INTRODUCTION

Pulmonary inflammation and fibrosis may concur in the context of myriad acute and chronic disorders affecting the lung parenchyma or small airways (e.g., bronchioles). The etiologies of these various disorders have not been clarified, but clinical, radiographic, and physiologic features are often distinctive and overlap between the various disorders. These heterogeneous chronic interstitial lung diseases (CILD) share many of the following clinical features: exertional dyspnea; bilateral infiltrates on chest radiographs; physiologic abnormalities of restrictive lung defect, decreased diffusing capacity (D_LCO), and increased alveolar-arterial oxygen gradient [$P(A - a)O_2$] at rest or with exertion; absence of pulmonary infection and neoplasm; and histopathologic features of inflammation and fibrosis, with or without granulomatous or vascular lesions in the pulmonary parenchyma. Some of the CILD primarily involve alveolar walls and interstitium, but proximal airways may be involved incidentally. In addition, a group of disorders preferentially involve the small airways (terminal and respiratory bronchioles); the distal alveolar spaces may be involved incidentally or may be spared. Disorders affecting the small airways alone are usually characterized by exertional dyspnea; clear chest radiographs with preserved or increased lung volumes; physiologic defects of airways obstruction, air trapping, impaired D_LCO, and widened $P(A - a)O_2$; absence of infection and neoplasm; histopathologic features of constricted small-airway lumina (i.e., constrictive or obstructive bronchiolitis). The spectrum of clinical, radiographic, physiologic, and histopathologic manifestations is wide, and significant overlap between these diverse disorders exists.

Many of these CILD are discussed in detail elsewhere in this text, and their features are not reiterated here; they include idiopathic, collagen vascular-associated, and radiation- or drug-induced pneumonitis/fibrosis; pneumoconiosis and pneumonitis of occupational or environmental origin; sarcoidosis; eosinophilic pneumonias; hypersensitivity pneumonitis; and rare inherited diseases (e.g., neurofibromatosis, tuberous sclerosis, Hermansky-Pudlak syndrome, metabolic storage disorders, and hypocalciuric hypercalcemia). This chapter discusses in detail selected major disease syndromes of unknown etiology exhibiting distinctive clinical, radiographic, or histopathologic features. The clinical course and treatment of these diverse disorders are variable and are discussed in detail in the following sections.

DISEASES OF THE BRONCHIOLES AND SMALL AIRWAYS

Bronchiolitis Obliterans with Organizing Pneumonia

A wide spectrum of inflammatory disorders may involve terminal and respiratory bronchioles, resulting in diverse clinical syndromes. The literature is confusing, as the terms *bronchiolitis obliterans* (with or without organizing pneumonia), *cryptogenic organizing pneumonia, obliterative* (*mural*) *bronchiolitis,* and *organizing pneumonia* have often been used interchangeably to refer to a heterogeneous group of bronchiolar inflammatory disorders with diverse clinical expression. We first review bronchiolitis obliterans organizing pneumonia (BOOP), also called *cryptogenic organizing pneumonia.* BOOP may complicate collagen vascular disease, exposures to toxic fumes or pharmacologic agents, organ transplantation (e.g., bone marrow or lung), or specific pulmonary infections (e.g., *Legionella,* viruses, *Mycoplasma* species). When no cause can be elicited, the term *idiopathic BOOP* or *idiopathic cryptogenic organizing pneumonia* has been applied. BOOP is characterized by a subacute process, focal alveolar infiltrates (mimicking pneumonia), and granulation tissue obstructing small bronchioles and extending into the lung parenchyma. The prognosis and clinical expression of BOOP differ markedly from those of other disorders involving small bronchioles, to be discussed later (e.g., obliterative bronchiolitis, diffuse panbronchiolitis, respiratory bronchiolitis).

Epidemiology

The precise incidence of BOOP is not clear, as many cases have likely erroneously been ascribed to other disorders (e.g., desquamative interstitial pneumonitis, eosinophilic pneumonia, pulmonary fibrosis). BOOP probably has been underrepresented in the literature, as cases lacking histologic confirmation have not been reported. In 1985, Epler and colleagues identified 67 patients with BOOP (17 of whom had collagen vascular disease) gleaned from a review of 2500 open lung biopsies performed from 1950 to 1980. Investigators at Ohio State University detected 16 cases of BOOP within a 4-year period, accounting for 4% of referrals for obstructive lung disorders. Cordier et al. detected 16 cases of BOOP in 6 years at a leading referral center in France. Katzenstein and colleagues identified 24 cases by retrospective review of pathologic files at the University of Alabama from 1972 to 1984. These and other studies suggest that even large referral centers diagnose only two to four cases of BOOP annually. BOOP usually presents in the fifth through sixth decades of life, but persons of any age may be affected. There is no sex predominance.

Clinical Features

Nonproductive cough, dyspnea, fever, weight loss, and malaise are typical presenting features. Despite pronounced constitutional symptoms in some patients, extrapulmonary involvement does not occur. The course is usually subacute, with symptoms developing within 2 weeks to 6 months. An antecedent upper or lower respiratory tract infection or flulike illness is noted in 40%–60% of patients within 1 to 3 months of onset of symptoms. Crackles are present on physical examination in 60% of patients; 40% manifest a mid-inspiratory squeak. Despite the presence of airways obstruction, overt wheezing is rare. Clubbing is not a feature of BOOP, as in is in several other CILD. No characteristic laboratory aberrations are noted. The eythrocyte sedimentation rate is elevated in 80% of cases; one third exhibit leukocytosis.

Chest Radiographic Findings

Chest radiographs reveal single or multiple segmental or lobar alveolar infiltrates in more than two thirds of patients (Fig. 1). A basilar predominance is more common, but any lobe can be affected. Patchy, unilateral or bilateral air space consolidation, often with air bronchograms, has been noted in 62%–79% of patients. In some patients, the infiltrates migrate or wax and wane, either spontaneously or in apparent response to antibiotics. The fleeting nature of these infiltrates may cause them to be mistaken for pneumonia, particularly when patients have been treated with antibiotics. Dense lobar infiltrates with consolidation contrast sharply with the interstitial nature of infiltrates seen in idiopathic pulmonary fibrosis (IPF) and many other CILD. However, diffuse reticulonodular infiltrates, indistinguishable from those of IPF or other CILD, are noted in 20%–40% of cases of BOOP (Fig. 2). In 4%–10% of cases, chest radiographic findings are normal or exhibit only hyperinflation. Pleural effusions, cavitary lesions, and intrathoracic lymphadenopathy are not features of BOOP. The pattern on chest radiographs influences prognosis. Dense alveolar infiltrates are associated with a pronounced component of organizing pneumonia, a more acute course, and greater responsiveness to corticosteroids (Fig. 3). By contrast, a diffuse reticulonodular or interstitial pattern has been associated with a more chronic course and lower rate of response to therapy.

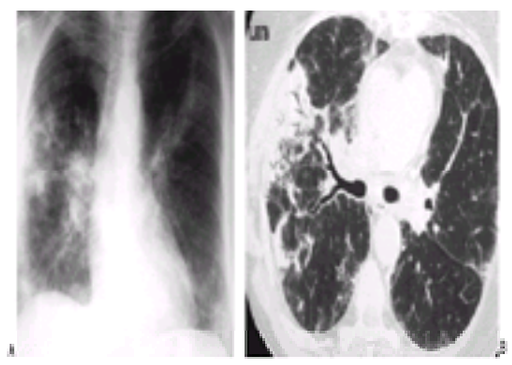

FIG. 1. A: Bronchiolitis obliterans organizing pneumonia. PA chest radiograph from a 67-year-old woman demonstrates patchy bilateral infiltrates. She had been given three prior courses of antibiotics by her personal physician during the preceding 7 weeks because of persistent cough, fever, and dyspnea, with no improvement. Changes revealed by transbronchial lung biopsy were consistent with BOOP, and corticosteroids (1 mg of prednisone per kilogram of body weight per day) were initiated. **B:** CT demonstrates dense alveolar infiltrates with striking air bronchograms in the periphery of the right lung.

FIG. 2. Bronchiolitis obliterans organizing pneumonia. Chest radiograph demonstrates diffuse reticulonodular infiltrates in a 27-year-old woman who presented with a 6-week history of cough and progressive dyspnea. Transbronchial lung biopsies demonstrated features consistent with BOOP. Corticosteroid therapy (60 mg of prednisone daily for 1 month, with a subsequent taper) was initiated, with complete resolution of symptoms and normalization of chest radiograph. (Reproduced with permission from Neagos GR, Lynch JP III. Making sense out of bronchiolitis obliterans. *J Respir Dis* 1991:12;807.)

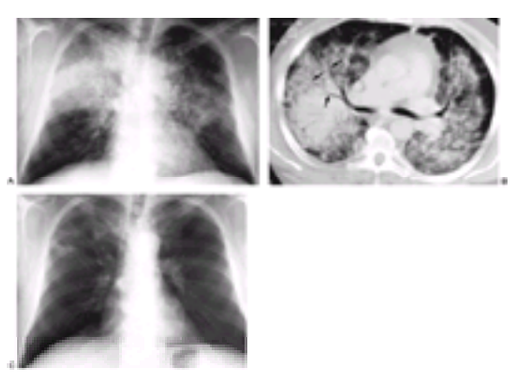

FIG. 3. A: Bronchiolitis obliterans organizing pneumonia. PA chest radiograph from a 62-year-old man demonstrates confluent alveolar infiltrates in both upper lobes with extensive air bronchograms. He had been treated with broad-spectrum parenteral antibiotics for 2 weeks without improvement and with worsening findings on

chest radiographs. **B:** High-resolution CT from the same patient demonstrates confluent alveolar infiltrates and striking air bronchograms (*arrows*). Transbronchial lung biopsies demonstrated typical features of BOOP. Corticosteroids were initiated, and the process resolved during the next few weeks. **C:** PA chest radiograph from the same patient 3 weeks after institution of corticosteroid therapy demonstrates nearly complete resolution of alveolar infiltrates.

High-Resolution Thin-Section Computed Tomography

High-resolution thin section computed tomography (CT) typically reveal single or multiple focal alveolar nodular infiltrates or areas of consolidation (with air bronchograms) (Fig. 1B and Fig. 3B). In some cases, a feeding vessel or bronchus leading into the area of consolidation or nodular opacity may be seen. Reticulonodular interstitial infiltrates are noted in one quarter of patients. Other findings include ground-glass opacities and peribronchiolar nodules extending into the lung parenchyma in a centrifugal fashion from involved airways. Honeycombing is not seen in BOOP. Pleural effusions are observed in <10% of patients and are rarely prominent. Mediastinal lymphadenopathy has been noted, but is usually minor (lymph nodes <1.5 cm in size).

Pulmonary Function Tests

A restrictive defect, with reductions in lung volumes (e.g., vital capacity, total lung volume) is characteristic of BOOP. Other physiologic aberrations include reduced D_LCO, hypoxemia, and a widened $P(A - a)O_2$. Despite the involvement of small airways, a purely obstructive defect is rare (except in smokers). The lack of obstruction has been attributed to the patchy nature of airway involvement. Some regions are completely obstructed (resulting in loss of entire units and reduced lung volumes), whereas other areas are spared. Bronchodilators are generally ineffective. Functional deficits may markedly improve or normalize following corticosteroid therapy.

Histopathologic Features

The histologic hallmark of BOOP is polypoid masses of granulation tissue filling (and obstructing) terminal and respiratory bronchioles and alveolar ducts (Fig. 4). The plugs of loose granulation tissue are composed of aggregates of inflammatory cells, edematous fluid, debris, fibrin, and fibrous connective tissue. The inflammatory infiltrate is composed of lymphocytes, plasma cells, foamy macrophages, and scattered polymorphonuclear leukocytes, eosinophils, and multinucleated giant cells. Extension of the inflammatory process to contiguous alveolar ducts and alveolar spaces results in the “organizing pneumonia” component. Fibrous connective tissue (e.g., fibroblasts, myofibroblasts, collagen) may extend from the small-airway lumina into the alveolar spaces, but extensive fibrosis or honeycombing is lacking. Even when extensive consolidation is present, the alveolar architecture is preserved. These histologic features have variably been ascribed to organizing pneumonia, lipoid pneumonia, cholesterol pneumonia, and resolving pneumonia. Other distinctive features of BOOP include bronchocentricity and patchy involvement; these features can readily be appreciated on low-power magnification of lung biopsy specimens. This “organizing pneumonia” component has been associated with an excellent prognosis and high rate of response to corticosteroid therapy. Histologic features of BOOP overlap with those of other inflammatory lung disorders (especially hypersensitivity pneumonitis, desquamative interstitial pneumonitis, chronic eosinophilic pneumonia, and pulmonary infections). Foamy macrophages in alveolar spaces may erroneously suggest the diagnosis of desquamative interstitial pneumonitis (DIP). BOOP differs from constrictive or mural bronchiolitis obliterans (to be discussed later), which is characterized by fibrous connective tissue obliterating bronchioles and alveolar ducts but lacks an intense inflammatory component. Fiberoptic bronchoscopy with bronchoalveolar lavage (BAL) and transbronchial lung biopsies (TBB) can substantiate the diagnosis of BOOP in some cases, provided the salient histologic features are present and alternative causes have been reliably excluded. BAL in BOOP reveals increases in polymorphonuclear leukocytes (often exceeding 40%), with less striking increases in eosinophils or lymphocytes. These findings are nonspecific. Patients who have marked increases in BAL fluid lymphocytes generally have a more acute course, more prominent component of organizing pneumonia, and higher rate of corticosteroid responsiveness compared with patients who have low or normal BAL lymphocyte counts. Increases in BAL neutrophils or eosinophils have limited prognostic value. Given the patchy nature of BOOP and the small sample size of TBB, video-assisted thoracoscopic lung biopsy should be performed in equivocal or nondiagnostic cases.

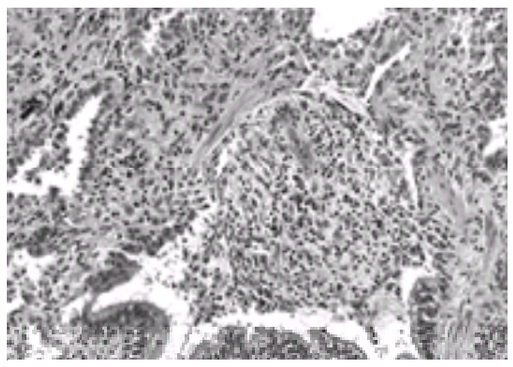

FIG. 4. Bronchiolitis obliterans organizing pneumonia. Photomicrograph of open lung biopsy specimen demonstrates a plug of organizing granulation tissue within a respiratory bronchiole. A peribronchiolar mononuclear inflammatory cell infiltrate is also evident. H&E stain, oil immersion. (Reproduced with permission from Neagos GR, Lynch JP III. Making sense out of bronchiolitis obliterans. *J Respir Dis* 1991:12;801.)

Pathogenesis

Although the pathogenesis has not been elucidated, BOOP likely represents a distinctive and stereotypic host response to diverse injurious or inflammatory stimuli. The frequent association of antecedent viral or respiratory tract infection in idiopathic BOOP suggests that inhaled antigens may induce bronchiolar or alveolar injury. The histologic features of BOOP are usually of uniform age, suggesting that BOOP is an inflammatory reaction to one injurious stimulus, not to recurrent injury. Immune complex deposition in response to inhaled antigens may elicit a brisk inflammatory response. The prominence of neutrophils and neutrophil products in BAL fluid suggests a role for neutrophils in the pathogenesis. However, lymphocytes and macrophages undoubtedly are also important. The evolution of the lesions depends on the balance between the inflammatory process and reparative mechanisms (e.g., fibrosis, remodeling).

Therapy

Corticosteroids are the cornerstone of therapy for BOOP. Studies assessing optimal dose or duration of corticosteroid therapy for BOOP have not been performed. Most investigators advocate initial treatment with prednisone (1 mg/kg/day), but lower doses may be adequate in mild cases. Favorable responses are achieved with corticosteroids in 60%–80% of cases. Symptomatic improvement may be evident within 2 to 3 days; radiographic resolution usually ensues within 1 to 4 weeks. Corticosteroid therapy has been associated with marked reduction in BAL fluid neutrophils, collagenase activity, and myeloperoxidase activity in responding patients. The dose and rate of taper of corticosteroid need to be individualized according to clinical symptoms and results of chest radiographs and pulmonary function tests. In patients showing prompt and dramatic responses to corticosteroids, the dose may be tapered to 40 mg/day within 2 to 6 weeks. A more gradual taper may be appropriate for patients with persistent disease. The dose of prednisone may be tapered to 20 to 30 mg on alternate days within 4 to 6 months, provided patients remain in continuous remission. Because of the potential for relapse with premature discontinuation of therapy, low-dose corticosteroids should be continued for a minimum of 12 to 18 months unless serious adverse effects develop. Prolonged therapy may be required for selected patients exhibiting a propensity to relapse. Serious sequelae associated with BOOP are rare. Pulmonary fibrosis occurs in <20% of patients and fatalities in 3%–10%. Immunosuppressive or cytotoxic agents should be considered in patients failing to respond or experiencing adverse effects of corticosteroids. Data evaluating these agents are limited to anecdotal cases and small series.

Rapidly Progressive BOOP

A subset of patients with BOOP exhibit a more fulminant course, leading to death or severe fibrosis and honeycombing. Cohen et al. articulated the clinical features of 10 such patients seen at three medical centers from 1979 to 1992. The onset of symptoms was rapid (ranging from 3 days to 2 months). Bilateral basilar crackles were noted in 9 of 10; all had dyspnea and hypoxemia. Nine required mechanical ventilatory support. All but one patient were current or former smokers. Possible etiologic factors included connective tissue disease, nitrofurantoin, gold, and exposure to birds. BAL (performed in five patients) demonstrated increases in eosinophils and/or neutrophils. Histopathologic features were consistent with BOOP, but features of diffuse alveolar damage, alveolar septal inflammation, end-stage fibrosis, and honeycombing were also present. Despite aggressive therapy with corticosteroids in all patients (five of whom also received immunosuppressive agents), seven died. Although data regarding therapy are limited, we advise treating with “pulse” methylprednisolone (1000 mg daily for 3 days), followed by high-dose prednisone (1 mg/kg

per day for 2 weeks, with a gradual taper). Cyclophosphamide or azathioprine should be added for steroid-recalcitrant cases.

Obliterative Bronchiolitis (Constrictive Bronchiolitis)

Obliterative bronchiolitis (OB) is a rare disorder characterized by progressive fibrosis and obliteration of bronchiolar lumina, resulting in progressive dyspnea and air flow obstruction. The terms *constrictive bronchiolitis, mural bronchiolitis,* and *pure bronchiolitis obliterans* are synonymous. Most cases of OB have occurred in the context of specific underlying disorders or risk factors, including collagen vascular disease (particularly rheumatoid arthritis), inhaled toxins, drugs (e.g., penicillamine), lung or bone marrow transplantation, infection, and diverse autoimmune, inflammatory, and vasculitic disorders. When no associated disorder can be identified, the term *idiopathic* is used. The prevalence is not known, but idiopathic OB is much less common than BOOP. Turton and colleagues detected 10 patients with OB among 2094 patients with airways obstruction. Five had rheumatoid arthritis; two had an antecedent chest infection; three cases were idiopathic. Many cases of OB diagnosed before 1985 likely represented BOOP.

Clinically, OB differs markedly from BOOP in clinical features, prognosis, and responsiveness to therapy. Patients with OB present with dyspnea and severe air flow obstruction, which progresses relentlessly during weeks to months. Severe reductions in FEV_1 and FEV_1/FVC ratio are characteristic. Air trapping (increased residual volume, or RV) or hyperinflation (increased total lung capacity, or TLC) are common associated features. Chest radiographic findings are usually normal or demonstrate only hyperinflation. However, diffuse reticular or finely nodular shadows, reflecting peribronchiolar inflammation and fibrosis, may be observed. High-resolution CT may reveal peribronchiolar nodular infiltrates and patchy increases in attenuation, accentuated by expiration, which reflect localized air trapping.

Histopathology

Obliterative (constrictive) bronchiolitis is centered on membranous and respiratory bronchioles and is characterized by fibrosis in submucosal and peribronchiolar regions, encircling and encroaching bronchiolar lumina. Necrotic bronchiolar epithelial cells and a mixed polymorphous inflammatory infiltrate may be seen. As the lesion progresses, peribronchiolar fibrosis dominates, resulting in concentric narrowing (and cicatrization) of bronchiolar lumina. Intrabronchial tufts of granulation tissue and extension to the alveolar interstitium are not seen, as they are in BOOP. The lesions are patchy and may be missed, even on open lung biopsy, unless several sections are reviewed. Remnants of destroyed bronchioles may occupy only a few millimeters; the surrounding lung parenchyma may be normal. Serial sections and trichrome stains may be required to identify the progressive narrowing of the caliber of bronchiolar lumina and the peribronchiolar scars. Late findings including bronchiolectasia with mucostasis, distortion of airway walls, bronchial metaplasia, and smooth-muscle hyperplasia.

Therapy

OB typically progresses relentlessly to severe air flow obstruction and ultimately death. In contrast to BOOP, OB rarely responds to therapy. Because of the devastating course, high-dose corticosteroids or immunosuppressive or cytotoxic agents are generally tried, but results have been disappointing.

Bronchiolitis Obliterans Complicating Bone Marrow Transplantation

Bronchiolitis obliterans is a well-recognized complication of bone marrow transplantation, principally in allogeneic recipients manifesting chronic graft-versus-host disease in skin, mucous membranes, liver, or extrapulmonary sites. Bronchiolitis obliterans complicates allogeneic bone marrow transplantation in 10%–12% of long-term survivors with graft-versus-host disease. The prevalence in allogeneic recipients without graft-versus-host disease or autologous recipients is rare (<1%). Bronchiolitis, occasionally with fibrinous obliteration of lumina, is the cardinal feature on lung biopsy or necropsy. The clinical course is indolent, developing 1.5 to 10 months after transplantation. Pulmonary symptoms include cough (60%), dyspnea (50%), wheezing (25%), or coldlike or flulike symptoms (25%). Declines in FEV_1 and VC and increases in RV are characteristic. Chest radiographic findings are normal or reveal mild hyperinflation in 80% of affected patients. In the remaining patients, reticular or finely nodular infiltrates may be noted. The diagnosis of OB can be presumed in bone marrow transplant recipients with a chronic course, progressive air flow obstruction, and lack of evidence for infection. BAL may be adequate in this context to exclude infection. TBB is more specific, but the risk may not be justified, particularly when thrombocytopenia or severe air flow obstruction is present. Prognosis is poor. Augmented immunosuppression is usually administered, but improvement occurs in <20% of patients.

Bronchiolitis Obliterans Complicating Lung Transplantation

Bronchiolitis obliterans, believed to represent a form of chronic lung allograft rejection, complicates lung or heart-lung transplantation in 30%–60% of recipients. Clinically, OB is characterized by progressive airways obstruction, cough, dyspnea, and recurrent lower respiratory tract infections. OB develops 9 to 18 months following lung or heart-lung transplantation. The lesion is never seen in the first 60 days after transplantation. Prevalence approximates 30% by 2 years after transplantation. By 5 years, OB syndrome develops in >50%. Histologically, bronchiolitis obliterans in affected lung allografts is similar to constrictive bronchiolitis or pure bronchiolitis obliterans, described earlier. Dense fibrous plaques narrow or obliterate the small airways. Submucosal and epithelial mononuclear cell infiltrates may be present, but the dense perivascular lymphocytic infiltrates characteristic of acute allograft rejection are lacking. Concomitant features include mucostasis, foam cells in distal airways, and epithelial metaplasia. Lymphocytic bronchitis or bronchiolitis, characterized by peribronchiolar and peribronchial lymphocytic infiltrates, but without fibrosis, may be a precursor of OB in some recipients. Risk factors for development of OB include recurrent episodes of acute allograft rejection, cytomegalovirus (CMV) pneumonitis, large-airway ischemic injury in the initial period after transplantation, heightened immunologic activity against the donor (as assessed by the primed lymphocyte test), and enhanced cell-mediated cytotoxicity. CMV infection may upregulate class I and II histocompatibility (HLA) antigens on epithelial and endothelial cells, thereby amplifying the process. Lung or heart-lung transplant recipients with OB demonstrate submucosal and intraepithelial mononuclear cell infiltrates, enhanced expression of class II HLA antigens on bronchiolar epithelial and lung endothelial cells, and increased number of dendritic cells (e.g., antigen-presenting cells) in the airways. These features support the premise that OB is a form of chronic lung allograft rejection. In other organ allografts, chronic rejection is associated with disappearance or dissolution of structures within the allograft [e.g., vanishing bile duct syndrome (liver), disappearance of renal tubules (kidney), accelerated coronary artery disease (heart)].

The course of OB is indolent. Asymptomatic reductions in expiratory flow rates (e.g., $FEF_{25\%-75\%}$, FEV_1) usually precede the onset of clinical symptoms. Initial symptoms are nonproductive cough, “bronchitis,” or “chest cold.” Physical examination findings are usually unimpressive, but rales or rhonchi develop later. Chest radiographic findings are usually normal, but hyperinflation or bronchiectatic changes develop in the late phases. Once airways obstruction occurs on pulmonary function tests, a downhill course is nearly inevitable. A rapid course (with fall in FEV_1 below 40% of predicted) can occur as early as 3 to 4 months in some patients. In others, pulmonary function stabilizes after an initial decline. Gas exchange is preserved until late in the course. Airways become colonized with *Pseudomonas aeruginosa, Staphylococcus aureus,* or *Aspergillus* species. Progressive dyspnea ensues, which may culminate in respiratory failure. The diagnosis of OB can be established by TBB in more than 75% of affected patients. Because the lesion is patchy, a negative biopsy result does not exclude OB. In this context, a clinical diagnosis of OB syndrome can be made if a sustained and progressive loss in FEV_1 (>15% decline) or $FEF_{25\%-75\%}$ (>25% decline) has been documented and alternative causes of airways obstruction have been excluded.

Once developed, OB typically worsens, but the rate of progression is highly variable. Augmented immunosuppression with pulse methylprednisolone, antilymphocytic agents (e.g., antilymphocyte sera or globulin, OKT3 antibody), FK506, and aerosolized cyclosporine have been tried for OB or OB syndrome, with anecdotal successes. However, sustained remissions are unusual, and most patients experience continued or persistent decline in pulmonary function. Because the prognosis in untreated patients is dismal, most investigators treat OB aggressively with two to four cycles of augmented immunosuppression. The risk-to-benefit ratio of this approach is uncertain, as the rate of complications and short-term and long-term efficacy have not been well defined. In our experience, response to therapy is rarely dramatic. The lesions stabilize (often for 6 to 24 months) in some patients, but one third or more of affected recipients die of respiratory failure within 2 to 3 years of onset of symptoms. Secondary bacterial or fungal pneumonias may accelerate the course. Aggressive treatment and prophylaxis of airway infections may reduce the risk for secondary infections and prolong survival. It is hoped that prophylactic regimens against CMV and improved operative techniques to reduce large-airway ischemia may lower the incidence of OB. Repeated transplantation has been performed in patients with progressive OB refractory to augmented immunosuppressive therapy. Success with repeated transplantation has been less than with initial transplant procedures. Given the scarcity of donor organs, repeated transplantation for OB is controversial.

Follicular Bronchiolitis

Follicular bronchiolitis, a rare disorder most commonly seen in association with rheumatoid arthritis or other connective tissue disorders, exhibits features that overlap with those of OB and BOOP. The relationship of follicular bronchiolitis to these other bronchiolar disorders is not clear. Pulmonary function tests may reveal restriction or airways obstruction. In contrast to OB, which results in intramural or intraluminal compression and distortion of bronchioles, follicular bronchiolitis typically compresses bronchioles externally from lymphoid follicles. A pronounced lymphocytic infiltration within bronchiolar walls may also be evident. Chest radiographs demonstrate reticular or reticulonodular opacities, corresponding to these peribronchiolar cellular infiltrates. The prognosis is more favorable than in OB, as approximately 50% respond to corticosteroid therapy.

Respiratory Bronchiolitis

Respiratory bronchiolitis is a rare disorder of cigarette smokers with features overlapping with those of BOOP. Lung biopsy reveals clusters of pigmented, golden-brown macrophages in respiratory and membranous (terminal) bronchioles and adjacent alveolar spaces. Chronic inflammation and fibrosis may be present but are invariably mild. Most patients are asymptomatic or note mild cough or dyspnea. Chest radiographic findings may be normal or demonstrate accentuated bronchopulmonary markings (“dirty lungs”) resembling those of chronic interstitial pneumonitis. Constitutional symptoms, fever, or dense alveolar infiltrates do not occur in respiratory bronchiolitis, as they do in BOOP. Prognosis has been favorable, but data have been derived from a few small series.

The histologic lesion termed *respiratory bronchiolitis* was initially described by Niewoehner and associates in 1974 as an incidental necropsy finding in young asymptomatic smokers who died of nonpulmonary causes. The cardinal feature was clusters of pigmented macrophages in respiratory and terminal bronchioles. The macrophages had abundant cytoplasm with finely, granular, golden-brown pigment. The coarse granules typical of hemosiderin were absent. Peribronchiolar inflammation or fibrosis was noted but was never severe. This lesion was referred to as *small-airways disease* and was believed to represent a reaction to cigarette smoke with minimal clinical significance. In 1987, Myers and colleagues described a similar lesion in six smokers in whom open lung biopsies had been performed for suspected CILD. Four of the cases were identified during a review of all open lung biopsies at the University of Alabama from 1972 to 1984; two additional cases had been referred for pathologic consultation. All were heavy smokers, usually in the third or fourth decade of life. Five had mild symptoms of cough or dyspnea. Chest radiographs demonstrated bilateral interstitial or reticulonodular infiltrates in five. The dominant histologic feature was aggregates of pigmented macrophages within respiratory and terminal bronchioles and adjacent alveolar ducts and spaces. Electron microscopy demonstrated numerous phagolysosomes and “smoker's inclusions” within alveolar macophages. Severe fibrosis or honeycombing was uniformly absent. The prognosis was excellent. In 1989, Yousem et al. extracted 18 cases of respiratory bronchiolitis from the open lung biopsy files of Boston University and an extensive pulmonary pathology consultation collection. All 18 patients were smokers; mean age was 36 years. Symptoms were mild and were limited to cough, dyspnea, or sputum production. Chest radiographs revealed bilateral reticulonodular infiltrates, with a basilar predominance, in 13 patients (72%). Chest radiographic findings were normal in five patients (28%). Pulmonary function tests revealed consistent reductions in diffusing capacity; mild degrees of airway obstruction, with preserved lung volumes, were also noted. Open lung biopsies demonstrated pigmented macrophages in bronchioles and alveolar spaces, with bronchiolar and peribronchiolar inflammation or fibrosis. Severe fibrosis or honeycombing was never evident. The clinical course was benign. Symptoms resolved in 13 patients (81%); five (19%) remained stable; none worsened. Symptoms improved in 12 of 15 following cessation of smoking. Of three patients who continued to smoke, symptoms persisted in two. Only two patients were treated with corticosteroids; symptoms improved in both. Since these sentinel reports, the clinicopathologic syndrome of respiratory bronchiolitis-associated ILD has been further characterized. Cough, dyspnea, and sputum production are the predominant symptoms. Bilateral basilar rales are noted in 40% of patients; clubbing does not occur. Chest radiographs may show fine reticulonodular interstitial infiltrates, bronchial wall thickening, and ring shadows with normal lung volumes. High-resolution CT has been performed in only a few patients. Fine irregular nodules (2 to 3 mm) are most characteristic. Additional features include foci of patchy ground-glass opacities, atelectasis, emphysema, and peripheral blebs. BAL profiles in respiratory bronchiolitis are similar to those of smokers and do not manifest the striking neutrophilia observed in BOOP. Histologically, the strictly peribronchiolar distribution of respiratory bronchiolitis contrasts with the patchy, subpleural involvement noted in usual interstitial pneumonitis (UIP). Honeycombing, a cardinal feature of UIP, is absent in respiratory bronchiolitis. Intra-alveolar accumulation of macrophages may be observed in DIP. The process is uniform and diffuse with DIP and lacks the peribronchiolar distribution seen in respiratory bronchiolitis. The prognosis in respiratory bronchiolitis is excellent, even in the absence of therapy. No deaths have been attributed to respiratory bronchiolitis, and serious pulmonary fibrosis is rare. However, data are limited, and long-term observational studies involving large numbers of patients with respiratory bronchiolitis are lacking. Smoking cessation is the cornerstone of therapy. Corticosteroids should be reserved for patients with persistent or progressive symptoms despite smoking cessation.

Diffuse Panbronchiolitis

Diffuse panbronchiolitis (DPB) is a chronic, progressive bronchiolar inflammatory disorder characterized by pansinusitis, cough, sputum production, diffuse micronodular shadows on chest radiographs, progressive bronchiectasis, and increases in cold-agglutinating antibodies. Panbronchiolitis shares many features with cystic fibrosis, but these disorders are unrelated. The etiology of DPB is not known, but a strong genetic basis is evident. Virtually all cases have been described in Japan and Korea. Fewer than 10 patients with DPB have been described in the United States. More than 60% of patients with DPB express HLA-B54, an antigen restricted to Oriental populations. The incidence of HLA-B54 is 10%–11% in Japanese and Chinese populations and 3% in Koreans. By contrast, HLA-B54 is invariably lacking in Caucasians, blacks, Hispanics, and American Indians.

Clinical Features

Characteristically, chronic sinusitis begins in the second or third decade of life. Chronic cough, sputum production, and bronchiectasis follow 10 or more years after the onset of sinusitis. In time, colonization of the lower respiratory tract with *Hemophilus influenzae* and eventually *P. aeruginosa* develops. Once colonization with *P. aeruginosa* occurs, the course accelerates. Repetitive suppurative infections lead to progressive respiratory failure. Pulmonary function tests in DPB demonstrate airways obstruction, hypoxemia, and air trapping (increased RV). Chest radiographs demonstrate widely disseminated, small (1 to 4 mm), ill-defined nodules, with a predilection for the lung bases. Lung volumes may be normal or increased during the early phases, but destruction of bronchioles and lung parenchyma eventually results in volume loss. Ring shadows, tramlines, and dilated, ectatic bronchioles reflect cystic bronchiectasis. High-resolution CT reveals diffuse nodular and rounded opacities (representing fluid-filled or inflamed bronchioles), dilated bronchi and bronchioles, bronchiolectasis, and cystic bronchiectasis. In contrast to BOOP, DPB is not characterized by dense focal alveolar infiltrates. BAL reveals intense neutrophilia (typically exceeding 40%); lymphocytes are usually normal or slightly increased. Erythrocyte sedimentation rate and levels of C-reactive protein are usually elevated. Serum immunoglobulins are normal or increased. Persistent elevation of polyclonal cold-agglutinating antibodies is a distinctive feature. Although circulating antibodies against *Mycoplasma pneumoniae* are absent, many patients respond clinically to long-term therapy with erythromycin, suggesting an infectious etiology.

