessible specific lesions may be helpful, providing confirmation of the metastatic disease and an opportunity to determine the receptor status and *HER-2* expression as it relates to the metastatic disease—even when this information is available concerning the primary tumor.

It is important that the patient be able to identify with one physician member of the multidisciplinary treatment team. This can be a very supportive relationship and reduces the number of visits for the patient while continuing to provide optimal coordinated follow-up.

What can be said in conclusion?

Looking back at the list of questions that compose the format of this chapter, I am reminded of the much longer list of questions and concerns brought by patient and family to the initial interview. I am convinced there is nothing more devastating to the people of our time than to hear the words—no matter how carefully delivered—that announce the diagnosis of cancer. Those words change forever one's life and his or her confidence about the future. For a woman who often has such awesome responsibilities to children, spouse, and extended family, I believe the words have an even greater weight. For most women today, breast cancer is their greatest fear. The physician should remember this when providing for her needs and should listen intently as her responsible physician and member of her team. Finally, the goal is to reduce or eliminate this list of questions. This can only be accomplished through more questions and the research to find their answers.

Treatment of In Situ Breast Cancer

Gordon Francis Schwartz

When our surgical predecessors more than two generations ago began to use the “in situ” label to describe an “earlier,” noninvasive stage of breast malignancy, they never realized the controversy their contributions would create several decades later. Until recently, it was believed that success in breast cancer therapy was directly related to the magnitude of the operation the surgeon could perform. The term *radical* was virtually always part of the description of the operative procedure employed to “cure” patients. It was not until screening mammography to achieve earlier detection became ubiquitous in the 1970s that our patients first questioned the appropriateness of their reward, that is, mastectomy, for their diligence.

Lobular carcinoma in situ (LCIS) and ductal carcinoma in situ (DCIS) were first described and first named by Foote and Stewart in 1941 and 1946, respectively.^{1,2} *Lobular neoplasia* was first suggested as an alternative term for LCIS by Lattes³; the term *carcinoma* was challenged by Haagensen⁴ as being misleading because the disease was not considered malignant in its own right. The name itself often led to more aggressive procedures based only on this unfortunate designation and the anxiety it engendered, affecting both patients and their doctors. Within the past 2 decades, largely because of screening mammograms, DCIS has come to occupy its own place on the program of virtually every breast cancer conference. Moreover, the discussion changes from one program to the next, with enthusiastic and outspoken advocates of what appear to be widely disparate philosophies about diagnosis, classification, and treatment.

LOBULAR CARCINOMA IN SITU (LOBULAR NEOPLASIA)

The treatment of LCIS, or lobular neoplasia, as some breast specialists prefer to call this risk marker, has been the source of considerable controversy. It was initially thought that this lobular proliferation of the breast epithelium, if untreated, led to the development of invasive lobular carcinoma in that breast. Haagensen was among the first to challenge this shibboleth with studies that indicated that LCIS was only a marker of risk and not itself malignant in the customary sense of the term.^{3,5} He considered it a benign pathologic-clinical entity when it occurred by itself, without a coexisting invasive

carcinoma. Despite Haagensen’s efforts to effect a name change for this condition, from the anxiety-invoking term “lobular *carcinoma* in situ” to the less awesome “lobular neoplasia,” LCIS remains the most commonly used name.

How is lobular carcinoma in situ diagnosed?

LCIS is almost always an incidental finding in a breast biopsy specimen, the biopsy having been performed for another reason. Unlike DCIS, it does not form a mass, it does not produce nipple discharge, and there are no mammographic findings to signal its presence. It is often multicentric and occurs bilaterally. Metastasis does not occur in LCIS. The lesion often involves both the acini of the lobules and the terminal ducts, and within the ducts, its differentiation from DCIS is sometimes difficult.

The evolution of LCIS within the mammary acini remains controversial. Within the lobules are two types of cells: epithelial cells, and beneath them, lining the cell membrane, the myoepithelial cells. These latter cells are not regularly seen within the acini. The proliferating cells of LCIS arise from the epithelial cells, filling the lumina of the acini to form solid rounded structures. These neoplastic cells are only slightly larger than the normal acinar epithelial cells, and mitoses are unusual. As these cells increase in number, they fill the acini, and the lobules become enlarged and more obvious. However, the diagnosis is not dependent on the number or size of the affected acini; rarely, a single lobule may be involved. Although most of the acini involved by LCIS are crowded with these cells, the cells do not have to fill the lumina to merit the diagnosis of LCIS. Occasionally, if a group of isolated lobules of LCIS is seen within the fat of the breast, it may be mistaken for infiltrating carcinoma. However, normal lobules may also be seen similarly isolated in the mammary fat.⁵

How can one tell the difference between lobular carcinoma in situ extending into ducts and ductal carcinoma in situ extending into lobules?

LCIS often involves both the acini of the lobules and the terminal ducts, and within the ducts, its differentiation

from DCIS is sometimes difficult. The involvement of small ducts by LCIS at the ductulobular junction is often confusing. LCIS cells may form buds around the periphery of a duct, displacing the glandular epithelium, in a pattern that resembles Paget's carcinoma of the nipple. These growth patterns are commonly called *pagetoid spread* because of the presumed extension of LCIS cells into the epithelium of the ducts. Whether this finding represents DCIS extending backward into the lobule or LCIS extending into the duct is often a difficult decision for a pathologist.⁶

These occasional findings at the ductulobular junction have also led to the question of whether LCIS and DCIS have a common origin in a stem cell lesion capable of going in either direction, that is, ductal or lobular. If a common precursor cell for both DCIS and LCIS could be documented, this would in part explain why the invasive cancers that develop subsequently in women with LCIS may be of ductal or lobular character and occur in almost equal proportions.

When the terminal ducts of the breast are involved by LCIS—and this may occur even to the point of the ducts' being more extensively involved than the contiguous lobules—the stain for E-cadherin can help to distinguish between LCIS and DCIS.^{7,8} E-cadherin is a transmembrane glycoprotein responsible for calcium-dependent cell-to-cell adhesion. This protein is usually absent in LCIS but not in DCIS. Thus, at least in theory, DCIS cells stain for E-cadherin, and LCIS cells do not. Studies to date support this hypothesis with reasonable accuracy. Because current treatment recommendations for LCIS and DCIS differ, this distinction does assume clinical significance. Because a difficult distinction between LCIS and DCIS implies that the DCIS is almost always small in volume and of low nuclear grade, however, many DCIS experts would not recommend any treatment more aggressive than local excision and surveillance anyway. The major question then becomes whether to re-excise the area encountered to examine the contiguous breast tissue for additional areas of disease. Re-excision is generally not indicated for LCIS, whereas DCIS usually requires wider excision.

Quite recently, staining for high-molecular-weight (HMW) cytokeratins has been added to staining for E-cadherin at the Armed Forces Institute of Pathology (AFIP) to help differentiate borderline lesions into lobular and ductal phenotypes. The staining characteristics for these two markers are reversed in LCIS and DCIS, compared with the staining for E-cadherin. The stains for HMW cytokeratin are negative in DCIS and positive for E-cadherin; the opposite is true in LCIS, namely (perinuclear) staining for HMW cytokeratins but absence of staining for E-cadherin.⁹ This simple-sounding (if expensive) way to differentiate these two lesions from each other is complicated by two groups of hybrid cells: positive hybrids that exhibit both markers, and negative hybrids that exhibit neither. The AFIP uses a designation *mammary intraepithelial neoplasia (MIN)* for an intermediate proliferation that cannot be assigned to either ductal or lobular origin by light microscopy; these hybrids may represent as many as half of the lesions designated MIN. The other half of these can be separated into lobular or ductal origin by these staining characteristics.

For reasons that remain unexplained, LCIS most often occurs in premenopausal women, or in postmenopausal

women who are using estrogen replacement therapy, with or without concurrent progestins.

What was the initial experience with surveillance alone for patients with lobular carcinoma in situ?

The early Columbia studies of Haagensen convinced that institution's surgeons to observe rather than treat these patients, so that long-term data are available in that patient population. Two of the largest series of such patients are from the Columbia-Presbyterian Medical Center and from Memorial Sloan-Kettering Cancer Center.^{5,10} Observations at the two institutions were similar, with only a minority of patients developing a subsequent invasive cancer. Their treatment options were initially quite different, however—surveillance alone, versus mastectomy, often bilateral—and the differences in treatment were considered to be related to where in New York City the diagnosis was made—West Side (Columbia-Presbyterian) or East Side (Memorial).

How common is lobular carcinoma in situ?

Because LCIS occurs uncommonly and is generally an unforeseen finding in a breast biopsy specimen obtained for another reason, Haagensen reviewed almost 10,000 benign breast biopsies to determine the actual incidence of LCIS. He found that LCIS was identified in 2.7% of biopsies for benign breast lesions. However, Page and colleagues found LCIS in only 0.5% of more than 10,000 benign biopsies at Vanderbilt University.¹¹

What has been the subsequent experience with surveillance alone for lobular carcinoma in situ?

That patients with LCIS are at increased risk for invasive breast cancer at some time in the future is not questioned. All major studies have made this observation, although the reported incidence of subsequent breast cancer varies, from a low of 4% to a high of 35%. In the longest follow-up series, the probability of a woman's developing an invasive carcinoma was 13% by 10 years after the diagnosis of LCIS, 26% after 20 years, and 35% by 35 years, roughly a 1% increase per year.¹² Of crucial importance is the observation that after an initial diagnosis of LCIS, both breasts are at the same risk. Therefore, there appears to be no logical reason to perform mastectomy of *only* the breast known to harbor LCIS. The appropriate prophylactic procedure would be *bilateral* total mastectomy.

Whether there is a quantitative risk relationship between the extent of LCIS in the biopsy specimen and the likelihood of a subsequent breast cancer is also uncertain. Although studies indicate a trend in this direction, it has not been proved. Bodian and associates noted a 1.6-fold greater risk if more than 10% of the total number of lobules in a specimen were involved by LCIS, compared with specimens that had less than 10% of the lobules involved.¹² This difference was not statistically significant.

Are there any other risk factors for the development of invasive cancer in the patient with lobular carcinoma in situ?

Family history of breast cancer in the mother or a sister of a woman with LCIS might convey additional risk; this is of most concern in women who are diagnosed with LCIS before age 40 years. From the reported experience of Haagensen, the breakpoint between an even greater risk than the risk usually associated with the diagnosis of LCIS occurred at age 40 years.