Histologic Features

The distinctive early lesion of DPB are small, poorly circumscribed nodules centered on respiratory bronchioles (bronchiolocentric). These nodules correspond to dense peribronchiolar and intraluminal infiltrates of acute and chronic inflammatory cells. An alveolar component is lacking or minimal. The walls of respiratory bronchioles are thickened; airway lumina may be filled with mucus or intraluminal neutrophils. Foamy macrophages and proliferating lymphoid follicles are common associated features. As the disease advances, destruction of bronchiolar walls results in bronchiolectasis and proximal bronchiectasis. Narrowing and obliteration of bronchiolar lumina, ectatic bronchioles, hypersecretion of mucus, and cystic destruction of proximal bronchioles and bronchi may ensue. Histologic features of DPB overlap with those of obliterative (constrictive) bronchiolitis, but the high frequency of sinus and lower respiratory tract infections and bronchiectasis characteristic of DPB are lacking in OB.

Therapy

The prognosis of DPB is poor, with a 5-year survival from the time of diagnosis of 40%; 10-year survival is 25%. Corticosteroids or immunosuppressive agents are not efficacious and may exacerbate infections. Long-term low-dose erythromycin (600 mg/d) ameliorates symptoms and chest radiographic and physiologic findings in some cases, and is recommended. Its impact on long-term prognosis has not been defined. The mechanism of action of erythromycin is not clear, as the dose is below the minimal inhibitory concentration (MIC) for most pathogenic organisms cultured from sputum.

Bronchocentric Granulomatosis

Bronchocentric granulomatosis (BCG), a granulomatous inflammatory disorder involving and destroying bronchi and bronchioles, was initially described in 1973 by Averill Liebow, a renowned pulmonary pathologist. Bronchial walls were infiltrated and replaced by inflammatory cells (predominantly eosinophils, lymphocytes, and mononuclear cells), with extensive necrosis. Bronchial lumina were filled with necrotic exudate, inflammatory cells (particularly eosinophils), epithelioid cells, and multinucleated giant cells. Foci of organizing pneumonia were observed in the distal alveolar spaces and interstitium. Pulmonary vessels contiguous to involved bronchi were often surrounded by inflammatory cells, but true vasculitis was lacking. Predominant clinical manifestations included fever, cough, malaise, dyspnea, and wheezing. Chest radiographs demonstrated patchy infiltrates, consolidation, mucoid impaction, or atelectasis. We are reluctant to make the diagnosis of BCG, as virtually all cases are associated with a specific underlying disease. Asthma or allergic bronchopulmonary aspergillosis (ABPA) has been noted in 30%–50% of cases of BCG. In this context, blood or tissue eosinophilia, increased serum IgE levels, or intrabronchial *Aspergillus* hyphae may be found. Findings of BCG have been described in Wegener's granulomatosis, rheumatoid arthritis, BOOP, and diverse infectious etiologies. It is likely that BCG represents a hypersensitivity response to a variety of intrabronchial antigens rather than a specific disease entity. Therapy should be directed to the underlying disease. Corticosteroids are highly efficacious for ABPA or asthma. When BCG is caused by an infectious granulomatous process (e.g., tuberculosis, fungal infection, nocardiosis, echinoccosis), antimicrobial therapy directed against the responsible organism may be curative.

PULMONARY VASCULITIS

Systemic necrotizing vasculitis involving the lung occurs primarily in the context of the granulomatous vasculitis syndromes (e.g., Wegener's granulomatosis, Churg-Strauss angiitis, lymphomatoid granulomatosis) or pulmonary-renal syndromes (e.g., microscopic polyangiitis, pauci-immune glomerulonephritis). Classic

polyarteritis nodosa rarely involves the lung. Pulmonary arterial aneurysms are well-recognized complications of Takayasu's disease. Pulmonary hemorrhage (usually caused by capillaritis) rarely complicates Behçet's disease or Henoch-Schönlein purpura.

Antineutrophil Cytoplasmic Antibodies

Circulating autoantibodies directed against cytoplasmic components of neutrophils and monocytes (e.g., ANCA) are frequently found in patients with necrotizing small-vessel vasculitis, associated with pulmonary capillaritis or glomerulonephritis. ANCA with differing antigenic specificities have been noted and have differing prognostic and clinical significance. Antibodies with antigenic specificity for proteinase 3 exhibit a cytoplasmic pattern on immunofluorescence (c-ANCA); antibodies with antigenic specificity for myeloperoxidase (MPO) exhibit a perinuclear pattern (p-ANCA). Antibodies with distinct antigenic determinants are observed in different types of vasculitis. c-ANCA (PR3-ANCA) are detected in 70%–93% of patients with untreated Wegener's granulomatosis and may be found in patients with microscopic polyangiitis (MPA) or Churg-Strauss syndrome (CSS). More than 50% of patients with MPA, CSS, or pauci-immune glomerulonephritis demonstrate circulating p-ANCA (MPO-ANCA), whereas p-ANCA is rarely found in Wegener's granulomatosis. Detectable ANCA (typically p-ANCA) are present in <20% of patients with macroscopic polyarteritis nodosa (PAN). c-ANCA is relatively specific for small-vessel vasculitis (>90% specificity), but p-ANCA may be observed in a myriad of inflammatory disorders in which vasculitis is lacking (e.g., collagen vascular disease, inflammatory bowel disease).

Wegener's Granulomatosis

Wegener's granulomatosis, the most common of the pulmonary granulomatous vasculitides, typically involves the upper respiratory tract (e.g., sinuses, ears, nasopharynx, oropharynx, trachea), lower respiratory tract (bronchi and lungs), and kidneys, with varying degrees of disseminated vasculitis. Major histologic features include a necrotizing vasculitis involving small vessels (i.e., arterioles, venules, and capillaries), extensive necrosis, and granulomatous inflammation. The estimated prevalence of Wegener's granulomatosis is between 1.3 to 3 cases per 100,000 persons per 5-year period. The peak incidence is in the fourth through sixth decades of life; children or adolescents are rarely affected. There is no sex predominance.

Clinical Features

Clinical manifestations are protean, and virtually any organ can be involved. Upper airway symptoms often dominate. Pulmonary involvement occurs in more than two thirds of patients; glomerulonephritis, in 55%–85%. Although Wegener's granulomatosis usually involves multiple organs, limited variants exist involving only one or two organs. This subset of patients has a more favorable prognosis. DeRemee proposed a staging classification based on involvement of ear, nose, throat (E), lung (L), and kidney (K), to stratify patients with single or multiorgan involvement. Other diagnostic criteria proposed by the American College of Rheumatology in 1990 include nasal or oral inflammation, abnormalities on chest radiographs, abnormal urine sediment, and granulomatous inflammation on biopsy. Many classic features lacking in the early phases of the disease may evolve months or even years after the initial presentation. High titers of circulating c-ANCA may support the diagnosis in the appropriate clinical context, even when histologic features are not definitive. However, the specificity of c-ANCA has been challenged.

Upper Airway Involvement

The upper respiratory tract (e.g., sinuses, ears, nasopharynx, oropharynx, trachea) is involved in >90% of patients. Chronic persistent sinusitis, epistaxis, and otitis media are often the presenting and dominant clinical features of Wegener's granulomatosis, but they are often mistakenly thought to represent allergic or infectious etiologies. Sinus radiographic or thin-section CT findings are abnormal in >85% of patients with Wegener's granulomatosis. Thickening or clouding of the sinuses is characteristic; erosion or destruction of sinus bones may occur. Secondary pyogenic sinus infections are common and may be difficult to distinguish from exacerbations of Wegener's granulomatosis. Otologic involvement occurs in 30%–50% of patients. Otalgia and refractory otitis media are common early symptoms of Wegener's granulomatosis. Chronic otitis media, chronic mastoiditis, or hearing loss develops in 15%–25% of patients. The nasopharynx is involved in 60%–80% of patients. Clinical manifestations include epistaxis, nasal septal perforation, persistent nasal congestion or pain, and mucosal ulcers. Saddle nose deformity, resulting from destruction of the nasal cartilage, occurs in 10%–25% of patients. Sore throat or hoarseness may reflect ulcerations or granulomatous involvement of the pharynx or vocal cords. Despite the propensity for Wegener's granulomatosis to affect the upper respiratory tract, histologic confirmation may be difficult. Biopsy specimens of upper airway lesions often demonstrate nonspecific findings of necrosis and chronic inflammation. The cardinal histologic features of vasculitis and granulomatous inflammation may be lacking. A review of 126 biopsy specimens from upper airway or nasopharyngeal lesions in patients with Wegener's granulomatosis seen at the National Institutes of Health revealed the triad of granulomas, vasculitis, and necrosis in only 16% of specimens. Dual features of vasculitis plus granulomas or vasculitis plus necrosis were each noted in 21% of patients. Generous samples of involved sites or samples from additional sites are critical to substantiate the diagnosis. Ocular involvement occurs in 20%–50% of patients with Wegener's granulomatosis. Manifestations may be superficial (e.g., conjunctivitis, scleritis), but uveitis, vasculitis, or compression of the optic nerve may lead to blindness in 2%–9% of patients. Proptosis from a retro-orbital granulomatous inflammatory process has been described in 10%–22% of patients and may compromise the blood supply to the optic nerve. In this context, surgical decompression may be required in patients failing to respond to aggressive medical therapy.

Involvement of Trachea and Bronchi

Stenosis or narrowing of the trachea or major bronchi from granulomatous involvement develops in 10%–30% of patients with Wegener's granulomatosis. The rate of asymptomatic involvement of major airways is even higher. Tracheal or bronchial involvement is nine times more common in female patients and is usually associated with severe sinusitis. Tracheal stenosis is usually circumferential and localized, extending only 3 to 5 cm below the glottis. However, more extensive involvement of the distal trachea or main bronchi may occur. A recent study from the Mayo Clinic cited endobronchial abnormalities in 30 of 51 patients (59%) with Wegener's granulomatosis undergoing bronchoscopy. Four (13%) had tracheal or bronchial stenosis. Extensive endobronchial abnormalities were noted in 11 patients with normal chest radiographic findings. Ulcerating tracheobronchitis was the most common lesion and eventually resulted in progressive stenosis in seven patients followed on a long-term basis. Persistent dyspnea or wheezing may reflect scarring at the site of previous endobronchial inflammation. Stridor or wheezing is a clinical clue to the development of large-airway (trachea or main bronchi) stenosis. Truncation (flow rate limitation) of the inspiratory portion of the flow-volume loop is a sensitive indicator of physiologically significant upper airway obstruction. When the site of obstruction is fixed, both inspiratory and expiratory portions are affected (Fig. 5). Bronchoscopy or spiral CT more objectively quantitates the degree of airway stenosis. Histologic confirmation of the diagnosis is difficult, as endobronchial biopsies usually demonstrate nonspecific changes (e.g., necrosis or inflammation). In the Mayo Clinic study, endobronchial biopsy specimens fulfilled specific histologic criteria for Wegener's granulomatosis in only 3 of 17 patients. Serum titers of c-ANCA did not correlate with endobronchial inflammation. Severe stenosis of large airways may necessitate treatment with YAG (yttrium-argon-garnet) laser, dilation, or placement of Silastic airway stents. Severe upper airway obstruction may mandate tracheostomy. Tracheal reconstruction has been successfully performed in patients with severe tracheal stenosis refractory to medical therapy but is a formidable undertaking.

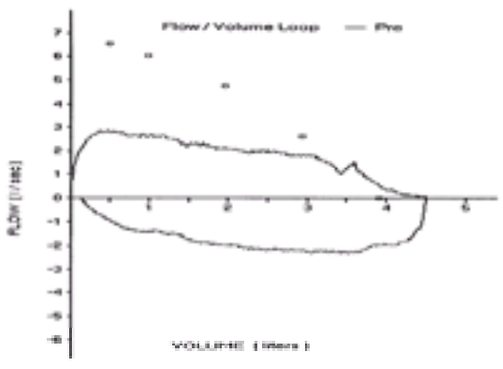

FIG. 5. Wegener's granulomatosis. Flow-volume loop from a 34-year-old woman with tracheal (subglottic) stenosis caused by Wegener's granulomatosis. Note the truncation of both inspiratory and expiratory limbs, consistent with fixed upper airway obstruction.

Lung Involvement

Pulmonary symptoms (e.g., cough, dyspnea, hemoptysis) are noted in approximately one third of patients with Wegener's granulomatosis, caused by parenchymal necrosis, endobronchial inflammation and cicatrix formation, or alveolar hemorrhage. Pulmonary function tests may demonstrate airways obstruction (particularly when endobronchial involvement is prominent), restriction, or mixed patterns. Despite a relatively low prevalence of clinical symptoms, abnormalities on chest radiographs are noted in more than 80% of patients at some point during the course of the disease. Single or multiple nodules or nodular infiltrates are characteristic; cavitation is noted in one quarter (Fig. 6). Other features include focal pneumonic infiltrates (Fig. 7), large mass lesions (Fig. 8), pleural effusions, stenosis of trachea or bronchi, or

atelectasis. Hilar or mediastinal lymphadenopathy has only rarely been described. Extensive alveolar or mixed interstitial alveolar infiltrates may be seen in patients with pulmonary capillaritis and alveolar hemorrhage (Fig. 9). Open (or thoracoscopic) lung biopsy is usually required to substantiate the diagnosis of pulmonary Wegener's granulomatosis. When focal pulmonary infiltrates or nodules are present, the triad of vasculitis, granulomas, and necrosis can be found in >90% of patients by surgical biopsy. By contrast, the yield of endobronchial or transbronchial lung biopsies is only 3%–18%. Massive alveolar hemorrhage is a rare but potentially fatal complication of Wegener's granulomatosis, reflecting diffuse injury to the pulmonary microvasculature. In this setting, rapidly progressive glomerulonephritis is present in >90% of patients. By contrast, 40% manifest upper airway symptoms. The role of surgical lung biopsy in the setting of diffuse alveolar hemorrhage is controversial. Histopathologic features are usually nonspecific. Alveolar hemorrhage dominates. Inflammation and necrosis of the alveolar capillaries (termed *capillaritis*) may be noted, but the granulomatous vasculitis or extensive parenchymal necrosis characteristic of Wegener's granulomatosis at other sites is lacking. For severe pulmonary hemorrhage, we believe the risk of surgical lung biopsy outweighs the benefit. A presumptive diagnosis of diffuse alveolar hemorrhage (DAH) can often be established on the basis of clinical and radiographic features, circulating c-ANCA, and bronchoscopy with BAL. Large numbers of hemosiderin-laden macrophages, bloody or serosanguinous BAL fluid, and absence of infectious etiologies support the diagnosis of DAH (Fig. 10). Biopsy of extrapulmonary sites of involvement may substantiate the diagnosis. However, DAH is a medical emergency requiring aggressive therapy with intravenous pulse methylprednisolone (1 g daily for 3 days) pending the results of a diagnostic workup with biopsies and ancillary laboratory studies. Conventional therapy with oral cyclophosphamide and a tapering regimen of corticosteroids are appropriate once the diagnosis of Wegener's granulomatosis has been confirmed.

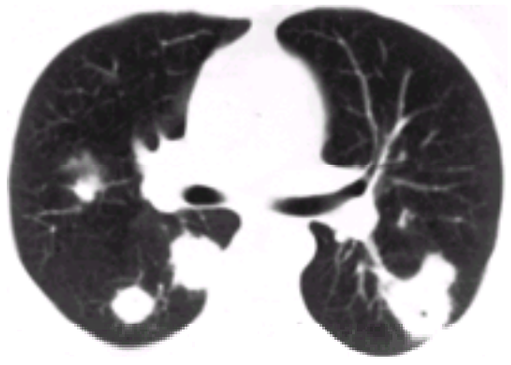

FIG. 6. Wegener's granulomatosis. CT demonstrates multiple focal nodules in a 40-year-old man. Open lung biopsy demonstrated a necrotizing granulomatous vasculitis consistent with Wegener's granulomatosis. (Reproduced with permission from Orens JB, Sitrin RC, Lynch JP III. The approach to nonresolving pneumonia. *Med Clin North Am* 1994: 78;1160, Fig. 8B.)

FIG. 7. Wegener's granulomatosis. PA chest radiograph demonstrates dense focal alveolar infiltrates in an 18-year-old female patient with sinusitis, cough, fever, and cutaneous nodules. Serum antineutrophil cytoplasmic antibody was positive (c-ANCA titer of 1:1200). Skin biopsies demonstrated a leukocytoclastic vasculitis. Sinus biopsies revealed a granulomatous necrotizing vasculitis consistent with Wegener's granulomatosis. Chest radiographs normalized within 2 weeks of initiation of cyclophosphamide and prednisone therapy.

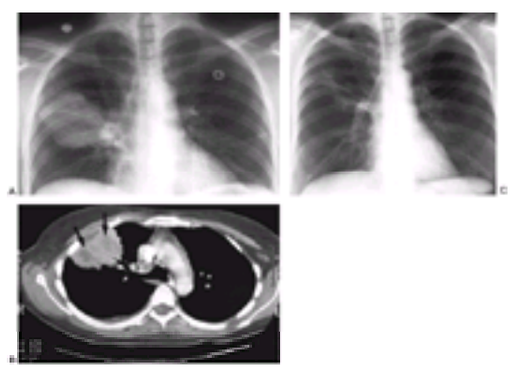

FIG. 8. A: Wegener's granulomatosis. PA chest radiograph demonstrates right upper lobe mass in a 36-year-old woman with leukocytoclastic vasculitis, fever, sinusitis, and cough. **B:** CT in the same patient reveals a mass lesion in the anterior segment of the right upper lobe with areas of focal necrosis (*arrows*). Transbronchial lung biopsies demonstrated granulomatosis vasculitis with extensive necrosis and a polymorphous inflammatory cell infiltrate consistent with Wegener's granulomatosis. **C:** PA chest radiograph from same patient 5 weeks after initiation of therapy with cyclophosphamide and prednisone, showing nearly complete resolution of right upper lobe mass.

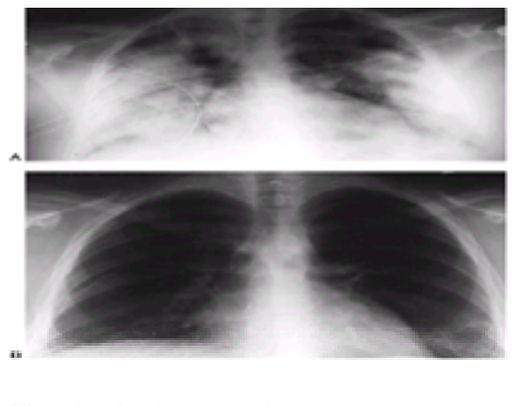

FIG. 9. A: Alveolar hemorrhage caused by Wegener's granulomatosis. PA chest radiograph from a 13-year-old girl demonstrates extensive, confluent alveolar infiltrates. She presented with severe dyspnea, fever, and hemoptysis. Urinalysis demonstrated microscopic hematuria and proteinuria. Open lung biopsy demonstrated massive pulmonary hemorrhage and capillaritis but no granulomas. Review of a prior sinus biopsy demonstrated extensive necrosis and inflammatory exudate with occasional multinucleated giant cells but no definite vasculitis. Pulse methylprednisolone, followed by oral prednisone and cyclophosphamide, was instituted. **B:** PA chest radiographs from the same patient 3 weeks later demonstrate complete clearing of the alveolar infiltrates. After institution of therapy, she remained asymptomatic. Cyclophosphamide was discontinued after 15 months, and prednisone was discontinued after 18 months.

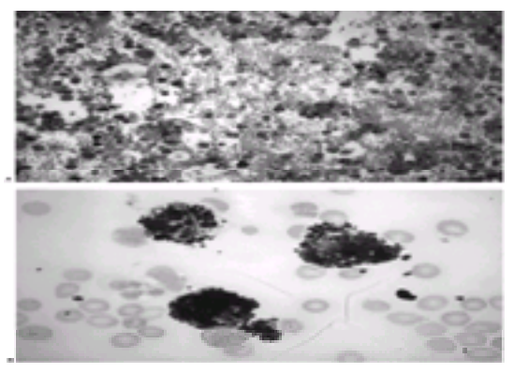

FIG. 10. A: Hemosiderin-laden macrophages. Photomicrograph of BAL fluid demonstrating numerous hemosiderin-laden macrophages with adjacent red blood cells indicating alveolar hemorrhage. Wright stain, low power. **B:** Photomicrograph of BAL fluid showing hemosiderin-laden alveolar macrophages stained blue by iron stain. Prussian blue stain, high power. *See color plate 11.*.

Renal Involvement

Glomerulonephritis (pauci-immune) occurs in 70%–85% of patients at some point in the course of the disease, but only 11%–17% of patients exhibit severe renal insufficiency at presentation. Granulomatous vasculitis is observed in <8% of renal biopsy specimens from patients with Wegener's granulomatosis. The characteristic renal lesion of Wegener's granulomatosis is a segmental focal glomerulonephritis. With more fulminant forms, a necrotizing, crescentic glomerulonephritis is observed. Immune complexes have been noted in a minority of cases. These histologic findings are nonspecific and can be found in diverse immune-mediated or infectious disorders. Clinically evident renal insufficiency may be subtle and progress indolently. Microscopic hematuria or proteinuria precedes detectable abnormalities of renal function. Once renal failure is present, rapid progression may ensue within days or weeks. Aggressive and prompt institution of therapy is mandatory to avert irreversible renal damage. Even in oliguric renal failure, substantial recovery of renal function can be achieved in most patients. Chronic renal failure remains a major cause of death, and 10%–30% of patients with Wegener's granulomatosis eventually require long-term dialysis. Renal transplantation has been successfully accomplished in patients with end-stage renal disease in whom Wegener's granulomatosis is in complete remission. Recurrence of Wegener's granulomatosis has been rare following transplantation. Other rare urologic complications of Wegener's granulomatosis include necrotizing vasculitis involving the ureters, penis, or prostate (anecdotal reports).

Central or Peripheral Nervous System Involvement

Central or peripheral nervous system involvement occurs in <4% of patients at initial presentation, but eventually it develops in 10%–34%. Mononeuritis multiplex or polyneuritis accounts for >50% of neurologic complications. Other manifestations include cerebral infarction or hemorrhage, cranial nerve palsies, focal deficits or seizures from cerebral mass lesions, diabetes insipidus (secondary to granulomatous involvement of the hypothalamus), quadriparesis or paraparesis (reflecting involvement of the spinal cord microvasculature), generalized seizures (reflecting meningeal involvement), and visual loss (from compression of the optic nerve or vasculitis of the vasculature). Vasculitis of the central nervous system has only rarely been confirmed histologically, because of inaccessibility or risks associated with biopsies. The diagnosis is usually supported by histologic confirmation at extraneural sites or by noninvasive studies (e.g., electromyelogram, magnetic resonance imaging, or CT of the brain) in patients with neurologic symptoms and previous documentation of Wegener's granulomatosis. Cerebral angiography is ill advised, because the small vessels affected in Wegener's granulomatosis are below the sensitivity of angiography. In some patients, biopsy of the sural nerve or other affected nerves may substantiate the diagnosis.

Other Organ Involvement

Constitutional features (e.g., malaise, fatigue, fever, weight loss) occur in one third or more of patients with Wegener's granulomatosis. Nondeforming polyarthritis involving medium and large joints occurs in two thirds of patients and parallels activity of the systemic disease. Articular symptoms usually remit with cytotoxic or corticosteroid therapy. Cutaneous lesions are present in 40%–50% of patients during the course of the disease. Manifestations are protean and include palpable purpura, subcutaneous nodules, papules, petechiae, ulcers, and nonspecific erythematous or maculopapular rashes. Skin biopsy may demonstrate granulomatous vasculitis with necrosis but most often reveals nonspecific changes of leukocytoclastic vasculitis. Cardiac involvement is rarely documented ante mortem, but prevalence rates of 10%–15% have been estimated. Coronary arteritis and pericarditis are the most common clinical features. Cardiomyopathies, conduction defects, and fatal arrhythmias may reflect necrotizing vasculitis or granulomatous inflammation involving the myocardium or coronary arteries. Gastrointestinal manifestations (e.g., abdominal pain, diarrhea, hemorrhage, and perforation) have been cited in <5% of patients with Wegener's granulomatosis. This may in part reflect inaccessibility of lesions or lack of an aggressive diagnostic approach. In a review of the literature, granulomatous or vascular lesions within the gastrointestinal tract were found in 23 of 59 necropsies performed in patients with Wegener's granulomatosis.

Histopathology

The cardinal histopathologic features of Wegener's granulomatosis include a necrotizing vasculitis affecting arterioles, venules, and capillaries; granulomatous inflammation; geographic parenchymal necrosis; hemorrhagic infarcts; and areas of fibrosis. Well-formed sarcoidlike granulomas are uncommon, but multinucleated giant cells, epithelioid cells, and collections of histiocytes are usually evident in involved organs. Vascular walls are infiltrated by mononuclear cells and neutrophils, with occasional multinucleated giant cells and eosinophils (Fig. 11). Fibrinoid necrosis and thrombosis within vascular lumina are early findings. Later, fibrosis of vascular walls may result in stenosis or obliteration of the lumina. A pronounced fibroblastic component, with concentric rings of collagen and connective tissue matrix, may be present. These histologic features may not be found if small or nonrepresentative biopsy specimens are obtained. Granulomas and vasculitis of small vessels may be observed with infections (particularly with mycobacterial and fungal etiologies). Thus, special stains should be performed in any granulomatous or necrotic lesion to exclude infectious causes.

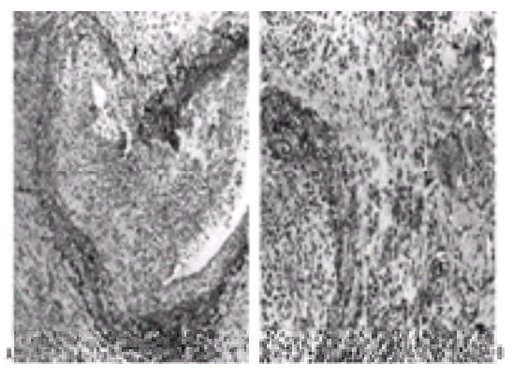

FIG. 11. A: Wegener's granulomatosis. Photomicrograph of lung biopsy specimen demonstrates transmural inflammation of a small vessel with partial destruction of elastin framework (*arrow*). Note the inflammation of the intima and marked narrowing of the vascular lumen. Pentachrome stain. (Courtesy of Andrew Flint, M.D., Department of Pathology, University of Michigan Medical Center.) **B:** Photomicrograph of lung biopsy specimen demonstrating multinucleated giant cells surrounding necrotic debris (*arrows*). A markedly inflamed blood vessel is present in the left portion of the field. Pentachrome stain. (Courtesy of Andrew Flint, M.D.)

Laboratory Features

Anemia, thrombocytosis, or leukocytosis has been noted in 30%–40% of patients with Wegener's granulomatosis. Leukopenia or thrombocytopenia is rare in the absence of cytotoxic therapy. Peripheral blood eosinophilia is not a feature of Wegener's granulomatosis. Polyclonal hypergammaglobulinemia occurs in up to 50% of patients. Serum complement levels are normal or elevated. Circulating immune complexes have been found but are of no clinical value in either the diagnosis or follow-up. Renal function tests (serum creatinine, blood urea nitrogen) and urinalysis should be obtained in all patients initially. Striking increases in erythrocyte sedimentation rate and levels of C-reactive protein are characteristic of active, generalized disease. However, erythrocyte sedimentation rate or levels of C-reactive

protein can be normal with active disease, particularly when only a single site is involved. Serial determinations of the erythrocyte sedimentation rate or levels of C-reactive protein are useful in monitoring the disease but are nonspecific, as elevations may occur in the presence of coexisting infections. c-ANCA are helpful in the initial diagnosis of Wegener's granulomatosis and in monitoring response to therapy. Increases in c-ANCA have been noted in >90% of patients with active generalized Wegener's granulomatosis, and in 40%–70% of patients with active regional Wegener's granulomatosis. Changes in c-ANCA usually correlate with disease activity and are unaffected by intercurrent infections. However, c-ANCA titers may persist in 30%–40% of patients even after complete clinical remission has been achieved. Serial determinations of c-ANCA provide a useful adjunct to the clinical data, but treatment decisions should not rely exclusively on c-ANCA titers.

Pathogenesis

The cause of Wegener's granulomatosis is unknown. The preponderance of disease in the upper and lower respiratory tracts, the intensity of mononuclear infiltrates, and the granulomatous character are consistent with an exaggerated cellular immune response to inhaled antigen(s). Increases in serum immunoglobulins, B-cell activity, circulating autoantibodies (c-ANCA), and immune complexes suggest that humoral mechanisms are also operative. The presence of polymorphonuclear leukocytes in the inflammatory vasculitic process, and of circulating autoantibodies directed against neutrophil cytoplasmic components, suggest a role for neutrophils and c-ANCA in the pathogenesis and evolution of the disorder. Exacerbations of Wegener's granulomatosis during intercurrent infections, and the frequent relapses observed in patients with Wegener's granulomatosis who are chronic nasal carriers of *S. aureus,* suggest that infections may amplify the inflammatory process, possibly by eliciting an antibody and acute-phase response.

Therapy

Before therapy became available, >80% of patients with Wegener's granulomatosis died within 3 years of onset of symptoms, usually of progressive renal insufficiency. Corticosteroids improved survival modestly. In the 1970s, the introduction of cyclophosphamide led to dramatic improvement in prognosis and survival. Oral cyclophosphamide (1 to 2 mg/day) combined with corticosteroids (1 mg/kg/day, with taper) is the treatment of choice for Wegener's granulomatosis. Remissions are achieved in 70%–93% of patients with this regimen; early mortality has been <15%. Late sequelae of vasculitis (e.g., cerebrovascular accidents, myocardial infarction, renal failure, hypertension) or complications of cyclophosphamide therapy (e.g., opportunistic infections, neoplasms) contribute to long-term mortality and morbidity. The dose of cyclophosphamide may need to be adjusted to maintain acceptable blood counts (particularly a leukocyte count of >3000/mm3). Corticosteroids ameliorate many of the inflammatory manifestations of Wegener's granulomatosis and are important as adjunctive therapy. The dose of corticosteroid needs to be individualized according to the clinical response and presence or absence of adverse effects. We attempt to taper to alternate-day prednisone (e.g., 60 mg every other day) within the first 2 to 3 months. Thereafter, we taper the prednisone gradually by 10-mg decrements every 1 to 3 months, until a maintenance dose of 15 to 20 mg every other day is achieved. Thereafter, the rate of taper may be slowed. Cyclophosphamide should be continued for a minimum of 12 months after complete clinical and laboratory remission has been achieved. Shorter duration of therapy has been associated with unacceptably high rates of relapses and late sequelae. Relapses occur in 20%–50% of patients as the regimen is tapered or discontinued, but reinstitution of therapy is usually efficacious. Prolonged therapy may be required in patients exhibiting a propensity to relapse. Unfortunately, cyclophosphamide is associated with a myriad of complications. Opportunistic infections (particularly herpes zoster) occur in 20%–30% of patients receiving cyclophosphamide. Other complications include bone marrow toxicity, pulmonary toxicity, alopecia, gastrointestinal symptoms (e.g., nausea, vomiting, diarrhea, hepatotoxicity), stomatitis, infertility, and oligospermia. Cyclophosphamide may induce both solid and hematologic neoplasms. Malignant lymphomas or hematologic malignancies have been noted in 1%–3% of patients with Wegener's granulomatosis who are receiving cyclophosphamide. Hemorrhagic cystitis occurs in 30%–50% of patients but is severe in <6% of patients. A recent, long-term study of 146 patients with Wegener's granulomatosis treated with cyclophosphamide cited seven cases of transitional cell carcinoma of the bladder. Antecedent hematuria had been noted in all patients. The risk for bladder carcinoma correlated with duration and total dose of cyclophosphamide therapy; cigarette smoking may amplify the risk. The incidence of bladder cancer following first exposure to cyclophosphamide is 5% at 10 years and 16% at 15 years. The risk persists for many years after discontinuation of cyclophosphamide. Serial urinalyses at 3- to 6-month intervals are advised in patients receiving cyclophosphamide and are sensitive in detecting bladder carcinomas. The presence of hematuria (macroscopic or microscopic) warrants cystoscopy. Intermittent intravenous high-dose (pulse) cyclophosphamide has been used to treat Wegener's granulomatosis, but results have been unimpressive. Early responses were noted in 13 of 14 patients treated with pulse cyclophosphamide in a nonrandomized trial at the National Institutes of Health. However, sustained remissions were achieved in only three patients (21%). Pulse cyclophosphamide is less toxic than daily oral cyclophosphamide but is less effective and is not recommended.

Other Therapeutic Options

In view of the rarity of Wegener's granulomatosis, prospective, randomized trials assessing therapy have not been performed. Anecdotal successes have been noted with other immunosuppressive or cytotoxic agents (e.g., azathioprine, methotrexate, and chlorambucil), but we consider these agents as second-line. Chlorambucil (Leukeran) may be oncogenic, and data are limited evaluating its efficacy as therapy for Wegener's granulomatosis. We do not employ chlorambucil in the treatment of Wegener's granulomatosis. Azathioprine (Imuran) is clearly less effective than cyclophosphamide, but it may be effective in maintaining remissions in patients experiencing adverse effects from cyclophosphamide. In an early report from the National Institutes of Health, cyclophosphamide successfully induced remissions in all 10 patients whose disease had been refractory to therapy with azathioprine. Azathioprine cannot be considered a first-line agent. Oral methotrexate, administered once weekly, may be used for patients with Wegener's granulomatosis in whom serious adverse effects develop from cyclophosphamide. A recent prospective (but nonrandomized) study at the National Institutes of Health treated 42 patients who had non–life-threatening Wegener's granulomatosis with oral methotrexate (mean dose, 20 mg/week) combined with corticosteroids. Treatment regimens before entry into the study included no prior therapy (16); corticosteroids alone (14); corticosteroids plus trimethoprim/sulfamethoxazole (6); cyclophosphamide plus corticosteroids (4); azathioprine (2). The four patients receiving cyclophosphamide were switched to methotrexate because of toxicity (hemorrhagic cystitis or leukopenia). All other patients had failed to achieve remissions with prior treatment regimens. Exclusion criteria included acute renal failure, pulmonary hemorrhage, serum creatinine levels of >2.5 mg%, and chronic liver disease. However, all patients had active disease at entry into the study, including glomerulonephritis in 21 (50%) and lung involvement in 22 (52%). Methotrexate was initiated at a dose of 0.3 mg/kg once weekly and was increased to tolerance up to a maximal dose of 20 to 25 mg once weekly. Prednisone was initiated at a dose of 1 mg/kg daily and gradually tapered as improvement occurred. Remissions were achieved in 30 of 42 patients (71%). Median time to remission was 4.2 months. Of the 30 patients achieving remission, 11 (36%) relapsed at a mean of 29 months. A second remission was induced in six of eight patients following a second course of methotrexate and prednisone. Toxicity was generally mild, but *Pneumocystis carinii* pneumonia developed in four patients (two of whom died). Methotrexate pneumonitis developed in three, which resolved with cessation of therapy. Asymptomatic elevation in transaminases was noted in 24% and always resolved with reduction of dose. Titers of c-ANCA did not correlate with disease activity. These data are encouraging and support the use of methotrexate plus prednisone in patients experiencing adverse effects from cyclophosphamide and as initial therapy in patients with mild Wegener's granulomatosis. Additional data are required to evaluate the role of methotrexate as therapy for Wegener's granulomatosis more fully.

Trimethoprim/Sulfamethoxazole

Anecdotal responses have been observed with trimethoprim/sulfamethoxazole (T/S), but firm data affirming the efficacy of T/S are lacking. In a nonrandomized clinical trial, DeRemee and colleagues at the Mayo Clinic cited favorable responses with T/S in a subset of patients with Wegener's granulomatosis. DeRemee added T/S to a previously failing regimen of cyclophosphamide/prednisone in 31 patients with indolent but progressive Wegener's granulomatosis. Favorable responses were noted in 26 patients; late relapses were observed in four patients in this group. In addition, T/S was given as initial therapy in 15 patients with limited Wegener's granulomatosis. In this context, 14 responded; only three experienced late relapses. On the basis of these favorable results, DeRemee advocated T/S (one double-strength tablet twice daily) as initial therapy for patients with limited disease (lacking renal disease or generalized vasculitis) or for patients with progressive disease despite cyclophosphamide and corticosteroids. If no improvement was evident after 8 weeks, prednisone and/or cyclophosphamide were introduced. Although other investigators have cited favorable responses with T/S, data are limited. A prospective study at the National Institutes of Health found that T/S (alone or combined with corticosteroids) as initial therapy for Wegener's granulomatosis was ineffective in all nine patients. Nonetheless, a role for T/S in attenuating the course of the disease is plausible. Stegeman and colleagues evaluated the efficacy of T/S in preventing relapses in patients with Wegener's granulomatosis who were in remission during or after treatment with cyclophosphamide and prednisone. Patients were randomized to either T/S (160 mg trimethoprim/800 mg sulfamethoxazole) twice daily or placebo in addition to conventional treatment with cyclophosphamide and prednisone. At 24 months of follow-up, 82% of patients assigned to T/S were in remission, compared with only 60% in the placebo group. The annual rate of respiratory and nonrespiratory infections was also lower in the T/S group. Titers of ACNA did not differ between groups. Although this study did not address T/S as primary (initial) therapy for Wegener's granulomatosis, T/S did reduce the rate of relapses in patients with Wegener's granulomatosis following conventional treatment with cyclophosphamide/prednisone. Its mechanism of action is not known, but T/S may suppress autoantibody formation by direct antimicrobial effects or by indirect immunosuppressive or anti-inflammatory effects. Relapses of Wegener's granulomatosis are more frequent coincident with respiratory infections or in patients with chronic nasal carriage of *S. aureus.* Low-grade bacterial infection may prime neutrophils to express target antigens (e.g., c-ANCA) on the cell surface and may trigger local immune responses. The antimicrobial effect of T/S may abrogate these effects, thus limiting neutrophil activation and further tissue damage. Although these data are intriguing, the role of T/S has not been defined. In view of its low toxicity, T/S may be considered as adjunctive therapy in patients with persistent, indolent disease despite cyclophosphamide and corticosteroids. We do not believe T/S should supplant conventional therapy with cyclophosphamide/corticosteroids.

Polyarteritis Nodosa

Classic (macroscopic) polyarteritis nodosa (PAN) is a necrotizing vasculitis involving small and medium-sized muscular arteries. PAN differs from Wegener's granulomatosis in that microscopic vessels (e.g., small arterioles, venules, capillaries) are spared, and a granulomatous component is lacking in PAN. Macroscopic aneurysms involving the renal, mesenteric, or hepatic arteries can be demonstrated by angiography in more than two thirds of patients. Clinical manifestations

predominantly affect the kidneys, gastrointestinal tract, central nervous system, skin, heart, and viscera. Clinical lung involvement complicates PAN in <2% of cases. Most previous reports of PAN with lung involvement probably represented either Churg-Strauss Syndrome (CSS) or microscopic polyangiitis (MPA). These entities are discussed in detail later in this chapter. Circulating ANCA (typically p-ANCA) have been detected in <20% of patients with PAN. By contrast, circulating ANCA (typically c-ANCA) are found in most patients with Wegener's granulomatosis, MPA, or CSS. Most cases of PAN are primary or idiopathic, but secondary forms (e.g., caused by hepatitis B virus or tumor antigens) are well recognized. Patients with PAN and hepatitis B antigenemia are usually treated with antiviral therapies in combination with plasmapheresis or immunosuppressive agents. For PAN without hepatitis B antigenemia, corticosteroids (alone or in combination with cyclophosphamide) are the mainstay of therapy. Five-year survival exceeds 75% but may be worse in the presence of adverse prognostic factors (e.g., gastrointestinal tract or central nervous system involvement, renal failure, loss of >10% of body weight, age of >50 years). The optimal doses of corticosteroid have not been delineated in randomized trials. For mild to moderate cases, initial therapy with prednisone (1 mg/kg per day for 1 month), followed by a gradual taper, is reasonable. For more severe or fulminant cases, we initiate therapy with high-dose intravenous methylprednisolone (500 to 1000 mg daily for 3 days), followed by oral prednisone (1 mg/kg/day or the equivalent) for 4 to 6 weeks. The dose of corticosteroid and rate of taper need to be individualized according to the response and clinical course. Cyclophosphamide is a highly effective drug for PAN, even in steroid-refractory cases. We routinely add oral cyclophosphamide (2 mg/kg/day) to corticosteroids, but some investigators reserve this agent for more severe or steroid-recalcitrant cases. Randomized European multicenter trials cited higher response rates (and fewer relapses) in regimens employing oral cyclophosphamide plus corticosteroids compared with corticosteroids alone. Survival did not differ between groups. Intravenous pulse cyclophosphamide (administered once monthly) may be less toxic than oral cyclophosphamide and appears to be equally efficacious. Patients responding to therapy with cyclophosphamide should be continued on this agent for at least 1 year after induction of remission. Relapses warrant reinstitution of therapy with corticosteroids plus cyclophosphamide. Plasmapheresis can be considered as adjunctive therapy in patients with fulminant PAN refractory to conventional therapy but should not be used routinely. In two randomized trials (that included patients with PAN or CSS), the addition of plasma exchange to prednisone or prednisone and cyclophosphamide did not improve prognosis or mortality.

Microscopic Polyangiitis

Microscopic polyangiitis (previously termed *overlap polyangiitis syndrome*) has clinical and histopathologic features overlapping with those of classic PAN and CSS. Predominant clinical manifestations are glomerulonephritis and pulmonary capillaritis (manifested as alveolar hemorrhage), but other organs may be involved. Microscopic polyangiitis is rare, with an estimated prevalence of 2.4 cases per million (range, 0.9 to 5.3). Mean age at onset is approximately 50, but all ages may be affected. There is a slight male predominance. As its name implies, microscopic polyangiitis (MPA) involves small vessels (arterioles, venules, and capillaries). MPA appears to be identical to what Zeek termed “hypersensitivity angiitis” in 1952. In the mid-1980s, the term *microscopic polyarteritis* was adopted to distinguish this disorder from macroscopic (classic) PAN. Capillaries are invariably involved in MPA, but arterioles may be spared. Thus, the term *microscopic polyangiitis* has replaced *microscopic polyarteritis.* Circulating ANCA (usually c-ANCA) have been demonstrated in a majority of patients with MPA, suggesting a possible relationship with other ANCA-associated pulmonary vasculitides (e.g., Wegener's granulomatosis and CSS). The defining criteria for MPA are less crisp than those for either Wegener's granulomatosis or CSS. In 1994, a panel of experts convened at the Chapel Hill Consensus Conference to provide defining criteria for vasculitis. MPA and PAN were distinguished primarily by histologic features. Small vessels (capillaries, venules, arterioles) were invariably involved in MPA but were always spared in classic PAN. Medium-sized or small arteries could be affected in either MPA or PAN. Granulomas were absent in both disorders.

Clinical Features

The predominant manifestations of MPA are alveolar hemorrhage and rapidly progressive glomerulonephritis, features rarely seen in classic PAN. The clinical features of MPA were articulated by Savage and colleagues in 1985. A necrotizing, crescentic glomerulonephritis with few or no immune deposits (termed *pauci-immune*) is characteristic of MPA. Alveolar hemorrhage occurs in 30%–50% of patients and is often the dominant (and most life-threatening) manifestation (Fig. 12). A prodromal respiratory illness precedes the onset of vasculitis in one third of patients. Arthralgias and myalgias may be prominent. Sinus or upper airway involvement may occur but is rarely a prominent or presenting feature. Oral ulcers have been noted in up to 21% of patients with MPA and may mimic Wegener's granulomatosis. Cutaneous involvement (leukocytoclastic vasculitis) is common. Renal infarcts, renal vasculitis, and visceral aneurysms, cardinal features of PAN, are rarely observed in MPA. Peripheral neuropathy occurs in 50%–80% of patients with PAN, but in only 10%–20% of patients with MPA. Circulating immune complexes and rheumatoid factor have been noted in 40% of patients with MPA and antinuclear antibodies in 21%. These nonspecific tests have been supplanted by ANCA, which have been detected in 50%–90% of patients with MPA. By contrast, ANCA are present in <20% of patients with PAN. Several features of MPA (e.g., circulating ANCA, small-vessel vasculitis, glomerulonephritis, and pulmonary capillaritis) may be observed in patients with Wegener's granulomatosis or CSS. Both of these latter vasculitic disorders exhibit a granulomatous component, which is lacking in MPA. Asthma or eosinophilia (in blood or tissue), characteristic features of CSS, are not found in MPA. A firm diagnosis of MPA requires that these alternative diagnoses be definitely excluded.

FIG. 12. Alveolar hemorrhage caused by microscopic polyangiitis. PA chest radiograph demonstrates diffuse alveolar infiltrates involving all lobes. Within 24 hours, the infiltrates worsened and severe respiratory failure developed; mechanical ventilatory support with positive end-expiratory pressure (PEEP) at 16 cm H_2O was required to achieve acceptable oxygenation. Because of the severity of respiratory failure, no lung biopsy was performed. Urinalysis demonstrated numerous red cells and occasional red cell casts. Serum creatinine level was 1.4 mg%. One gram of pulse methylprednisolone (Solu-Medrol) was administered daily for 3 days. Renal biopsy demonstrated glomerulonephritis and a necrotizing vasculitis involving renal arterioles; no granulomas were present. Cyclophosphamide was instituted (2 mg/kg daily) and corticosteroids were continued. Within 5 days, the infiltrates had cleared completely and serum creatinine level was 0.6 mg%.

Histopathology

Like other ANCA-associated vasculitides, MPA principally affects small arterioles, venules, and capillaries. A granulomatous component is lacking and eosinophils are rare or absent, in contrast to what is observed in CSS and Wegener's granulomatosis. Immune complexes are nondetectable or present in only small amounts in involved tissue (*pauci-immune*).

Treatment

Diverse regimens employing prednisone, azathioprine, cyclophosphamide, and plasmapheresis, alone or in combination, have been used to treat MPA. Because of the rarity of MPA, data regarding therapy are limited. Treatment regimens have been extrapolated from studies that have incorporated patients with MPA, CSS, and PAN. In this context, overall survival appeared to be similar with various regimens, including corticosteroids alone, corticosteroids plus oral cyclophosphamide, corticosteroids plus intravenous cyclophosphamide, corticosteroids plus plasma exchange, and corticosteroids plus cyclophosphamide plus plasma exchange. Plasmapheresis adds another level of complexity and should be reserved for fulminant or refractory cases. Most investigators use oral cyclophosphamide (2 mg/kg/day) and corticosteroids (1 mg/kg/day, with gradual taper), similar to the regimen used in Wegener's granulomatosis. Favorable responses are achieved in >80% of cases; 10-year survival exceeds 70%. As with Wegener's granulomatosis, treatment should be continued for a minimum of 1 year after complete clinical and laboratory remission has been achieved.

Churg-Strauss Angiitis (Allergic Angiitis and Granulomatosis)

CSS, also termed *allergic angiitis and granulomatosis,* was originally reported in 1951 by Churg and Strauss, who described 13 patients with asthma, peripheral eosinophilia, constitutional symptoms, and systemic necrotizing vasculitis. These investigators noted that CSS shares histologic features with PAN, but is distinct from classic PAN. In 1957, Rose and Spencer identified 32 patients with asthma and features consistent with CSS from a necropsy series of 111 patients with PAN. Only sporadic reports of CSS were described during the next two decades. In 1977, Chumbley and co-workers reviewed 30 patients with CSS seen at the Mayo Clinic during a 24-year period. A review of the files of the Armed Forces Institute of Pathology in 1981 revealed only four cases of CSS. As of 1982, only 138 cases of CSS had been published. The annual incidence of CSS has been estimated at 2.4 cases per million. In 1984, Lanham and colleagues reported 16 additional patients with

CSS (only eight of whom had histologic confirmation of vasculitis) seen at a large referral hospital in England during a 6-year period, and suggested that the rarity of CSS in part reflected the stringent criteria required for the diagnosis. They suggested that the diagnosis of CSS could be made even when not all classic criteria (e.g., necrotizing vasculitis, extravascular granulomas, tissue eosinophilia) were present. A concept of “limited forms” of CSS, analogous to limited Wegener's granulomatosis, has been suggested. Cardinal features required for the diagnosis include an allergic diathesis and eosinophilic component (either in blood or tissue).

Clinical Features

Pulmonary involvement (characteristically manifested as asthma) is present in virtually all patients. Focal alveolar infiltrates are present on chest radiograph in 30%–70% of cases. Diffuse alveolar hemorrhage is a rare complication. Pulmonary nodules or cavitary lesions are rarely observed in CSS, as they are in Wegener's granulomatosis. Typically, a history of atopy and asthma precedes the development of vasculitis by months or even years. Hay fever, nasal polyposis, allergic rhinitis, and sinusitis are noted in more than two thirds of patients. Otolaryngeal manifestations include nasal crusting or nasal polyposis in up to 75% of patients with CSS and nasal perforation in 5%. Peripheral blood eosinophilia is usually prominent during the asthmatic and vasculitic phases. Increasingly severe and more frequent exacerbations of asthma precede the development of necrotizing vasculitis. Constitutional symptoms are usually prominent. Fever, weight loss, or malaise are noted in >90% of patients. Arthralgias or myalgias occur in one third of patients. Central or peripheral neurologic involvement occurs in 40%–63% of patients with CSS. Peripheral neuropathy or mononeuritis multiplex predominates; cerebral infarction has rarely been described. Cutaneous manifestations (e.g., subcutaneous nodules, purpura, or petechiae) occur in two thirds of patients. Skin biopsy may demonstrate nonspecific findings of leukocytoclastic vasculitis; when dense eosinophilic infiltrates are noted, the diagnosis of CSS is strongly suggested. Cardiac involvement occurs in 30%–50%. Cardiac failure and pericarditis are the most common clinical manifestations. Cardiac involvement may reflect primary coronary vasculitis or eosinophilic endocarditis with associated fibrosis. Abdominal viscera are involved in 20%–40%. Abdominal pain or perforation of a viscus resulting from ischemia are well-recognized complications. Renal failure is rare with CSS, but hypertension develops in nearly 50% of patients. The mean age of onset is in the middle to late 40s, but the range is wide (14 to 75 years). Laboratory studies demonstrate elevations in the erythrocyte sedimentation rate and blood eosinophil counts in >80% of patients during acute exacerbations. Both erythrocyte sedimentation rate and blood eosinophil counts usually correlate with activity of disease. Circulating ANCA (both p-ANCA and c-ANCA) have been noted in a majority of patients with CSS.

Histopathology

The salient histologic features of CSS include a necrotizing vasculitis involving small arteries and veins, with eosinophilic and granulomatous components. The pronounced eosinophilic and granulomatous character distinguishes CSS from other pulmonary vasculitides. Eosinophilic infiltration of vascular walls is usually striking; mononuclear cells, neutrophils, and occasional multinucleated giant cells are also present. Granulomas and eosinophils in extravascular tissues are hallmarks of the disorder. Palisades of histiocytes and giant cells surround a central eosinophilic core. The diagnosis can be supported even when histologic features are not definitive, provided the clinical and laboratory features are characteristic. The lesions in diffuse alveolar hemorrhage demonstrate nonspecific findings of capillaritis.

Therapy

Corticosteroids have been the mainstay of therapy, with remissions in >80% of patients. Immunosuppressive and cytotoxic agents have also been tried. Prospective, randomized trials (that enrolled patients with PAN or CSS) have evaluated various medical regimens, including corticosteroids alone; corticosteroids plus oral cyclophosphamide; corticosteroids plus pulse cyclophosphamide; corticosteroids plus plasma exchange; and the combination of corticosteroids, cyclophosphamide, and plasma exchange. Long-term (10-year) survival is similar with the various regimens (3-year survival, 80%–90%; 10-year survival, 72%–78%). Pulse (once-monthly intravenous high-dose) cyclophosphamide was comparable with oral cyclophosphamide and steroids for PAN or CSS. Given the high remission rate with corticosteroids and the potential late sequelae associated with cytotoxic agents, we consider prednisone as first-line therapy for mild to moderate cases of CSS (1 mg/kg/day for 4 weeks, followed by a gradual taper). Oral cyclophosphamide (2 mg/kg/day) is added for more fulminant cases or when unfavorable prognostic features are present [e.g., proteinuria >1 g/day, severe gastrointestinal involvement, cardiomyopathy, renal insufficiency (serum creatinine levels of >1.6 mg%), or central nervous system involvement]. Asthma, polyarthritis, myalgias, ophthalmologic signs, weight loss, or cutaneous involvement do not influence prognosis. For fulminant or refractory cases, more rapid control of the disease can be accomplished with aggressive combination therapies. In this context, pulse methylprednisolone (1 g daily for 3 days) followed by oral prednisone (1 mg/kg/day) combined with cyclophosphamide (2 mg/kg/day) is advised. Plasma exchange may be added in patients failing or experiencing adverse effects from therapy, but it has been associated with an increased risk for infectious complications. Plasmapheresis may be given three times per week for the first 2 to 3 weeks, and at decreasing frequency during the next 2 to 4 months.

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis (LYG) was initially described in 1972 as a necrotizing vasculitic disorder having several features in common with Wegener's granulomatosis and atypical lymphoma. Histologic features include atypical lymphohistiocytic infiltrates surrounding small and medium-sized arteries and veins, associated with pronounced necrosis of involved organs. The angiocentric pattern, presence of multinucleated giant cells, granulomatous component, and mixed inflammatory cellular infiltrates mimic Wegener's granulomatosis. However, the pronounced cellular atypia resembles a lymphoid malignant disorder (Fig. 13). Clinical manifestations of LYG are protean. Virtually any organ can be involved, but pulmonary, constitutional, neurologic, and cutaneous manifestations predominate. Glomerulonephritis has only rarely been noted. Aberrations on chest radiographs are almost invariably present (Fig. 14). Multiple nodular lesions are typical, but single mass lesions, alveolar infiltrates, cavitary lesions, or pleural effusions may be found. In early studies, anecdotal responses were noted with regimens employing oral cyclophosphamide and corticosteroids (similar to treatment of Wegener's granulomatosis). Subsequent studies have failed to substantiate benefit from corticosteroids alone or in combination with immunosuppressive or cytotoxic agents. Recent investigations utilizing molecular biologic and immunohistochemical techniques (e.g., T-cell gene rearrangements, monoclonal stains) suggest that most (if not all) cases of LYG represent diverse lymphoreticular disorders, including malignant lymphoma, angioimmunoblastic lymphadenopathy, and T-cell lymphomas. LYG should not be classified as a true vasculitis, but rather as a stereotypic response to diverse lymphoreticular disorders. Although optimal therapy has not been clarified, combination chemotherapeutic regimens for malignant lymphoma are appropriate for many patients.

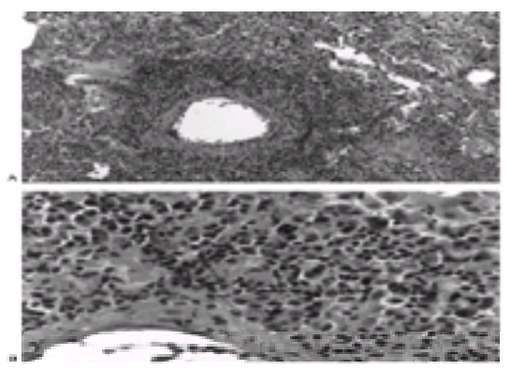

FIG. 13. A: Lymphomatoid granulomatosis. Photomicrograph of open lung biopsy specimen demonstrates intense mononuclear infiltrates surrounding a blood vessel. H&E, high power. (Courtesy of S. Hammar, M.D, University of Washington, Seattle.) **B:** Photomicrograph of specimen from same patient showing polymorphous infiltrate composed of atypical lymphoid and histiocytic cells. Granuloma is not a characteristic histologic abnormality despite the suggestion in the term. H&E, oil immersion. (Courtesy of S. Hammar, M.D, University of Washington, Seattle.)

FIG. 14. Lymphomatoid granulomatosis. PA chest radiograph demonstrates multiple nodular mass densities throughout both lung fields. Open lung biopsy specimen

demonstrates changes consistent with lymphomatoid granulomatosis.

Behçet's Syndrome

Behçet's syndrome is a systemic vasculitis whose major manifestations include oral and genital ulcers, iritis, phlebitis, and nervous system involvement. Recurrent venous thromboses occur in one quarter of patients with Behçet's syndrome. Other possible sites of involvement include skin, gastrointestinal tract, kidneys, heart, joints, and epididymis. Lung involvement occurs in only 1%–5% of cases. Diverse pulmonary manifestations include transient infiltrates, mass lesions, pleural effusions, hemoptysis, aneurysms of the pulmonary arteries, arterial and venous thromboses, pulmonary infarcts, and pulmonary hemorrhage. Massive, fatal hemorrhage from rupture or erosion of pulmonary arterial aneurysms has been described. Behçet's syndrome is more common in the eastern Mediterranean basin but is worldwide in distribution. The onset of disease is most common in the third through fifth decades of life. Histologic features are nonspecific. A necrotizing vasculitis (composed of lymphocytes, plasma cells, and polymorphonuclear leukocytes) involves arteries, veins, and capillaries. Varying degrees of fibrosis, thrombosis, and necrosis are evident. The etiology is not known, but deposits of immune complexes and complement may be prominent in involved tissues. Because of the rarity of this disease, controlled therapeutic trials have not been performed. Corticosteroids, combined with cyclophosphamide or azathioprine, are most commonly employed. Colchicine has been advocated as adjunctive therapy for arthralgias or erythema nodosum. When pulmonary arterial aneurysms are documented, prompt resection should be accomplished.

Hughes-Stoven Syndrome

In 1959, Hughes and Stoven described a symptom complex of pulmonary artery aneurysms and recurrent venous thromboses (especially of the vena cava). A review of the literature up to 1981 identified only 12 patients with Hughes-Stoven syndrome; 11 were young males. Symptoms included fever, central nervous system symptoms resulting from increased intracranial pressure, hemoptysis, arthralgias, and skin rash. Nine died of massive hemoptysis caused by rupture of pulmonary arterial aneurysms. Surgical resection of pulmonary aneurysms was accomplished in all three survivors. Cerebral thrombophlebitis was present in 6 of these 12 cases. Histologic features of involved tissue demonstrated a necrotizing vasculitis. Most if not all cases of “Hughes-Stoven syndrome” likely reflect unrecognized pulmonary vasculitis from other causes (e.g., CSS, Behçet's syndrome).

Takayasu's Arteritis

Takayasu's arteritis is a rare vasculitis primarily affecting large vessels (e.g., aorta and its branches). It may cause arterial stenoses, aneurysms, and distal arterial insufficiency. The most common site of involvement is the subclavian arteries, near their junction with the aorta. The absence of radial pulses has given rise to the term *pulseless disease.* Most series have been reported from Japan, the Orient, and Mexico. Takayasu's arteritis is rare in the United States and Europe. Only 32 cases were given the diagnosis at the Mayo Clinic between 1971 to 1983. The incidence among Caucasians has been estimated at 2.6 cases per million per year. Most patients present between ages 20 and 30; the disease is rare in the elderly. There is a striking female predominance.

Clinical Features

Dominant clinical manifestations, which are related to cessation of blood flow in the aorta or its branches, include claudication of arms or legs, dizziness (reflecting occlusion of the carotid or vertebrobasilar arteries), ischemic cardiac disease, visual loss, and back pain (reflecting aortic aneurysms). Multiple vascular bruits or absent or reduced pulses are characteristic findings on physical examination. Fever, malaise, weight loss, and anemia are noted in more than one third of patients and myalgias or arthralgias in nearly 60%. Elevations in the erythrocyte sedimentation rate may be striking and may be a surrogate marker of disease activity. Results of tests for antinuclear antibodies and rheumatoid factor are negative. Renovascular hypertension occurs in approximately 40% of patients. Aortic insufficiency or aneurysms of the root of the aorta, when present, are major causes of death and warrant surgical correction. Pulmonary vasculitis is rarely recognized ante mortem, but pulmonary arterial aneurysms or stenoses have been documented in up to 50% of patients by pulmonary angiography or necropsy. The diagnosis of Takayasu's disease is usually made on the basis of aortic angiographic findings of occlusions, stenosis, luminal irregularities, tortuosity, or aneurysms in a young woman with arterial occlusive symptoms. Dilatation of the aortic root or aortic insufficiency may occur. Similar findings may be observed on pulmonary arteriography. Bypass grafts for aortic occlusive lesions have been successfully performed in some patients. Histopathology is rarely confirmed, except at the time of resection or bypass of arterial lesions. Salient features are a granulomatous, sclerosing arteritis indistinguishable from giant cell (temporal) arteritis.

Therapy

Corticosteroids are the cornerstone of therapy. Most experts initiate therapy with prednisone (1 mg/kg/day) for 4 to 6 weeks, followed by a gradual taper according to symptoms and sedimentation rate. Cyclophosphamide should be considered for severe cases or patients failing corticosteroids. With aggressive medical therapy, survival exceeds 90%, and severe sequelae can be averted. Factors associated with increased mortality include severe systemic hypertension, aortic incompetence, and marked aneurysm formation. Far-advanced stenoses or occlusions caused by inactive, sclerotic lesions are not influenced by immunosuppressive therapy. In these circumstances, when symptoms of vascular compromise are evident, angioplasty, surgical reconstruction, or bypass grafts should be performed.

Henoch-Schönlein Syndrome

Henoch-Schönlein syndrome is a necrotizing vasculitis principally affecting children; major manifestations are palpable purpura, hematuria, and abdominal pain. Lung involvement is exceedingly rare, but extensive alveolar hemorrhage and capillaritis have been described. Henoch-Schönlein syndrome is caused by circulating immune complexes, with IgA reacting to target antigens in the renal glomerulus, skin, or gastrointestinal tract. A small-vessel vasculitis, associated with pronounced deposition of IgA in glomerular capillaries and affected vessels, is pathognomonic. Henoch-Schönlein syndrome is often self-limited and may not require therapy. Corticosteroids should be considered for severe or protracted cases.

ALVEOLAR HEMORRHAGE SYNDROMES

Autoimmune diffuse alveolar hemorrhage (DAH) may occur as a result of diffuse injury to the pulmonary microvasculature (termed *capillaritis* or *endotheliitis*). The course is typically abrupt, associated with bilateral alveolar infiltrates, hemoptysis, hypoxemia, and iron deficiency anemia. Glomerulonephritis is present in the vast majority of cases of DAH with immune-mediated causes (hence the term *pulmonary-renal syndromes*). Etiologies of DAH include antiglomerular basement membrane disease, systemic necrotizing vasculitis, idiopathic glomerulonephritis (immune complex or pauci-immune), collagen vascular disease, bone marrow transplantation, HIV infection, and exposure to exogenous agents or drugs. Idiopathic pulmonary hemosiderosis, a rare cause of recurrent DAH, occurs primarily in children and remains a diagnosis of exclusion.

Diagnostic Evaluation of Diffuse Alveolar Hemorrhage

The clinical features of DAH may be similar, regardless of etiology. Hemoptysis and a fall in the hematocrit support the diagnosis of DAH but are etiologically nonspecific. Nonimmune causes of DAH include endobronchial tumors, ulcerative tracheobronchitis, arteriovenous malformations or aneurysms, hemorrhagic pneumonia, bronchiectasis, congestive heart, failure, uremia, thrombocytopenia, coagulopathy, pulmonary veno-occlusive disease, and massive pulmonary embolism. The nonimmune causes must be excluded in patients with severe DAH. Depending on the clinical scenario, coagulation profiles and ancillary tests (e.g., echocardiogram, pulmonary angiography) may be required to establish a specific diagnosis. Fiberoptic bronchoscopy is useful to look for a site of active bleeding and rule out an infectious etiology. The role of lung biopsies is controversial and will be discussed later. Urinalysis and renal function tests should be performed in cases of suspected DAH, as rapidly progressive glomerulonephritis is a nearly invariable feature of immune-mediated pulmonary-renal syndromes. A battery of serologic studies may disclose an immunologic cause of DAH. These include antinuclear antibody (ANA), antineutrophilic cytoplasmic antibody (ACNA), antiglomerular basement membrane antibody (anti-GBM antibodies), and serum complement. However, the results of tests for anti-GMB antibodies or ANCA may not be available for several days. In this context, biopsy of kidney, lung, or other involved sites (e.g., skin, sinuses) may be required.

The role of open (or thoracoscopic) lung biopsy in the evaluation of DAH is controversial. Lung biopsies are seldom definitive, as gross and histologic findings may be similar irrespective of underlying etiology. Lung biopsies typically demonstrate flooding of alveolar spaces with blood, associated with diffuse injury to the pulmonary microvasculature (capillaritis). Capillaritis is a distinctive histologic lesion characterized by neutrophilic infiltration of capillaries, fragmented neutrophils (leukocytoclasis), and necrosis of the capillary walls. However, this lesion is nonspecific and may be seen in DAH complicating a variety of immune disorders (e.g., systemic necrotizing vasculitis (SNV), systemic lupus erythematosus, anti-GBM disease, idiopathic or immune complex-mediated rapidly progressive glomerulonephritis). Hemosiderin-laden macrophages within the alveolar spaces and interstitium may reflect prior episodes of DAH. Immunofluorescent studies are difficult to interpret in lung tissue and may be misleading. Surgical (open or thoracoscopic) lung biopsy carries significant morbidity, with the potential for prolonged air leak and secondary infections in patients with DAH and marginal pulmonary reserve. Thus, we see no role for surgical lung biopsy in patients with severe or acute DAH. Fiberoptic

bronchoscopy with BAL, which can be performed with little morbidity even in intubated patients, is usually adequate to exclude infectious etiologies and may support the diagnosis. Gross blood in the airways, bloody or serosanguinous BAL fluid, and hemosiderin-laden macrophages in BAL fluid strongly suggest DAH in the appropriate clinical setting. Thoracoscopic lung biopsy may have a role in selected patients with a more indolent course, negative serologies, and nondiagnostic renal biopsy and bronchoscopy.

Serologies, renal biopsies (with immunofluorescent stains), or biopsies of extrapulmonary and extrarenal sites (when vasculitis is present) may differentiate the various causes of pulmonary renal syndromes. When urinary sediment or renal function tests suggest glomerulopathy, percutaneous renal biopsy (to include immunofluorescent stains) should be performed. Renal biopsies in immune-mediated DAH demonstrate focal or diffuse glomerulonephritis, with extracellular proliferation (crescents) and necrosis. These findings, although distinctive, are nonspecific. However, the pattern of immunofluorescent staining is pivotal in establishing a specific etiologic diagnosis. A linear pattern of immunofluorescence is pathognomonic for anti-GBM disease. Either a lumpy-bumpy pattern (indicating immune complexes) or negative immunofluorescence (termed *pauci-immune*) can be seen with SNV, systemic lupus erythematosus, or idiopathic rapidly progressive glomerulonephritis. In critically ill patients with severe DAH, percutaneous renal biopsy may be logistically difficult or impractical. In this context, empiric therapy with pulse methylprednisolone (1 g daily for 3 days), possibly combined with cytotoxic agents or plasmapheresis, is reasonable pending results of serologic studies.

Specific Disorders Associated with Diffuse Alveolar Hemorrhage

Antiglomerular Basement Membrane Disease

Antiglomerular basement membrane (anti-GBM) disease, also termed *Goodpasture's syndrome,* is the prototype of pulmonary-renal syndromes, manifested as DAH and rapidly progressive glomerulonephritis (RPGN). Isolated RPGN without DAH may occur, but isolated DAH without RPGN is exceptionally rare. Anti-GBM disease accounted for 18%–32% of immune-mediated DAH syndromes in two recent series. Anti-GBM disease typically presents in patients between 20 and 40 years of age. There is a distinct male predominance. A specific cause has not been elucidated, but exposure to inhaled hydrocarbons and antecedent viral illnesses (particularly influenza) have been cited as risk factors. Cigarette smoking enhances the risk for DAH in patients with circulating anti-GBM antibody.

Clinical Features

Pulmonary manifestations usually dominate in the early phases of the disease. Hypoxemic respiratory failure, with widespread alveolar infiltrates on chest radiographs, is characteristic. Hemoptysis occurs in 70%–80% of patients and anemia in 85%. In 20%–30% of cases, the disease is limited to the kidneys. Organs other than lung or kidney are not involved, but constitutional symptoms (e.g., fatigue, weakness) may be prominent. Gross hematuria has been noted in 10%–41% of patients with anti-GBM disease. Microscopic hematuria or proteinuria are virtually always present. Renal function may be normal in 40%–60% of patients at presentation, but progressive renal failure develops within days to weeks. Oliguria, severe renal failure, or >50% crescents on renal biopsy are associated with a poor prognosis and low rate of recovery of renal function. Early institution of therapy is critical to optimize outcome. Circulating anti-GMB antibodies are detectable by radioimmunoassay or enzyme-linked immunosorbent assay (ELISA) in >95% of patients. These assays are highly specific (95%) but are performed in only a few research laboratories, and results are usually not available for a few days. Prognosis for recovery is related to the severity of the renal lesion. Prompt therapy is mandatory to avert irreversible loss of glomerular function. Thus, percutaneous renal biopsy should be done in any patient with significant abnormalities in urinary sediment or renal function pending the results of serum anti-GMB antibody assays. Identification of the pathognomonic linear immunofluorescent pattern on renal biopsy allows institution of therapy with plasmapheresis and immunosuppressive/cytotoxic therapy (to be discussed later). Serial measurement of serum anti-GBM antibodies is invaluable to monitor the course of the disease. Results of other serologic studies are negative or nondiagnostic.

Histopathology

Renal biopsy with immunofluorescent stains is the preferred method of establishing the diagnosis. Conventional light microscopy demonstrates a proliferative glomerulonephritis with cellular crescents. Foci of interstitial fibrosis or tubular atrophy may be observed but are rarely prominent. These histologic features are nonspecific. However, intense immunofluorescent linear deposits of IgG along glomerular basement membranes are pathognomonic for anti-GBM disease. Linear deposits of IgM or IgA have rarely been described. As was discussed earlier, open (or thoracoscopic) lung biopsies are rarely helpful. Histologic features are dominated by extensive intra-alveolar hemorrhage and hemosiderin-laden macrophages. Foci of neutrophilic “capillaritis,” hyaline membranes, and diffuse alveolar damage are concomitant features. Extensive necrosis and large-vessel vasculitis are not found. These histopathologic features are nonspecific. Immunofluorescent stains of lung tissue are not reliable. Because of its potential morbidity, we rarely employ open or thoracoscopic lung biopsies in the evaluation of DAH. A diagnosis can usually be substantiated by renal biopsies, BAL, and appropriate serologic studies.