An understanding of the typical course of the breast cancer that may develop is also crucial to the formulation of a treatment plan when LCIS is encountered. Both breasts, not just the one in which the LCIS was detected, are at about the same long-term risk for subsequent breast cancer. This observation suggests that LCIS, if not excised, does not itself progress to invasive cancer. Moreover, such lack of progression may be inferred by the histology of the subsequent breast cancer. In the review by Bodian and associates, only 27% of the subsequent breast cancers were invasive lobular carcinomas; the remainder were invasive ductal carcinoma, with several subtypes of ductal carcinoma found.¹² If progression from LCIS to invasive cancer were the rule, it would be expected that the later invasive cancer would be of the same origin. (Although purely invasive lobular carcinoma constitutes only about 10% of all breast cancers, many cancers seem to have both lobular and ductal features in association with each other.)

How has the management of lobular carcinoma in situ evolved?

Despite the reluctance of the medical community to change the name of LCIS to lobular neoplasia or another less threatening term, the treatment of LCIS has undergone significant evolution as physicians have accepted the concept that what had initially been considered a “real” cancer was in fact a marker of increased risk. Before its recognition as a marker, rather than as being malignant in its own right, it was most often treated by mastectomy. As this disease became better understood, unilateral mastectomy was abandoned as treatment, in favor of surveillance alone. To be sure, there are women for whom the specter of a subsequent invasive breast cancer is too great to endure, and this increased risk for developing a potentially life-threatening cancer leads them to choose mastectomy, with or without reconstruction. However, it must be stressed that mastectomy, in this context, is a prophylactic, not therapeutic, procedure. If chosen, it should be bilateral because both breasts are at about equal risk. Unilateral mastectomy, even with so-called mirror-image biopsy of the opposite breast, is not a logical choice. If the diagnosis of LCIS is made on the basis of a biopsy of one breast for an unrelated benign finding, it should be accepted that LCIS may also be present in the contralateral breast as well, given its predilection for bilaterality and multicentricity. Radiation therapy for LCIS is never indicated.

It has been a major undertaking to convince many surgeons that observation alone is appropriate when LCIS is detected. As recently as 1988, surgical oncologists were surveyed about

their approach to LCIS, and one third of the respondents still advocated mastectomy. A slim majority, 54%, advised observation alone. When a similar questionnaire was sent to the same physician groups in 1996, 10% of the respondents still recommended unilateral mastectomy, suggesting their lack of information about this disease or their conviction that LCIS is a premalignant lesion.¹³

What advice should be given to the patient who has a core biopsy that reveals lobular carcinoma in situ?

The difficulty in making the diagnosis of LCIS with certainty in borderline situations is magnified when the specimen is a core biopsy performed to explore a mammographic finding. This is often true whether the tissue is obtained with a standard core needle or a vacuum-assisted core device (Mammotome [Biopsy Medical Instruments, Irvine, CA]). What should the next recommendation be—surgical needle-guided biopsy to excise the area in its entirety, or careful follow-up, usually a 6-month-interval mammogram? This problem has been addressed by several teams of breast specialists with modestly different conclusions based on small series of patients.^{14–16} Because the diagnosis of LCIS in these situations is probably an incidental finding, this decision should be made in part by reviewing the reason for the original recommendation for biopsy (e.g., mass, parenchymal distortion, calcifications). If the microscopic findings *in addition to* the LCIS are not concordant with the mammograms, a surgical procedure would be mandated. When a suitable explanation for the mammographic findings is documented by the core biopsy and the explanation would not itself demand a surgical procedure, the incidental finding of LCIS would not play a role in this decision, and open surgical biopsy would not be recommended based only on the finding of LCIS. This recommendation is not valid if the microscopic sections are equivocal (i.e., LCIS vs. DCIS, LCIS vs. ADH [atypical ductal hyperplasia]) or if the pleomorphic form of LCIS is the diagnosis. Because LCIS itself is not considered malignant and is known to be multicentric and bilateral, attempting to excise all of it from the breast is futile and unnecessary. The same recommendations are valid if a core biopsy reveals atypical lobular hyperplasia (ALH) only.

What advice should be given to the patient with lobular carcinoma in situ?

Patients whose otherwise benign breast biopsies reveal the presence of LCIS should be informed that a marker for increased risk has been detected. They should be aware of the nomenclature and of the inaccurate use of the word *carcinoma* in this diagnostic phrase as the term is customarily employed. Because mammography has become the mode of diagnosis for DCIS, the differences between DCIS and LCIS should be discussed with the patient. Even when DCIS is treated by observation alone, it requires clear surgical margins (see the discussion of DCIS that follows) and is considered a unilateral threat, unlike LCIS. The patient should be informed that LCIS is usually multicentric and bilateral but requires no further treatment after its diagnosis. However, the patient

should be informed of her two options: either bilateral total mastectomy with or without reconstruction, or lifetime observation. If mastectomy is chosen, it must be done with the patient's understanding that it is a prophylactic, not therapeutic, procedure. When acquainted with the risk for subsequent invasive cancer, using an approximation of a 25% risk in the next 25 to 30 years, the patient's choice depends on her own perceptions of this risk. Is her glass 75% full or 25% empty?

The Society of Surgical Oncology (SSO) has addressed this subject, in part, in its position statement on prophylactic mastectomy, updated in 2001: "Clinicopathologic presentations that portend risk of cancer with a specific indication for bilateral prophylactic mastectomies include . . . atypical hyperplasia of lobular . . . origin," and indications for unilateral prophylactic (contralateral) mastectomy in patients with a diagnosis of the ipsilateral breast include "lobular carcinoma in situ in the remaining breast . . . and . . . development of either invasive lobular or ductal carcinoma in a patient who elected surveillance of lobular carcinoma in situ."¹⁷ The SSO did not make a recommendation for mastectomy in these situations. Its statement was issued, at least in part, "to guide insurance programs in determining coverage and help patients (who elect prophylactic mastectomy) to obtain reimbursement."¹⁷ In 1996, the National Surgical Adjuvant Breast Project (NSABP) findings, in their review of 182 women with LCIS (only) enrolled in Protocol B-17, concluded that there was no reason to perform mastectomy on women with LCIS.¹⁸

LOBULAR CARCINOMA IN SITU SUMMARY

Since its presence and significance were first understood about two generations ago, and its acceptance as a risk marker, rather than as cancer *sui generis*, has been almost universally adopted, research interest in LCIS as a separate proliferative lesion has waxed and waned. The origin, detection, treatment, and even prevention of other breast proliferations or neoplasms moved LCIS into the background, so that interest in LCIS is generally resurrected only when its diagnosis is in doubt or its presence in conjunction with other lesions mandates consideration of its coexisting effects as well. It has now been well accepted by most breast experts that the treatment of LCIS is based on the patient's perceptions of the risk-to-benefit ratio, choosing between the subsequent theoretical development of an invasive and, therefore, possibly life-threatening cancer and the immediate effects of bilateral mastectomy. Additionally, no correlation has yet been made between the known genetic mutations that increase the risk for invasive cancer (e.g., *BRCA1*, *BRCA2*) and the occurrence of LCIS, or whether the combination of any genetic mutation and a personal history of LCIS implies a greater risk than either of these factors alone.

If we could identify precisely which patients with LCIS today will develop a "real" cancer tomorrow, perhaps we could tailor treatment to fit the situation. Using today's knowledge, however, bilateral mastectomy is unnecessary surgery for most women with LCIS. In a specialty practice devoted to breast diseases for more than 25 years, I have not yet performed a bilateral mastectomy for LCIS.

DUCTAL CARCINOMA IN SITU

What was the initial treatment for ductal carcinoma in situ?

Although the initial descriptions of what we currently call DCIS may have been formulated in 1946, it was not until 2 decades later that the difference between its behavior and that of frankly invasive breast cancer was really considered. In 1956, in the first edition of his book, *Diseases of the Breast*, Haagensen noted the various subgroups of "intraductal" carcinomas (i.e., comedo, solid, cribriform, and low papillary—morphologic definitions that still partially survive).¹⁹ His patients' cancers were found as palpable masses with a mean diameter of almost 5 cm, and most had axillary node metastasis. The 5-year survival rate for these women was 58%, leading him to comment that the pathologists' suggestion that these tumors were "noninfiltrating" did not take into account the small portion of the entire epithelium that could be examined in any individual case, irrespective of how many microscopic sections were studied. Haagensen thought these cancers should be treated no differently from other invasive breast cancers, which at that time were managed by radical mastectomy.

As initial experience with mammography was gained in the late 1960s and early 1970s, these smaller and entirely intraductal cancers were detected with increasing frequency, usually as tiny groups of clustered calcifications, not yet forming an actual mass. Nevertheless, the standard of care remained mastectomy. It was assumed that despite the absence of invasion in the sections studied, progression to invasive cancer would inevitably occur. This assumption was based, in general, on observations of the coexistence of DCIS with invasive carcinomas, as well as on studies of patients who subsequently developed breast cancer after prior biopsies for what was thought to be benign disease but that on review demonstrated DCIS. This led to the recommendation for mastectomy, albeit with the expectation that the likelihood of the patient's dying of breast cancer without mastectomy would be negligible.

What has led to a reassessment of the management of ductal carcinoma in situ?

It was not until the late 1970s that Betsill and his colleagues suggested that untreated DCIS did not necessarily progress to invasive cancer, at least in some patients.²⁰ That observation has, in part, led to the current controversy about the treatment of this disease, compounded by the increasing incidence of DCIS detected by mammograms. This has occurred as screening mammography for asymptomatic women has been embraced as a major advance in the discovery of earlier malignancies and as notable improvements in mammographic technique, such as magnification films, have detected tiny, subtle changes within the breast.

In the past several years, current experience, including our own data, indicates that as many as one fourth of nonpalpable breast cancers (those detected by mammography) will prove to be DCIS. As implied by the name, DCIS appears to arise

within ducts of the breast that become greatly dilated as the process evolves. In the usual scenario, when necrosis occurs within the lumina of the ducts, the precipitation of radiographically opaque inorganic material, usually containing calcium, leads to the mammographic discovery of these areas of intraductal disease as areas of clustered “calcifications” on a mammogram. It had been assumed that if the process continues without interference, the involved ducts grow in number and volume until finally discovered by the patient or physician as a palpable mass. At some time in this process, the formerly intraductal, cytologically malignant but biologically noninvasive cells penetrate through the basement membrane of the ducts, and the disease becomes invasive, with all of the implications of any invasive carcinoma.

As this inevitable progression of DCIS to invasive carcinoma has been challenged, with a minimum risk to the patient of developing a subsequent, life-threatening cancer, the importance of the identification of DCIS at some early stage in its natural history that will obviate the obligatory treatment of the *entire* breast (whether by mastectomy or by irradiation) has become a topic of great debate. If, as now accepted, DCIS is not always accompanied by invasion or does not necessarily progress to this stage, to prescribe lesser treatment for DCIS—that is, excision—than for invasive carcinoma implies an obligation to recognize when simple identification and excision of DCIS at this one site constitutes adequate treatment. This premise, however, also implies that the eradication of DCIS at one location ensures that the site detected is no greater in significance than what might be a concurrent, as yet undetected but more important (e.g., invasive) finding at another location within the same breast. We have reported that in our own series of patients with mammographically detected malignancy, other (multicentric) foci of DCIS may occur in other quadrants of the breast, but the likelihood of an unsuspected *invasive* cancer is remote.

What is the significance of *clinical* ductal carcinoma in situ?

The separation of *clinical* from *subclinical* DCIS to permit a more careful comparison of equivalent diseases was first suggested by Gump and coworkers, and their distinction also has great implications for treatment.²¹ DCIS presenting as a palpable mass, as nipple erosion (Paget’s carcinoma), or as nipple discharge is not the same as DCIS presenting as an area of calcifications on a screening mammogram or discovered as an incidental finding in a specimen of breast tissue removed for another reason. Haagensen and his contemporaries detected cancer based on clinical findings, whether as mass, nipple erosion, or nipple discharge; the so-called intraductal cancers that he treated had a mean diameter of almost 2 inches!

Staging systems for breast cancer have not yet addressed the entire spectrum of DCIS, so that all DCIS is considered stage 0, Tis. This presumes the absence of any invasion, however microscopic. Microinvasion of any size changes the staging to stage I, T1mic. The subdivision of DCIS into categories for consideration is somewhat arbitrary. Therefore, it is easier from the treatment viewpoint to discuss *clinical* DCIS (vide infra) than *subclinical* DCIS, which is detected by mammography or as an incidental finding. Current data indicate that there are patients in whom DCIS is *not* inexorably followed

by invasive cancer, but I do not consider most women with *clinical* DCIS among that group. Except for highly selected patients, until data are available that refute this recommendation, patients with clinically detected DCIS should continue to undergo treatment that includes the entire breast, that is, irradiation or mastectomy, and selected patients should undergo axillary sentinel node biopsy. Exceptions to this dictum might be made for those patients with small (<1 cm diameter), palpable, but biologically favorable types of DCIS.

Therefore, using these definitions, the term *palpable DCIS* is almost an oxymoron. A palpable mass, even if largely intraductal, should not be considered noninvasive. As already noted, the appropriate designation should probably be “no invasion documented in the sections studied.” Except in the case of such specially selected patients, these allegedly intraductal but palpable lesions are often accompanied by microinvasion, even when not seen, and the appropriate treatment addresses the entire breast and, arguably, the axilla as well.

Some of these predominately intraductal but palpable lesions may achieve considerable size and may be accompanied by clinically involved axillary nodes. They are characterized by their firmness, their fairly well-delimited margins, and an abundance of malignant-appearing calcifications on mammography. Patients with these large lesions are usually not candidates for treatment by irradiation because of the difficulty of excising all of the calcifications that permeate the ducts contiguous to and even at great distance from the mass itself. The palpable masses called DCIS that radiotherapists currently seek to treat are small ones, amenable to wide local excision with clear surgical margins.

What is the major histopathologic dilemma in the diagnosis of ductal carcinoma in situ?

The controversy about DCIS begins with a more careful definition. As noted previously, Haagensen and others carefully separated the term *intraductal* from the term *noninfiltrating*. The terms were not then considered synonyms! As radiographic techniques improved and the mammographic detection of smaller masses, then areas of nonpalpable calcifications, became more common, the terms *noninvasive*, *in situ ductal*, *intraductal*, *noninfiltrating*, and *DCIS* have become interchangeable. As currently used, each of these defining terms confirms the absence of invasive carcinoma. Additionally, rather than each being an entity unto itself, there is probably a continuous spectrum of “neoplastic activity” from what pathologists currently call atypical ductal hyperplasia (ADH) through DCIS to invasive carcinoma. The sometimes subtle changes that characterize the differences between these lesions (i.e., from ADH to DCIS and from DCIS to microinvasive carcinoma) often confound the most experienced pathologists. When shown the same slides, even renowned pathologists often disagree among themselves when trying to distinguish among these borderline lesions.²² For example, Page has stated that the lesion should be considered DCIS instead of ADH if at least two duct spaces are involved.²³ Other pathologists consider geometric size more important, 2.0 mm being the cutoff between ADH and DCIS.²⁴ Irrespective of this controversy, even if labeled as DCIS, the lesion described in this scenario would be considered low grade, and the diagnostic designation on the “bottom

line” of the pathology report should not influence patient care. The recognition of these difficulties in distinguishing what might be called low-grade DCIS from ADH has even led to the suggestion for a new name to describe these borderline lesions—MIN, ductal type, or ductal intraepithelial neoplasia (DIN).²⁵ The only difference between this system and current ones is avoiding the use of the term *carcinoma* in the body of the report. Instead, the terms, *DIN 1-a*, *DIN 1-b*, *DIN 1-c*, *DIN 2*, and *DIN 3* are used to describe the progression of changes that start with ADH and end with the comedo type of DCIS. Changing the terminology in this manner only minimally addresses the major question of classification in general.

Within the past few years, differences in architecture or morphology have gradually assumed less significance than nuclear grade, the presence and amount of necrosis, and immunohistochemical findings such as steroid hormone receptors, proliferation markers (e.g., Ki-67), and gene products (e.g., *HER-2*, *p53*). Because no current system combines ease of use, clear prognostic value, and reproducibility well enough to be uniformly acceptable, the optimal combination of these factors to influence treatment recommendations remains elusive. At a conference on DCIS held in Philadelphia in April 1997, the classification of DCIS was a major topic of discussion. About 30 distinguished scientists, including 20 breast pathologists from the United States and Europe, gathered for a consensus conference to attempt to codify the microscopic features that distinguish subsets of DCIS from one another. The intent of this conference included the identification of specific morphologic features of DCIS subgroups that convey prognosis. The proceedings of this conference have been published and are summarized in the next section.²⁶

Microscopic Considerations

How is ductal carcinoma in situ currently classified?

Although DCIS was considered a single entity until recently, it is perhaps the ubiquitous use of screening mammography and the exponential increase in its frequency that have changed the way in which DCIS is regarded by most pathologists. The heterogeneity of DCIS is now well accepted among pathologists, and cases of DCIS with comedo features are probably outnumbered by those without.²⁷ When DCIS is detected as a palpable mass in the breast, its comedo features are almost invariably present. Less universally accepted has been the system of classification that describes differences in architecture. The major and customary architectural patterns that have been popularized are the comedo, solid, cribriform, papillary, and micropapillary types, although only rarely do any of these exist alone. Often, the papillary and micropapillary types are grouped together, so that four, rather than five, major subsets of DCIS based on architecture may be enumerated by some investigators. Unfortunately, criteria for differentiating among these various patterns are not clearly defined, so that comparisons of different studies of DCIS are difficult. When such studies are reviewed by other pathologists, as many as one third of the cases are reclassified.²⁸ There is no current system of classification of DCIS used by pathologists that combines the three ingredients required to make clinicians

comfortable—ease of use, reproducibility among pathologists, and, most important, *clinical significance*.

Prior classifications emphasized morphology, dividing DCIS into two basic groups, comedo and noncomedo. In general, the comedo type of DCIS is described as composed of pleomorphic cells, usually with a high mitotic rate, accompanied by central ductal necrosis. The absence of these factors then defines the noncomedo type, whether solid, cribriform, or otherwise described. Implied in this two-tiered system is a greater degree of aggressiveness of the comedo form of DCIS and its putative greater likelihood of recurrence in patients treated by less than mastectomy.

Only recently have pathologists addressed other factors, such as cytonuclear differentiation and biologic markers. This classification separates DCIS into three categories on the basis of the first two of these factors, cytonuclear and architectural differentiation. These categories are *poorly differentiated*, *intermediately differentiated*, and *well-differentiated* DCIS, also described as nuclear grades III, II, and I, respectively. These differences are best described by pathologists as they view slides. Already, the prior system of classification used by many American pathologists (comedo and noncomedo) has been replaced by a system that stresses nuclear grade, necrosis, and cell polarity, with architecture a secondary consideration only. The report of the consensus conference in 1997 emphasized the importance of nuclear grade in stratifying DCIS, with less emphasis given to architectural patterns and to the presence of necrosis.²⁶ The most promising area of research into the prediction of outcome following treatment is the use of genomic markers to stratify breast cancers. Gene expression patterns analyzed by complementary DNA (cDNA) microarrays may provide a “molecular portrait” of each lesion that correlates with prognosis. If this were to become available, each patient’s treatment could be individualized with much greater precision and certainty about outcome. These patterns are currently being explored in invasive cancers, with interesting relationships being observed, and it is not fanciful to assume that DCIS might ultimately be stratified in the same way.

Quantifiable biologic markers, such as steroid hormone receptors, measurements of proliferation rate (Ki-67), and identification of gene products (*p53*, *c-erbB-2*), are now always available because they may be retrieved from paraffin blocks of formalin-fixed tissue. (They no longer need to be retrieved from fresh specimens within minutes.) Their roles in differentiating ADH from DCIS, or in defining degrees of aggressiveness of DCIS to aid in therapeutic recommendations, are currently unclear. Whether they are independent variables or only mirror what the pathologist can describe is also controversial.

Because DCIS itself is not a threat to the patient’s outcome, it is only those patients who will develop invasive cancer who theoretically require (prophylactic) treatment. It is now accepted that at least some patients, perhaps a majority, with DCIS will never develop invasive cancer. What is currently unclear is how to make this distinction and recommend appropriate therapy for those who are in jeopardy.

Therapeutic Considerations

If pathologists cannot agree about the very definitions of in situ carcinoma, and if at both ends of the spectrum the

subtleties between ADH and DCIS and those between DCIS and microinvasive ductal carcinoma are even more contentious, it is not surprising that treatment recommendations for DCIS are equally controversial. Early in the days of its recognition, patients with DCIS underwent mastectomy, usually with axillary dissection. Treatment was based on the (incorrect) presumption that an earlier stage of an inexorable, obligatory progression from DCIS to invasive cancer had been detected. Treatment for this earlier stage was the same as for its invasive successor, but with a better outcome anticipated.