Pathogenesis

Anti-GBM antibodies are directed against the a_3 chain of type IV collagen, an antigen highly expressed in both alveolar and glomerular basement membranes. The stimulus for anti-GBM antibody formation remains speculative, but both environmental and genetic factors may play roles. A genetic susceptibility is plausible, as anecdotal cases of anti-GBM disease have been described in siblings, first cousins, and identical twins, and links between anti-GBM disease and the HLA-DR2 histocompatibility antigen have been noted. Exposure to cigarette smoke, hydrocarbon-containing solvents, hard-metal dust, influenza A2 virus, chlorine gas, and D-penicillamine have been associated with anti-GBM disease. These exogenous factors may injure the basement membrane, resulting in increased capillary permeability and exposure of the Goodpasture antigen (a_3 chain of type IV collagen), which elicits a helper T-cell response. Stimulation of IgG synthesis results in deposits of IgG along the alveolar and capillary basement membranes. Anti-idiotypic (blocking) antibodies and activated suppressor ($CD8^+$) T cells may facilitate resolution of the process, but this is speculative. Pulmonary edema, infection, and cigarette smoking have been associated with an increased risk for DAH in patients with circulating anti-GBM antibody, possibly because of increased lung capillary permeability that allows access of the antibody to the alveolar spaces.

Treatment

Before the availability of therapy, mortality associated with anti-GBM disease exceeded 90%, with mean survival of 6 months. Plasmapheresis, introduced as a therapeutic option for anti-GBM disease in the mid-1970s, was quickly adopted worldwide and is considered as part of standard therapy. Current therapy involves a combination of plasmapheresis (to eliminate circulating anti-GBM antibodies) plus immunosuppressive agents (to suppress antibody synthesis). Prognosis of anti-GBM disease is influenced by the severity of the renal lesion at the outset. In one study, 22 of 23 patients with oliguria or a serum creatinine level of 6 mg% failed to recover, even with aggressive therapy. By contrast, 15 of 17 with nonoliguric renal failure and a serum creatinine level of >6 mg% recovered or improved with plasmapheresis and immunosuppressive/cytotoxic therapy. Thus, prompt diagnosis and initiation of therapy are mandatory to avoid irreversible renal failure. Because of the rarity of anti-GBM syndrome, only one randomized trial has compared immunosuppressive therapy alone versus the combination of immunosuppressive therapy and plasmapheresis. In that study, combined therapy was associated with more rapid disappearance of anti-GBM antibody and improved renal function. End-stage renal disease requiring chronic dialysis developed in 6 of 9 patients treated with immunosuppressive agents alone (compared with 2 of 8 in the plasmapheresis group). The incidence of recurrent pulmonary hemorrhage was similar (4 in each group). Optimal dose and duration of plasma exchange have not been defined. Plasma exchanges have usually been done daily or every 2 to 3 days for the first 10 to 21 weeks, until clinical improvement has occurred and serum anti-GBM antibodies are nondetectable. Less frequent plasmapheresis (every 3 to 5 days) has been used, with purported success. The optimal immunosuppressive regimen has not been delineated. For acute, life-threatening DAH, pulse methylprednisolone (1 g daily for 3 days), following by a corticosteroid taper, is advised. Once the DAH is controlled, oral prednisone (1 mg/kg/day) may be substituted, and oral cyclophosphamide (2 mg/kg/day) or azathioprine (2 to 3 mg/kg/day) are added to suppress continued antibody synthesis. No studies have specifically compared cyclophosphamide with azathioprine, but we favor cyclophosphamide. Immunosuppressive agents should be continued until the clinical syndrome has resolved and anti-GBM antibodies have disappeared. In most cases, symptoms resolve and circulating antibodies clear within 8 weeks, irrespective of the initial titer. Renal function usually recovers in patients with minor functional impairment. Dialysis-dependent patients rarely recover renal function. A 4- to 6-month trial may be adequate in some cases. Long-term survival rates exceed 85%. Late recurrences have been rare.

Systemic Necrotizing Vasculitis

Pulmonary hemorrhage is a well-recognized complication of Wegener's granulomatosis and MPA, and may rarely complicate CSS, Behçet's syndrome, mixed cryoglobulinemia, and other systemic necrotizing vasculitides. Necrotizing vasculitis accounts for 40%–55% of DAH syndromes. Regardless of the specific underlying vasculitic disorder, rapidly progressive glomerulonephritis (RPGN) is a nearly invariable feature. A cardinal feature of DAH complicating vasculitis is diffuse damage to the pulmonary endothelium (capillaritis). The histologic features are nonspecific. Granulomatous or eosinophilic components, geographic necrosis, or vasculitis involving larger vessels (e.g., arterioles) are usually not evident. High-dose intravenous (pulse) methylprednisolone (1 g daily for 3 days) should be given for acute, fulminant DAH. Long-term therapy with oral cyclophosphamide and corticosteroids is appropriate for necrotizing vasculitis. The specific regimens have been discussed in greater detail in the sections on pulmonary vasculitis.

Collagen Vascular Disorders

Collagen vascular disorders, principally systemic lupus erythematosus (SLE), account for 10%–30% of pulmonary-renal syndromes. Pulmonary hemorrhage is a

well-recognized, albeit rare, complication of SLE, but only sporadic cases of DAH have been described complicating rheumatoid arthritis, progressive systemic sclerosis, polymyositis, or dermatomyositis. Recently, Schwarz and colleagues described two patients with polymyositis, progressive respiratory failure, and DAH secondary to pulmonary capillaritis. Management is similar to that for DAH complicating SLE. DAH complicating SLE usually occurs in patients with a prior history of SLE and active disease elsewhere (e.g., fever, arthritis, serositis). However, DAH has been the sole and presenting feature of SLE in some cases. As in other DAH syndromes, results of lung biopsies are nonspecific, showing hemorrhage and foci of capillaritis. Granular deposits of complement (C3) and IgG have been noted in some cases (suggesting immune complex deposits) but this has not been uniform. Intravenous pulse methylprednisolone is the treatment of choice for severe DAH. For less severe cases, high-dose prednisone may be adequate. Plasmapheresis or immunosuppressive/cytotoxic drugs may be required for patients failing to respond to corticosteroids.

Idiopathic Rapidly Progressive Glomerulonephritis

DAH may complicate idiopathic RPGN, a primary renal disorder of unknown etiology. Immune complexes are present in serum or renal tissue in 20% of patients with idiopathic RPGN. When no immune complexes are found, the term *pauci-immune glomerulonephritis* has been used. Clinical features of idiopathic RPGN are similar, irrespective of whether immune complexes are present. Progressive renal failure is the predominant manifestation and major cause of morbidity in this disease. Lung involvement (typically capillaritis) occurs in 20%–50% of cases but is rarely severe. Some patients manifest mild hemoptysis and transient alveolar infiltrates but are otherwise asymptomatic. However, occasional patients manifest life-threatening DAH and require mechanical ventilatory support. Fever, myalgias, malaise, and a flulike illness precede the renal lesion in nearly two thirds of patients. Other organs are not involved and systemic vasculitis is lacking. All ages may be affected, but idiopathic RPGN has a predilection for adults in the sixth and seventh decades; there is a male predominance (2:1 ratio). In untreated patients, progressive renal failure develops within a few weeks to months; nearly 75% require dialysis. The prognosis is poor among patients presenting with serum creatinine levels of >6 mg% or with oliguria. Renal biopsy demonstrates crescentic, rapidly progressive glomerulonephritis (with or without immune complexes). These features are nonspecific. Circulating ANCA (typically p-ANCA) are present in up to 70% of cases with idiopathic RPGN.

Optimal therapy is controversial. A variety of treatment regimens incorporating corticosteroids, immunosuppressive/cytotoxic drugs, and plasmapheresis, alone or in combination, have been tried. In one multicenter, randomized trial, survival and renal function were similar with three treatment regimens utilizing corticosteroids alone, corticosteroids plus oral cyclophosphamide, or corticosteroids plus intravenous cyclophosphamide. Most investigators treat initially with pulse methylprednisolone (30 mg/kg/day for 3 days), followed by high-dose prednisone (2 mg/kg on alternate days) until remission or stability has been achieved. Cytotoxic agents or plasmapheresis can be reserved for fulminant or corticosteroid-refractory cases. A prolonged course of therapy is usually not necessary, as it is in other pulmonary-renal syndromes. Therapy for 4 to 6 months may be adequate in responding patients.

Bone Marrow Transplantation

DAH has been noted in 6%–21% of bone marrow transplant recipients receiving high-dose chemotherapy. Acute respiratory failure and secondary infections are serious, and potentially lethal, complications of DAH. The etiology is likely diffuse injury to the pulmonary microvasculature resulting from the effects of chemotherapy or radiation, compounded by an intense cellular inflammatory response. The onset of DAH frequently coincides with marrow recovery and neutrophils within BAL fluid. High-dose corticosteroids have been associated with improved survival, supporting an immune-mediated mechanism. Methylprednisolone in intravenous doses of 125 to 250 mg every 6 hours for 3 to 5 days, followed by prednisone tapered gradually during 2 to 4 weeks, is suggested. Low-dose prednisone appears to be no better than supportive therapy (approximately 90% mortality).

Human Immunodeficiency Virus (HIV) Infection

DAH may rarely complicate HIV infection. Pulmonary vasculitis has been noted at necropsy in patients with acquired immune deficiency syndrome (AIDS). CMV exhibits tissue tropism for endothelial cells, and CMV pneumonitis has recently been implicated as a cause of DAH. Disseminated viremia, visceral involvement, microangiopathic anemia resulting from intravascular hemolysis, viral giant cells within pulmonary endothelial cells, and pulmonary capillaritis have been noted. Antiviral therapy (e.g., ganciclovir) is usually efficacious.

Exogenous Agents

DAH rarely complicates the administration of exogenous agents (e.g., trimellitic anhydride, isocyanates, lymphangiogram dye) or drugs (D-penicillamine, “crack” cocaine). Glomerulonephritis has been observed in DAH associated with D-penicillamine, but not with the other agents. Results of serologic studies (e.g., anti-DNA, ANA, anti-GBM antibody) have been negative. Lung biopsies have revealed nonspecific alveolar hemorrhage with no evidence for vasculitis or immune deposits. Treatment involves discontinuation or avoidance of the implicated agent or drug. For severe cases, a brief course of high-dose corticosteroids is warranted. Plasmapheresis may be considered for fulminant cases refractory to corticosteroids, but data supporting its use are lacking.

Idiopathic Pulmonary Hemosiderosis

Idiopathic pulmonary hemosiderosis (IPH) is a rare cause of recurrent DAH of unknown etiology. It occurs almost exclusively in children. The natural history is variable, but repetitive episodes of DAH for many years is characteristic. Three-year mortality rates of 30%–50% have been cited. Extrapulmonary involvement does not occur, and vasculitis is lacking. Results of serologic studies (including anti-DNA, ANA, ANCA, serum complement) are negative. Because the clinical features of IPH overlap with those of other immune-mediated DAH syndromes, negative renal and lung biopsy findings are required to substantiate the diagnosis of IPH. Many of the reported cases of IPH in adults occurred before the availability of serologic markers (e.g., ANCA, anti-GBM antibody) or immunofluorescent studies. In many cases initially considered “idiopathic,” other features of systemic vasculitis or connective tissue disease developed months or even years after the initial presentation. In two studies comprising 85 patients with DAH, only one patient had IPH. The diagnosis of IPH can be made only in individuals with recurrent episodes of DAH, no extrapulmonary involvement, negative lung and kidney biopsy findings, negative serology findings, and no alternative etiology after an exhaustive investigation and long-term follow-up. Because of its rarity, optimal treatment of IPH is not known. Corticosteroids are the mainstay of therapy. Long-term (and possibly indefinite) therapy may be required to prevent recrudescent disease. Alternate-day corticosteroids should be considered after the first 6 to 12 months to minimize long-term side effects. Immunosuppressive or cytotoxic agents may be used in patients refractory to or experiencing adverse effects from corticosteroids. As circulating antibodies have not been identified, we see no role for plasmapheresis.

PULMONARY ALVEOLAR PROTEINOSIS

Pulmonary alveolar proteinosis (PAP), also termed *alveolar phospholipidosis,* is a rare syndrome of unknown cause originally described by Rosen and colleagues in 1958. They reviewed histologic material from 27 patients, referred from across the world, who had undergone lung biopsy or autopsy. The distinctive histologic features included extensive flooding of alveolar spaces with a granular, eosinophilic material; however, an inflammatory component was lacking. It has since been established that the intra-alveolar material is composed primarily of lipoprotein (surfactant apoproteins). This thick, viscid, surfactant-like material fills the alveolar spaces, resulting in cough, dyspnea, and impaired gas exchange. The exact incidence of PAP is unknown. By 1980, only 260 cases had been published. The prevalence has been estimated at one case per million adults per 5-year period. The disease is two to three times more common in male patients, most of whom are between 20 and 50 years of age, but all ages may be affected. The clinical features and course are variable, and spontaneous remissions occur in 20%–30% of cases. Some patients manifest a waxing and waning course for many years.

Clinical Features

Symptoms of cough and exertional dyspnea develop insidiously and typically progress for weeks or months. The cough is usually nonproductive, but some patients expectorate plugs of grayish-yellow viscid sputum. Hemoptysis has been noted in 3%–24% of patients. A sensation of chest tightness or heaviness is present in one third of patients. Constitutional symptoms of weight loss, malaise, and fatigue may be present, but extrapulmonary involvement does not occur. Up to 20% of patients are asymptomatic. Physical examination reveals rales over involved areas; wheezing is unusual. Cyanosis has been noted in up to 20% of cases, and clubbing in 29%–40%. Chest radiographs (discussed in greater detail below) typically reveal bilateral alveolar infiltrates. Serum lactate dehydrogenase (LDH) is increased in approximately 80% of patients; no other distinctive laboratory features exist. Patients with PAP have an increased susceptibility to infections with *Nocardia* species, *S. aureus, Mycobacteria,* and fungi. This heightened susceptibility to infections reflects defects in alveolar macrophage chemotaxis, phagocytosis, and microbicidal activity and obstruction of the alveolar spaces with the thick debris. Defects in alveolar macrophage function reverse following therapeutic whole-lung lavage. Because of the rarity of the disorder and the nonspecificity of symptoms, the mean interval between onset of symptoms and diagnosis often exceeds 1 year. Untreated PAP usually progresses indolently for months to years. Before the availability of therapy, one third of patients died of respiratory failure or infectious complications. Treatment with whole-lung lavage (to be discussed later) is usually efficacious, but relapses occur in 15%–30% of treated patients.

Chest Radiographs

Chest radiographs typically demonstrate symmetric, fluffy, perihilar alveolar infiltrates (a “bat wing” appearance) (Fig. 15A). Asymmetric or even unilateral involvement

occurs in 20% of patients. The infiltrates exhibit an alveolar or ground-glass pattern, but reticulonodular patterns or mixed interstitial-alveolar patterns have been noted. Differential diagnosis includes pulmonary edema (cardiac and noncardiac), BOOP, alveolar hemorrhage syndromes, DIP, and a wide spectrum of ILD. Persistent linear interstitial infiltrates have been noted in some patients, which may represent areas of fibrosis. Intrathoracic lymphadenopathy, cavitary lesions, or pleural effusions are not features of PAP. CT more clearly reveals the distinctive alveolar involvement, often with striking air bronchograms (Fig. 15B). However, chest CT is expensive and not required for either staging or follow-up of PAP.

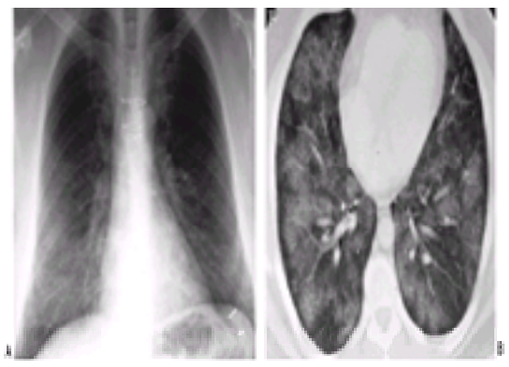

FIG. 15. A: Pulmonary alveolar proteinosis. PA chest radiograph demonstrates bilateral, predominantly basilar infiltrates in a 50-year-old man with progressive exertional dyspnea. **B:** CT in the same patient demonstrates multiple foci of ground-glass opacification throughout through parenchyma. Open lung biopsy demonstrates classic features of PAP.

Pulmonary Function Tests

The major physiologic aberration is intrapulmonary shunt, resulting in hypoxemia and a widened $P(A - a)O_2$. DLCO is usually reduced, but pulmonary function tests in PAP may be normal. Vital capacity or lung volumes are only mildly affected. Expiratory flow rates and FEV_1 are usually normal, but airways obstruction may be noted in smokers. These physiologic aberrations typically improve or normalize following treatment with whole-lung lavage.

Histologic Features

Grossly, the lung is consolidated, and alveolar spaces and respiratory bronchioles are filled with a granular, amorphous, acidophilic material (Fig. 16). The alveolar septa are usually normal. Interstitial inflammation and fibrosis are not features of PAP. However, hyperplastic type II pneumocytes may be observed. These histologic features bear some resemblance to those of *P. carinii* pneumonia but lack the interstitial inflammatory component, diffuse alveolar damage, and foamy intra-alveolar exudate seen in that condition. The intra-alveolar material in PAP contains phospholipids (surfactant-like material) that stain bright pink with periodic-acid Schiff (PAS) reagent and negative with alcian blue. The diagnosis of PAP has usually been established by open lung biopsy. However, the diagnosis can sometimes be made by fiberoptic bronchoscopy. The gross characteristics of BAL fluid are distinctive. The lavage effluent reveals thick, viscid, opaque, yellowish-white milky fluid that sediments into multiple layers on standing. Positive PAS and negative alcian blue stains of the foamy BAL fluid may confirm the diagnosis. Large numbers of PAS-positive, eosinophilic acellular bodies, and alveolar macrophages containing granular eosinophilic material within phagocytosomes or cytoplasm, may be found in BAL fluid. High levels of surfactant proteins A (SP-A) and D (SP-D) have been found in BAL fluid from patients with PAP; these stain intensely using immunohistochemical methods. These immunohistiochemic techniques are limited to a few research laboratories. SP-A is highly glycosylated, which may account for the positive PAS staining.

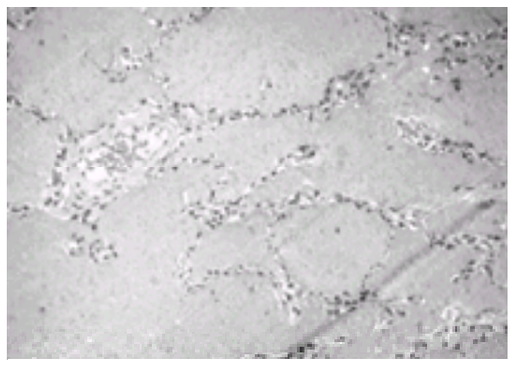

FIG. 16. Pulmonary alveolar proteinosis. Photomicrograph of open lung biopsy specimen demonstrates complete filling of alveolar spaces with a dense proteinaceous exudate. The alveolar architecture is preserved. H&E, high power. (Reproduced with permission from Lynch JP III, Chavis AD. Chronic interstitial pulmonary disorders. In: Victor L, ed. *Clinical Pulmonary Medicine.* Boston: Little, Brown; 1992:250, Fig. 11-15.)

BAL or transbronchial lung biopsies may substantiate the diagnosis, provided the typical PAS-positive intra-alveolar exudate is evident. Thoracoscopic or open lung biopsies are warranted when bronchoscopic findings are equivocal or nondiagnostic. Electron microscopy and transmission electron microscopy are primarily research techniques. These techniques demonstrate alveolar macrophages engorged with phagolysosomes, complex inclusions, lamellar bodies, cholesterol inclusions, and lipid droplets. Concentric, laminated lamellar bodies containing phospholipids, tubular myelin, and myelin structures within alveolar spaces or in BAL fluid are pathognomonic for PAP.

Pathogenesis

The pathogenesis of PAP is not known. The massive accumulation of surfactant-like phospholipids within the alveolar spaces suggests that abnormal turnover of phospholipids (e.g., by impaired clearance) or excessive production of surfactant (by type II pneumocytes) is responsible. Defects in the clearance or degradation of surfactant lipoproteins may reflect dysfunction of type II pneumocytes. The inciting signals or stimuli for PAP have not been identified, but a history of exposure to hydrocarbons, chemicals, chlorinated resins, fiberglass, aluminum, cadmium, titanium, silica, asbestos, volcanic ash, or a variety of solvents has been elicited in up to 50% of patients. Exogenous dusts or metals may overwhelm the normal clearance mechanisms of the lung. A variety of animal models resembling PAP have been produced by inhalation of fine dust particles (e.g., silica, crushed fiberglass, volcanic ash, bismuth, nickel, aluminum, antimony, titanium). In these models, inhaled dust particles elicit an influx of macrophages into the alveolar spaces, followed by proliferation of type II pneumocytes and accumulation of phospholipid. The alveolar macrophages ingest and become engorged with the phospholipid material. The alveolar spaces become filled with lipoproteinaceous material from the hyperplastic type II pneumocytes and disintegrating phospholipid-laden macrophages. These pathologic features strikingly resemble the lesion of PAP in humans. Chronic ingestion of certain drugs (e.g., amiodarone, chlorphentermine, and iprindole) induces a PAP-like reaction in animals. Inhibition of phospholipase may be responsible for the excessive accumulation of the lamellar, phospholipid inclusions in alveolar macrophages and within alveolar spaces in these affected animals. Cases of drug-induced PAP in humans have not been described, but these animal models may provide clues to possible mechanisms for PAP. No genetic basis for PAP has been found in humans, but PAP has rarely been reported in siblings. Lesions resembling PAP have been described in mice with severe combined immunodeficiency (SCID mice). These mice exhibit excessive amounts of eosinophilic surfactant-like material in alveolar spaces and BAL fluid and marked increases of SP-A and SP-B in BAL fluid. In animals, distinct forms of spontaneous PAP have been described. In one form, macrophages were unable to digest the phospholipoprotein complex. Other models are consistent with a defect in surfactant homeostasis. In humans, secondary forms of PAP (termed *pseudoproteinosis*) rarely complicate hematologic malignancies, AIDS, solid tumors, tuberculosis, specific infections, and interstitial pneumonitis. In these cases, involvement is usually focal and patchy. The intra-alveolar material in pseudoproteinosis may represent necrotic debris and exudate rather than the surfactant-like material characteristic of PAP. In secondary forms of PAP, remission of the underlying disease is the critical determinant of a successful outcome. Whole-lung lavage, the treatment of choice for primary PAP, is of doubtful value in secondary PAP.

Treatment

Corticosteroids, trypsin, heparin, acetylcysteine, and pancreatic enzymes have been used to treat PAP, but none are efficacious. Whole-lung lavage, introduced by Ramirez and colleagues in 1965, is the treatment of choice for PAP. Whole-lung lavage physically removes the copious, thick viscid material, allowing the alveolar spaces to re-expand and participate in gas exchange. When occupational exposure to solvents, chemicals, or dust is suspected as the cause, withdrawal from that occupation is warranted. Treatment is not required in every patient with PAP, as the disease may be mild and associated with minimal symptoms in some cases. Unilateral lung lavage has potential morbidity and should be performed by individuals who have experience with the technique. This is best accomplished under general anesthesia to ensure adequate control of the airway and optimal ventilatory management. A double-lumen endotracheal tube is placed. The most severely involved lung is allowed to deflate, and the opposite lung is ventilated with oxygen and anesthetic. Unilateral lung lavage is then carried out with successive aliquots (500 to 1000 mL) of sterile isotonic saline solution (warmed to body temperature), and the effluent is immediately suctioned and removed. With repeated instillation, the lavage effluent progressively thins. Chest percussion and rotating the patient during the procedure may enhance clearance of the thick, viscid material. The procedure is terminated after the lavage effluent no longer returns significant viscid material or markedly improves. The volume of fluid instilled is considerable, ranging from 20 to 50 L. The duration of the procedure takes on average 3 to 5 hours. Once it has been completed, the lavaged lung is ventilated. Extubation can usually be accomplished within 1 hour of completion of the procedure. Patients are observed to ensure adequate ventilation. Potential complications of the procedure include pneumothorax, pulmonary edema, spillage of lavage fluid into the contralateral lung, worsening respiratory failure, bronchospasm, and aspiration pneumonia. With proper technique and control of the airway, these adverse events occur in <5% of patients. Most patients can be discharged within 24 hours after lavage has been completed. Gradual improvement in symptoms, arterial blood gases, and chest radiographs occurs during the next few weeks. We prefer to wait 4 to 6 weeks before performing unilateral lavage of the contralateral lung. For more fulminant or severe cases, the contralateral lung can be lavaged immediately or a few days after the initial lavage.
Whole-lung lavage is highly efficacious. Symptomatic, physiologic, and radiographic improvement is noted in 75%–95% of patients. Fatalities are rare. Recurrent disease requires repeated lavage in 15%–30% of patients within 1 to 5 years. Serial chest radiographs, oximetry (or arterial blood gases), and LDH should be monitored at 3-month intervals for the first year to rule out relapse. Thereafter, follow-up at 6- to 12-month intervals may be adequate in asymptomatic patients. Recrudescent disease warrants repeated lavage.

EOSINOPHILIC GRANULOMATOSIS

Pulmonary eosinophilic granulomatosis (also termed *histiocytosis X* or *Langerhans' cell granulomatosis*) is a rare granulomatous disease usually seen in smokers. It may present with cough, dyspnea, and interstitial, reticulonodular, or cystic changes on chest radiographs. Eosinophilic granulomatosis (EG) accounts for <4% of chronic ILD. The precise incidence is unknown, but prevalence rates of one to five cases per million population have been suggested. Pulmonary EG is almost exclusively seen in Caucasians, suggesting a genetic predisposition, but a specific genetic defect has not been elucidated. There is a slight male predominance. Pulmonary EG is rare in children and typically affects adults between ages 20 and 50. More than 90% of patients with pulmonary EG are smokers, suggesting an etiologic relationship.

Clinical Features

Clinical features of pulmonary EG are variable. Ten percent to 25% of patients with pulmonary EG are asymptomatic, with incidental findings on chest radiographs. Cough and dyspnea are the most common symptoms, noted in 60%–75% of patients. Symptoms usually develop insidiously during several weeks or months. Physical examination is usually unremarkable, but rales, rhonchi, wheezes, or diminished breath sounds may be present. Clubbing occurs in <5% of patients. Pneumothorax, caused by rupture of subpleural cysts, occurs in 6%–20% of patients and may be the presenting feature (Fig. 17). Pneumothoraces frequently recur and may require surgical pleurodesis. At thoracotomy, numerous subpleural cysts and blebs are usually evident. Low-grade fever, malaise, weight loss, and anorexia are present in 15%–30% of patients. There are no distinctive hematologic or serologic aberrations in pulmonary EG. Blood eosinophil counts are normal. Extrapulmonary involvement (particular osteolytic bone lesions or diabetes insipidus) occurs in 15%–20% of adults with pulmonary EG. By contrast, EG in children (typically in children under age 10) is characterized by prominent osseous and extrapulmonary manifestations. The incidence of bronchogenic carcinoma is increased in smokers with pulmonary EG. In one study of 93 patients with pulmonary EG, five cases of bronchogenic carcinoma were noted, for an annual risk of 1040/100,000. Cigarette smoking amplifies the cancer risk.

FIG. 17. Eosinophilic granulomatosis. PA chest radiograph demonstrates far-advanced cystic changes throughout lung parenchyma and bilateral pneumothoraces in a patient with pulmonary EG.

Chest Radiographic Features

Conventional chest radiographs typically reveal diffuse reticular, reticulonodular, or cystic lesions that preferentially involve the middle and upper lung zones, sparing the costophrenic angles (Fig. 18). Cystic radiolucencies, 5 to 15 mm in diameter, reflect dilated bronchi and bronchioles, with peribronchial thickening or areas of destroyed lung parenchyma. Nodules (typically 2 to 5 mm in size) are centered around bronchioles and reflect cellular granulomatous lesions (Fig. 19). The combination of pneumothorax, upper lobe cysts, and finely nodular lesions strongly suggests the diagnosis of pulmonary EG. Other CILD with a predilection for upper lobe involvement include sarcoidosis, granulomatous infections, silicosis, ankylosing spondylitis, and chronic eosinophilic pneumonia. Pleural effusions and intrathoracic adenopathy are not features of EG.

FIG. 18. A: Eosinophilic granulomatosis. Coned-down view of PA chest radiograph demonstrates finely nodular and cystic densities throughout lung parenchyma in a 56-year-old man with progressive cough and dyspnea. Transbronchial lung biopsies demonstrated typical histologic features of EG. S-100 stains were also positive. **B:** CT in the same patient demonstrates multiple, well-defined cystic spaces with walls measuring 1 to 2 cm in size. A few ill-defined, scattered interstitial nodules are also present but are subtle.

FIG. 19. Eosinophilic granulomatosis. PA chest radiograph demonstrates finely nodular densities throughout lung parenchyma in a 52-year-old woman with progressive cough and dyspnea. Transbronchial lung biopsies demonstrated typical histologic features of EG. S-100 stains were also positive.

High-Resolution Thin-Section Computed Tomography

High-resolution thin-section CT is far more accurate than conventional chest radiographs in defining the nature and extent of the parenchymal lesions. Numerous thin-walled cysts are observed in >90% of patients with pulmonary EG (Fig. 18B). Peribronchiolar nodules (typically 1 to 4 mm in diameter) are present concomitantly in 60%–78% of patients. The nodules, which correspond to cellular granulomatous lesions around small bronchioles, may be missed on conventional chest radiographs. Coalescence of nodules may result in lesions exceeding 10 mm. This nodular component rarely occurs in the absence of the cystic lesions. Foci of cavitation (resulting from necrosis within the peribronchiolar inflammatory nodules) have been noted on high-resolution CT in up to 20% of patients with pulmonary EG but are rarely evident on plain chest radiographs. As the disease progresses, the nodules are replaced by cysts, some of which become confluent. The cysts or nodules are usually associated with areas of intervening normal lung tissue. Shadows that appear reticular on chest radiographs actually represent the walls of cysts. The cystic lesions correspond to dilated small bronchi and bronchioles or destroyed lung parenchyma. In the early phases, cysts are round and small (<4 mm), but they may enlarge and assume distorted shapes. Confluence of cysts may result in bullous lesions exceeding 2 to 3 cm in diameter. Both the cystic and nodular lesions have a predilection for the upper and middle lung zones, with relative sparing of the costophrenic angles. There is no central or peripheral predominance. Cystic radiolucencies may be seen in other pulmonary disorders, but the nature and anatomic distribution of the cystic lesions in pulmonary EG are distinctive. The cysts in pulmonary EG are thin-walled, often regular in size, and are associated with nodules.

Numerous parenchymal cysts are the hallmark of lymphangioleiomyomatosis (LAM). In LAM, the cysts are distributed evenly throughout all lobes and lack the nodular component characteristic of EG. Honeycomb cysts are characteristic features of IPF or UIP. In contrast to cysts in pulmonary EG, honeycomb cysts in UIP have a distinctive affinity for subpleural, peripheral, and basilar regions of the lungs. Ground-glass opacities or septal bands are evident in IPF or UIP but are rarely a prominent feature of pulmonary EG. In chronic obstructive pulmonary disease, emphysematous “cysts” may be seen, but these are more irregular in size and have a thicker wall than the cysts of pulmonary EG. The combination of cysts and nodules strongly suggests the diagnosis of pulmonary EG, particularly when the lesions preferentially affect the middle and upper lung zones.

Pulmonary Function Tests

Aberrations in pulmonary function tests are noted in >80% of patients with pulmonary EG. Reduction in D_LCO occurs in 70%–80% of patients. Severe impairment in D_LCO is associated with more extensive honeycombing and a worse prognosis. Reductions in VC and/or TLC occur in 50%–80% of cases. Pure restrictive and mixed obstructive-restrictive patterns may be observed. The mean FEV_1 is often reduced, but the FEV_1/FVC ratio is usually normal or increased. Air trapping (increased RV) is noted in nearly 50% of patients with pulmonary EG, but hyperinflation (TLC >110% of predicted) is rare. Pulmonary function tests are normal in 15%–20% of patients with pulmonary EG. Pulmonary function tests may not correlate with symptoms or chest radiographs. Serial pulmonary function tests are advised to monitor the course of the disease. Cardiopulmonary exercise tests in patients with pulmonary EG usually show reductions in exercise tolerance, maximal workload, oxygen consumption (O_{2max}), and anaerobic threshold, and worsening gas exchange and increased ratio of dead space to tidal volume (V_D/V_t) with exercise. Several factors may limit exercise tolerance, including obliteration or loss of the pulmonary microvasculature, impaired pulmonary mechanics, air flow obstruction, and hypoxemia.

Histopathology

Histologically, pulmonary EG is characterized by inflammatory, cystic, nodular, and fibrotic lesions distributed in a bronchocentric fashion. The diagnosis of pulmonary EG usually requires thoracoscopic lung biopsy, but TBB may be adequate provided the salient features are present. The disease appears to evolve in distinct phases. Early in the course, proliferation of atypical histiocytes (i.e., Langerhans' cells) dominates. Later, granulomatous inflammation ensues, followed by destruction and fibrosis of lung parenchyma. In individual patients, all phases of the disorder may be seen concomitantly. Pulmonary EG may be strongly suspected by the distinctive distribution and pattern of lesions on low-power light microscopy. The combination of numerous peribronchiolar nodules and cysts, accompanied by intervening zones of normal lung parenchyma and a stellate pattern of fibrosis, is highly characteristic. Numerous discrete, focal nodules, representing cellular inflammatory lesions, may be seen under low-power magnification. The nodules are centered around bronchioles or may be distributed in subpleural regions. These lesions extend by fingerlike extensions into the adjacent alveolar interstitium, resulting in a distinctive star-shaped or stellate pattern (Fig. 20). High-power light microscopy may show intensely cellular granulomatous lesions involving bronchioles and alveolar walls. In some cases, plugs of immature connective tissue within bronchioles, alveolar ducts, and alveolar spaces may resemble BOOP. The granulomatous lesions are comprised of aggregates of Langerhans' cells (the cornerstone of the diagnosis) admixed with lymphocytes, plasma cells, eosinophils, macrophages, and neutrophils.

FIG. 20. Eosinophilic granulomatosis. Low-power photomicrograph of open lung biopsy specimen demonstrates stellate pattern of fibrosis. H&E stain. (Reproduced with permission from Lynch JP III and Chavis AD. Chronic interstitial pulmonary disorders. In: Victor L, ed. *Clinical Pulmonary Medicine.* Boston: Little, Brown; 1992:243, Fig. 11-14C.)