Only as screening mammograms detected DCIS as smaller and smaller clusters of calcifications did this almost universal recommendation for mastectomy begin to change. The spectrum of disease or diseases that is represented by the term *DCIS* influences differences in therapy as physicians review each patient's situation individually. As already noted, the term *subclinical DCIS* has evolved to describe these mammographic findings or the incidental finding of DCIS in a (benign) biopsy specimen, the procedure having been performed for another reason. Clinically evident DCIS is represented by Paget's carcinoma, the presence of nipple discharge as the presenting symptom, or a palpable mass that is called DCIS.

How is Paget's carcinoma treated?

Paget's carcinoma, presenting as nipple erosion, is a form of breast carcinoma that may be entirely noninvasive. It grows initially within the milk sinuses of the nipple and extends within the ducts beneath the nipple in an apparently intraductal, but not always in situ, manner. The development of the disease may be multicentric within the breast. Patients with Paget's disease rarely have axillary node metastasis, unless a mass representing invasive carcinoma accompanies the nipple and areolar findings. Tempting as it may be to consider less aggressive surgical procedures, mastectomy with axillary dissection or sentinel lymph node (SLN) biopsy has remained the treatment of choice except in unusual situations. The mammograms in Paget's disease may be helpful in defining the retroareolar spread of disease. Although not well described in the literature, it has been our observation that calcifications in a branching distribution in the retroareolar area may help outline the intraductal spread of Paget's disease, proving its widespread character and the need for mastectomy.²⁹

Although it is not necessarily true that the absence of retroareolar calcifications proves a more limited distribution of disease, when the calcifications are seen to be distributed in this pattern, the failure of any procedure that does not treat the entire breast can be appreciated. Nevertheless, we have treated several women with Paget's carcinoma by irradiation only, *not* excising the nipple–areolar complex. This choice is tenable only when the biopsy of the nipple indicates a relatively confined distribution of disease. These several patients have also been quite vocal and unequivocal in their desire to retain their breast. Despite this limited success with what should be considered a quasi-experimental approach, Paget's carcinoma should be considered as clinical DCIS, at the least. Untreated, Paget's carcinoma is inevitably progressive, albeit slowly.

How is ductal carcinoma in situ presenting as nipple discharge managed?

Patients presenting with spontaneous nipple discharge due to intraductal carcinoma are tempting candidates for treatment by something less than mastectomy. Because the mammograms in these patients rarely show evidence of mass or calcifications, and the usual morphology of the malignant cells is less rather than more aggressive, why not consider these patients within the group to be followed by surveillance alone? That had been our initial query as we began to search for patients with DCIS who might be candidates for local excision alone. However, after the first two patients so treated experienced recurrence relatively promptly, and we then reviewed the mastectomy specimens in other patients with the same presenting symptoms, we became more convinced that nipple discharge as the first sign of DCIS implies an uncertain intraductal, usually multicentric, distribution peripherally. At least in the traditional sense, in these patients it is impossible to perform a local excision (“lumpectomy”) that definitively circumscribes the macroscopic disease. Irradiation as an alternative to mastectomy is not usually suitable because, if one believes that the macroscopic extent of the disease must be excised before irradiation, the nipple and areola must be part of the tissue sacrificed. Additionally, if one also believes in additional radiation to the site of the primary lesion, there is no specific site to boost.

Within the past few years, ductal lavage and ductoscopy have emerged as techniques to gain less invasive access to the ductal system of the breast through cannulation of retroareolar ducts, by obtaining effluent from duct irrigation for cytologic examination or by direct visualization, respectively. Proponents of these techniques claim that the diagnosis and extent of intraductal lesions, including carcinoma, can be aided by one or both of them. At this time, both should be considered experimental techniques, subjects for clinical trials but not yet part of the standard surgical armamentarium. Neither is currently indicated to influence a therapeutic decision.

How is the axilla to be treated in patients with ductal carcinoma in situ presenting as nipple discharge?

Treatment of the axilla is more controversial in patients with clinical DCIS detected as nipple discharge than in patients with intraductal carcinoma detected as Paget's disease or as a palpable mass. If frank invasion is present, treatment includes the same attention to the axilla as for any other invasive cancer when invasion is questioned, even if the invasion is termed *focal* or *microinvasive*. At least a sentinel node biopsy is a reasonable recommendation, with a more extensive dissection if the sentinel nodes are positive for metastasis.

It is more difficult to justify treatment of the axilla in patients in whom microscopic sections fail to detect any question of invasion whatsoever. However, because most of these particular patients are currently treated by mastectomy, and a total mastectomy includes the removal of the axillary prolongation (tail of Spence) of the breast, the lowermost axillary lymph nodes—those in what would be called by anatomists

the external mammary group—and some of those in the central or scapular group of the level I nodes, which are impossible to separate from the axillary tail tissue, are often included within the specimen. Would these also be the sentinel nodes? Likely so, but impossible to prove, so it would not be considered “overkill” to perform SLN biopsy as a separate step in these patients. SLN biopsy is difficult to perform after mastectomy, so in patients with DCIS presenting as nipple discharge who are to be treated by mastectomy, SLN biopsy is a reasonable recommendation to accompany the mastectomy.

One must remember that DCIS presenting as nipple discharge is not considered subclinical, which would have implied the same treatment algorithm as for DCIS detected as mammographic calcifications. Our current inability to measure the extent of the disease within the ductal system makes any treatment that does not address the entire breast inappropriate.

How is the diagnosis of subclinical ductal carcinoma in situ made?

As greater experience has been garnered in the use of less invasive techniques such as stereotactic core biopsy using a large-bore, vacuum-assisted needle, stereo-core biopsy is a suitable, if not the preferable, first step in the diagnosis of mammographic findings when feasible.^{30,31} Needle-guided (also known as wire-directed) surgical excision using preoperative needle localization and confirmatory specimen radiography remains the traditional procedure if stereo-core biopsy cannot be performed. In either case, concordance between biopsy findings and the mammograms must be ensured. Open surgical needle-guided biopsy, when used as the first diagnostic step, may be performed as a wide excision with the intent of achieving microscopically clear margins, or as a more limited procedure to make the diagnosis only. With a wide primary excision if the findings are benign, a larger volume of tissue may have been removed than necessary. If the first procedure had been a limited excision and if the diagnosis is malignant, a second procedure is mandated to achieve wider margins. This should be discussed with the patient so that she has input into the technique used, especially if the mammographic findings are indeterminate and the breast is relatively small. There is no danger to the patient if the area of DCIS needs to be re-excised to gain wider margins around it (see the section on margins, later). Stereotactic core biopsy to determine the diagnosis before any other surgical procedure solves this dilemma; if DCIS is documented, the surgical procedure can be planned accordingly to clear the margins around the area of DCIS.

When a patient requires surgical excision following core biopsy or re-excision of an area of DCIS following an initial needle-guided biopsy, a postbiopsy mammogram is imperative. Because the treatment of DCIS is not an emergency, enough time should elapse between the initial procedure and the postbiopsy mammogram to optimize the visualization of possible residual calcifications. This may take as long as 2 to 3 months in some patients. When core biopsy is performed, a specimen radiograph and a radiograph of the breast immediately following the biopsy should be obtained to ensure

removal of the most significant calcifications. A radiopaque clip should be placed at the site of calcifications so that this area can be localized again when further surgery is performed. Not infrequently, core biopsy may remove most, even all, of the calcifications; if all of the calcifications have been removed by the initial procedure, without the clip the area cannot be accurately identified.

What are treatment options for subclinical ductal carcinoma in situ?

The therapeutic options for DCIS detected as a mammographic finding or as an incidental finding in a biopsy performed for another reason include total mastectomy, local excision and radiation therapy, and local excision alone, with or without the addition of an endocrine agent such as tamoxifen or an aromatase inhibitor.³² Because these are such widely disparate treatments, it is not surprising that choosing among them for individual patients has become controversial. DCIS now represents 25% to 30% of newly diagnosed, mammographically detected cancers in all age groups of women who undergo periodic screening mammograms (usually at 40 years and older in the United States). Although it is generally accepted that many patients with DCIS, if untreated, do not subsequently develop invasive carcinoma of the same breast, the ability to distinguish which women will be spared has eluded us. The reports that discuss the implied natural history of this disease, in patients untreated because the diagnosis was initially overlooked, fail to demonstrate that even a simple majority of these patients developed invasive carcinoma. Nevertheless, until recently, mastectomy had been the overwhelming choice of treatment for this disease, and currently the generally accepted choice is either mastectomy or irradiation, depending on the availability of radiation therapists and their influence on local tradition. In our own practice, needle-guided biopsy for mammographically detected lesions was initiated in 1974, and until 1978, mastectomy was the customary “reward” for those patients who were diligent enough to have their “cancers” (DCIS) detected in such an early stage. As more and more patients with subclinical DCIS were encountered in response to technical improvements in mammograms and the greater acceptance of screening mammography by the medical profession and by the public alike, questions relating to the extent of disease within the breast, the possibility of occult invasion, and the likelihood of axillary metastasis began to be addressed.

These questions were addressed at the second consensus conference on DCIS, held in 1999, at which time the management of DCIS was the principal subject of discussion.³² The consensus meeting was attended by a similar number of scientists as the conference in 1997, including DCIS specialists from various disciplines, including surgery, radiation and medical oncology, pathology, radiology, epidemiology, biostatistics, and medical genetics. The conference focused on the following end points of treatment: breast conservation, risk for a second event in the ipsilateral breast (invasive or in situ), risk for metastasis from a subsequent invasive carcinoma, risk for contralateral DCIS or invasive cancer, and breast cancer-specific mortality.

How does one choose the appropriate treatment for patients with ductal carcinoma in situ?

The goal of treatment for DCIS is breast conservation, with optimal cosmesis and a minimal risk for an ipsilateral second event, either further DCIS or invasive carcinoma. The several factors that influence the recommendation for treatment of the breast include size of the area of DCIS, its biology, and margin status. Regardless of the goal of breast conservation, there are some women for whom mastectomy remains the optimal treatment; this group probably represents less than 25% of all of the women with DCIS, but mastectomy could be performed for any patient if it were her preference.

When is mastectomy appropriate?

Although breast conservation may be the goal of treatment for DCIS, mastectomy is indicated in the following circumstances:

1. Large areas of DCIS so that the entire lesion cannot be adequately excised (see the section on margins, later) while preserving a cosmetically satisfactory breast
2. Multiple areas of DCIS in the same breast that cannot be encompassed through a single incision (there may be a small group of patients with two, or even more, tiny areas of low-grade DCIS who might be treated by local excision alone, but radiation oncologists are uncomfortable treating patients with more than one site of DCIS in the same breast)
3. Inability to undergo radiation therapy because of other medical problems (e.g., collagen-vascular disease, prior radiation to the chest for another illness) and for whom treatment by excision alone is not appropriate³²

Skin-sparing mastectomy with immediate reconstruction is suitable for most DCIS patients who require mastectomy, especially if the diagnosis had been made by core biopsy. This technique still must remove nipple and areola, and we usually include a small (1-cm) rim of skin around the areolar margin. If an open biopsy has been performed, it is safest if this biopsy site is excised with the mastectomy specimen, either in continuity or separately. If a surgical biopsy incision is so far from the center of the breast that it cannot be included in the skin-sparing incision easily, two incisions can be employed, excising the biopsy site separately. This approach differs from what would be the recommendation for invasive cancer. Proximity of DCIS to the back of the breast (i.e., a close posterior margin) is irrelevant in DCIS if the pectoral fascia is excised with the mastectomy specimen. A close posterior margin should not imply the need for postoperative radiation therapy to the chest wall, as it might if the primary lesion had been invasive cancer.

When and how is breast conservation employed?

Most women with DCIS are candidates for breast conservation, which involves wide local excision of the disease within

Table 23–1 Ductal Carcinoma In Situ Protocol: Information Essential for a Therapeutic Recommendation for Breast Conservation

1. The extent of the calcifications in the breast on the preoperative mammograms
2. Proof that all of the malignant calcifications have been removed on a postexcision mammogram
3. Review of all of the slides made from the tissue removed at the time of biopsy to document the absence of invasion
4. New slides made from the paraffin blocks of the tissue removed, looking for invasion if any questions remain and for the determination of immunohistochemical markers
5. Margin status, confirming at least 10-mm clear margins around any evidence of ductal carcinoma in situ, or completely negative shaved margins from the biopsy site

the breast, with or without accompanying radiation therapy (Table 23–1). All patients for whom breast conservation is anticipated should undergo a postexcision mammogram to ensure that all of the suspicious calcifications have been removed. This step may be avoided only if the specimen radiograph performed at the time of initial biopsy shows all of the suspicious calcifications to be well within the excised tissue, and the margins are widely clear (≥ 10 mm) microscopically. Even then, it is not redundant to obtain a postbiopsy mammogram before giving a final recommendation about treatment. The timing of the postbiopsy mammogram is flexible. Because any residual calcifications must be imaged, the mammogram should not be performed until the patient is comfortable enough to undergo the compression that is necessary to achieve a technically optimal mammogram. Magnification films of the biopsy site are also advisable. In some patients, this postbiopsy mammogram may not be feasible for 2 or 3 months after the initial biopsy. Patients and physicians should not feel intimidated by any delay necessary to complete this important step, because the treatment of DCIS is not an emergency. In fact, contraction of the surgical biopsy site is an advantage if re-excision is planned. The volume of tissue removed at the second operation is usually less if the procedure is performed later rather than sooner after the initial procedure.

What is the significance of clear surgical margins in the treatment of ductal carcinoma in situ?

Several factors may influence the likelihood of recurrence after breast conservation, including the size or volume of DCIS within the breast, the biology (nuclear grade) of the malignant cells, the age of the patient at diagnosis, and the width of the surgical margin around the area of DCIS. Only one of these can be controlled by treatment, namely, the width of the margin. Virtually all of the published data about DCIS indicate that wider margins are associated with a lower likelihood of recurrence (second event), so that the only argument is the appropriate width of this margin. We agree that the margins should be at least 10 mm circumferentially around any area of DCIS. This margin width seems to be the best compromise between achieving a suitable cosmetic result and minimizing the likelihood of a second event.^{32–34}

Because clear surgical margins seem to predict success when breast conservation is employed, whether the breast is

irradiated or the patient is merely observed after excision, appropriate attention should be paid to achieving clear margins. The careful excision of a small area of calcifications is more difficult than a breast biopsy performed for a palpable lesion, especially if the surgeon wishes to spare a small breast from a significant cosmetic deformity. Not infrequently, a second specimen may be required to ensure that the mammographic abnormality has been removed. Because most needle-guided biopsies are performed for benign disease (our current benign-to-malignant ratio is 3:2, 40.7% of needle-guided biopsies proving to be for malignant disease), the pathologist's enthusiasm for the appropriately defined specimen must be tempered by the surgeon's and the patient's concern about the total outcome, including cosmetic concerns.

How the margins are measured is also variable, with most pathologists relying on inking the edges of the specimen in different ways (e.g., applying different colored inks each 90 degrees around the periphery of the specimen). We have never accepted this technique as optimal. These specimens are not smooth marbles that lend themselves to being coated by India ink in a uniform way. The excised tissue contains "nooks and crannies" related to varying proportions of fat, stromal elements, and glandular breast tissue. Excision of the primary site with separate dissection of the margins and the base of the wound and the application of metallic clips to these sites is our preferred alternative. This part of the procedure is best described as trying to peel an onion from the inside out. After the "lesion" has been excised according to the surgeon's judgment (best guess), arcs of tissue are excised from the edges of the biopsy site—for example, the superior, inferior, medial, and lateral wound margins—and from the base of the wound (the deep margin). As many marginal biopsies may be taken as the surgeon feels is appropriate. Each of these specimens is submitted to the pathologist in formalin in a separate, labeled container. If a single margin is positive, the appropriate area in the breast can be re-excised. If multiple margins are involved, perhaps the patient would be better served by mastectomy. Although we do not perform frozen sections on these marginal biopsies, if one did so, a positive frozen section margin would allow the removal of additional tissue at that site before closing of the wound.

The importance of margins was also discussed at the Philadelphia DCIS Consensus Conference in April 1997. The surgeons present at this conference generally felt that this technique of assessing margins by their separate excision was at least equivalent to the pathologists' inking putative margins of an excised specimen.²⁶ What's been left behind is more important than what's been removed! This is especially appropriate for the many patients with DCIS who have been referred for treatment recommendations following initial biopsy and diagnosis elsewhere. Re-excision of the primary site and dissection of wound margins and base are more precise than inking the margins of the specimen because the specimen is almost never uniform in its consistency or shape.

How should the excision site be managed?

When the specimen is sent to the pathologist, grossly apparent areas of abnormality may be examined by frozen section, and if malignancy is confirmed, a portion of the specimen may be

saved for receptor and cytometric studies. It is more important, however, to determine invasion, if present, because treatment decisions in these particular cases are more likely related to the presence of invasion than to the quantification of receptors. Moreover, these studies may be performed subsequently, with even more accuracy, by immunohistochemical assay on formalin-fixed tissue from the paraffin blocks.

The earlier detection of mammographic abnormalities has led to greater technical difficulties for the surgeon and surgical pathologists. More often than not, there are no grossly apparent abnormalities in the breast tissue even though the calcifications are known to be within the specimen. We rely on the radiologist to confirm the presence of the calcifications within the excised tissue by specimen radiography, and often a clip is placed at the exact site within the specimen, as small as it may be. Both the specimen and the specimen radiograph are sent to the surgical pathologists so that they can be alerted to the exact site of the area of greatest concern, even within an already small specimen.

Additionally, because the orientation of the intraductal disease is segmental and often follows the distribution of the ductal anatomy, there is justification for excision of DCIS with orientation of the specimen toward the nipple. This implies a pyramid-shaped specimen, the apex of this pyramid being toward the nipple. When feasible, it is helpful to the pathologist to tag the apex of this pyramid with a suture to orient the specimen more carefully.

The application of metallic clips to wound margins and base offers precise localization of this site on subsequent mammograms. Because recurrence is most commonly detected as new calcifications at or near the same site as the primary lesion, using these clips to demarcate this area on subsequent mammograms facilitates the radiologist's detection of a new problem. We have used this technique of clipping wound margins and base for almost 20 years to prepare patients for irradiation following local excision (and axillary dissection) for invasive carcinomas. Both radiation therapists and radiologists have found it helpful to determine the site of the previous lesion accurately in this way.

How should the operative specimen be handled?

As with most of the treatment algorithms for DCIS, we use size as a treatment criterion. It is relatively easy to measure the area of calcifications on the mammogram, but this measurement often underestimates the extent of the DCIS within the breast. Lagios has suggested that the pathologist cut and embed each specimen sequentially when DCIS is suspected to ensure the most accurate measurement of size.³⁵ This lengthy approach is probably the most accurate one, but it is rarely employed outside research protocols because it is so costly and labor intensive. The ideal surrogate for the measurement of size by step-sections has not been found. What is needed is a technique that is accurate, reproducible, and cost-effective. Many small areas of DCIS are not easily defined by a single dimension, that is, diameter. Some are rectangular or irregular as DCIS propagates along the course of intramammary ducts. Perhaps a preferable measurement should be the total area of DCIS, the greatest length times the greatest width, as

measured by assessment of the area of calcifications on the mediolateral or craniocaudal mammographic projection. If, over time, we could assess more accurately the discrepancy between the mammographically measured disease (calcifications) and the actual disease measured microscopically, an appropriate algorithm could be generated that would be both reproducible and valid. Currently, measurement of the mammographic findings is the most reproducible estimate of size. The specimen radiograph should confirm the excision of the area in question, or a postoperative mammogram is indicated to substantiate this important criterion.

How should the axilla be treated in patients with subclinical DCIS?

Because DCIS is noninvasive, there should be no reason to address the axillary nodes in these patients. Before the advent of axillary sentinel node biopsy, this was not a major question because even the few publications that noted an infrequently encountered axillary metastasis in patients with DCIS did not consider this justification for the routine dissection of the axilla. Because SLN biopsy has so significantly decreased the morbidity associated with axillary surgery, whether SLN biopsy should be part of the treatment for DCIS has emerged as a new question.

If the data about axillary metastasis in DCIS are analyzed carefully, they are almost always associated with the presence of microinvasion or occult invasion in the breast, or with patients undergoing mastectomy because of the extent of DCIS within the breast. The consensus conference in 1999, as did the consensus conference on sentinel node biopsy in 2001, concluded that SLN biopsy is not indicated in patients with DCIS treated by breast conservation with or without radiation.^{32,36} In patients undergoing mastectomy for DCIS because of the wide extent of malignant-appearing calcifications in the breast, SLN biopsy is an appropriate consideration for two reasons: (1) should there be unexpected invasion detected in the specimen, a subsequent axillary procedure after mastectomy is difficult; and (2) in the presence of widespread DCIS in the breast, even the most careful microscopic examination of the specimen might overlook a tiny area of invasion. In these cases, the pathologist's diagnosis of noninvasive disease may be entirely correct, but only for the sections studied, irrespective of how carefully the specimen is dissected. It is virtually impossible to serial-section the entire breast in these cases to rule out the presence of invasion without equivocation, and the negligible morbidity of SLN biopsy in these patients is warranted to gain the additional assurance of a negative axilla.