The cardinal histologic feature of pulmonary EG is the finding of aggregates of Langerhans' cells (also termed *histiocytosis X cells*) within the peribronchiolar nodules, air spaces, or alveolar interstitium (Fig. 21). Langerhans' cells are moderately large, ovoid histiocytes with pale eosinophilic cytoplasm, indented (grooved) nuclei, inconspicuous nucleoli, and finely dispersed chromatin. Langerhans' cells can usually be recognized under high-power light microscopy and may comprise >50 % of cells in the active cellular lesions in some patients. Langerhans' cells may be found in normal lung but rarely constitute >3% of cells. Eosinophils may be conspicuous, but the number of eosinophils is variable and is not a reliable diagnostic criterion. When light microscopic features are nondiagnostic, immunohistochemical stains [e.g., S-100 protein and common thymocyte antigen (OKT6)] or electron microscopy may substantitate the identity of Langerhans' cells. These ancillary techniques are discussed later. It should be emphasized that neither S-100 nor OKT6 stains are required to diagnose pulmonary EG, provided the light microscopic features on hematoxylin-eosin stains are distinctive.

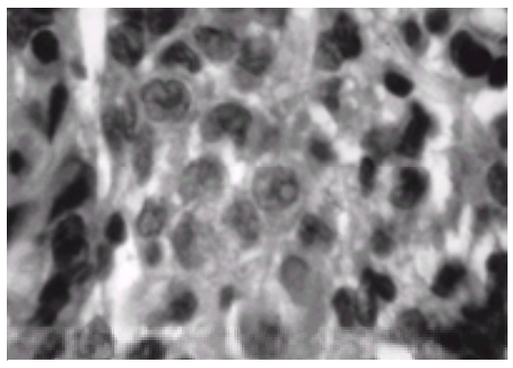

FIG. 21. Eosinophilic granulomatosis. Photomicrograph of open lung biopsy specimen demonstrates an intense cellular infiltrate with multiple Langerhans' cells exhibiting the characteristically clefted nuclei. H&E, high power.

As the inflammatory process evolves, bronchioles and alveolar interstitium may be destroyed or replaced by fibrotic connective tissue, resulting in dilated, distorted bronchioles and alveolar parenchymal cysts. Blebs, subpleural cysts, and interstitial and intraluminal fibrosis may be prominent. The pulmonary microvasculature may be infiltrated or destroyed, even in areas remote from the bronchocentric nodular lesions. In late phases of pulmonary EG, the distinctive Langerhans' cells and inflammatory cells may no longer be present, and the lung may take on the appearance of an end-stage honeycomb lung, indistinguishable from that of other CILD. The retention of a nodular or stellate configuration may be a clue to the diagnosis.

Ancillary Diagnostic Techniques

Historically, electron microscopy was used to identify Langerhans' cells when light microscopy was not definitive. Langerhans' cells contain distinctive intracytoplasmic rod- or racquet-shaped inclusions (termed *Birbeck granules* or *X-bodies*), 42 to 45 nm in thickness, that have trilaminar membranes and a central line (Fig. 22). Because of the complexity and expense of electron microscopy, immunohistochemical staining for S-100 protein or OKT6 has supplanted this technique. Immunostains for S-100 protein may distinguish Langerhans' cells from other histiocytes. This technique can be performed in paraffin-embedded biopsy specimens and is less time-consuming and avoids the sampling problems associated with electron microscopy. Large aggregrates of S-100-positive histiocytes within stellate nodules or granulomatous lesions are virtually pathognomonic of EG. Staining for S-100 is most intense in the active cellular lesions and diminishes in fibrotic or acellular areas. Langerhans' cells may be found in open lung biopsy specimens or BAL fluid in other ILD but are distributed randomly and in small numbers (rarely exceeding 2% of cells). Lung endocrine cells may also stain for S-100 protein but can be distinguished from Langerhans' cells by histologic criteria or counterstains (e.g., with chromogranin).

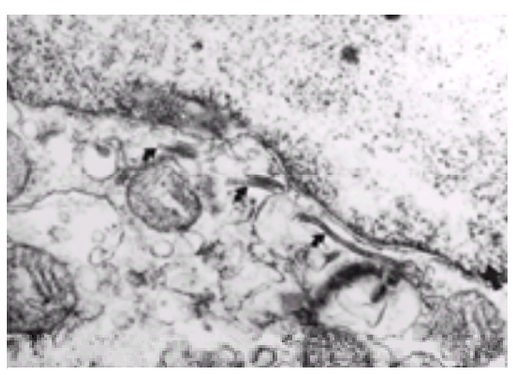

FIG. 22. Eosinophilic granulomatosis. Electron microscopy. Langerhans' histiocyte. *Curved arrows* depict Birbeck granules in the cytoplasm. *Straight arrow* points to the nucleus. (Courtesy of Theodore F. Beals, M.D., Department of Pathology, Veterans Affairs Medical Center, Ann Arbor, Michigan 48109.)

Langerhans' cells also express OKT6, whereas lymphocytes and monocytes do not. Intense staining for OKT6 may establish the diagnosis in equivocal cases, but this technique requires fresh or frozen tissue and so is less practical than S-100 staining. In addition, rare OKT6-positive cells may be observed in BAL fluid or lung tissue in patients with diverse pulmonary disorders. Chollet et al. analyzed BAL fluid from 131 patients with various pulmonary diseases. All 18 patients with pulmonary EG had OKT6-positive cells on BAL (mean, 5.6% cells). By contrast, the mean number of OKT6-positive cells in other conditions was only 0.20% (none exceeded 2.8%). Thus, >3% of cells staining for OKT6 is relatively specific for EG.

Langerhans' cells also express other markers, including HLA-DR, Fc receptor, CD4 antigen, CD1a and CD1c (markers of a family of antigen-presenting molecules), and leucyl-B-naphthylamidase. These latter techniques are limited to research laboratories.

It should be emphasized that the diagnosis of pulmonary EG can usually be established by conventional histologic stains (e.g., hematoxylin-eosin) and light microscopy. Because of the heterogeneous distribution of the lesions, surgical (e.g., open or thoracoscopic) lung biopsy is usually required to confirm the diagnosis. However, transbronchial lung biopsies may be adequate provided the salient histologic or immunohistochemical features are present. Because of the potential for sampling error associated with transbronchial lung biopsies, we obtain multiple (four to six) specimens from both the upper and lower lobes and employ S-100 stains when the diagnosis is suspected. When features are not definitive, thoracoscopic biopsy should be done.

Pathogenesis

The pathogenesis of pulmonary EG is unknown, but it probably represents an uncontrolled immune response initiated or regulated by Langerhans' cells. Langerhans' cells are prominent in the early inflammatory lesions and may act as accessory cells that drive the immune/inflammatory response. Proliferation of these atypical histiocytes (Langerhans' cells) may be a reactive or neoplastic process. Recent studies using X-linked polymorphic DNA probes in female patients with disseminated, osseous, or extrapulmonary forms of Langerhans' histiocytosis (histiocytosis X) were consistent with a clonal neoplastic disorder. The pathogenesis of these nonpulmonary forms of Langerhans' histiocytosis probably differs from that of pulmonary EG, a disease that differs markedly in clinical expression and prognosis. Pulmonary EG likely represents an exuberant immune (reactive) response to inhaled irritants or allergens. Tobacco smoke has been strongly implicated as a causative factor, as 90%–97% of patients with pulmonary EG are smokers. The peribronchiolar (bronchocentric) distribution of lesions is consistent with a response to inhaled stimuli. Cigarette smoke may stimulate and recruit Langerhans' cells to the lung. Replication of Langerhans' cells in the alveolar structures may perpetuate an alveolitis. Tobacco glycoprotein, a potent immunostimulant isolated from cigarette smoke, acts as a T-cell mitogen and may stimulate macrophage cytokine production (i.e., interleukin-1 and interleukin-6). The relevance of tobacco glycoprotein to pulmonary EG has not been elucidated, but altered peripheral blood lymphocyte responses to tobacco glycoprotein in vitro have been noted in patients with pulmonary EG. Cigarette smoking has been associated with hyperplasia of pulmonary neuroendocrine cells and increased levels of bombesin-like peptides in the lower respiratory tract. Bombesin is chemotactic for monocytes and mitogenic for fibroblasts, and it may play a role in inflammatory or fibrotic responses. Immunohistochemical stains have noted large numbers of bombesin-positive neuroendocrine cells in the lungs of patients with pulmonary EG (particularly within the airways). Open lung biopsies revealed a >10-fold increase in bombesin-like peptides in specimens from patients with pulmonary EG compared with specimens from normal smokers or patients with IPF. Although neither neuroendocrine cells nor bombesin-like peptides are specific for EG, these findings may provide clues to pathogenic mechanisms. Hyperplasia of neuroendocrine cells may recruit and activate mononuclear phagocytes and Langerhans' cells to the lung. Other immune effector cells (e.g., lymphocytes, monocytes, plasma cells, eosinophils) or humoral factors (e.g., immune complexes) may play contributory roles in the pathogenesis of pulmonary EG.

Course and Prognosis

The prognosis of pulmonary EG is variable. The disease stabilizes or becomes less severe in more than two thirds of patients, usually within 6 to 24 months of onset of symptoms. In 15%–31% of patients, the disease progresses, resulting in destruction of lung parenchyma and irrevocable loss of pulmonary function. Severe late sequelae include pulmonary fibrosis, cor pulmonale, and respiratory failure. Fatalities have been noted in 6%–25% of patients. Rarely, the course is rapid, progressing to respiratory failure within a few weeks. Multisystemic disease, honeycombing on chest radiograph, severe reduction in diffusing capacity (D_LCO), and multiple

pneumothoraces have been associated with a poorer prognosis.

Therapy

Because of the rarity of pulmonary EG and its highly variable natural history, the role of therapy is controversial. Cessation of cigarette smoking is mandatory. Corticosteroids, vinca alkaloids (vinblastine or vincristine), D-penicillamine, and a variety of immunosuppressive and cytotoxic drugs have been associated anecdotally with claims for success, but data affirming their efficacy are lacking. Prognosis for adults with localized pulmonary EG is generally excellent, so therapy should be reserved for patients with severe, progressive, and debilitating disease. Although controlled trials have not been performed, Schonfeld and co-workers cited improvement in 12 of 14 patients with progressive pulmonary EG following institution of prednisone (initial dose of 40 mg/day). Others have failed to confirm the efficacy of corticosteroids. Given the lack of firm data, we are skeptical about the benefit of corticosteroids. However, an empiric trial for 3 to 6 months is reasonable in selected patients with fulminant or severe disease. Prolonged therapy should be continued only for patients manifesting objective and unequivocal responses. Alternative agents (e.g., vinblastine, cyclophosphamide, or D-penicillamine) can be considered for corticosteroid-recalcitrant cases, but their efficacy has not been proved. We are reluctant to use these agents for pulmonary EG, because the potential for adverse effects (including oncogenesis) may outweigh the benefit. Single-lung transplantation has been successfully accomplished in patients with EG and end-stage pulmonary fibrosis.

LYMPHANGIOLEIOMYOMATOSIS

Pulmonary lymphangioleiomyomatosis (LAM) is a rare, idiopathic fibrocystic lung disorder almost exclusively affecting premenopausal women. LAM has very rarely been described in postmenopausal women. Anecdotal case reports of LAM in male patients likely represented tuberous sclerosis or diffuse pulmonary lymphangiomatosis, disorders that share clinical and histologic features with LAM. There is an understandable confusion in acknowledging the terms as representing separate clinical entities because of phonetic similarities. Several authors have previously used the term *lymphangiomyomatosis* rather than *lymphangioleiomyomatosis.* Diffuse pulmonary/intrathoracic lymphangiomyomatosis is characterized by dilated lymphatic vascular lesions; the condition occurs in male or female patients and is not associated with smooth-muscle proliferation. This variceal condition is clinically and histologically distinct from LAM.

LAM is exceptionally rare. Published data is derived from a few series (often extracted from consulting pathologists' files) and anecdotal case reports. In 1990, Taylor and colleagues reported 32 patients with LAM followed at Stanford and the Mayo Clinic. The largest clinical series, reported by Kitaichi et al. in 1995, described 46 patients with LAM from Japan, Korea, and Taiwan. Based on an informal consensus among experts, an estimated 200 to 300 patients have been accumulated through personal files and publications. Interested patients and/or family members recently compiled a list of an additional 100 to 150 affected patients and formed an LAM organization with the support of the National Institutes of Health in the United States. Owing to the nonspecificity of clinical findings and lack of awareness of LAM, the prevalence may be underestimated by historical analyses. Data from the Mayo Clinic suggest an apparent increase in the incidence of LAM in the last decade. This apparent increase could simply reflect an increased awareness of the disorder. Very rough estimates suggest a prevalence ranging from no to three cases per 100,000 population in the United States.

Clinical Features

The classic clinical presentation of LAM is quite distinctive. Women of childbearing age present with spontaneous pneumothorax, hemoptysis, slowly progressive exertional dyspnea, or chylothorax. The mean age at onset of symptoms is approximately 30 years. Dyspnea is nearly invariably present, beginning in the third or fourth decade of life, and progresses inexorably for years. Pneumothoraces occur in 50%–80% of patients with LAM. Chylous effusions occur in 7%–39%, and hemoptysis or focal alveolar hemorrhage in 28%–40%. The clinical course of LAM is heterogeneous. In early reports, most patients died of progressive respiratory failure within 5 to 10 years of onset of symptoms. The life expectancy appears to be highly variable, and prolonged survivorship has been noted in some patients. In the cohort of LAM patients from Stanford and the Mayo Clinic, 25 of 32 patients (78%) were alive 8.5 years after the diagnosis; mean survival was 10.0 years. Kitachi and colleagues cited a lower survival (38% at 8.5 years after the diagnosis) in a cohort of 46 patients with LAM in Asia. Studies assessing the impact of specific therapeutic modalities are lacking but are discussed later.

Pulmonary Function Tests

Pulmonary function tests in LAM typically demonstrate air flow limitation (often with air trapping), impaired D_LCO, and hypoxemia. Lung volumes are usually preserved and may be increased. In the series reported from Stanford and the Mayo Clinic, obstructive or mixed obstructive-restrictive defects were noted in 78% of patients. Reductions in D_LCO were noted in 96% and hypoxemia was present in 77%. In the series reported by Kitaichi et al., 29% exhibited a pure obstructive air flow limitation; restrictive defects or mixed obstructive-restrictive defects were noted in 26% and 36%, respectively. TLC was increased (>120% of predicted) in 30%. Reductions in D_LCO (<80% of predicted) and PaO_2 (<80 torr) were observed in 97% and 81% of patients, respectively. Resting arterial blood gases may be normal in the setting of mild disease, but decreases in PaO_2 and widened $P(A - a)O_2$ are typical as the disease progresses. Exercise performance is impaired; an excessive ventilatory response and increased dead space ventilation are characteristic features on formal exercise testing. Air flow obstruction and impairments in diffusing capacity, exercise capacity, and gas exchange correlate primarily with the extent of airway cystic lesions. However, muscular proliferation in small airways, destruction of pulmonary microvasculature, loss of alveolar support, and loss of parenchymal interdependence may be important contributory mechanisms of physiologic aberrations.

Chest Radiographs

Conventional chest radiographs demonstrate a wide spectrum of abnormalities. These include pneumothoraces; bilateral interstitial, reticulonodular, or cystic radiolucencies; pleural effusions; or hyperinflation (Fig. 23). Early in the course of the disease, chest radiographic findings may be normal. With disease progression, cystic lesions, reticulonodular infiltrates, or pneumothoraces invariably develop. Pneumothoraces have been noted at the time of presentation in 39%–53% of patients with LAM, and reticulonodular infiltrates in 47%–85%. As the disease progresses, both these features are present in >80% of patients. The reticulation actually represents the walls of the numerous alveolar cysts. In some cases, well-defined cystic or bullous lesions may be evident. Hyperinflation develops as the disease worsens and is seen in up to two thirds of patients in the late phases of the disease. Pleural effusions (typically chylous) occur in 11%–29% of patients. Mediastinal or hilar lymphadenopathy is not a feature of LAM.

FIG. 23. Lymphangioleiomyomatosis. PA chest radiograph from a 39-year-old woman with LAM demonstrates severe hyperinflation and large cysts and bullous changes. Surgical clips are present on the right from a previous thoracotomy and pleurodesis for recurrent pneumothoraces.

High-Resolution Computed Tomography

High-resolution CT findings are highly distinctive in LAM. The cardinal feature is numerous thin-walled cysts (usually <20 mm in diameter) distributed diffusely throughout both lungs; the intervening lung parenchyma is normal (Fig. 24, Fig. 25, and Fig. 26). Nodules, interstitial fibrosis, cavitary lesions, and intrathoracic lymphadenopathy, features that may be observed in other CILD, are not features of pulmonary LAM. Focal ground-glass opacities have been noted in up to 59% of patients with LAM in some series, and may reflect focal alveolar hemorrhage, pulmonary hemosiderosis, or diffuse proliferation of smooth-muscle cells. However, the cystic lesions predominate. Cystic lesions may be seen on high-resolution CT in other pulmonary disorders (e.g., pulmonary EG, IPF, emphysema), but the distribution of cysts differs among these disorders. In LAM, the cysts are distributed throughout the lung fields, without a predilection for specific regions or lobes. By contrast, in pulmonary EG, the cysts are preferentially distributed in the upper or middle lung zones and are usually associated with a nodular component (which is lacking in LAM). In IPF, areas affected by the disease are patchy and heterogeneous, and cysts are preferentially distributed in the peripheral, subpleural, and basilar regions of the lungs. In addition, reticular or ground-glass opacities are usually prominent associated features in IPF. Cystic or bullous lesions seen in smokers with emphysema do

not have well-formed walls and tend to be more extensive in the upper lobes. Tuberous sclerosis, an autosomal dominant disorder associated with mental retardation and cutaneous manifestations, is associated with pulmonary cystic lesions indistinguishable from those of LAM in approximately 1% of patients. Tuberous sclerosis can be distinguished from LAM on clinical grounds, as neurologic or cutaneous manifestations are not observed in LAM.

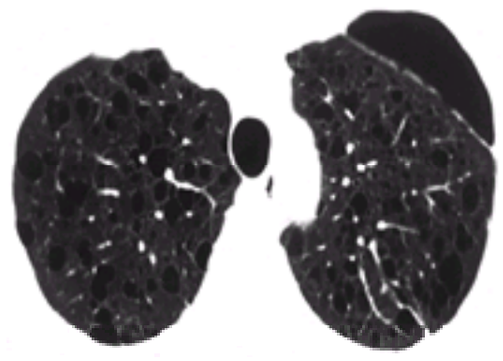

FIG. 24. Lymphangioleiomyomatosis. CT in a 41-year-old woman with LAM demonstrates multiple, thin-walled cystic radiolucencies in upper lobes bilaterally with large zones of intervening normal lung parenchyma, consistent with LAM.

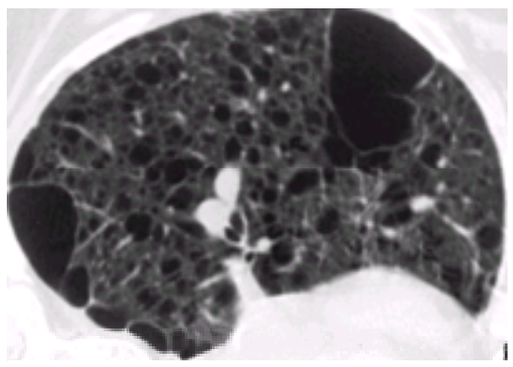

FIG. 25. Lymphangioleiomyomatosis. CT in a 44-year-old woman with LAM demonstrates multiple, thin-walled cystic radiolucencies bilaterally. Note the two large lesions, representing confluent cysts.

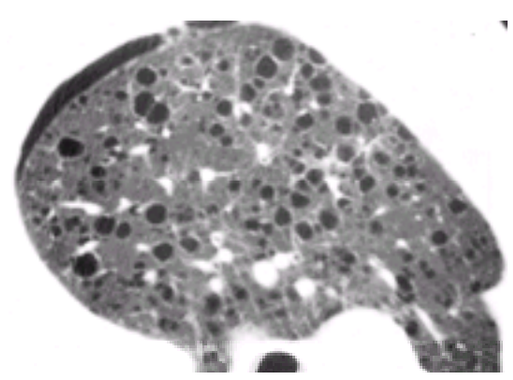

FIG. 26. Lymphangioleiomyomatosis. CT demonstrates multiple, thin-walled cystic radiolucencies throughout lung parenchyma. Note small associated pneumothorax, a typical finding in LAM. (Courtesy of R. Schmidt, M.D, Ph.D., University of Washington, Seattle.)

Histopathologic Features

At thoracotomy, innumerable small cysts are seen on the lung surface, ranging from a few mm to 3 cm (Fig. 27A). Light microscopy demonstrates diffuse proliferation of immature/atypical smooth muscle in the walls of the cysts and throughout the peribronchial, perivascular, and perilymphatic regions of the lungs (Fig. 27B, Fig. 27C). These proliferating smooth-muscle cells may form highly organized nodules or fascicles but are not considered malignant. The smooth-muscle cells are heterogeneous, and phenotypically they may exhibit features of either spindle cells or epithelioid cells. Electron microscopy shows myofilaments in the smooth-muscle cells of the lung lesions and dense deposits of collagen fibers. Extension of these smooth-muscle proliferations may destroy surrounding lung parenchyma, forming the characteristic cysts. The diffuse distribution of the muscular and cystic lesions explains the clinical manifestations of LAM. Compression of the conducting small airways results in air flow obstruction and alveolar disruption. Pneumothoraces result from rupture of subpleural cysts. Obstruction of pulmonary vessels may cause venular congestion and disruption, resulting in hemoptysis and hemosiderosis. Lymphatic obstruction may cause chylothorax. The extent of cystic LAM lesions on open lung biopsy is an important determinant of prognosis; predominantly cystic lesions suggest a worse prognosis and survival. The extent of smooth-muscle proliferation or hemosiderosis does not correlate with survival.

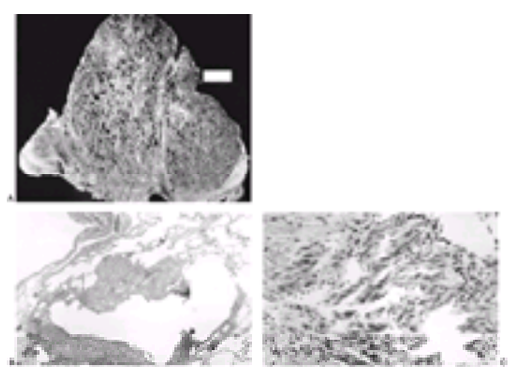

FIG. 27. A: Lymphangioleiomyomatosis. Gross appearance of lung removed from a patient with LAM. Note the numerous cysts throughout the lung parenchyma. **B:** Photomicrograph of lung biopsy specimen demonstrates aggregates of characteristic smooth-muscle bundles in the walls of cysts and in the peribronchial areas. H&E, low power. **C:** Photomicrograph of lung biopsy specimen demonstrates aggregates of characteristic smooth-muscle bundles with a spindle appearance. H&E, high power.

Immunohistochemical stains of the proliferating smooth-muscle cells in LAM are positive for muscle-specific actin, desmin, and melanoma-related marker (HMB-45). HMB-45 is never found in normal smooth muscle. In the absence of melanoma or clear-cell tumor of the lung (which also stains for HMB-45), positive staining for HMB-45 in the lung is highly specific (>95%) for LAM. Progesterone and estrogen receptors have been demonstrated in the nuclei of proliferating smooth muscle in some patients with LAM, but these findings are not consistently present.

Extrapulmonary lymphangioleiomyomas or cysts may involve the spleen, kidney, liver, abdominal or retroperitoneal lymph nodes, uterus, and ovaries in patients with LAM. Renal angiomyolipomas have been noted in 15%–47% of patients with pulmonary LAM and may give rise to local pain, bleeding, or compression of renal parenchyma.

Differential Diagnosis

The diagnosis of LAM is strongly suggested by the constellation of spontaneous pneumothorax, preserved or increased lung volumes, chylous pleural effusions, and air flow obstruction in women in the third or fourth decade of life. Hemoptysis may be an associated feature (noted in up to 40% of patients). When the clinical presentation is typical, the diagnosis can be strongly suspected based on the radiologic findings (particularly high-resolution CT). Other clinical entities that may be confused with LAM include pulmonary EG, metastatic low-grade sarcomas, tuberous sclerosis, emphysema, and small-airways disease with smooth-muscle proliferation. The diagnosis of LAM needs to be substantiated by lung biopsy. Transbronchial lung biopsy may be diagnostic in some cases, but surgical lung biopsy is warranted when TBB findings are nondiagnostic or equivocal.

Treatment

Given the rarity of LAM, controlled therapeutic trials have not been performed and optimal therapy is controversial. Although a specific hormonal abnormality has not been identified, LAM is exclusively a disease of women and may be exacerbated by estrogens (endogenous or exogenous) or pregnancy. Proliferation of uterine smooth-muscle cells is also regulated by estrogen. Treatment of LAM is directed toward reducing estrogens, either by surgical oophorectomy or anti-estrogen regimens (e.g., progesterone, tamoxifen, androgens, luteinizing hormone-releasing agonists). Exogenous estrogens are strongly contraindicated. Oophorectomy has been considered “gold standard” therapy by some, but results have generally been disappointing. In the retrospective review from Stanford and the Mayo Clinic, oophorectomy was ineffective in all 16 patients. Despite anecdotal responses of improvement or stabilization following oophorectomy, oophorectomy alone was never associated with improvement in the group of patients reported by Kitaichi and colleagues. Medroxyprogesterone acetate has been tried, either alone or combined with oophorectomy, as therapy for LAM. Intramuscular medroxyprogesterone acetate (400 to 800 mg monthly) alone was associated with stabilization or improvement in 2 of 19 and 4 of 8 patients in two series. This form of therapy appears to be more effective in managing chylous effusions; its efficacy in alleviating the airway or cystic lesions is less clear. Tamoxifen has been advocated by some, but data justifying its use are lacking. In four series, tamoxifen, given alone or in combination with other agents, was associated with improvement in only 2 of 31 treated patients. Tamoxifen has partial estrogen-agonist activity, so we believe this agent should not be used in LAM. Anecdotal responses have been cited with synthetic analogues of luteinizing-releasing hormone, but data are sparse. Interferon-a has been tried, but results have been unimpressive. Unfortunately, current therapeutic regimens for LAM are of limited efficacy. In the review by Kitaichi and colleagues, diverse therapeutic options were evaluated in 40 patients. Only two improved; nine stabilized, and the remaining patients deteriorated. In this cohort of patients, factors associated with a poor prognosis included worsening air flow obstruction at 2 years after the initial examination; increase in percentage of predicted TLC at 2, 3, and 5 years after the initial exam; predominantly cystic LAM lesions (compared with predominantly smooth-muscle proliferation) on open lung biopsy; and higher grades of histologically abnormal areas and cystic lesions on open lung biopsy.

Despite the lack of firm evidence that treatment reverses the course of the disease, the course of LAM in the absence of therapy is poor, with inexorable progression. The rate of progression of LAM varies widely among patients regardless of therapy. LAM has been known to continue even after menopause. Given the poor prognosis of untreated LAM, an empiric trial with intramuscular medroxyprogesterone acetate, oophorectomy, or both is reasonable. The influence of pregnancy on the outcome is unknown, but anecdotal cases have documented progression or acceleration of LAM during pregnancy. We believe pregnancy should be avoided, but this is best left to the informed patient's wishes. Unilateral lung transplantation is an established mode of therapy for far-advanced disease. Three-year survival following lung transplantation for LAM approximates 60%–70%. Recurrence of LAM has been reported in transplanted lung allografts in two patients with LAM, raising questions regarding the long-term outcome of transplantation in this patient population. It is hoped that ongoing research efforts and future studies will shed further light on the pathogenesis of LAM and provide new strategies for curative therapy.

PULMONARY AMYLOIDOSIS

Intrathoracic amyloidosis may rarely complicate primary or secondary amyloidosis in which systemic involvement is evident. In addition, primary pulmonary amyloidosis, lacking extrapulmonary or systemic components, may occur. Amyloidosis comprises a heterogeneous group of diseases characterized by deposition of an insoluble b-pleated fibrillar protein in the extracellular matrix of involved tissues. Amyloid protein takes up Congo red stain and exhibits apple-green birefringence under polarized microscopy (Fig. 28). Primary amyloidosis, the most common variant, can be idiopathic or associated with plasma cell dyscrasias (such as multiple myeloma). This is associated with deposition of the immunoglobulin light-chain fragment (amyloid AL). Secondary amyloidosis (amyloid AA) may complicate diverse chronic inflammatory conditions (e.g., bronchiectasis, tuberculosis, malaria, chronic infections, and diverse collagen vascular disorders or inflammatory disorders). Amyloid AA protein is an apolipoprotein associated with HDL-3 that is produced by proteolysis of serum amyloid A proteins. Familial amyloidosis has also been described. Amyloid protein may also be found with advanced age (senile amyloidosis). Prealbumin has been associated with familial and senile forms of amyloidosis. Clinically significant pulmonary involvement occurs in more than one third of patients with primary systemic amyloidosis but only rarely complicates secondary forms of amyloidosis. Primary or secondary forms of systemic amyloidosis differ from primary pulmonary amyloidosis, a disorder localized to the lungs, tracheobronchial tree, pleurae, and/or mediastinal lymph nodes.

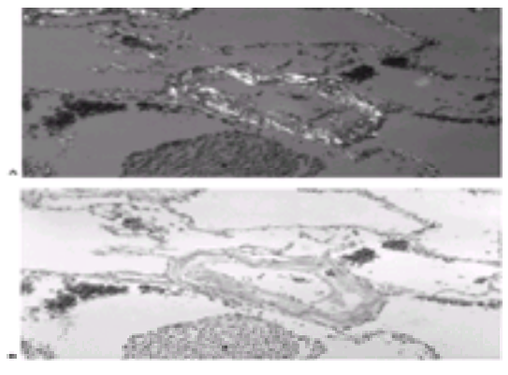

FIG. 28. A: Amyloidosis. Photomicrograph of open lung biopsy specimen demonstrates amyloid deposition within the wall of a pulmonary vessel. H&E. **B:** Photomicrograph of open lung biopsy specimen demonstrates amyloid deposit displaying apple-green birefringence under polarized microscopy following staining with Congo red.

Pulmonary Amyloidosis Associated with Primary Systemic Amyloidosis

Although it has long been recognized that primary systemic amyloidosis tends to involve the lung, reports of lung involvement have been infrequent. Although the prevalence of pulmonary involvement in primary systemic amyloidosis has not been elucidated, diffuse amyloid deposits in an alveolar septal pattern may occur. A recent review of the Mayo Clinic experience from 1980 to 1993 identified 35 patients with primary systemic amyloidosis, of whom 20 had pulmonary involvement manifesting as diffuse interstitial infiltrates; four had coexisting pleural effusions. The median survival in this series was 16 months. Because cardiac amyloidosis is a frequent concomitant feature, it is difficult to determine the influence of pulmonary amyloidosis on prognosis. However, the presence of pulmonary amyloidosis in patients with primary systemic amyloidosis is generally considered a harbinger of a poor outcome.

Localized or Primary Pulmonary Amyloidosis

Primary or localized pulmonary amyloidosis is characterized by amyloid deposits limited to the lungs and associated structures (i.e., tracheobronchial tree, lung parenchyma, pleurae, and hilar or mediastinal lymph nodes). Most patients with localized tracheobronchial amyloidosis are in the fifth to sixth decade of life. Amyloid deposition in the lung resulting from secondary or familial amyloidosis is not included in this category. In 1983, Thompson and Citron identified 126 published cases of primary pulmonary amyloidosis in the world literature (67 tracheobronchial, 59 lung parenchymal). Of the 67 patients with tracheobronchial disease, 57 had multifocal submucosal plaques and 10 had amyloid tumorlike masses. A review of three recent series cited involvement of the tracheobronchial tree in 23 of 89 patients with pulmonary amyloidosis.

Tracheobronchial amyloidosis is generally localized to the airways and spares the lung parenchyma. Relatively flat submucosal plaques of amyloid protein or tracheobronchial nodules may be seen. These may be single, diffuse, or multifocal and are not associated with systemic amyloidosis. Patients may be asymptomatic or

may have hoarseness, wheezing, dyspnea, hemoptysis, cough, atelectasis, recurrent pneumonia, or chronic infections. Respiratory symptoms may be related to airway narrowing or stenosis or involvement of the nasopharynx, sinuses, or larynx. Tracheobronchial amyloidosis has been associated with tracheobronchopathia osteoplastica, a rare disorder of unknown cause characterized by the presence of calcified or cartilaginous submucosal nodules within the tracheobronchial tree. Localized tracheobronchial amyloidosis is not associated with primary systemic amyloidosis, but its course may not be benign. In a study by Hui and colleagues at the Armed Forces Institute of Pathology, three of the seven patients for whom follow-up data were available died of respiratory failure or recurrent pneumonia. Management has included observation, intermittent bronchoscopic resection, surgical resection, and laser therapy. Resection or biopsy may be complicated by severe bleeding (see below).

Nodular Amyloid Lesions (Amyloidomas)

Localized pulmonary amyloid nodules (amyloidomas) are uncommon lesions that may be seen in older patients (on average in the sixth decade) and are generally not associated with primary systemic amyloidosis. Lesions may be single or multiple, ranging in size from 0.4 to 15 cm (average, 3 cm) (Fig. 29). Amyloidomas occur most frequently in the lower lobes and may be asymmetric when multiple nodules are present. Amyloidomas may calcify and rarely cavitate. Metaplastic bone or cartilage formation may occur. Amyloidomas are usually asymptomatic and present as incidental findings on chest radiographs (Fig. 29) or autopsy. However, cough or hemoptysis may occur. For solitary nodules causing symptoms, resection is usually curative. However, biopsy or resection of nodular mass lesions may cause significant bleeding (see below).

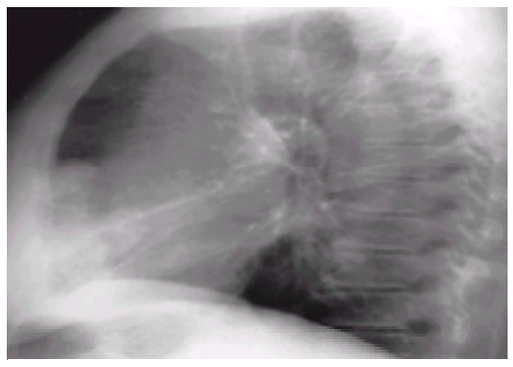

FIG. 29. Amyloidosis. PA chest radiograph demonstrates a solitary pulmonary nodule in the retrosternal space. Open lung biopsy specimen demonstrates typical features of amyloidosis. (Courtesy of D. Godwin, M.D., University of Washington, Seattle.)

Diffuse Interstitial Infiltrates

Amyloid deposits in the alveolar septa and interstitium may appear as reticulonodular or micronodular lesions on chest radiographs or CT scans and cause physiologic aberrations, including restrictive defects, decreased D_LCO, widened $P(A - a)O_2$, and pulmonary hypertension (Fig. 30). Alveolar septal amyloidosis is most commonly seen in primary systemic amyloidosis and is relatively uncommon in primary pulmonary amyloidosis. Although diffuse interstitial infiltrates were noted in 6 of 48 patients with primary pulmonary amyloidosis reported by Hui and colleagues from the Armed Forces Institute of Pathology, none of 17 patients with primary pulmonary amyloidosis recently reviewed by the Mayo Clinic group exhibited this radiographic pattern. Some authors have suggested that patients with interstitial pulmonary infiltrates likely represent a subset of patients with primary systemic amyloidosis and have unrecognized amyloid deposits in other organs. As the amyloid deposits and infiltrative process in the alveolar septa often involve the pulmonary vasculature, biopsy or resection of pulmonary lesions may be associated with an increased risk for bleeding.

FIG. 30. Amyloidosis. PA chest radiograph demonstrates diffuse bilateral reticulonodular infiltrates in a patient with pulmonary amyloidosis. Small bilateral pleural effusions are also present. (Courtesy of D. Godwin, M.D., University of Washington, Seattle.)

Other Manifestations of Amyloid Deposits

Hilar and mediastinal adenopathy resulting from amyloid deposition may occur in conjunction with tracheobronchial amyloidosis and either primary or secondary forms of amyloidosis. The adenopathy may be unilateral or bilateral (with or without calcification). Pulmonary amyloidosis occurring in elderly patients has been termed *senile pulmonary amyloidosis.* Autopsy studies have detected senile pulmonary amyloidosis in approximately 10% of patients older than 80 years and in 50% of patients older than 90 years. These deposits are usually incidental findings and are not associated with primary systemic amyloidosis or specific symptoms. Pleural effusions (caused by amyloid deposits along the pleural surface) may occur in primary systemic amyloidosis or as a complication of primary pulmonary amyloidosis. Amyloid effusions are exudative and may be hemorrhagic. Transudative pleural effusions may reflect cardiac amyloidosis. Other rare pulmonary manifestations include obstructive sleep apnea (secondary to involvement of the tongue) and respiratory muscle weakness (caused by amyloid infiltrating the diaphragm).

Bleeding Manifestation with Amyloidosis

Hemoptysis may complicate any form of pulmonary amyloidosis (including alveolar septal or tracheobronchial involvement). Focal or diffuse hemorrhage may occur when amyloid deposits involve vessels. In one retrospective review by Yood and colleagues, 41 of 100 patients with amyloidosis experienced one or more episodes of bleeding (three of which were fatal). Manifestations included petechiae, ecchymoses, gastrointestinal bleeding, hematuria, hemoptysis, and bleeding after biopsy. Hemoptysis occurred in only two patients. Although the excessive bleeding associated with amyloidosis is most often caused by amyloid infiltration of blood vessels, isolated deficiency of factor X has been cited as a cause of the bleeding diathesis in some patients with amyloidosis. The risk for pulmonary hemorrhage following lung biopsy is of concern, but firm data assessing risks are not available.

Treatment of Amyloidosis

Unfortunately, no proven therapy for amyloidosis is available. In secondary forms of amyloidosis, aggressive treatment of the underlying disease may delay or reverse the deposition of amyloid protein. Alkylating agents may be effective in amyloidosis associated with plasma cell dyscrasias (e.g., multiple myeloma) but are of unproven efficacy in other forms of amyloidosis and may increase morbidity. Colchicine has been used in both primary and secondary forms of amyloidosis, but its value is doubtful. Interferon-a has been tried but appears to be ineffective. Anecdotal responses have been reported with dimethylsulfoxide and 4'-iodo-4'-deoxydoxorubicin (a new anthracycline), but data are sparse. No proven effective treatment is available for diffuse amyloid infiltrating the tracheobronchial tree or lung parenchyma. Resection of localized amyloid deposits surgically or by laser may be beneficial in symptomatic foci involving the trachea, larynx, or bronchi. In rare cases, laryngeal dilation or tracheostomy have been required. It is hoped that ongoing and future studies will provide strategies for new therapeutic approaches.

INTRODUCTION

Drug-induced disease is one of the most common iatrogenic illnesses. In the last decade, the lung has been recognized increasingly often as a target organ. Fewer than 25% of drug reactions are truly allergic in origin; the mechanisms of overdose, side effects, and drug interaction are predictable with most drugs. On the other hand, idiosyncratic and allergic or hypersensitivity reactions are unpredictable and are estimated to occur in about 5% of patients receiving any drug. In drug-induced pulmonary disease, an abnormality on the chest x-ray film or a symptom complex is the most common form of presentation. Drug-induced pulmonary disease is diagnosed by maintaining a high index of suspicion in the appropriate clinical setting.

In this chapter, we provide a brief overview of drug-induced pulmonary disease. There are many isolated case reports of drugs that are believed to have caused an adverse pulmonary reaction, but these are vague and doubtful and are excluded from the review. In the first part of the chapter, we discuss various pleuropulmonary patterns of response to drugs. The second part addresses the pulmonary effects of different categories of drugs, including anti-inflammatory, antimicrobial, and antineoplastic agents.

Table 1 summarizes the more common clinical presentations of pulmonary toxicity induced by noncytotoxic medications, including illicit drugs, and Table 2 does the same for pulmonary toxicity induced by cytotoxic agents, including radiation. Some unusual manifestations of drug-induced pulmonary toxicity are listed in Table 3. Not all the medications listed in the tables are discussed in the text.

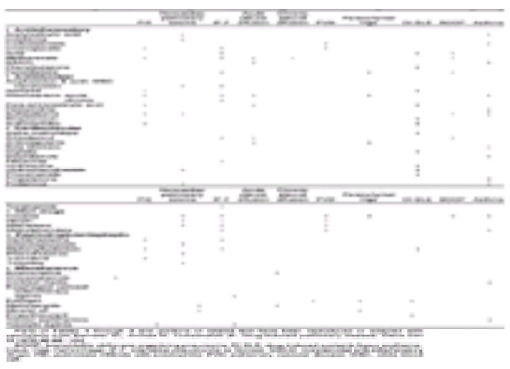

TABLE 1. *Clinical presentation of pulmonary toxicity induced by noncytotoxic drugs*

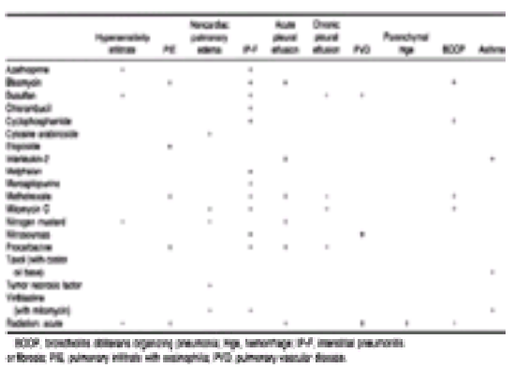

TABLE 2. *Clinical presentation of pulmonary toxicity induced by cytotoxic drugs and radiation*

Presentation	Causative agent(s)
Alveolar proteinosis	Busulfan
Bronchial necrosis	Radiation therapy, brachytherapy
Bronchospasm (paradoxical)	Nebulized β_2-adrenergic agonists Intravenous hydrocortisone
Calcification (parenchymal)	Antacids, calcium, phosphorous Vitamin D
Cough	ACE inhibitors
Goodpasture's syndrome	Penicillamine
Lung mass(es) ± cavitation	Amiodarone, bleomycin
Mediastinal widening	
Lymphadenopathy	Diphenylhydantoin, methotrexate Potassium iodide
Lipomatosis	Corticosteroids
Mediastinitis	Esophageal variceal sclerotherapy
Panlobular emphysema	Methylphenidate
Pneumothorax	Nitrosoureas, bleomycin
Pseudosepsis syndrome	Chronic salicylate intoxication

ACE, angiotensin-converting enzyme.

TABLE 3. *Unusual manifestations of drug-induced pulmonary toxicity*

PATTERNS OF RESPONSE

Hypersensitivity Reactions

Pulmonary responses to some drugs may be best thought of in terms of a hypersensitivity reaction (Table 1). Typically, the symptoms consist of cough, dyspnea, and fever, with the appearance of an infiltrate on the chest x-ray film. Occasionally, a pleural effusion is seen. In some instances, there may be laboratory manifestations characteristic of hypersensitivity responses, such as peripheral eosinophilia or, more specifically, a positive lymphocyte transformation test response to the offending drug. The adverse response usually remits after cessation of the drug. Corticosteroids may hasten the recovery, although they are generally not needed.

Noncardiogenic Pulmonary Edema

Several factors are responsible for the transvascular flow of fluid. One factor, the filtration coefficient of permeability of the vascular endothelium, is believed to be altered in cases of noncardiogenic pulmonary edema. Overdoses of sedatives and narcotics are most commonly associated with altered permeability of the pulmonary vasculature. Most patients with noncardiogenic pulmonary edema also display some degree of central nervous system depression; it is unclear whether the response represents a drug effect, “neurogenic pulmonary edema,” or a combination of the two. Other drugs that cause noncardiogenic pulmonary edema characteristically produce an idiosyncratic response within minutes to hours after absorption.

Interstitial Pneumonitis or Fibrosis

A number of drugs have the potential for causing either an interstitial pneumonitis or an interstitial fibrosis. In some cases, the interstitial pneumonitis has many of the features of a hypersensitivity state, and the difference may be semantic rather than real. In other cases, few features of a hypersensitivity state are seen, and the interstitial pneumonitis represents only the precedent inflammatory state of a fibrosing process.

Pleural Effusions

An acute pleural effusion in association with drugs has been reported to be part of a hypersensitivity reaction. Anticoagulants cause effusion by leading to a pleural hemorrhage. A chronic pleural effusion develops after long-term use of a drug. In some instances, this is a manifestation of a retarded hypersensitivity-like response (methotrexate and procarbazine) or is associated with an interstitial fibrosis (busulfan and methotrexate).

Pulmonary Vascular Responses

Busulfan and cromoglycate are included as possible causes of pulmonary vascular responses because biopsy specimens from patients who display hypersensitivity reactions to these drugs may show an inflammatory vascular response as well. It is unclear what role the angiitis *per se* plays in the development of these disease processes. Illicit drugs are capable of causing angiitis and hypertension; the drugs and their diluents are given intravenously and are filtered by the pulmonary capillaries, where they incite their untoward effects. Heroin-induced pulmonary edema is frequently encountered in urban medical centers. An overdose of methadone and propoxyphene (Darvon) can cause a similar reaction. Corticosteroids are mentioned as causing pulmonary vasculitis, but evidence is at best suggestive. In an autopsy review of patients with rheumatoid arthritis, pulmonary vasculitis was found to occur in 29% of patients receiving corticosteroids but in none of the patients who were not taking them.

Alpha-adrenergic nasal sprays have been associated with interstitial fibrosis and obliterated pulmonary vessels on histologic examination. This response, seen in patients who abuse the sprays on a long-term basis, may be caused by the effects of repeated vascular constriction. The chest roentgenogram shows normal parenchyma with prominent pulmonary vasculature. Pulmonary function testing reveals a drop in the DLCO (diffusing capacity) that is proportional to the degree of pulmonary hypertension.

Estrogen-containing drugs are also capable of causing pulmonary hypertension. Affected patients fall into two distinct categories: those with congenital heart disease and those without. In the first group, the relationship between estrogen and pulmonary hypertension appears to be well established, although uncommon; in the second group, the relationship remains only suggestive. Case reports have implicated oral contraceptives as a cause of “primary” pulmonary hypertension in patients who have taken the drug for 6 months to 5 years. In one study, predisposing factors for pulmonary hypertension were found in three of six patients (family history, corrected ductus, and connective tissue disease); the other three were apparently normal.

Pulmonary Parenchymal Calcification

Drug-related calcium deposition in the lungs is very rare. It is usually associated with the soft-tissue calcification seen in the milk-alkali syndrome or with hypercalcemic states of other causes. Drugs known to have precipitated calcium deposition include antacids, calcium, phosphorus, and high doses of vitamin D (Table 3).

Parenchymal Hemorrhage

Hemoptysis as the manifestation of an adverse drug effect is most frequently caused by a drug-related pulmonary embolus leading to pulmonary infarction. Pulmonary hemorrhage and hemoptysis can be a manifestation of penicillamine-induced Goodpasture's syndrome, lipoid pneumonia, or chronic radiation pneumonitis.

Spontaneous pulmonary hemorrhage has been reported in patients who were taking oral anticoagulants for 13 days to 3 years. Initial symptoms were dyspnea, hemoptysis, and cough. The presenting feature was either hemoptysis or an infiltrate on the chest roentgenogram. Anticoagulants also may cause a hemothorax, manifested as a pleural effusion associated with a decreasing hematocrit.

Mediastinal Manifestations

Although not necessarily representing a pulmonary disease, adverse mediastinal responses appear initially as an abnormality on the chest x-ray film. Diphenylhydantoin occasionally produces a pseudolymphoma syndrome, manifested as peripheral lymphadenopathy (Table 3). It produces mediastinal lymphadenopathy only rarely, however. The enlarged nodes regress 1 to 2 weeks after cessation of the drug. Potassium iodide has been reported to produce fever, cough, and pruritus, with hilar and mediastinal lymphadenopathy that cleared on discontinuance of the drug. Transient hilar adenopathy may accompany a hypersensitivity-like response to methotrexate. Mediastinal lipomatosis resulting from corticosteroid use is a well-recognized entity.

Drug-Induced Lupus Erythematosus

A number of drugs have been implicated as causative factors in the systemic lupus erythematosus (SLE) syndrome, and it is estimated that they play an activating role in 5%–12% of cases (Table 1). It is still controversial whether the drug exposes a latent case of lupus or actually causes the disease. Animal experiments have not helped to clarify this issue. Acetylator status may be important, for cases of hydralazine- and isoniazid-related SLE are noted more frequently in slow acetylators of these drugs.

The lungs and pleurae are involved in 50%–75% of cases of spontaneous SLE, whereas they are involved in 80% of cases of drug-induced SLE. Patterns of response include the following: (1) pleural effusion with or without pleuritic pain, (2) pleuritic chest pain with or without effusion, (3) atelectatic pneumonitis, (4) diffuse interstitial pneumonitis, and (5) alveolar infiltrates. Positive biochemical markers of SLE are found more frequently than are systemic signs, and the pleuropulmonary manifestations usually regress with removal of the agent.

It is estimated that >90% of cases of drug-induced SLE are caused by diphenylhydantoin, hydralazine, isoniazid, or procainamide. Sulfonamides that have been implicated include acetazolamide, sulfadiazine, sulfamethoxypyridazine, sulfasalazine, and sulfisoxazole.

Hydralazine differs from most drugs in this category in that only 25% of patients have pleuropulmonary symptoms. In one review, the percentages of symptomatic

patients found to have chest roentgenographic abnormalities were as follows: (1) pleural thickening (57%), (2) pleural effusion (36%), (3) pulmonary fibrosis (21%), (4) elevated hemidiaphragm (7%), (5) segmental atelectasis (7%), and (6) migratory pneumonitis (7%). Hydralazine-induced SLE is seen in 10%–20% of patients receiving prolonged therapy with doses of 400 mg/d or greater (although it has been reported in patients who received therapy for <1 month and those who received <100 mg/d). It is more common in women (50%–90%), Caucasians, and slow acetylators.

Procainamide-induced SLE is a time- rather than dose-dependent phenomenon. For example, in one study clinical SLE developed in 50% of patients by 3 months, and by 1 year all had a positive test for antinuclear antibodies (ANA). Resolution of the syndrome within a few days to weeks after discontinuance of the drug is the rule; occasionally, corticosteroids are necessary to control symptoms.

Drug-induced bronchospasm/asthma

Drug-induced bronchospasm is caused by a variety of agents (Table 1 and Table 2). Mechanisms are diverse and poorly understood. Acetylsalicylic acid produces worsening bronchospasm in about 4% of asthmatic patients. Other nonsteroidal anti-inflammatory agents (NSAIDs) can produce a similar reaction and should be avoided in aspirin-sensitive patients. Dipyridamole increases the concentration of the bronchoconstrictor adenosine, which can cause significant bronchospasm in some patients with underlying obstructive lung disease. Theophylline is the drug of choice for treatment and/or prophylaxis in these patients. Vinblastine appears to act synergistically with mitomycin to produce bronchospasm. Administration of nebulized medications, such as pentamidine, or propellants can further irritate already hyperreactive airways. Paradoxical bronchospasm (Table 3) has been reported with the use of nebulized beta agonists as well as intravenous hydrocortisone (not reported with other steroid preparations).

Bronchiolitis Obliterans Organizing Pneumonia

Bronchiolitis obliterans organizing pneumonia (BOOP) has been described as a response to a variety of medications (Table 1 and Table 2). Patients frequently have isolated or patchy air space opacities indistinguishable from those of idiopathic BOOP. This reaction is usually reversible with discontinuation of the drug and sometimes requires treatment with corticosteroids.

EFFECTS OF DRUGS AND RADIATION

Anti-inflammatory Agents

Sodium cromoglycate has been associated with a hypersensitivity-like response, accompanied by fever, eosinophilia, and pulmonary infiltrates.

Overdoses of acetylsalicylic acid (ASA) can produce central respiratory stimulation and noncardiogenic pulmonary edema. Therapeutic serum levels are in the range of 10 to 20 mg/dL. At levels of 35 mg/dL, respiratory alkalosis is seen. Severe hyperpnea is manifested at levels of 50 mg/dL. At a serum level of 45 mg/dL, noncardiogenic pulmonary edema is seen. The pulmonary capillary wedge pressure is normal. Abnormalities on chest x-ray films take 3 to 8 days to clear.

The ASA triad is a syndrome characterized by asthma, nasal polyposis, and drug sensitivity. It was initially described following the use of ASA, but other anti-inflammatory drugs can also produce this reaction (Table 1). The first manifestation of the syndrome is vasomotor rhinitis with a watery discharge. Typically, this develops in the second or third decade in a person who is not atopic and who has previously taken ASA. The reaction is at first intermittent, later perennial. It is followed by the appearance of nasal polyps, and by midlife most patients demonstrate an asthmatic response.

The syndrome is not a hypersensitivity response, despite the asthma and angioedema that may be seen following absorption of the drugs. Results of skin and immunologic tests are negative. Furthermore, other forms of salicylic acid (such as sodium salicylate) do not produce a response in the ASA-sensitive patient. The mechanism of action is postulated to be an inhibition of prostaglandin (PG) synthetase and a disruption in the balance between naturally occurring bronchoconstrictor (PGF_{2a}) and bronchodilator (PGE series) prostaglandins. The usual response to this disruption is bronchoconstriction, but bronchodilation also has been reported. Most of the drugs that produce this response fall into the broader category of anti-inflammatory nonsteroidal analgesics, and it is for this reason that the ASA triad has been called *analgesic asthma* by some authors.

The frequency of the syndrome in asthmatic patients is approximately 4%. Patients may or may not be atopic (3% vs. an expected 10% in one series). Family studies reveal rare clusterings.

Treatment starts with avoidance of the offending drug. Beta-adrenergic agonists reverse the airways response. Corticosteroids diminish the recovery time, but even pretreatment does not prevent the response. Nasal polypectomy is reserved for symptoms of nasal obstruction only; it does not alter the response to ASA, and the polyps usually recur.

Tartrazine (FD&C yellow dye No. 5) is not an analgesic, and it is not known to affect PG biosynthesis. However, it can provoke symptoms of the ASA triad in a small number of ASA-sensitive patients. As a dye, it is contained in a number of medications and food products.

Methotrexate is increasingly being used in low doses (lower than the usual chemotherapeutic dose) as an anti-inflammatory drug for a few conditions, especially rheumatoid arthritis and Wegener's granulomatosis. Typically, the patient is given 10 to 15 mg once a week. Pulmonary reactions develop in about 5% of these patients, most commonly in the form of granulomatous pneumonitis. The onset is insidious and associated with cough, dyspnea, and low-grade fever. Histologically, weakly formed granulomas are seen in most patients. In a recent prospective evaluation of 124 patients receiving low-dose methotrexate, pneumonitis occurred in 3.2% of patients. Pulmonary function tests did not allow detection before clinical symptoms. Methotrexate pneumonitis also seems to predispose patients to *Pneumocystis carinii* pneumonia.

Penicillamine can cause unique pulmonary complications, including BOOP, SLE, and Goodpasture's syndrome (Table 3).

Gold is widely used orally and intramuscularly for the treatment of rheumatoid arthritis. The intramuscular preparations can cause interstitial pneumonitis and fibrosis that is almost always reversible by discontinuation of the gold injections, but sometimes additional treatment with corticosteroids may be required.

Antimicrobial Agents

Griseofulvin, isoniazid, para-aminosalicylic acid, penicillin, streptomycin, the sulfonamides, and tetracycline are all capable of producing a drug-induced SLE syndrome. In addition, isoniazid has been reported to cause a hypersensitivity-like pneumonitis with peripheral eosinophilia. Penicillin has been reported as generating a hypersensitivity pneumonitis distinct from systemic anaphylaxis, with peripheral eosinophilia (as high as 80%), alveolar infiltrates, pleural effusions, and positive skin test results. Sulfonamides can cause a true Loeffler's syndrome, with fever, cough, dyspnea, migratory infiltrates, and peripheral eosinophilia. A hypersensitivity pulmonary response also has been reported following the use of a sulfonamide-containing vaginal cream.

Para-aminosalicylic acid is estimated to produce a hypersensitivity-like response in approximately 0.3%–5.0% of patients receiving the drug. Common adverse responses include fever (up to 10°F), rash, malaise, headache, dry cough, eosinophilia, alveolar infiltrates, and lymphadenopathy. Pleural effusion and hepatomegaly have been seen. The symptoms usually start during the third week of treatment and gradually disappear within 2 to 3 weeks after discontinuance of the drug. Cases of angioneurotic edema with laryngeal edema, cough, and wheezing also have been reported.

Of all the antimicrobial drugs, nitrofurantoin is perhaps the most commonly reported as causing an adverse pulmonary reaction. To gain an appreciation of the relative risk, the manufacturer collected data during a 16-year period. During that time, 237 cases of adverse pleuropulmonary reactions were reported in an estimated 44 million courses of the drug. Reactions to nitrofurantoin are classified as acute or chronic, with no definite relationship between the two types, although both can be fatal.

Lymphopenia is seen during the acute reaction, with a decrease in both the B- and the T-cell population. Results of the lymphocyte transformation test against nitrofurantoin need not be positive for a patient to display an adverse reaction. The following acute reactions are seen: (1) acute asthma (rare), (2) acute tracheobronchitis with a normal chest roentgenogram (very rare), (3) pleural effusions (usually seen in association with hypersensitivity pneumonitis), and (4) hypersensitivity pneumonitis (the most common response).

The onset of symptoms of the hypersensitivity pneumonitis usually occurs within 2 hours to 10 days after start of the medication (although onset has been known to be delayed as long as 1 year). Typically, the patient has fever, chills, dyspnea, and cough. This response is seen much more quickly after subsequent uses of the drug.

Physical examination often suggests more diffuse involvement than is seen on the chest roentgenogram. Pleuritic pain and pleural rubs may be present.

The roentgenogram reveals diffuse alveolar or alveolar-interstitial infiltrates. Pleural effusions may be present. Various degrees of peripheral eosinophilia can be seen, as well as eosinophils in the sputum.

Treatment is based on discontinuance and avoidance of the drug. Corticosteroids and antihistamines provide symptomatic relief. The infiltrates clear spontaneously within a 24- to 48-hour period.

The chronic reactions occur less commonly and are estimated to represent 3% of all pleuropulmonary reactions to nitrofurantoin. There is no relationship to the acute response, and deaths are more frequently encountered in this type. Two patterns of response occur—interstitial fibrosis and a desquamative interstitial pneumonitis.

The interstitial fibrosis starts insidiously after 6 months to 6 years of therapy. Symptoms are cough and dyspnea without fever, eosinophilia, or pleural effusion. Desquamative interstitial pneumonitis was described in three patients who received the drug for 2 to 5 years. In contrast to the symptoms of interstitial fibrosis, which show only a variable response to corticosteroid therapy, the symptoms of desquamative interstitial pneumonitis reversed well with treatment.

Sulfasalazine is an effective antibiotic for the treatment of inflammatory bowel disease. It has been reported to cause several pulmonary reactions, including BOOP, pulmonary infiltrates with eosinophilia, pulmonary fibrosis, and asthma. Some overlap may exist in these pathologic presentations. Treatment consists of discontinuing sulfasalazine and the administration of corticosteroids. Although most of the side effects of sulfasalazine are considered to be caused by sulfapyridine (the carrier component), mesalamine (the clinically beneficial component without the carrier sulfapyridine) has also been reported to cause pulmonary toxicity.

Pentamidine given intravenously or by nebulizer can cause bronchospasm. Pretreatment with nebulized albuterol or ipratropium may prevent this adverse effect.

Amphotericin B can be associated with impaired pulmonary function, particularly if administered with granulocyte transfusion. This has also been reported with the liposomal form of amphotericin B. The treatment is to stop the medication and administer corticosteroids. Concomitant granulocyte transfusion and administration of amphotericin B should be avoided.

Cardiovascular Agents

Amiodarone hydrochloride, an antiarrhythmic drug, can cause pulmonary toxicity in about 6% of patients receiving the drug. The clinical features include dyspnea, chest pain, cough, elevated sedimentation rate, and diffuse interstitial and patchy alveolar infiltrates in the roentgenogram. Histologically, an accumulation of foamy macrophages in the alveolar spaces, hyperplasia of type II pneumocytes, and widening of alveolar septa are noted. Increased levels of cytosolic free calcium may cause injury. Cessation of the drug and administration of corticosteroids lead to radiographic resolution in about 2 months.

Amiodarone pneumonitis rarely occurs in patients who have been taking the drug in doses of <400 mg/d for <2 months. The diagnosis of amiodarone pneumonitis is really one of exclusion. Pulmonary embolism, congestive heart failure, and pneumonia are the main differential diagnoses in patients suspected of having amiodarone pulmonary toxicity, and they should be excluded first. Computed tomography (CT) of the lung (without the administration of contrast) may be helpful, because amiodarone is an iodinated compound and appears more dense than usual infiltrates of other etiologies. Bronchoalveolar lavage may be helpful in excluding infection. Results of a gallium scan are positive in almost all patients with amiodarone pneumonitis. A positive gallium scan can help differentiate amiodarone pneumonitis from pulmonary embolism or congestive heart failure (in which the gallium scan is negative) as long as infection has been excluded as a cause for the positive scan. In patients receiving amiodarone, a picture suggestive of adult respiratory distress syndrome (ARDS) may develop when they are exposed to a high F_IO_2 (fraction of inspired oxygen), as during anesthesia for surgical procedures. In an unusual presentation, amiodarone pulmonary toxicity may take the form of parenchymal mass lesion(s), which may show cavitation (Table 3).

Angiotensin-converting enzyme (ACE) inhibitors can produce an irritating cough in about 10%–25% of patients receiving them. The cough occurs with all ACE inhibitors, and changing from one to another does not help. Cough usually resolves within 1 to 2 weeks of stopping the medication, which is both diagnostic and therapeutic.

Beta blockers can exacerbate chronic obstructive lung disease and precipitate bronchospasm. Some examples, in decreasing order of likelihood to cause bronchoconstriction, are propranolol, timolol, nadolol, atenolol, and labetolol. They should be used with extreme caution in patients with a potential for bronchospasm.

Hydrochlorothiazide can cause noncardiac pulmonary edema. Patients present with dyspnea, cough, and a low-grade fever within a few hours of taking the medication. The chest roentgenogram shows changes of pulmonary edema; in cases in which the wedge pressure has been measured, it has always been normal. Treatment is supportive, and the patient should avoid the medication thereafter.

Psychotropic Medications

Overdose of tricyclic antidepressants may be associated with pulmonary complications in about a third of cases, usually in the form of noncardiac pulmonary edema or aspiration. Treatment is supportive and may include mechanical ventilation.

A series of three cases of phenothiazine-induced pulmonary edema has been reported. The authors hypothesized that it is neurogenic in origin, caused by hypothalamic dysfunction.

Trazodone overdose has been reported to cause eosinophilic pneumonia and respiratory failure.

Illicit Drugs

The use of illicit drugs has reached epidemic proportions, resulting in an increased incidence of pulmonary toxicity. The pulmonary manifestations relate not only to the substance used, but also to the route of administration. Narcotic addiction remains a major health problem, with noncardiogenic pulmonary edema occurring as a complication of heroin, methadone, and cocaine abuse.

Pulmonary edema develops within a few hours of use, and the patient appears with constricted pupils and depressed respiration. The chest radiograph shows alveolar infiltrates, usually in “bat wing” distribution. Pathologic studies reveal congested, enlarged lungs with an influx of neutrophils and pigmented macrophages. The therapy is supportive, with administration of oxygen, narcotic antagonism, and mechanical ventilation if needed.

Cocaine is a highly addictive substance. Pulmonary complications are related to all forms of administration. Noncardiogenic pulmonary edema can occur with cocaine regardless of the route of administration. Increased membrane permeability probably occurs as a result of alveolar capillary injury. Pulmonary edema has been reported with freebase inhalation, intravenous freebase, and even “body packing” (smugglers swallowing packets of cocaine, which leak into the gastrointestinal tract). Other reported complications of smoking freebase cocaine include barotrauma, massive hemoptysis with diffuse alveolar hemorrhage, interstitial pneumonitis, recurrent pulmonary infiltrates with bronchospasm, and BOOP. Reduced diffusing capacity, decreased expiratory flow rates, and bronchial asthma have also been associated with smoking of freebase cocaine.

An acute pulmonary syndrome temporally related to inhalation of crack cocaine has also been described and is characterized by fever, hemoptysis, alveolar infiltrates, and respiratory failure. The lung tissue in this entity (“crack lung”) reveals alveolar hemorrhage, interstitial and intra-alveolar inflammatory cells, and deposition of IgE in lymphocytes and macrophages. The patients tend to respond to systemic corticosteroids.

Snorting cocaine causes cartilaginous ischemia and can lead to nasal septal perforation. Burns of the oropharynx and larynx can also occur from inhaling hot gases during smoking of freebase cocaine.

Miscellaneous Agents

Estrogens may produce an adverse pulmonary response through a number of mechanisms: pulmonary embolus, drug-induced SLE syndrome, and pulmonary hypertension. It has been estimated that the risk for development of thromboembolic disease in age-matched patients taking oral contraceptives is increased from 5 to 47/100,000. Some associated variables shown to increase the risk include advancing age, obesity, and prolonged bed rest. Thrombogenic risk is directly proportional to

the estrogen content of the oral contraceptives.

Pleural thickening is the most common pleuropulmonary side effect of long-term use of methysergide or bromocriptine. A ground-glass appearance on the chest x-ray film can clear spontaneously with cessation of the drug. A pleural effusion may be seen. Onset may be acute, with pleuritic pain and a rub, or may be more insidious. The effusion may be unilateral or bilateral. Pulmonary fibrosis also has been seen with long-term methysergide use. Onset is slow (6 months to 6 years), with cough and dyspnea. The fibrosis may be diffuse; alternatively, localized areas of pleuropulmonary fibrosis may resemble a mass lesion. The fibrosis may reverse on discontinuance of the drug.

Administration of contrast media is an underestimated cause of drug-induced bronchospasm. Most patients receiving intravenous contrast media show a subclinical reduction in FEV_1 (forced expiratory volume in 1 second) within 5 minutes; this returns to normal within 30 minutes. Severe reactions can occur but are relatively rare.

Esophageal variceal sclerotherapy with either sodium tetradecylsulfate, ethanolamine, or sodium morrhuate can cause changes on chest roentgenograms in up to 85% of patients, but these are rarely of clinical significance. Mediastinal widening resulting from noninfectious mediastinitis occurs in 33% of patients. Pleural effusion occurs in 25% of patients, atelectasis in 10%–15%, and pulmonary infiltrates in 10% of patients. Self-limited fever and chest pain are common in the first 24 hours after the procedure. Serious complications, including ARDS, occur in <2% of patients undergoing esophageal sclerotherapy, and these should be suspected if the fever and chest pain last for >24 hours.

Tocolytic medications (albuterol, terbutaline, ritodrine), used to inhibit uterine contractions during premature labor, can cause noncardiac pulmonary edema in 0.5%–5% of cases. These beta-mimetic drugs produce peripheral vasodilation and an increase in the intravascular fluid volume. When the drug is stopped, the vasomotor tone returns to normal, pushing excess fluid out into the tissues, including the lungs.

Antineoplastic Drugs

The adverse pulmonary responses most often produced by antineoplastic drugs are interstitial pneumonitis and interstitial fibrosis (Table 2). The distinction between these two patterns of response is not sharp, and there may be progression from one state to another. In general, the presentation of interstitial pneumonitis tends to be a systemic hypersensitivity response, with fever, malaise, and a rapid decline in respiratory function. Although both entities can emerge from days to years after a medication is started and resolve during days to months, interstitial pneumonitis is more likely to present earlier and resolve quickly. The pathologic differences are also not profound. Interstitial pneumonitis presents with evidence of larger numbers of inflammatory cells and less fibrosis than does interstitial fibrosis. Of the two, interstitial pneumonitis is the more likely to resolve on discontinuation of the drug.

Common symptoms include dyspnea and cough of insidious onset. The cough is usually dry, although a thick white sputum may be present at times. Malaise, fatigue, and fever are occasionally found. Physical examination generally reveals tachypnea and fine crackles that are heard best in the bases. An interstitial infiltrate is the most common roentgenographic abnormality. Pulmonary function testing is consistent with a restrictive ventilatory defect (low vital capacity or total lung capacity) and a reduced D_LCO; the flow rates are usually preserved. The D_LCO is the most sensitive parameter and can be used to follow the patient as a predictive test. Hypoxemia is common.

Diagnosis is made by lung biopsy. The list of causes of pulmonary infiltrates in the immunocompromised host always includes infection, and infiltrates should be sought with appropriate stains and cultures. Treatment is discontinuance of the agent. Steroids may or may not help but probably should be tried. The response may be followed by serial determinations of PaO_2 (partial pressure of arterial oxygen) and D_LCO and by chest roentgenograms.

Occasionally, factors such as total cumulative dosage, patient age, or prior use of agents that may act synergistically (e.g., radiation) can be used to anticipate an untoward response.

The manifestations of drug-induced pulmonary toxicity caused by antineoplastic agents are listed in Table 2.

Azathioprine

At least six cases of azathioprine hypersensitivity pneumonitis have been reported, but the incidence remains well below 1%.

Bischloroethylnitrosourea

Bischloroethylnitrosourea (BCNU) has been reported to cause interstitial pulmonary infiltrates. One report suggested a dose-related phenomenon; a hacking cough developed in 4 of 28 (14%) patients. The mean cumulative dose in patients with symptoms was 2030 mg/m^2; for those without symptoms, it was 710 mg/m^2. Interstitial infiltrates were seen on the chest roentgenogram in three of the four patients, but all four had interstitial fibrosis on lung biopsy. Symptoms progressed despite cessation of therapy, and one patient died of respiratory failure. Another study could find no dose-dependent relationship but suggested that interstitial infiltrates were more common when BCNU was used concomitantly with cyclophosphamide. Of the 10 patients, nine had received other agents capable of causing interstitial fibrosis. In both studies, the pulmonary function tests commonly showed a decreased D_LCO, PaO_2, and vital capacity. The projected incidence varied from 1.1% to 14%.

Another peculiar complication of nitrosoureas is pneumothorax (Table 3).