What has been the experience treating patients with ductal carcinoma in situ by irradiation?

Comparing treatment of DCIS by lumpectomy only and lumpectomy and irradiation, the National Surgical Adjuvant Breast Project (NSABP) has reported the results of their Protocol B-17, initially in 1993 with an update in 1997^{37,38} (Table 23–2). Radiation decreased the likelihood of both invasive and noninvasive recurrence. Invasive recurrence after radiation was 3.9%; after lumpectomy alone, it was 13.4%; recurrence as DCIS only was 8.2% in the irradiated group and 13.4% in nonirradiated patients. On the basis of this study, the NSABP recommended radiation therapy for *all* women with DCIS when breast preservation was employed.

The European Organization for Research and Treatment of Cancer (EORTC) also carried out a prospective randomized trial comparing radiation and local excision alone for DCIS. In their preliminary reports, this group also noted a reduction in the incidence of invasive and noninvasive recurrence in the radiated patients.³⁹

Solin and colleagues, in a multi-institutional study, followed a group of 418 women (442 cases of DCIS) treated by breast conservation for a median follow-up time of 9.4 years. All of these women underwent radiation therapy for DCIS. Of this group, there were 48 local recurrences, with a 15-year actuarial rate of local recurrence of 16%. These data supported their conclusion that irradiation was an appropriate treatment for DCIS.⁴⁰

Unfortunately, these widely read and accepted publications failed to contain any subset analysis, based on morphologic or biologic parameters, that might identify subgroups of the DCIS population who might fare as well with local excision alone. The NSABP recommendation was for irradiation for *all* DCIS patients who have breast conservation. In some respects, the NSABP reports, carrying the weight of a prospective clinical trial by a widely respected group of investigators, were a giant leap backward in the treatment of DCIS. We and others have strongly emphasized the importance of multiple factors, such as tumor size, margin status, nuclear grade, necrosis, steroid hormone receptors, growth rate, and immunohistochemical markers, that may determine the likelihood of recurrence after breast conservation. Various combinations of these factors may predict more precisely which patients may be treated by breast conservation alone, which might require radiation, and which might be best served by mastectomy.

Table 23–2 Results of Local Excision and Radiation Therapy for Mammographically Detected Ductal Carcinoma In Situ

Study	No. of Breasts	Follow-up Time (months)	Recurrence (%)	Invasive (%)
Silverstein et al., 1999 ³³	237	106 (mean)	20	46
Fisher et al. (NSABP), 1999 ³⁸	410	128 (mean)	15	48
Solin et al., 2001 ⁴⁰	422	112 (mean)	16	53
Julien et al. (EORTC), 2000 ³⁹	507	51 (median)	10	45

Table 23–3 Results of Treatment of Ductal Carcinoma In Situ by Local Excision and Surveillance Alone

Study	No. of Patients	Follow-up Time (months)	Recurrence (%)	Invasive (%)
Schwartz, 2002 ⁴⁶	256	75 (mean)	28	37
Schreer, 1996 ⁴⁵	102	31 (mean)	14	60
Arnesson et al., 1989 ⁴³	169	80 (median)	22	36
Silverstein et al., 2003 ⁵¹	346	70 (mean)	28 (10-yr actuarial)	41
Lagios et al., 2002 ⁴¹	79	135 (mean)	22	59

What is the contemporary experience with treating selected patients with DCIS by excision alone?

In 1975, Lagios and coworkers began to offer selected patients with DCIS the possibility of local excision only, neither mastectomy nor irradiation⁴¹ (Table 23–3). Their studies of these women have been the most elegant and their follow-up has been the longest. Thus far, 22% of their patients have developed local recurrence, either further DCIS or invasive duct carcinoma, after a mean follow-up of 135 months. No breast cancer deaths have occurred in this group. Independently influenced by similar observations and in response to patients' greater participation in their own health care, in 1978 we began to offer highly selected patients the same option—local excision alone—with the caveat that perhaps as many as 30% to 40% (our initial estimates) of patients so treated would develop a subsequent invasive carcinoma of the same breast.

The surveillance option after local excision for patients with LCIS having been championed by most investigators, extrapolation of the same treatment from LCIS to DCIS was understandable, but not accurate. The follow-up observations of Haagensen about LCIS provided evidence for a more firm commitment to the surveillance option for LCIS. At the time this study was initiated, however, there was only a smattering of information available about patients with DCIS treated by local excision alone. Since that time, other reports have been published, but they have almost invariably addressed DCIS generically, without separating cases considered subclinical from the others. Thus, it has been difficult, almost impossible, to glean meaningful information about the treatment of *subclinical* DCIS from the extant literature. In addition to the 79 patients reported by Lagios, however, there were both British and Swedish reports of patients with subclinical DCIS, detected by mammographic screening, treated by excision and surveillance alone. The group of patients reported by Carpenter and colleagues from Charing Cross Hospital in London included 28 women treated by excision alone, with a mean follow-up of about 3 years.⁴² Four women (14%) had subsequent local recurrence. The group of women reported by Arnesson and associates from the University Hospital of Linköping, Sweden, included 38 treated by local excision alone.⁴³ After a mean follow-up of 60 months, 5 patients (13%) had recurrence.

In 1992, we reported our own initial experience with 72 cases of subclinical DCIS in 70 patients treated by local excision and surveillance alone. The mean and median follow-up times for this group were 49 months and 47 months, respectively, with the longest follow-up being 168 months. Of the lesions in this group, all were detected as calcifications

on a screening mammogram or as an incidental finding in a biopsy performed for another reason (60 and 12, respectively). Eleven patients (15.3%) had recurrence—either further DCIS (8) or invasive duct carcinoma (3)—with the recurrences being detected from 8 to 85 months after initial diagnosis.⁴⁴

Our rate of recurrence was comparable to that reported by Lagios; we differed only in the likelihood of invasion. He noted that half of the recurrences in his series were invasive. Arnesson observed 40% (2 of 5 patients) invasive recurrence, and Carpenter found only DCIS in the 4 patients who developed recurrence after local excision alone. None of these earlier studies, our own or those of Lagios, or the two European series, included enough patients to speak authoritatively about the subsequent danger of developing “worse” (i.e., invasive) cancer after initial treatment for DCIS.

Schreer reported her results of DCIS treated by local excision alone in 102 cases, with a mean follow-up of 56 months.⁴⁵ Recurrence was noted in 23.5% of patients, and 42% of these were invasive in character. Of the patients who had recurrence, 22 of 24 did so at or near the same site as the initial disease had been detected.

Our own updated experience with excision alone is noted in the following section.

Which patients with ductal carcinoma in situ may be managed by excision alone?

Because neither the NSABP nor the EORTC tried to define subsets of patients who might have done equally well without radiation therapy, and encouraged by our initial success, we have continued to offer highly selected patients with DCIS the opportunity to be treated by local excision and surveillance alone. The selection criteria are as follows:

1. *Calcifications not more than 6 cm² in area as measured on the mammograms, in either the craniocaudal or the mediolateral projection.* This is similar to Lagios's criterion of not more than 2.5 cm in diameter, but because the distribution of calcifications on the mammogram is often linear and rectangular rather than circular, this measurement of area rather than diameter alone may be more appropriate and easier to determine. This rule may be broken for patients with slightly larger areas of DCIS if the breast is large enough to accept a wider local excision with a good aesthetic result. To some degree, it is size of DCIS versus size of breast that helps in this determination. See criterion number 3, below.
2. *Absence of invasion or microinvasion.* The inclusion of patients with what is called *microinvasion* with those who

have entirely noninvasive lesions leads to a greater incidence of recurrence and will adversely affect outcome. Failure to treat the entire breast in patients with invasion, however “micro” it is described, jeopardizes overall survival.

3. *Adequate local excision of the primary site.* As already mentioned, this is the only criterion that the surgeon can control because tumor biology and size are intrinsic properties of the tumor itself. Attention to the margins of the excision specimen is the surgeon’s responsibility. The goal of excision is the best compromise between the cosmetic result and the widest possible local excision, the optimum being greater than 10-mm (1.0-cm) clear margin in all directions around the area of DCIS. A patient with a small breast has little tolerance for a large excision, whereas a buxom patient can obviously lose more tissue volume around the edges of her area of DCIS. It is for this reason that the actual size of the measured area of calcifications on the mammogram is only a relative criterion for the use of surveillance as opposed to radiation or mastectomy.
4. *Localized disease.* Recurrence is more likely if there are multiple foci of DCIS within the breast. Radiation therapists also generally prefer not to treat these patients. Therefore, when the mammogram shows more than a single site of malignant-appearing calcifications, mastectomy is usually considered. This admonition about multiple foci becomes only a relative contraindication when the areas in question are small and near each other. If all of the suspicious areas of calcification can be excised through a single incision, and clear margins are achieved around the entire site, then surveillance remains an option to consider. If, however, DCIS is proven at several areas of the breast that are geographically unreachable through the same incision, then mastectomy is the most reasonable and safest treatment option.
5. *Nuclear grade or presence of comedo features.* It has been argued that patients with the comedo subtype of DCIS will have recurrence if the whole breast is not treated. Our own observations do not support this conclusion entirely, although we do agree that the more aggressive-appearing forms of DCIS are more likely to recur than those with different architectural features. The presence of comedo features alone is not enough to disqualify a patient for consideration of breast conservation if adequate margins can be achieved.
6. *Absence of residual malignant-appearing calcifications on a postexcision mammogram.* Even if the specimen radiograph shows that the calcifications provoking the biopsy have been removed and match the preoperative mammograms, an additional postoperative mammogram is recommended. This should include magnification films of the site. If this film must be postponed until the breast is comfortable enough to undergo the films optimally, so be it. No jeopardy to breast or outcome is incurred by whatever interval is required to ensure that all of the calcifications have been removed.
7. *A compliant, motivated patient.* The patient who undergoes breast conservation for DCIS, with or without radiation, must accept the lifetime need for careful follow-up. The first mammogram of the affected breast is performed 6 months after treatment. Mammograms are then taken at 6-month intervals for 3 years, then annually thereafter. The

contralateral breast is imaged annually. Clinical examinations are at 6-month intervals.