Bleomycin

Interstitial fibrosis is the most commonly mentioned adverse pulmonary response to bleomycin. An acute response consisting of cough and dyspnea has been reported, however. These symptoms may occur separately or together, and were found in 6% of 274 patients in one study. The cough may be so severe as to limit use of the drug. The response usually occurs shortly after injection, but a response did not develop in one patient until the eighth month of treatment. Tracheitis also has been described, although infrequently.

Bleomycin is deposited in the skin and lungs, and not unexpectedly, the two organs displaying the most serious side effects are the skin (ulcerations) and the lung (interstitial fibrosis). The pulmonary manifestation appears to be a result of toxic accumulation, although cases have been reported of a hypersensitivity reaction.

Four patients have been described in whom a reversible interstitial pneumonitis developed after they received total doses ranging from 133 to 1000 mg. Two of the four displayed peripheral eosinophilia (12%–16%), and biopsy of one showed eosinophilic infiltration of the distal air spaces. Pleural effusions, interstitial infiltrates, and alveolar infiltrates all appeared on the roentgenograms. Results of immunofluorescence studies for immunoglobulins, complement, and fibrinogen were negative. Corticosteroids were given to three of the four patients, and all four showed resolution of the infiltrates and symptoms.

Interstitial fibrosis occurs in approximately 11% of patients receiving the drug. The incidence is reported to be only 3%–5% when the total dose is below 450 mg, but 35.3% when the level of 500 mg is exceeded. In a histologic study of 37 patients (34 of 37 specimens were obtained at autopsy), 12 of 37 were found to have interstitial pneumonitis at different stages of development. Total doses ranged from 115 to 800 mg/m^2. Histologic changes consisted of fibrinous exudate, atypical proliferation of alveolar cells, hyaline membranes, squamous metaplasia, epithelial dysplasia of distal air spaces, and interstitial and intra-alveolar fibrosis. Alveolar septa were broadened, with edematous fluid and mononuclear inflammatory cell infiltration, and showed signs of extensive fibrosis. Work on animal models indicates that bleomycin-induced lung injury is characterized by an increase in collagen synthesis in the interstitium.

Bleomycin-induced pulmonary toxicity may therefore be seen as a spectrum of changes. The drug is accumulated in the lungs. There may be an initial toxic inflammatory response that later becomes fibrotic. The earlier the response is identified, the more amenable the lung is to full recovery. Fibrotic states are quite resistant to reversibility, even after cessation of the drug and with the use of corticosteroids. The D_LCO may be the most sensitive parameter for following the patient. Factors that appear to increase the toxic potential include (1) advancing age, (2) total cumulative dose (high F_IO_2), and (3) prior radiation to the thorax. The histologic changes of bleomycin-induced interstitial fibrosis resemble those of busulfan lung as well as desquamative interstitial pneumonitis. The chest roentgenogram shows a nonspecific interstitial pattern. The most severe changes in both the histologic picture and the radiographic appearance are in the lung bases and subpleural areas (as opposed to busulfan toxicity, in which the roentgenographic abnormalities are more pronounced near the hilum). Symptoms include dry cough and dyspnea. Physical examination reveals tachypnea, basilar crackles, and concomitant hyperpigmentation of the skin. Diagnosis is by lung biopsy (Fig. 1), although sputum cytology may be of assistance (Fig. 2). Treatment is discontinuance of the drug. Steroids have been effective in some cases. If the patient's condition demonstrates reversibility, the roentgenographic findings (Fig. 3) and pulmonary function test results usually improve.

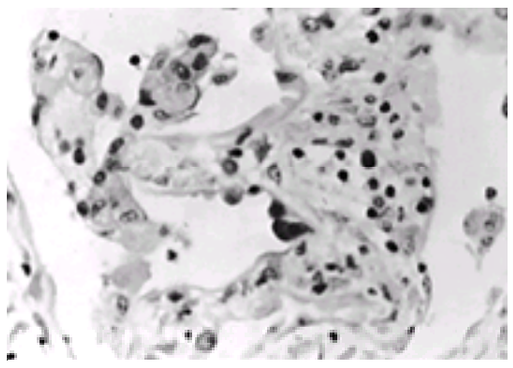

FIG. 1. Bleomycin lung. Hyperplastic alveolar epithelium, septal edema, septal fibrosis, and lymphocytic infiltrates are demonstrated in this open lung biopsy specimen. H&E, ×400. (Photomicrograph courtesy of Dr. G. Gephart, Department of Pathology, Cleveland Clinic Foundation.)

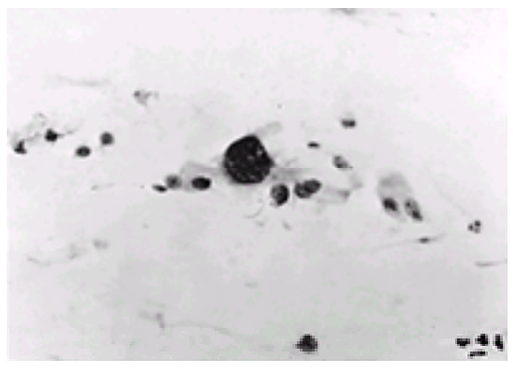

FIG. 2. An atypical cell from bronchial washings of a patient with bleomycin lung. The cell exhibits nuclear enlargement and hyperchromasia. Normal respiratory epithelium is also present. Papanicolaou's stain, x400. (Photomicrograph courtesy of Dr. G. Gephart, Department of Pathology, Cleveland Clinic Foundation.)

FIG. 3. Bleomycin pneumonitis. **A:** Posteroanterior chest x-ray film showing bilateral interstitial infiltrates. Total dose of bleomycin was 360 mg during 8 weeks. **B:** Marked clearing after steroid therapy. (Reproduced with permission from Brown L, et al. Successful treatment of bleomycin lung. *Cleve Clin Q* 1980;47:99.)

A more recently recognized pulmonary complication of bleomycin is BOOP presenting as nodular lesions mimicking metastasis.

Busulfan

Busulfan is considered the prototypic drug for cytotoxic drug-induced pulmonary damage. The usual case is one of long-term toxic damage to the lungs, with an insidious onset of symptoms after the patient has taken the drug for 3 to 4 years.

Abnormalities are found in pulmonary function tests or on the roentgenogram, or else symptoms are present in 2.5%–11.5% of patients treated with busulfan. Histologic evidence of toxicity can be seen in 12.5%–42.8% of all patients treated.

Histologic changes include organizing fibrinous edema with bizarre atypical cells (probably a type II pneumocyte). Alveolar lining cells and bronchiolar epithelial cells can both appear abnormal and may be dysplastic or neoplastic on sputum cytology. There may be evidence of edema or inflammatory cells in the interstitium or, more commonly, fibrotic changes.

The pulmonary function tests show hypoxemia, restriction, and a decrease in diffusing capacity. The D_LCO can be used to follow patients. Diffuse interstitial and alveolar infiltrates are typically seen on the chest x-ray film, but nodular densities, pleural effusions, or a normal picture may be seen as well.

Symptoms include cough, dyspnea, and fever. Diagnosis is made by sputum cytology or lung biopsy in the appropriate setting. Treatment is discontinuance of the drug and administration of corticosteroids. The damage is not commonly reversible.

Alveolar proteinosis has been reported in a number of patients receiving busulfan (Table 3). Unlike the usual type of alveolar proteinosis, busulfan-induced disease does not respond to therapeutic lavage.

Chlorambucil

Chlorambucil has been implicated as causing interstitial fibrosis in <5.1% of patients. Symptoms include the insidious onset of cough and dyspnea. Physical examination reveals fine basilar crackles and fever. Histopathology reveals alveolar lining cell dysplasia, interstitial round-cell infiltration, and interstitial fibrosis. Signs and symptoms show good reversibility following discontinuance of the drug and use of corticosteroids.

Cyclophosphamide

The pulmonary response to cyclophosphamide is similar to that seen with busulfan, although it is less common. The pulmonary function tests show hypoxemia, a decreased D_LCO, and restriction. Interstitial infiltrates are seen on the chest roentgenogram. Symptoms start insidiously; they include fever, cough, and dyspnea, and may develop after the patient has received the drug for many months. Diagnosis is by lung biopsy. Histologic study shows proliferation of atypical alveolar lining cells. Signs and symptoms may remit with discontinuance of the drug and the administration of corticosteroids.

Melphalan

Pulmonary toxicity is seen in <5% of patients receiving melphalan. Manifestations include interstitial fibrosis, plasma cell interstitial infiltration, and proliferation of bronchiolar and alveolar lining cells.

Methotrexate

An interstitial response to methotrexate may be acute or chronic, and is one of the more reversible of the cytotoxic drug-induced pulmonary reactions. This response has been described following the oral, intravenous, intramuscular, and intrathecal routes of administration.

In some patients, the reaction more closely resembles a hypersensitivity response, with the acute onset of transient hilar lymphadenopathy, eosinophilia, and defervescence with corticosteroids. In other cases, it is more characteristic of a direct toxic action, with fibrosis occurring while the patient is taking corticosteroids and the disability progressing to respiratory failure and death.

In one series, the incidence was 7 of 92, and in another it was approximately 2.5%. The incidence appears to be related to the frequency of dosing rather than to total dose (range, 40 to 6500 mg); the condition is rare, however, in patients receiving 20 mg/week.

There may be synergism with cyclophosphamide, especially in adrenalectomized patients, with an increased frequency and severity of response.

The histologic changes resemble those of desquamative interstitial pneumonitis or busulfan lung (but with fewer abnormal cells). There is alveolar damage, with hyaline membranes and prominent, sometimes atypical, alveolar lining cells; interstitial infiltrates with lymphocytes, plasma cells, and eosinophils; and occasionally, granulomas and giant cells or interstitial fibrosis.

The pulmonary function tests show restriction, hypoxemia, and a decreased D_LCO. There may be significant residual abnormalities following clinical recovery. The diffusing capacity is the most sensitive factor but does not allow detection of toxicity before clinical symptoms appear. The chest roentgenogram may be normal or show nodular or reticular nodular infiltrates in the bases and midlung zones, diffuse alveolar infiltrates, pleural effusions, or hilar lymphadenopathy. There may be permanent changes of pulmonary fibrosis.

The onset of symptoms usually occurs 10 days to 4 months after treatment starts. Typically, symptoms include cough, fever, and dyspnea. Headache and malaise are common prodromal symptoms. The differential diagnosis includes leukemic infiltrates (however, the patient is usually in remission when a methotrexate-induced reaction develops) and opportunistic infection. Diagnosis is by biopsy.

Treatment is cessation of the drug. Corticosteroids may hasten recovery. Approximately 7% of patients progress to interstitial fibrosis, and 8% die of respiratory failure.

Methotrexate also has been implicated as causing a pulmonary reaction that histologically resembles bronchiolitis obliterans.

Mediastinal and hilar adenopathy have also been described in patients receiving methotrexate.

Mitomycin

The incidence of pulmonary toxicity with mitomycin C is about 5%. The D_LCO declines by >20% in approximately one fourth of patients after they have received three cycles of chemotherapy. Unfortunately, the use of serial D_LCO measurements in patients receiving mitomycin cannot predict pulmonary toxicity. Typically, symptoms of cough, fatigue, and dyspnea develop insidiously during several months. The chest x-ray picture shows diffuse reticulonodular infiltrates, and physical examination reveals basilar crackles. Biopsy shows alveolar septal edema and fibrosis, alveolar lining cell hyperplasia, interstitial infiltration with mononuclear and plasma cells, and some atypia of the type II pneumocytes. Prednisone therapy can result in prompt clearing of both symptoms and roentgenographic abnormalities.

Nitrogen Mustard

Unilateral pulmonary edema was seen following instillation of nitrogen mustard into the pleural cavity for control of a recurrent pleural effusion in a patient with breast cancer. Other signs and symptoms included fever, cough, and rales. The reaction was self-limited and was believed to represent a local toxic reaction.

Procarbazine

A hypersensitivity response has been described following the use of procarbazine. It may start within hours of the first dose or may develop after the patient has received the medication for months. Diffuse interstitial infiltrates are seen on the chest roentgenogram. The reaction may terminate in respiratory failure. Pleural effusions and eosinophilia arise. Biopsy shows mononuclear and eosinophilic cell infiltrates and interstitial fibrosis. Diagnosis is by biopsy. Treatment is cessation of the drug and use of corticosteroids. The chest roentgenographic abnormalities may resolve within a month.

Common manifestations of pulmonary toxicity of the various antineoplastic medications are listed in Table 2. Table 3 lists some of the unusual manifestations.

Radiation

The effects of radiation on the lungs are shown in Table 2. Acute radiation pneumonitis can histologically mimic the effects of cytotoxic medications. Changes caused by radiation can resolve completely or progress to become subacute or chronic. Recent studies describe a pulmonary hypersensitivity reaction to radiation, with evidence of lymphocytosis in bronchoalveolar lavage fluid from areas outside the field of radiation. More recently, necrosis of the bronchus (Table 3) has been described following external beam radiation and brachytherapy.

CHAPTER

23 Upper Respiratory Tract Infections

Richard J. Blinkhorn, Jr.

R. J. Blinkhorn.: MetroHealth Medical Center, Cleveland, Ohio 44109.

INTRODUCTION

The goals of this chapter are threefold:

1. To present the anatomic, microbiologic, pathophysiologic, clinical, diagnostic, and therapeutic aspects of infections of the upper respiratory tract, which comprises the oral cavity, nose, pharynx, retropharyngeal tissues, paranasal sinuses, epiglottis, larynx, trachea, and bronchial tree down to the level of the bronchioles.
2. To clarify the relationship of infections in these areas to other diseases affecting the lungs, and the effects of such infections on ventilatory function in general.
3. To describe the complications of infections of the upper respiratory tract, including the syndromes with which they are associated, and methods of diagnosis and treatment.

INFECTIONS OF THE ORAL CAVITY

Infections of the oral cavity most commonly are odontogenic in origin, and, although rare, local spread to the deep fascial spaces may occur, with subsequent life-threatening parapharyngeal, retropharyngeal, or pleuropulmonary extension. It is beyond the scope of this chapter to describe all potential intraoral infections; only those infections with complications commonly involving the upper respiratory tract are reviewed.

Although the microbiologic aspects of abscesses of odontogenic origin are not fully elucidated, the evidence available suggests that anaerobes are involved at least as frequently as aerobes. The anaerobes involved most often are fusobacteria, *Bacteroides* species, and anaerobic streptococci, whereas the aerobic organisms most frequently isolated are streptococci. Except in hosts compromised by leukemia or diseases in which therapy has resulted in profound neutropenia, facultative gram-negative bacilli and *Staphylococcus aureus* are rarely isolated.

The parapharyngeal space is shaped like an inverted cone, with its base at the skull and its apex at the hyoid bone. Infections of this space may result from peritonsillar abscess, parotitis, mastoiditis, and molar tooth infection. Parapharyngeal abscess may invade the carotid artery or jugular vein, resulting in thrombosis and/or intravascular sepsis, sometimes with metastatic hematogenous spread and development of septic pulmonary emboli. The latter condition is referred to as *Lemierre's postanginal sepsis; Fusobacterium necrophorum* is the leading etiologic agent. Infection may spread to the mediastinum along the carotid sheath or extend into the retropharyngeal space. Appropriate treatment consists of antibiotics, surgical drainage, and emergency ligation of the carotid artery or jugular vein when involved.

The retropharyngeal space is located between the pharynx and prevertebral fascia extending from the base of the skull into the mediastinum. Infection of this space usually results from lymphatic spread to the retropharyngeal lymph nodes with subsequent suppuration and abscess. Afferent drainage to these nodes arises from the nasopharynx, adenoids, and sinuses. Retropharyngeal abscess is mainly a disease of young children, as these lymph nodes atrophy by 3 or 4 years of age. Common causative organisms include *Streptococcus pyogenes* and anaerobic bacteria. Spontaneous rupture into the pharynx may result in aspiration with pneumonia and empyema.

Ludwig's angina is a term that has been loosely applied to a heterogeneous array of infections involving the submandibular and sublingual spaces. First described in 1836, this is a diffuse, bilateral cellulitis of the floor of the mouth and upper cervical areas characterized by toxicity, fever, brawny indurated swelling of the submandibular space, tongue elevation, and dysphagia. A dental source of infection is found in 50%–90% of reported cases, with the second and third mandibular molars most commonly involved. Rapid progression of infection may result in edema of the neck and glottis, thereby precipitating asphyxiation. Treatment requires high-dose parenteral penicillin, airway monitoring, early intubation or tracheostomy when necessary, soft-tissue decompression, and surgical drainage.

RHINITIS

Acute rhinitis is a nonspecific term for infections of the internal nose and may represent the sole or main manifestation of the “common cold.” The common cold is a mild, self-limited, catarrhal syndrome that is the leading cause of acute morbidity and of visits to physicians in the United States. Annual epidemics of upper respiratory tract disease occur in the colder months in temperate areas, with a peak incidence from late August until spring in the United States. The major respiratory viruses causing colds include rhinoviruses, coronaviruses, parainfluenza viruses, and respiratory syncytial viruses. Influenza virus and adenovirus may produce the common cold syndrome but tend to be associated with more severe illness often involving the lower respiratory tract.

The incubation period is variable, averaging 48 to 72 hours. Cardinal symptoms are nasal discharge, nasal obstruction, sore throat, and cough. Median duration of illness is 1 week, although almost one quarter of colds last up to 2 weeks. Diagnosis of the specific virus involved is usually not possible on clinical grounds. Influenza and pharyngoconjunctival fever (adenovirus), however, when seen in a typical epidemiologic setting, can be recognized without benefit of viral culture or serologic tests. The main challenge to the physician is to distinguish the uncomplicated cold from the approximately 0.5% of cases with secondary bacterial sinusitis and the 2% with otitis media. Antibiotics have no place in the management of uncomplicated colds, but decongestants and cough suppressants may be beneficial. Although intranasal recombinant human interferon-a has been effective both as therapy and prophylaxis against rhinovirus infection, local nasal irritation has complicated long-term use, and activity against viruses other than rhinovirus has not been demonstrated.

SINUSITIS

The frontal, ethmoid, maxillary, and sphenoid sinuses are paired cavities, lined with mucosa, in the anterior portion of the skull. Predisposing factors to sinus disease can be categorized as local, regional, or systemic. The most common local predisposing cause of suppurative sinusitis is a viral upper respiratory tract infection. Inflammation and edema in the ostial-meatal complex can obstruct the sinus ostium, leading to hypoxygenation of the sinus, disturbed ciliary and mucous blanket function, and diminished local resistance. Other local nasal factors that cause obstruction in the ostial-meatal complex are nasal polyps, allergic rhinitis, foreign bodies, and nasal septal pathology. In hospitalized patients, nasogastric tubes may functionally obstruct sinus ostia, thereby predisposing to nosocomial sinusitis. The immotile cilia syndrome is another local factor predisposing to sinus disease, but it does not involve structural obstruction of sinus ostia. Regional factors include maxillary dental infections, and predisposing systemic factors include malnutrition, diabetes mellitus, long-term corticosteroid therapy, hypogammaglobulinemia, blood dyscrasias, and chemotherapy.

Although normal paranasal sinuses have long been thought to be sterile, transient colonization with organisms normally populating the upper airway may occur. Overgrowth of this transient resident flora may produce infection when local clearance mechanisms are impaired. In all studies of acute community-acquired maxillary sinusitis, >50% of isolates are either *Streptococcus pneumoniae* or unencapsulated *Haemophilus influenzae,* with *S. pyogenes, Branhamella catarrhalis,* and gram-negative bacilli accounting for the rest. Specimens for culture should be obtained by direct sinus aspiration, because nasal swabs and/or irrigation correlate with aspiration <65% of the time. When appropriate anaerobic cultures are performed, anaerobes can be isolated in at least 10% of acute cases, with a higher isolation rate of approximately 50% in chronic sinusitis. A mixed anaerobic infection with *Bacteroides* and anaerobic streptococci would suggest infection of odontogenic origin. Viruses have been isolated in approximately 15% of cases, usually in conjunction with or preceding bacterial infection. Invasive aspergillosis and rhinocerebral

phycomycosis occur in immunocompromised patients with granulocytopenia or uncontrolled diabetes mellitus with ketoacidosis, respectively.

Symptoms and signs suggesting acute sinusitis include purulent nasal discharge, facial pain or tenderness, nasal congestion, cough, fever, and a history of recent upper respiratory tract infection. In sphenoid sinusitis, headache is the most common initial symptom. Patients with chronic sinusitis often present with protracted nasal congestion, purulent nasal discharge, and facial pain. Because the typical complaints of acute sinusitis overlap with those of a prolonged but uncomplicated common cold, it may be difficult to make a diagnosis of sinusitis on clinical grounds. Valuable information may be obtained from transillumination of the maxillary and frontal sinuses. The finding of complete opacity of the sinus is strong evidence for the presence of active infection; conversely, the finding of normal light transmission is equally good evidence that no infection is present. Dullness, but not complete opacity, is less helpful. The most sensitive routine test for the diagnosis of acute sinusitis is radiologic examination of the sinuses; opacification, an air-fluid level, or mucosal thickening is strong evidence of active infection. The value of sinus radiology in patients with chronic sinusitis is limited, because radiographic abnormalities are persistent in such patients. Computed tomography (CT) and magnetic resonance imaging (MRI) are particularly useful in the examination of the ethmoid and sphenoid sinuses and for evaluation of suspected intracranial or orbital extension of infection.

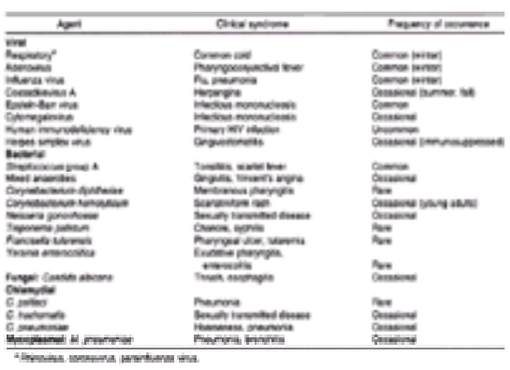
Nasal decongestants should be used in the supportive treatment of acute sinusitis, but antihistamines are to be avoided, as they may thicken purulent sinus fluid and impair drainage. Because sinus aspiration to determine a specific microbial etiology is not routinely indicated, empiric antimicrobial therapy should be primarily effective against *S. pneumoniae* and *H. influenzae.* Ampicillin or amoxicillin is recommended for the initial treatment of uncomplicated acute sinusitis. Sinusitis caused by b-lactamase-producing bacteria, including some strains of *H. influenzae* and *B. catarrhalis,* requires treatment with b-lactamase-resistant antimicrobial agents, such as amoxicillin/clavulanate, second-generation cephalosporins, trimethoprim/sulfamethoxazole, and the newer macrolides, azithromycin and clarithromycin.

Patients with cystic fibrosis or immotile cilia syndrome are predisposed to *Pseudomonas aeruginosa* and *Staphylococcus aureus* infection, whereas immunocompromised patients and patients with nosocomial sinusitis have a higher incidence of aerobic gram-negative bacterial infections, which are often polymicrobial. As mentioned earlier, cultures from patients with chronic sinusitis are often polymicrobial, and at least half harbor anaerobes. Empiric antimicrobial therapy in these unique clinical settings must be adjusted accordingly.

The principal goals of sinus surgery are to oxygenate, establish drainage, and remove diseased mucosa. Candidates for surgical intervention include those patients who have failed empiric therapy, who have rhinocerebral complications, or who have nosocomial infections or immunodeficiency. In addition, most patients with ethmoid or sphenoid disease or chronic sinusitis require corrective surgery. Therapy for fungal sinusitis requires immediate surgical debridement coupled with administration of systemic amphotericin B.

PHARYNGITIS

Acute pharyngitis is an inflammatory condition of the pharynx, and its principal symptom, sore throat, is a frequent accompaniment of many other respiratory illnesses. Many of the known microbial causes of pharyngitis are listed in Table 1, with the most common being group A streptococci, various respiratory viruses, and the Epstein-Barr virus associated with infectious mononucleosis. For the clinician, it is most important to differentiate viral from streptococcal pharyngitis, because of the latter's response to penicillin therapy and its potential sequelae of acute rheumatic fever and acute glomerulonephritis.



Agent	Clinical syndrome	Frequency of occurrence
Viral		
Respiratory[a]	Common cold	Common (winter)
Adenovirus	Pharyngoconjunctival fever	Common (winter)
Influenza virus	Flu, pneumonia	Common (winter)
Coxsackievirus A	Herpangina	Occasional (summer, fall)
Epstein-Barr virus	Infectious mononucleosis	Common
Cytomegalovirus	Infectious mononucleosis	Occasional
Human immunodeficiency virus	Primary HIV infection	Uncommon
Herpes simplex virus	Gingivostomatitis	Occasional (immunosuppressed)
Bacterial		
Streptococcus group A	Tonsillitis, scarlet fever	Common
Mixed anaerobes	Gingivitis, Vincent's angina	Occasional
Corynebacterium diphtheriae	Membranous pharyngitis	Rare
Corynebacterium hemolyticum	Scarlatiniform rash	Occasional (young adults)
Neisseria gonorrhoeae	Sexually transmitted disease	Occasional
Treponema pallidum	Chancre, syphilis	Rare
Francisella tularensis	Pharyngeal ulcer, tularemia	Rare
Yersinia enterocolitica	Exudative pharyngitis, enterocolitis	Rare
Fungal: Candida albicans	Thrush, esophagitis	Occasional
Chlamydial		
C. psittaci	Pneumonia	Rare
C. trachomatis	Sexually transmitted disease	Occasional
C. pneumoniae	Haemophilus pneumonia	Occasional
Mycoplasmal: M. pneumoniae	Pneumonia, bronchitis	Occasional

[a] Rhinovirus, coronavirus, parainfluenza virus.

TABLE 1. *Microbial agents associated with pharyngitis*

Viruses account for the majority of cases of pharyngitis in adults; mild-to-moderate pharyngeal discomfort frequently accompanies common colds. Sore throat is a major complaint in some patients with influenza, and the accompanying myalgia, headache, fever, and cough readily suggest the diagnosis. Adenoviral pharyngitis is usually more severe than the illness typical of the common cold, and conjunctivitis is a distinguishing feature present in one third to one half of cases. The presence of vesicles or shallow ulcers of the palate is characteristic of primary infection with herpes simplex virus, although gingivostomatitis is a more common presentation than acute pharyngitis. During the summer and fall months, pharyngitis caused by coxsackievirus, so-called herpangina, can be distinguished by the presence of small vesicles on the soft palate, uvula, and anterior tonsillar pillars. Exudative tonsillitis, fever, cervical adenopathy, and fatigue are characteristic features of infectious mononucleosis caused by Epstein-Barr virus, and approximately half of cases have associated generalized adenopathy or splenomegaly. Febrile pharyngitis has now been described as a characteristic feature of primary infection with human immunodeficiency virus, and it may mimic the mononucleosis syndrome.

Approximately 15% of all cases of pharyngitis are caused by group A streptococci, the bacterial pathogen most commonly isolated from patients of school age. It is not clear whether non-group A b-hemolytic streptococci, such as groups C and G, cause pharyngitis in nonepidemic settings. The severity of infection varies considerably, but generally there is marked pharyngeal pain, dysphagia, tender cervical adenopathy, and fever. In the majority of cases, an etiologic diagnosis is not possible on clinical grounds alone. For patients with mild illness, a throat culture should be obtained, with treatment dependent on a positive result. For patients with more severe clinical presentations, in whom prompt antimicrobial therapy would be beneficial, a rapid streptococcal antigen test should be performed. A positive result establishes the diagnosis of streptococcal pharyngitis, whereas a negative test result should be substantiated by a simultaneous throat culture.

The incidence of diphtheria has fallen dramatically in the past 50 years, but outbreaks still occur in unvaccinated populations in the United States. Most cases occur in the Southwest among blacks, Mexican-Americans, and American Indians. Pharyngeal diphtheria is characterized by small areas of exudate that coalesce to form a light- to dark-gray membrane that becomes progressively thicker and more difficult to remove. The condition usually involves little toxicity and only modest temperature elevation. Membranous spread to the larynx and trachea can cause life-threatening respiratory obstruction, characterized by inspiratory stridor and cyanosis. Secondary infection with streptococci or other bacteria may occur, and in such cases, toxicity, fever, and local pain may increase markedly. Lymphadenitis and subcutaneous swelling may result in a “bull neck” appearance. *Corynebacterium haemolyticum* has been increasingly identified as a cause of exudative pharyngitis in adolescents and young adults, and such infection may be associated with an erythematous, maculopapular, sometimes pruritic skin rash. Effective antimicrobial agents for either *C. diptheriae* or *C. haemolyticum* include penicillin, erythromycin, and tetracycline.

Pharyngitis accompanying sexually transmitted disease caused by *Neisseria gonorrhoeae, Chlamydia trachomatis,* and *Treponema pallidum* is not uncommon, but these agents would be rare causes of pharyngitis in an unselected general population. Gonococcal pharyngitis is being detected with increasing frequency, probably because of improved microbiologic isolation techniques and changes in patterns of sexual behavior. Asymptomatic gonococcal throat colonization is much more common than pharyngitis, as various series have shown that no more than 30% of those with positive pharyngeal cultures have any clinical manifestations. Ceftriaxone, administered intramuscularly in a single dose of 250 mg, is the drug of choice. Although *C. trachomatis* has been isolated from patients with pharyngitis, asymptomatic throat colonization occurs more often. Rarely, syphilis may present as a primary pharyngeal chancre.

Although exudative pharyngitis with cervical lymphadenopathy may complicate infection with *Yersinia enterocolitica* and *Francisella tularensis,* other manifestations of these systemic diseases usually dominate the clinical picture, and isolated pharyngeal disease would be quite rare. Similarly, when *Chlamydia psittaci, C. pneumoniae,* and *Mycoplasma pneumoniae* are associated with pharyngitis, the pharyngeal disease generally tends to accompany tracheobronchitis or pneumonia rather than occur as an isolated event.

EPIGLOTTITIS

First described in an adult, epiglottitis is a life-threatening disease observed most frequently in 1- to 6-year-old children, most often during the fall and winter. It is important to emphasize, however, that epiglottitis has been increasingly reported in adults during the past three decades. *Supraglottitis* may be the preferred term, as the infection involves the arytenoids, the aryepiglottic folds, and the epiglottis while sparing the pharynx, true vocal cords, and trachea. The infection can be primary or secondary to adjacent infections or trauma, and can result in acute diffuse inflammation, acute ulcerative inflammation, or epiglottitis with abscess formation on the free

edge, laryngeal surface, or lingual surface.

Acute epiglottitis develops in two distinct forms: gradually, within days, usually following an upper respiratory tract illness; or accelerated, within hours. The characteristic early symptoms are sore throat and dysphagia. Odynophagia thereafter becomes the predominant symptom and may be so severe that the patient would rather not eat or drink. The voice tends to be muffled rather than hoarse, and the temperature is usually strikingly elevated. Respiratory distress with tachypnea, dyspnea, and cyanosis occurs late and heralds acute airway obstruction. In this setting, the patient will be observed drooling, sitting up, leaning forward, and breathing quite deliberately. Examination should not be performed with the patient in the recumbent position. Despite the prominence of pain, the pharynx is usually normal in appearance. Attempts to visualize the epiglottis must be carried out with great caution, as even the slightest trauma can provoke acute respiratory obstruction. Auscultation of the chest may reveal inspiratory stridor. Cervical lymphadenopathy is present in about 25% of cases.

Roentgenograms of the chest often show hyperinflation, and there may be areas of atelectasis or pneumonitis. The epiglottic swelling can be seen on a lateral x-ray film of the neck. Laboratory examination shows an elevated white blood cell count with an increase in mature polymorphonuclear leukocytes and band forms.

Complications include septic arthritis, meningitis, empyema, and mediastinitis. Asphyxia and cardiopulmonary arrest are dreaded complications, and several factors contribute to the pathogenesis of respiratory tract obstruction. Edema of the lingual mucosa of the epiglottis causes curling of the epiglottis posteriorly and inferiorly, narrowing the air space, and edema of the aryepiglottic folds worsens the obstruction. During inspiration, these swollen structures are drawn downward into the airway, further reducing the size of the lumen. Inflammation of the supraglottic structures inhibits swallowing, leading to an accumulation of secretions and saliva that further compromises the airway.

Acute epiglottitis is a bacterial infection, as viruses have not been conclusively linked to the disease. In 80% of cases in children, *H. influenzae* type b can be isolated from the epiglottis and/or bloodstream. In adults, however, the etiologic agent is not always obvious, and blood cultures are negative in 70%–85% of cases. *H. influenzae* type b accounts for 20%–25% of cases in adults, with *Streptococcus pneumoniae,* b-hemolytic streptococci, viridans streptococci, nonencapsulated *H. influenzae, Moraxella catarrhalis,* and *Staphylococcus aureus* occasionally implicated. No etiologic agent can be recovered in up to 40% of adult cases.

The diagnostic and therapeutic approach depends on the clinical presentation. Unstable patients with “classic” epiglottitis (stridor, drooling, dyspnea, and fever) should be taken immediately to the operating room for direct laryngoscopy and nasotracheal or endotracheal intubation. Preparation should be made for emergency cricothyrotomy if intubation is not possible. The majority of adults and a large number of children, however, do not have classic presentations, and their management is less straightforward. In adults, indirect laryngoscopy or flexible nasal endoscopy is safe in the initial assessment, as no complications have been reported with this approach. Radiography, however, remains useful in differentiating other upper airway pathology (e.g., foreign body or abscess) from epiglottitis. In children, manipulating the upper airway is more hazardous, and radiography should be the initial procedure performed when suspicion of epiglottitis is low to moderate. The epiglottis of a stable child with normal radiographic findings should be visualized to rule out normal radiograph epiglottitis. Whereas intubation or tracheostomy is virtually mandatory in children with epiglottitis, whether this is appropriate in the management of adults remains a point of ongoing controversy. It is reasonable in adults to defer airway intervention as long as close follow-up by individuals specifically skilled in emergency airway control can be ensured. Stridor and infection with *H. influenzae* type b appear to increase the likelihood of acute airway obstruction.

Antimicrobial therapy should be directed against the common etiologic agents, and ampicillin/sulbactam, chloramphenicol, and second- or third-generation cephalosporins are reasonable choices until bacteriologic data are available. Although often administered in the hope of diminishing supraglottic edema, corticosteroids have not been conclusively shown to alter the course of the disease. Immunization against *H. influenzae* should reduce the incidence of childhood epiglottitis. The risk for development of invasive *H. influenzae* infection is considerably increased in both siblings and parents of patients with epiglottitis, and rifampin prophylaxis should be administered to these household contacts.

LARYNGOTRACHEOBRONCHITIS

Unlike epiglottitis, which is a bacterial disease, laryngotracheitis (croup) is usually the result of a viral infection. Peak incidence is in late fall, with a smaller peak in late spring; a pattern related to the prevalence of parainfluenza viruses in the community has been observed. The subglottic area and trachea are involved, whereas the area above the true vocal cords is spared. In children, croup usually occurs in the first half-decade of life and begins with rhinorrhea. The first sign of spread to the larynx is the gradual development of a harsh, barking cough and hoarse voice. Fever is variable. The major clinical features of croup are related to inflammatory edema and fibrinous exudate in the subglottic area, which narrows the airway and causes inspiratory stridor. Inflammation and edema commonly extend down the trachea and bronchi, producing thick, viscid secretions and ventilation-perfusion mismatch. Involvement of these lower airways, superimposed on the already-narrowed subglottic area, results in increased work of breathing and hypoxemia. As many as 3% of patients admitted with acute laryngotracheobronchitis may require an artificial airway for relief of obstruction, and this chance may reach 6% if sternal and chest wall retractions are present.