Using these criteria for selection, we reported our own results of breast conservation *without* radiation therapy in 249 women (256 breasts) in 2002.⁴⁶ Although not randomly selected for treatment, this is one of the largest groups of its kind, all patients treated by one surgeon in the same manner, with all of the pathology data reviewed by the same team of pathologists. The mean and median follow-up times of this group of 256 breasts are 75.6 and 66.5 months, respectively, with the longest follow-up being 247 months. The 5-year actuarial recurrence rate of our patients is 14.1%; the 15-year actuarial recurrence is projected to be 24.6%. This is slightly higher than the recurrence rate observed after radiation therapy for similarly selected patients. Of this entire group of breasts, there have been 71 “second events,” either DCIS or invasive cancer, or 27.7%. Of this group, 45 of 71, or 63.4%, were DCIS only; the remaining 26, or 36.6%, were invasive recurrences. No distinction was made between microinvasive (T1mic) and frankly invasive (T1 or greater) cancer. These observations, however, suggest that only a small proportion of these carefully selected women with subclinical DCIS will develop a potentially life-threatening (i.e., invasive) cancer. Our occurrence of subsequent invasive cancers continues to be less than that described by most investigators. The usually quoted figure is about half DCIS and half invasive recurrence. Ours is about two thirds DCIS and one third invasive, either microinvasion or frankly invasive cancer. At the time of this writing, the number of women currently being followed who have been treated by local excision and surveillance alone is more than 350.

Another interesting observation in this group of women is the time from initial diagnosis until the second event. Forty of the 71, or 56%, experienced the second event within 36 months of the initial diagnosis. In these 40, 60% of the DCIS second events and 50% of the invasive second events occurred within this 36-month interval. Speculating about the growth rates of these and other cancers, it is tempting to suggest that these patients did not have recurrence, but rather *persistence* of incompletely excised DCIS in the same area of the breast. All but two of our patients had their second event occur in the index quadrant, at or near the same site as the initial finding. If these observations stand and can be confirmed, they provide clues to the natural history of this disease. Moreover, if the breast is not treated by more than a wide local excision at the site, that breast remains at the same risk for developing a new, unrelated cancer as the other breast. We should never expect recurrence to be zero. These observations also make us reluctant to use the term *recurrence* for the second event that occurs in the same breast. Within this initial 3-year time period following the initial diagnosis, and perhaps even longer, whatever happens in that same breast is almost certainly persistence rather than recurrence of the disease initially detected. Because the calcifications that prompted the biopsy occur only after some degree of intraductal necrosis, we know that despite a successful local excision, there may be additional microscopic disease elsewhere in the same breast. For those women in whom this additional disease is or becomes clinically significant, progression through the natural history of DCIS will produce more calcifications and lead to subsequent detection similar to the first episode.

If our observations about second events are considered further, only about 10% of these women with DCIS developed invasive cancer following local excision alone. Even if this number is higher, should we be treating 100% of this group of women with radiation (or mastectomy) if only this small proportion will develop a theoretically life-threatening cancer subsequently? Should we not try to be more selective? Additionally, because an ipsilateral second event after radiation therapy usually calls for mastectomy, does the use of radiation at the time of initial diagnosis preclude an additional attempt at treatment by further local excision alone? Of our patients who have experienced their second event as DCIS alone, several have chosen to continue surveillance alone, without radiation or mastectomy. This includes one woman with bilateral DCIS with bilateral recurrence. Most of our patients in this situation are elderly (>70 years old), so that their concerns are not the same as if they were 30 years younger.

Documenting these observations about the nature of recurrence is crucial. If careful surveillance detects recurrence while it is yet noninvasive, patients may be more enthusiastic about this alternative to mastectomy or irradiation, because of the implication that recurrence (as DCIS only) does not endanger the patient. If a sizable segment of the group treated by excision and surveillance, however, does develop invasive carcinoma as the first sign of recurrence, there will be a small fraction of this group who will undoubtedly die from this disease, and for those women, however few, the price of surveillance alone was too high.

What is necessary to permit a more confident recommendation for local excision and surveillance alone for patients with ductal carcinoma in situ?

The challenge to those of us who would advocate local excision and surveillance as an option for those women whose subclinical DCIS is detected by screening mammography is to define precisely the ultimate risk for developing *invasive* cancer, not further DCIS—not only the likelihood that invasive cancer might occur, but also within what period of time it may occur. We must try to develop biologic markers that predict who is at greatest risk. Currently, tumor size, margins, and nuclear grade are the criteria often cited to suggest that certain patients with DCIS are more likely than others to develop recurrence. For example, the incidental finding of DCIS in a specimen of tissue removed for another reason has not been associated with either microinvasion or multicentricity, and no patient with incidental DCIS treated by excision and

surveillance has yet developed recurrence, either invasive carcinoma or DCIS.

What criteria may predict local recurrence?

The features associated with comedocarcinoma that are generally thought to predict local recurrence are the nuclear grade of the malignant cells and the degree of intraductal necrosis. Because intraductal cellular necrosis leading to calcification is the hallmark of detection of these lesions, and most DCIS is detected within clustered calcifications, it is not surprising that comedocarcinoma is the most common single histologic type of DCIS encountered. It is the presence of intraductal necrosis that provokes the term *comedo* as a modifier. The implication of intraductal necrosis needs to be reconsidered; all the lesions that were formerly defined as the comedo type of DCIS may need to be reclassified, based on other attributes, such as nuclear grade and presence, amount, and distribution of necrosis.

The first such attempt at categorizing subsets of DCIS to devise treatment algorithms is that proposed by Silverstein and colleagues—the Van Nuys Prognostic Index.⁴⁷ Despite valid criticism, this was the first time that investigators tried to fit an algorithm to individual patient circumstances to justify differences in treatment recommendations. Recently, Silverstein modified his prognostic index, renamed the University of Southern California Van Nuys Prognostic Index, to include age as an independent variable⁴⁸ (Table 23–4). His experience suggests that age is an independent variable that also factors into the likelihood of recurrence, younger women being more likely to have recurrence than older women. His index divided patients' ages into three groups: 39 and under, 40 to 60, and 61 and older. The index divided each of these factors (i.e., patient age, size of carcinoma, nuclear grade, and margin width) into a three-point system, with the total number of points, minimum 4, maximum 12, predicting the likelihood of recurrence. The higher the point total, the greater the chance of recurrence. Silverstein suggested that women with 4 to 6 points be considered for local excision alone and that those with 10 to 12 points were candidates for mastectomy. The intermediate group presents the greatest difficulty for treatment recommendations, although if the score is adversely affected by the margin width, an attempt should be made to re-excise the margins if breast conservation is desired. These are the patients for whom radiation therapy may be indicated. Whether this index can be consistently and reproducibly used elsewhere by surgeons, pathologists, and radiation oncologists in less dedicated practices remains a question.

Table 23–4 University of Southern California Van Nuys Prognostic Index Scoring System⁴⁸

Parameter	Score		
	1	2	3
Size (mm)	≤15	16–40	>40
Margin width (mm)	≥10	1–9	<1
Pathologic classification	Not high grade without necrosis (nuclear grades 1 and 2)	Not high grade with necrosis (nuclear grade 1 or 2)	High grade with or without necrosis (nuclear grade 3)
Age (yr)	>60	40–60	<40

We do not believe that this or any other “prognostic index” should be dogmatically used to influence treatment; we do believe that it represents a way to evaluate the variables that predict the behavior of DCIS and the likelihood of recurrence. In our own experience, for example, we have not found age to be a factor that independently influences recurrence, at least not when we have divided our patients into two groups, younger than 50 years and older than 50 years. It is probable that younger women have a greater chance of having nuclear grade 3 disease than older women; this alone would affect the chance of recurrence.

Molecular markers such as estrogen and progesterone receptors, Ki-67, *p53*, *HER-2* expression, *p21*, and others, have been explored as offering independent information about the likelihood of recurrence. None of these determinations has yet shown the ability to divide patients into subsets on which treatment recommendations can be reliably based. In most cases, unfavorable marker measurements correlated only with higher nuclear grade. In our own experience, the only statistical difference was noted when we used a combination of *p53* and *HER-2*. Patients had a greater chance of recurrence if both markers were elevated than if they were not. As noted very early in this chapter, perhaps gene expression patterns analyzed by cDNA microarrays will provide a “molecular portrait” of each lesion that correlates with recurrence.

Why is excision alone also appropriate considering current knowledge about ductal carcinoma in situ?

Another major reason to regard excision and surveillance as an option for many of these patients is the occasional difficulty in diagnosis. Although DCIS and ADH are not difficult to distinguish from each other in most cases, the line separating borderline lesions is fuzzy rather than precise, and skilled pathologists often interpret the same slides differently.²² Patients whose pathologists’ reports do not address these subtleties and merely state “benign” (ADH) or “malignant” (DCIS), without a modifier, might receive vastly different treatment recommendations from other patients with the same nonspecific designations. It is therefore important to resist making an immediate decision when encountering subclinical DCIS and to review and re-review the entire specimen. For example, we have encountered several biopsy specimens initially called DCIS but later reclassified by two senior surgical pathologists as ADH hyperplasia. Such lesions are appropriately treated by surveillance alone, especially if equivalently experienced pathologists disagree about the exact diagnosis.

What is the role of tamoxifen in the treatment of ductal carcinoma in situ?

As tamoxifen has become an important adjunct to the treatment of invasive cancer, its role in DCIS has also been questioned. Few studies, however, have analyzed the long-term effects of tamoxifen after treatment for DCIS. The NSABP B-24 trial did address this issue, randomizing DCIS patients to tamoxifen or placebo for 5 years after local excision and radiation; local excision only was not an option.⁴⁹ This study

documented in those receiving tamoxifen a decrease in the occurrence of invasive cancers in the involved breast, but not a significant decrease in the occurrence of DCIS. Estrogen receptor activity was not a criterion for prescribing tamoxifen in these DCIS patients. Whether tamoxifen is effective in estrogen receptor–negative DCIS patients is uncertain, but review of the B-24 data suggests that the benefits of tamoxifen in DCIS are confined to women whose DCIS cells are estrogen receptor positive. In many institutions, determinations of steroid hormone receptors, estrogen and progesterone receptors, are not routinely performed for DCIS. We think this is a significant omission, as it would also be in invasive cancers, whether or not tamoxifen is used.

No data are available to confirm or challenge the premise that the use of tamoxifen in women with DCIS prolongs survival, and thus far, no publications have championed the use of tamoxifen to improve survival. Because local treatment alone is so successful, the addition of tamoxifen to the treatment protocol, even if modestly effective in reducing the likelihood of a second event, may not be worth the equally modest risks of treatment. When offered to patients with the information about risks and benefits explained to them in detail, most women in our practice have chosen not to take tamoxifen.

With respect to the use of other hormonal agents (e.g., aromatase inhibitors) in lieu of tamoxifen in postmenopausal patients, no data are available to permit any decisions in this regard. One can only speculate that if these drugs prove to be more effective than tamoxifen in the treatment of invasive cancer, they may also prove to be more effective in the treatment of patients with DCIS.

How is recurrence of ductal carcinoma in situ treated?

Most of the extant literature about DCIS suggests that when a second event occurs following the treatment of DCIS by breast conservation with or without radiation, there is an equal chance of the second event’s being invasive cancer (usually microinvasive) as of its being DCIS. Our own data challenge this equivalence, with only about one third of the second events being any form of invasive cancer, either microinvasion (T1mic) or frankly invasive cancer (e.g., T1). When invasive cancer does occur, however, its treatment should be the same as for any invasive cancer of the same stage. However, the prior treatment of the DCIS may affect these recommendations. If radiation therapy had been employed at the time of the initial diagnosis of DCIS, the only tenable option for the patient is mastectomy, with the same attention to the axilla as if this were a primary cancer. Whether the newer techniques of partial breast irradiation may be employed in this situation is a subject for a clinical trial and must be considered investigative. If the initial treatment had been local excision alone, the option of breast conservation—namely, wide local excision, SLN biopsy, and radiation therapy—remains applicable, as if this were a primary breast cancer.

If the second event is DCIS only, without evidence of invasion, the usual recommendation for patients who have undergone previous radiation therapy remains mastectomy (with consideration of SLN biopsy). If, however, the initial treatment had been local excision alone without radiation, several

options remain open. The patient may be treated again by local excision alone, by local excision and radiation, or by mastectomy, using the same criteria cited at the time of her initial diagnosis. Although there may be a greater risk for additional recurrence in these patients, there are no data to suggest that any of these choices is now associated with a greater threat to life. We have treated several patients with second, and even third, DCIS events in the ipsilateral breast by additional attempts at local excision alone. It has been our experience, however, that as additional events occur, patients become more willing to undergo mastectomy and reconstruction instead of waiting for the “next shoe to drop.” Nevertheless, none of our patients has yet developed systemic metastasis, even when an invasive cancer has been the second event.

What is the threat to life from ductal carcinoma in situ?

Irrespective of the recommendations for treatment—mastectomy, breast conservation with radiation, or breast conservation alone—and with or without the addition of tamoxifen, the available data indicate that DCIS is rarely life-threatening, even when it recurs. Ten-year disease-specific survival is reported between 96% and 100%.⁵⁰ In our own practice, the only patient with DCIS who has died from breast cancer is an elderly woman who developed an invasive cancer of the contralateral breast about 5 years after her treatment for DCIS by local excision alone. The contralateral breast cancer was unrelated to the initial diagnosis of DCIS. She subsequently developed metastatic disease, presumably from the invasive cancer, without ever demonstrating evidence of local recurrence of the DCIS.

Because of the very small long-term threat associated with the diagnosis of DCIS, and because the publications that recommend radiation as the treatment for all patients with DCIS still recognize that as many as 80% of the patients will not develop a recurrence or a second event when treated by local excision alone, we must continue to search for the specific characteristics of DCIS that will permit us to separate precisely those destined to recur from those that will never be a threat to either breast or to life. Current information about nuclear grade and margins, for example, is but a crude basis on which to separate patients into treatment recommendation categories.

Our experience thus far has reinforced our own impression that for most patients with DCIS, wide local excision, with margins of at least 10 mm, is treatment enough, presuming that the local excision can be achieved with a cosmetically acceptable breast. Patients with large or multiple areas of DCIS are better treated by mastectomy, so that our own greatest dilemma is really which patients with DCIS are best served by radiation therapy after local excision. If one accepts the NSABP results (which is a significant leap, because not all investigators accept their data as totally valid), why should we irradiate 100 patients to benefit 10? Because 10% of DCIS events will recur even with radiation, and 80% will not recur even without radiation, should we not be searching for the characteristics of patients or disease that identify the 10% who truly benefit from radiation therapy? The same analysis applies to the addition of tamoxifen; our information about tamoxifen is even more speculative than that about radiation.

That the patient must recognize the limits of our current knowledge about this disease is implicit in the mutual agreement between patient and physician to choose breast conservation as an option. A clear understanding of the biology and natural history of the disease that we call subclinical DCIS still eludes us. As clinicians, we have been involved in the care of too many women with lethal breast cancers, so that reluctance to abandon traditional treatment in favor of lesser options is understandable. Our respect for breast cancer is too great! “Overkill” has always been assumed to be a more sound philosophy than “underkill” when dealing with malignancy. If we could be convinced that certain diseases that we currently call malignant, such as DCIS, are not inevitably followed by invasive, life-threatening cancers, and that even if recurrence does occur, there is a second opportunity for successful interference, perhaps there would be greater enthusiasm for less, rather than for more, treatment. Unless we can enroll our patients in protocols that observe rather than always treat this disease, we will never know which, if any, women with DCIS can be merely observed without facing the specter of subsequent invasive breast cancer.

Surgery for Breast Cancer

Daniel F. Roses and Armando E. Giuliano

The surgical options for the treatment of breast cancer have greatly broadened in recent decades as the acceptance of breast conservation and local radiotherapy, selective surgical approaches to axillary lymph nodes, reconstruction, and adjuvant systemic therapy, as well as the adoption of more precise approaches to radiographic and pathologic assessment, have made treatment far more selective. The retreat from a uniform reliance on mastectomy, however, has often blurred a definition of the appropriate extent of surgery. This lack of precision reflects in turn an uncertainty about the impact that different forms of local treatment may have on survival. Nevertheless, despite paradigms of breast cancer biology that emphasize the importance of systemic rather than local therapy, and therapeutic strategies that incorporate nonsurgical modalities for both local and systemic disease, modern breast cancer treatment continues to require, and has even amplified, the application of sound surgical principles and techniques for both the local control and the appropriate staging of disease.

DEVELOPMENT AND TOPOGRAPHIC ANATOMY OF THE BREAST

An appreciation of the topographic anatomy of the breast is essential not only for clinical and radiographic diagnosis but also for planning surgical strategies and delineating the optimal sites for incisions as well as the extent of the breast parenchyma and regional lymphatic drainage. An ever-increasing emphasis on the opportunities to achieve a satisfactory or even excellent aesthetic result through breast conservation or reconstruction, as well as an emphasis on more limited surgery for the axilla, has made topographic considerations in breast cancer surgery of particular importance.

How does breast topography develop embryologically?

Embryologically, the breast develops from an ectodermal ridge found in a 7-week embryo extending on each side from the base of the forelimb to the region of the hind limb.¹ This milk line persists by the ninth week only in the region of the future pectoral muscles, the remainder having involuted, although fragments may persist in a line from the axilla to the pubis. In a small percentage of women, this accessory tissue persists as accessory nipples, known as *polythelia*, or as accessory parenchyma in locations along this epithelial milk

line, most commonly in the region of the axilla. Rarely, an ectopically located remnant may develop into a formed mammary gland, known as *polymastia*. Conversely, the breast may fail to develop completely, referred to as *hypomastia* or *micro-mastia*; may not develop at all, known as *amastia*; or may fail to develop with an intact nipple, known as *amazia*. Complete or incomplete development of the breast may also be associated with an absence of the pectoral muscles and syndactyly, referred to as *Poland's syndrome*, after its original recognition by Alfred Poland in 1841.^{2,3} His original description followed an anatomic dissection of a cadaver with this anomaly that he observed while a medical student. Subsequent reports added the additional component of hypoplasia, or complete absence of the breast, as well as costal cartilage and rib defects.

In the third month of gestation, squamous epithelial cells infiltrate from the persistent ectodermal mass into the underlying mesenchyme in the pectoral region. The ductal epithelium develops from these invading epithelial buds, which further develop 16 to 24 secondary buds that will go on to develop into the lobes of the mature breast that radiate from the central nipple. Also in the third month, the original mesenchymal cells differentiate into the smooth muscle of the nipple and areola.

At the end of prenatal life, the epithelialized sprouts are canalized into the major lactiferous ducts, while secondary buds go on to form the small ducts leading to alveoli or terminal secretory ductules. Each of the lobes has excretory ducts and a single lactiferous duct, which opens into a lactiferous sinus situated beneath the nipple. Occasionally, the lactiferous duct terminates at the site of original epithelial invagination without development of an everted, formed nipple, which persists into adult life as an inverted nipple. At puberty, generally between the ages of 10 and 13 years, the lobes further develop their subdivisions, or lobules, which terminate in the alveoli or secretory units of the mature breast.

The mammary glands develop in much the same way as other apocrine glands, of which they are considered modifications. The glands of Montgomery around the areola, the secretion of which serves as a source of lubrication of the nipple during lactation, are considered as transitional between sweat and lactiferous glands. Sweat glands, as well as sebaceous glands and hair follicles, may also be found on the areola and periareolar skin. The connective tissue support for the mature breast, the suspensory ligaments first described by Sir Astley Cooper,⁴ forms at puberty from the mesoderm, from which the dermis of the skin as well as the subcutaneous superficial fascia also develop (Fig. 24–1).

What is the anatomic extent of the normal adult breast?

The rudimentary structures found in both the male and prepubertal female increase in size in the female at puberty and extend radially into the underlying breast fat. While each breast has a defined appearance on the unilateral, anterior chest wall, extending from the edge of the sternum medially to the anterior border of the latissimus dorsi muscle laterally and from the second rib superiorly to the seventh rib inferiorly (Fig. 24-2), ductal tissue may be found extending to the

clavicle and below the inframammary crease, as well as overlying the sternum, where it may fuse with the contralateral breast. About two thirds of the breast overlies the pectoralis major muscle, whereas the inferior and lateral extension overlies the serratus anterior muscle. The greatest density of breast tissue is seen in the upper outer quadrant, where it extends toward the axilla and, in fact, enters that anatomic plane through a defect in the encasing fascia of the axilla, described by Langer.⁵ The extension of breast tissue into the axilla through this foramen of Langer, an extension that disrupts the conical topography of the breast, was described by Spence.⁶ A prominence or lesion in this axillary tail of Spence may be

difficult to differentiate clinically from axillary lymphadenopathy. Discrepancy in breast size is common, as is the density of breast tissue in what appear to be topographically symmetrical breasts.

How is the axilla defined topographically?