The findings on chest roentgenograms vary from normal to evidence of hyperaeration and sometimes areas of atelectasis. The white blood cell count is usually normal, and there may be a predominance of lymphocytes. Parainfluenza virus types 1 through 3 has been implicated most frequently, but influenza virus, respiratory syncytial virus, coronavirus, rhinovirus, adenovirus, enterovirus, and coxsackievirus are all capable of producing the disease. Measles is an infrequent cause.

For the clinician, the initial step in management is to distinguish croup from epiglottitis (Table 2). Treatment of croup in children consists of creating an atmosphere of cool, moist air and administering oxygen in a humidified milieu to avoid drying of the respiratory tract. Antibiotics ordinarily are not necessary. The use of adrenal glucocorticoids and/or racemic epinephrine is controversial, particularly the latter.

Feature	Croup	Epiglottitis
Patient age	Younger (6 mo–3 y)	Older (3–6 y)
Season	Late spring, late fall	All year
Antecedent illness	Rhinorrhea	Uncommon
Clinical appearance	Child is lying down	Child is sitting
	Nontoxic condition	Toxic condition
	Not drooling	Drooling
Cough	Barking in quality	Absent
Voice	Hoarse	Muffled
Fever	Variable	High-grade
Leukocytosis	Absent	Present
Progression	Usually slow	Rapid
Causative agent	Parainfluenza virus type 1	*Haemophilus influenzae* type b

TABLE 2. *Distinguishing features of croup and epiglottitis*

Laryngotracheitis is more complex etiologically in adults and in both children and adults compromised by hematologic malignancy or neutropenia. In noncompromised adults, laryngotracheitis is often manifested by hoarseness and substernal pain, frequently of a burning quality. Influenza virus, parainfluenza virus, and adenovirus are the likely offending agents, but in addition, bacteria (particularly *H. influenzae*) and *M. pneumoniae* can produce the syndrome. If the patient is compromised and neutropenic, opportunistic organisms such as *P. aeruginosa* and species of *Klebsiella, Serratia,* and *Enterobacter* can be responsible. If the individual has defective delayed immune mechanisms and oral thrush is present, the *Candida* infection may move from the oropharynx to the larynx and trachea. In patients who are receiving immunosuppressive agents for severe underlying disease, herpesvirus 1 or 2 may cause laryngotracheitis, and the use of multiple antibiotics in a compromised host may encourage candidal superinfection.

In healthy adults with laryngotracheitis, failure to improve with supportive therapy mandates obtaining a tracheal culture for both viruses and bacteria. In the compromised host, if cough specimens or blood cultures do not show a presumed etiologic agent, it is necessary to obtain proper cultures by laryngoscopy, tracheal intubation, or bronchoscopy. These procedures may be difficult in such persons if thrombocytopenia is present; sometimes broad antimicrobial therapy must be given in the absence of a precise microbial diagnosis, but this is obviously undesirable, and whenever possible, therapy should be guided by proper Gram's stains and cultures.

Bacterial tracheitis in infants and older children has features of both epiglottitis and croup. Clinically, it is characterized by fever, toxicity, brassy cough, and often inspiratory stridor. In most cases, chest roentgenograms show patchy or focal infiltrates. The epiglottic and aryepiglottic folds appear normal on direct examination, but subglottic edema is present. Purulent secretions that are often profuse and thick can be seen, and these can produce tracheal obstruction. The isolated organism is often *S. aureus,* and there is a satisfactory response to appropriate antimicrobial agents. Endotracheal intubation is usually required to maintain a patent airway and handle copious secretions.

ACUTE BRONCHITIS (OR TRACHEOBRONCHITIS)

Acute inflammatory disease of the trachea and bronchi can be caused by a variety of stimuli, including constituents of tobacco and cannabis; ammonia; trace metals, such as vanadium and cadmium; air pollutants, such as sulfur dioxide; nitrogen dioxide; vegetable substances, such as bagasse, cotton, flax, hemp, and paprika; and a farrago of infectious agents, including viruses, mycoplasmas, bacteria, and parasites.

The role of viruses in bronchial disease has been defined best by the Tecumseh studies of respiratory illness. Infectious agents include respiratory syncytial virus, rhinovirus, echovirus, parainfluenza types 1, 2, and 3, herpesvirus, coxsackievirus, influenza, coronavirus, and adenovirus. It is virtually impossible to separate one virus from another clinically. All those capable of producing pharyngeal and nasal disease also can cause bronchitis. Some assumptions can be made on the basis of age and season of the year. In the very young, respiratory syncytial virus, parainfluenza types 1 through 3, and coronavirus are most frequently isolated. Among patients from 1 to 10 years of age, parainfluenza types 1 and 2, enterovirus, respiratory syncytial virus, and rhinovirus predominate. Above that age, influenza A and B, respiratory syncytial virus, and adenovirus are found most frequently. Parainfluenza types 1 and 3 and rhinovirus are found most frequently in the fall; influenza, respiratory syncytial virus, and coronavirus cause infections for the most part in winter and early spring, whereas enterovirus induces infections in summer and early fall. There are differences in the capability of the different viruses to produce lower respiratory tract disease; for example, the disease caused by parainfluenza virus is likely to be more severe than that caused by rhinovirus.

The bacteria most often recovered in acute purulent bronchitis are *H. influenzae, Streptococcus pneumoniae,* and *Moraxella* (*Branhamella*) *catarrhalis.* Acute bronchitis and transient mild pneumonitis are sometimes early manifestations of *Salmonella typhosa* infection. *Bordetella pertussis* is responsible for whooping cough in children; it is less well appreciated that it also may cause acute and subacute bronchitis in adults, as may *Legionella* infections.

There is increasing evidence that yeasts and fungi may produce bronchitis in the absence of parenchymal disease. This is true of *Candida albicans* and *C. tropicalis, Cryptococcus neoformans, Histoplasma capsulatum, Coccidioides immitis,* and *Blastomyces dermatitidis.* In the older literature, candidal bronchitis has been described in otherwise healthy hosts, but more recently it appears to be restricted to compromised hosts. *Geotrichum candidum* is also occasionally a cause of acute and subacute bronchitis.

As serologic analyses are performed more regularly, it has become clear that both *M. pneumoniae* and *C. pneumoniae* not infrequently cause acute bronchitis. Bronchitis also can occur during the migration of *Strongyloides* and *Ascaris* larvae, and a few cases of paroxysmal cough caused by the parasite *Syngamus laryngeus* have been reported either in residents of or visitors to Brazil, the Philippines, the West Indies, Puerto Rico, and British Guiana.

Cough is uniformly found in acute bronchitis, and it may be productive of mucoid or purulent sputum. The nature of the sputum may be helpful diagnostically. Except for adenovirus infections, the sputum in viral infections is almost always characterized by marked predominance of mononuclear cells on Gram's or Wright's stain. In contrast, in bacterial infections the sputum shows a predominance of polymorphonuclear leukocytes. *Mycoplasma* infections, like adenovirus infections, are usually associated with mononuclear cells, but there may be a striking predominance of polymorphonuclear leukocytes.

The cough may be accompanied by variable amounts of hemoptysis and/or substernal pain that is often described as being of a burning quality; it is usually accentuated on inspiration. Usually, the temperature is only minimally to moderately elevated; physical examination often shows harsh breath sounds, rhonchi, and variable amounts of expiratory wheezing.

Wheezy bronchitis is a specific clinical entity occurring for the most part in children who have a tendency to wheeze and a family history of atopy. Viruses appear etiologically related in only a minority of cases; rhinovirus and respiratory syncytial virus are the agents that have been most often isolated. The syndrome of intermittent, recurrent wheezy bronchitis in children also may result from reduced esophageal sphincter tone with reflux.

The organisms responsible for bronchitis in the compromised host may be quite different from the agents affecting the uncompromised individual. In older persons and immunocompromised hosts, herpes simplex virus type 1 may cause tracheobronchitis that may be manifested primarily by bronchospasm. Intravenously administered acyclovir is the treatment of choice. Such patients are also susceptible to gram-negative infections caused by species of *Klebsiella, Serratia, Enterobacter,* and *Pseudomonas.* If these gram-negative superinfections occur during antibiotic treatment of infections elsewhere, the organisms may be markedly resistant to antibiotics. The pharynx of alcoholics is colonized more frequently than the pharynx of nonalcoholics by enteric gram-negative organisms, particularly *Enterobacter* species and *Escherichia coli.* Pharyngeal colonization may be followed by aspiration and acute bronchitis.

The treatment of acute tracheobronchitis depends on the clinical setting in which it arises, the Gram's stain of expectorated sputum, the appearance of the sputum, and the findings on physical examination of the chest. If there are myriad polymorphonuclear leukocytes in the sputum, this suggests a bacterial etiology, and antibiotic administration can be predicated on the predominant organisms seen on smear. The bronchitis is not usually so severe as to mandate immediate therapy, and antimicrobial agents can be withheld until culture results are available. If no likely etiologic agent is recovered in culture and there are many polymorphonuclear cells in the sputum, the possibility of *M. pneumoniae* infection should be strongly considered. This usually responds to treatment with erythromycin or tetracycline.

If on routine culture no pathogenic micro-organisms are found and the sputum shows a polymorphonuclear predominance, acid-fast stains also should be obtained, and in appropriate geographic areas, potassium or sodium hydroxide preparations of sputum should be used to search for fungi and parasites.

The presence on physical examination of focal areas of diminished breath sounds suggests that inspissated mucus has caused atelectasis. This may be relieved by the use of humidifiers, bronchodilators, vigorous coughing, and, if needed, tracheal suction. Occasionally, there is diffuse diminution of air intake and/or inspiratory stridor; these findings indicate obstruction of major bronchi or the trachea, which requires sequentially vigorous coughing, suctioning, and intubation or even tracheostomy if needed.

The choice of antibiotic depends on the pathogen involved. There are striking differences in the penetration of antimicrobial agents into the bronchial secretions. However, it is still unclear whether the degree of antibiotic penetration can be related to clinical outcome. For empiric treatment of community-acquired acute purulent bronchitis, amoxicillin, second-generation cephalosporins, erythromycin, or tetracycline would be a reasonable choice. The newer macrolide antimicrobial drugs, clarithromycin and azithromycin, are very attractive agents for this indication, as their spectrum of activity includes the usual bacterial etiologic agents as well as *Mycoplasma* and *Chlamydia.* The choice of antimicrobial agent in nosocomial or ventilator-associated tracheobronchitis should be tailored to the specific organism isolated.

Acute bronchitis is ordinarily not a life-threatening disease. This permits an orderly search for a microbial etiology, careful assessment of environmental exposures, and evaluation for foreign body or esophageal reflux (or a tracheoesophageal fistula in infants). In most cases, supportive therapy, including adrenergic bronchodilators by aerosol if needed, suffices. If the bronchitis persists, fiberoptic bronchoscopy may be advisable. The disease may last for 6 to 8 weeks. A specific diagnosis can often be made only by the study of paired sera for rises in antibody titers against specific viruses. Exacerbations of chronic bronchitis in patients with chronic obstructive pulmonary disease are discussed in Chapter 43.

BRONCHIOLITIS

In the strictest sense, bronchiolitis, a disease of small airways, should be considered an illness of the lower respiratory tract; it is so frequently preceded by an infection of the upper respiratory tract, however, that it is included in the present chapter. Bronchiolitis is a disease of children. The annual incidence is six to seven cases per 100 children, with most cases occurring during the first 2 years of life.

Bronchiolitis was first described as a complication of measles and mumps, but in more recent years, it has been associated with most of the respiratory viruses, especially the respiratory syncytial virus. Although most cases of bronchiolitis are caused by viruses, *H. influenzae* type b and *M. pneumoniae* have been implicated in some cases. Outbreaks usually occur in winter and spring in temperate climates, epidemics usually being associated with respiratory syncytial virus, adenovirus, influenza, or parainfluenza virus.

Airways from 75 to 300 mm in diameter are involved. Following invasion by microorganisms, cellular infiltration and edema occur together with bronchiolar epithelial proliferation and necrosis. Mucous secretion is increased, after which mucus, inflammatory exudate, and cell debris obstruct the bronchioles. Adenoviruses cause a more severe disruption of the mucosa than do respiratory syncytial viruses and produce a necrotizing bronchiolitis, with a resultant higher mortality.

The initial symptoms of nasal discharge and cough are indistinguishable from those of the common cold. Within 1 to 2 days, fever and cough become prominent and are soon followed by tachypnea and suprasternal, substernal, and subcostal retraction. To prevent coughing and reduce the work of breathing, infants and children take rapid, shallow breaths. Deep breaths are accompanied by fine rales and diffuse expiratory wheezing and usually trigger a paroxysm of coughing. Hypercapnia and

cyanosis commonly occur as the work of breathing increases, and infants under 6 months of age may present with apnea.

The peripheral white blood cell count may be normal or moderately elevated. Blood gas analysis typically shows profound hypoxemia. Chest roentgenograms reveal hyperinflation, increased bronchial markings, and frequently areas of atelectasis or infiltrate. Densities on chest films may be more striking than the degree of clinical or radiographic evidence of small-airway obstruction, and thereby they may be misinterpreted as pneumonia. It should be emphasized, however, that these pulmonary densities represent predominantly areas of atelectasis.

A specific diagnosis often can be made retrospectively by study of paired sera for antiviral or antimycoplasmal antibodies. Nasopharyngeal secretions can be obtained for viral culture, but growth may require up to 14 days. Respiratory syncytial viral infection can be diagnosed rapidly by antigen detection using immunofluorescence techniques or ELISA (enzyme-linked immunosorbent assay).

In children under 2 years of age, the disease may be life-threatening, and therapy consists of oxygen and supportive treatment, with particular attention to proper ventilation. Corticosteroids are not effective. The value of aminophylline or b_2-adrenergic agents has not been established, although bronchodilators are frequently employed in the management of severely ill children. Ribavirin delivered by small-particle aerosol has been shown to hasten the clinical recovery and decrease virus shedding, although these effects are not dramatic. However, because it may cause irritation of the mucous membranes in caretakers, it is often delivered via an endotracheal tube in a closed system. Although antibiotics are not indicated in most children with bronchiolitis, nosocomial bacterial infections can occur in children receiving intensive supportive care. If the bronchiolitis occurs in fall and early winter, erythromycin should be considered for the possibility of *M. pneumoniae* infection. The incidence of nosocomial spread of respiratory syncytial viral infections is high, and preventive precautions should be implemented.

There is a high frequency of residual lung disease after an acute episode of bronchiolitis. In one series, most children studied 10 years after the disease showed some abnormality, including hyperinflation, small-airway disease, or abnormal gas exchange.

Etiology and antimicrobial treatment of acute sinusitis. *Ann Otol Rhinol Laryngol* 1981;90 (Suppl 84):68. *Prospective evaluation by an otolaryngologist of 113 patients with suspected bacterial sinusitis included puncture and aspiration of the maxillary antrum. The most common bacterial isolates were the pneumococcus and* H. influenzae, *and the response rate to appropriate antimicrobial therapy was 90%.*

Hall CB, et al. Aerosolized ribavirin treatment of infants with respiratory syncytial viral infection. *N Engl J Med* 1983;308:1443. *Ribavirin or placebo was administered to 33 infants in a double-blinded manner by continuous aerosol for 3 to 6 days. By the end of treatment, infants receiving ribavirin showed a significantly greater improvement in their overall severity-of-illness score, reduction in lower respiratory tract signs, and increase in arterial oxygen saturation.*

Hutt DM, Judson FN. Epidemiology and treatment of oropharyngeal gonorrhea. *Ann Intern Med* 1986;104:655. *Sixty patients with untreated pharyngeal gonorrhea were studied. The most effective treatment regimens were aqueous procaine penicillin G and oral tetracycline.*

Jones R, Sontos JI, Overall JC Jr. Bacterial tracheitis. *JAMA* 1979;242:721. *The authors reviewed eight cases of infants and children who were managed for an acute, infectious, upper airways obstructive disease with features common to both croup and epiglottitis, coined "bacterial tracheitis." Copious respiratory tract secretions were common, and six of the cases required endotracheal intubation.*

Kessler HA, et al. Diagnosis of human immunodeficiency virus infection in seronegative homosexuals presenting with an acute viral syndrome. *JAMA* 1987;258:1196. *Acute HIV infection was diagnosed in four individuals with negative HIV antibody tests presenting with fever, rash, myalgias-arthralgias, and pharyngitis by obtaining an HIV antigen test (all of which were positive).*

Komaroff AL, et al. Serologic evidence of chlamydial and mycoplasmal pharyngitis in adults. *Science* 1983;222:927. *In a study of 763 adult patients with pharyngitis, the authors found serologic evidence of infection (a fourfold increase in antibodies) with* Chlamydia trachomatis *in 20.5% and with* Mycoplasma pneumoniae *in 10.6% of the patients.*

Mayosmith MF, et al. Acute epiglottitis in adults. An eight-year experience in the state of Rhode Island. *N Engl J Med* 1986;314:1133. *Fifty-six cases of acute epiglottitis in adults were retrospectively reviewed. Indirect laryngoscopy was performed without complications and proved to be more reliable in making a diagnosis than were x-ray films of the neck.*

McGill TJ, Simpson G, Healy GB. Fulminant aspergillosis of the nose and paranasal sinuses: a new clinical entity. *Laryngoscope* 1980;90:748. *Fulminant aspergillosis of the nose and paranasal sinuses represents a new clinical entity occurring in immunocompromised individuals. It is marked by a rapidly progressive gangrenous mucoperiostitis. Control of the disease process requires radical sinus ablation, debridement of nasal structures, and antifungal chemotherapy.*

Miller RA, Brancato F, Holmes KK. *Corynebacterium haemolyticum* as a cause of pharyngitis and scarlatiniform rash in young adults. *Ann Intern Med* 1986;105:867. *During an 8-year period, 33 cases of* C. haemolyticum *pharyngitis were reviewed. In 20, a diffuse, erythematous, macular skin rash, often with a fine papular component, was present on the extremities and trunk. Rapid clinical improvement was seen with either penicillin or erythromycin therapy.*

Mitchell I, Inglis H, Simpson H. Viral infection in wheezy bronchitis and asthma in children. *Arch Dis Child* 1976;51:707. *Viruses were isolated in almost 15% of 360 children with wheezy bronchitis or asthma admitted to the hospital during a 3-year period. Isolation of viruses, the most common being respiratory syncytial virus and rhinovirus, was significantly more likely during February or August and for readmissions.*

Monto AS, Cavallaro JJ. The Tecumseh study of respiratory illness. II. Patterns of occurrence of infection with respiratory pathogens. *Am J Epidemiol* 1971;94:280. *During the first 3 1/2 years of the study of respiratory infections in Tecumseh, Michigan, certain repetitive, temporal patterns of isolation of infectious agents were found. For instance, rhinoviruses most commonly infected the upper respiratory tract, and such infection was associated with a low frequency of restricted activity; in contrast, parainfluenza and influenza A viruses most commonly infected the lower respiratory tract, and infection was associated with a high frequency of restricted activity.*

Seidenfeld SM, Sutker WL, Luby JP. *Fusobacterium necrophorum* septicemia following oropharyngeal infection. *JAMA* 1982;248:1348. *Anaerobic septicemia frequently is associated with an oropharyngeal source of infection, and fusobacteria are the organisms isolated most often. Proper treatment requires recognition of the oropharyngeal source of the septicemia and differentiation from endocarditis.*

Sherry MK, et al. Herpetic tracheobronchitis. *Ann Intern Med* 1988;109:229. *In nine patients with bronchospasm unresponsive to standard therapy, bronchoscopic, cytologic, and virologic studies confirmed the presence of necrotizing and exudative tracheobronchitis caused by herpes simplex virus. All patients were successfully treated with intravenous acyclovir.*

Su WY, et al. Bacteriological study in chronic maxillary sinusitis. *Laryngoscope* 1983;93:931. *The bacterial findings from 73 maxillary sinuses in 48 patients with chronic maxillary sinusitis, obtained by intraoperative culture of the antral mucosa, were reported. Anaerobic bacteria were never isolated from sinuses that were not inflamed, but they were the most important pathogen in chronic maxillary sinusitis.*

Trollfors B. Invasive *Haemophilus influenzae* infections in household contacts of patients with *Haemophilus influenzae* meningitis and epiglottitis. *Acta Paediatr Scand* 1991;80:795. *This study showed*

an increased risk for invasive H. influenzae *infections in both siblings and parents of children with invasive disease. Although rifampin prophylaxis is effective, <1% of all cases of invasive* H. influenzae *infection would be prevented.*

Wolf M, et al. Conservative management of adult epiglottitis. *Laryngoscope* 1990;100:183. *During a 10-year period, 30 adult cases of acute epiglottitis were reviewed. Two clinical forms of onset were noted (gradual and accelerated), and none of the patients required tracheotomy or intubation.*

CHAPTER

24 Community-Acquired Pneumonia

Richard J. Blinkhorn, Jr.

R. J. Blinkhorn, Jr.: MetroHealth Medical Center, Cleveland, Ohio 44109.

INTRODUCTION

Community-acquired pneumonia affects almost 4 million adults annually in the United States, and as much as one fifth of these require hospitalization. Pneumonia is the sixth leading cause of death, and the No. 1 cause of death from infectious diseases. In addition, community-acquired pneumonia accounts for 1% of all patient visits to primary care providers who treat adults. In the outpatient setting, the mortality rate of pneumonia is <5%, but among patients with pneumonia who require hospitalization, mortality rates approach 25%, especially if the individual requires admission to the intensive care unit.

ETIOLOGY

No specific causative organism can be established in 30%–65% of patients with community-acquired pneumonia, despite vigorous bacteriologic and serologic testing for specific pathogens. The incidence of pneumonia attributable to individual pathogens varies considerably and depends on factors such as age, presence or absence of underlying disease, integrity of the immune response, and residence in long-term care facilities (Table 1). It is important to remember that 70%–80% of patients in whom community-acquired pneumonia develops are older than 60 years or have a coexisting medical condition. Those patients are more likely to be colonized with enteric gram-negative bacilli, staphylococci, and *Moraxella catarrhalis* than are young, otherwise healthy persons (Table 2). These epidemiologic differences mandate using individualized diagnostic and treatment strategies based on age and the presence or absence of coexisting medical conditions. At the same time, the therapeutic approach may of necessity be largely empiric, as determination of the specific etiologic pathogen is frequently impossible.

Pathogen	Percentage of cases (range)
Streptococcus pneumoniae	39 (9–76)
Haemophilus influenzae	10 (0–46)
Legionella species	5 (0–15)
Chlamydia species	5 (0–16)
Aerobic gram-negative bacilli	4 (0–20)
Viruses, including influenza virus	4 (0–18)
Staphylococcus aureus	3 (0–10)
Unknown	30 (0–49)

[a] Literature review of selected community-acquired pneumonia studies.

TABLE 1. *Prevalence of micro-organisms that cause community-acquired pneumonia*[a]

Condition	Commonly encountered pathogens
Alcoholism	Oral anaerobes, gram-negative bacilli, *Streptococcus pneumoniae*
COPD	*S. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, gram-negative bacilli
Influenza season	*S. pneumoniae*, *Staphylococcus aureus*, influenza virus
Nursing home residency	*S. pneumoniae*, gram-negative bacilli, oral anaerobes, *H. influenzae*, *S. aureus*
HIV infection	*Pneumocystis carinii*, *S. pneumoniae*, *H. influenzae*, *Mycobacterium tuberculosis*

COPD, chronic obstructive pulmonary disease; HIV, human immunodeficiency virus.

TABLE 2. *Epidemiologic conditions related to specific pathogens in patients with community-acquired pneumonia*

DIAGNOSTIC STUDIES

The diagnosis of pneumonia is based on clinical findings that include respiratory symptoms (cough, sputum production, dyspnea, pleurisy), fever, abnormal sounds on chest auscultation, leukocytosis, and an infiltrate on chest film. These findings, however, may not be present in all persons with depressed immunity, in the elderly, or in individuals with so-called atypical pneumonia. Findings suggestive of pneumonia may also be seen in patients with noninfectious illnesses (e.g., pulmonary embolism, certain autoimmune diseases, and malignancy). The diagnostic confusion created by varying clinical signs is further complicated by the inherent limitations of diagnostic testing. No single test reliably establishes the presence of pneumonia. Nevertheless, the benefit of establishing the infectious cause of pneumonia early in the course of the illness is undisputed, and certain standard tests should be considered (Table 3).

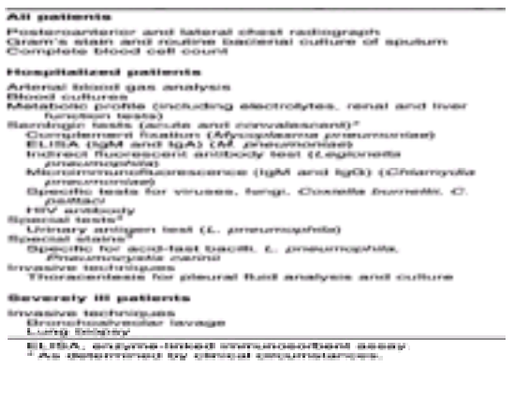

TABLE 3. *Diagnostic procedures for the evaluation of suspected community-acquired pneumonia*

A standard posteroanterior and lateral chest radiograph should be performed in all patients whose symptoms and physical examination suggest pneumonia. This test can be useful in assessing for the presence of pleural fluid, for differentiating pneumonia from conditions that may mimic it, and for demonstrating coexisting pulmonary diseases, such as sarcoidosis or bronchiectasis. Certain radiographic findings may lead to specific diagnoses—for example, cavitation suggestive of lung abscess, apical cavitation in tuberculosis, pneumatoceles in *Staphylococcus aureus* infection, and interstitial infiltrates in mycoplasmal, viral, or *Pneumocystis carinii* infections. The finding of multilobar involvement on chest films would also be helpful in identifying individuals at risk for more severe illness.

The acquisition of expectorated sputum for Gram's stain and culture is widely recommended for the initial evaluation of community-acquired pneumonia. To be of benefit, the specimen must be obtained carefully (admixed with as few oral secretions as possible), transported and processed quickly, confirmed as cytologically adequate (>25 white blood cells and <5 epithelial cells at x100 magnification), and obtained before institution of antimicrobial therapy. The sensitivity and specificity of routine bacterial cultures of sputum are poor, and these should generally be reserved for hospitalized patients. Inability to demonstrate a probable pathogen in an adequate respiratory tract sample may prompt consideration of legionellosis or infection with acid-fast bacilli, *Mycoplasma, Chlamydia, Pneumocystis,* or fungi in appropriate circumstances. Moreover, the identification on sputum Gram's stain of such virulent organisms as *S. aureus* or *Pseudomonas aeruginosa* should prompt consideration of inpatient care.

A number of invasive diagnostic techniques to obtain lower airways specimens, uncontaminated by oropharyngeal flora, have been described but are not indicated in most patients with community-acquired pneumonia. It may be useful, however, to have an early accurate diagnosis in patients who are severely ill and require admission to the intensive care unit, who are immunocompromised, or who are suspected of having HIV infection. In such patients, bronchoscopy with a protected specimen brush or bronchoalveolar lavage have reasonable sensitivity and specificity with low attendant risk and should be considered.

Routine laboratory tests are of little value in determining the etiology of pneumonia. These tests, however, may have prognostic significance, may influence the decision to hospitalize, and may affect the choice and dosing of antimicrobial therapy. Serologic testing is not useful in the initial management of pneumonia, but acute and convalescent serologic testing may help in the retrospective confirmation of a suspected diagnosis or in epidemiologic studies. Special serologic tests and stains are addressed later in the chapter as they pertain to specific etiologic agents.

HOSPITALIZATION AND SEVERE ILLNESS

The decision to hospitalize individuals with communityacquired pneumonia has historically been left to the experience and discretion of the admitting physician, as there are no firm guidelines. A series of well-recognized risk factors are indicative of an increased risk for death or a complicated course, and hospitalization should be strongly considered when multiple risk factors coexist (Table 4).

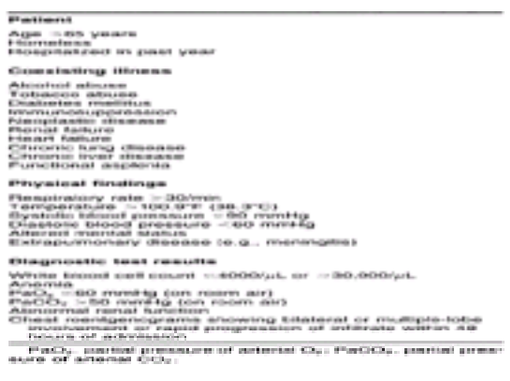

TABLE 4. *Factors that may increase morbidity and mortality in community-acquired pneumonia*

Multicenter prospective studies have validated these risk factors and identified five factors predictive of short-term mortality. These include age >65 years, altered mental status, abnormal vital signs, identification of a high-risk pathogen, and presence of neoplastic disease.

Although there is no universally accepted definition of severe community-acquired pneumonia, the presence of at least one of several recognized clinical findings justifies defining the illness as severe (Table 5). Severity of illness correlates well with likely etiologic pathogens. If severe pneumonia is identified, initial management in the intensive care unit is advised despite the lack of evidence that such support affects outcome.

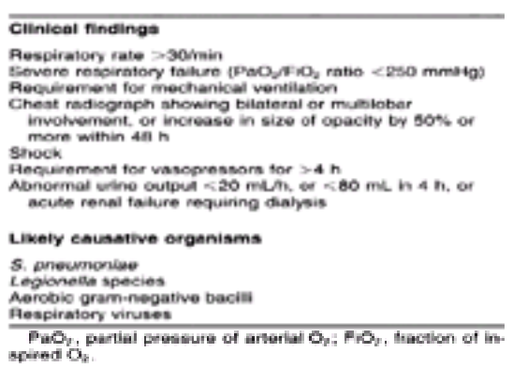

TABLE 5. *Severe community-acquired pneumonia: clinical findings and common pathogens*

In the remainder of this chapter, the specific pathogens most commonly encountered in patients with community-acquired pneumonia are reviewed, with an emphasis on the epidemiology, clinical presentation, diagnosis, and therapy for each. Certain pathogens may cause both community- and hospital-acquired infection, and those features unique to the hospital setting are reviewed in the following chapter.

PNEUMONIA CAUSED BY GRAM-POSITIVE BACTERIA

Pneumococcal Pneumonia

The incidence of pneumonia caused by *Streptococcus pneumoniae* has decreased sharply in many areas of the world. Surveillance studies now suggest an incidence of 20 cases of pneumonia per 100,000 young adults, as contrasted with an incidence of 700 cases per 100,000 young adults in the preantibiotic era. This reduction can be attributed in part to better hygiene and in part to the administration of antimicrobial agents to patients with upper respiratory tract infections before the onset of lower respiratory tract involvement. There is no evidence to suggest that the micro-organism is less prevalent in the community, that it has lost its virulence, or that natural host defenses have improved. Nevertheless, *S. pneumoniae* is still the most common cause of community-acquired pneumonia in patients of all ages, accounting for 15%–76% of cases in representative series.

Micro-organism

The pneumococcus, cultivated and isolated by Pasteur in 1881, is a gram-positive round, ovoid, or lanceolate coccus found in pairs or short chains. The distal ends of the paired cocci are usually pointed, and the organism has a capsule that is readily demonstrable on routine staining. More than 80 pneumococcal serotypes have been identified based on antigenic differences in their capsular polysaccharides. Serotypes are numbered in the order in which they have been identified, and virulent strains causing human disease were the earliest to be studied, identified, and assigned numbers. As a result, the lower-number serotypes are more likely to be implicated in human infection, and type 3 is considered the most virulent of the pneumococci. Unfortunately, the characteristic susceptibility of pneumococci to many antibiotic agents and the success of treatment regardless of the type involved have resulted in diminished interest in the antigenic structure of pneumococci, so that in most hospitals pneumococcal typing is no longer performed routinely. Serotyping may be useful, however, in areas experiencing an increasing incidence of penicillin-resistant pneumococcal disease. Certain serotypes (especially 6, 9, 19, and 23) have tended to be highly penicillin-resistant, and early recognition of their presence would facilitate empiric antimicrobial selection.

Susceptibility to Infection

The pneumococcus is the prototypic extracellular pathogen, capable of causing disease only as long as it remains outside phagocytes. Its rapid demise once ingested is largely the consequence of its inability to degrade its own hydrogen peroxide. The propensity for pathogenicity relates to the polysaccharide capsule that impairs phagocytosis. Effective clearance of the organism in the normal host, therefore, depends primarily on opsonization with immunoglobulin and complement. Pneumococcal infection is most prevalent in the extremes of life, with peak incidence rates occurring in newborns and infants up to 2 years old and adults in their 70s. Rates of disease in these groups appear related to lower reservoirs of antibody or to relatively weak immunoglobulin synthesis. A healthy adult is susceptible to pneumococcal pneumonia only if antibody to the capsular polysaccharide of the infecting serotype is lacking. In contrast, pneumococcal disease is greatly increased in people who have alterations in mucociliary clearance, defects of phagocytic function, defects in humoral immunity, alcohol or narcotic intoxication, malignancy, acquired immunodeficiency syndrome, and many other specific diseases (Table 6). A peculiar relationship between exposure to extreme cold and pneumococcal pneumonia has been observed for centuries, and the putative mechanism includes alterations in mucosal metabolism with impaired ciliary activity and depressed antibody secretion.

Defects of humoral systems
Immunoglobulin deficiency
Hypogammaglobulinemia
IgA deficiency
IgG subclass deficiency
Inadequate immunoglobulin production
Multiple myeloma
Chronic lymphocytic leukemia
Lymphoma
Human immunodeficiency virus infection
Sickle cell hemoglobinopathy
Bone marrow/renal transplantation
Chronic hemodialysis
Trauma; ??
C2, C3, or factor I deficiency
Defects of phagocyte function
Neutropenia
Hyposplenism, splenectomy
Alcoholism
Defects of mucociliary clearance
Viral respiratory infection
Chronic pulmonary disease
Asthma
Cigarette smoking
Chronic disease
Congestive heart failure
Renal failure, nephrotic syndrome
Cirrhosis
Autoimmune disease
Immunosuppression

TABLE 6. *Defects in host defense mechanisms that predispose to pneumococcal infection*

Pathogenesis

S. pneumoniae can be recovered from the nasopharynx of almost 40% of healthy adults, and an individual may carry up to four different serotypes. In both adults and children, most infections occur after the recent acquisition of a new serotype rather than after prolonged carriage. Binding to the nasopharynx is affected by interconversion between two phenotypes distinguished by colonial morphology—opaque and transparent. Transparent, but not opaque, variants adhere to nasopharyngeal epithelial cells.

Pneumococci gain access to the lung via aspiration of infected mucus and can be seen lining the alveolar walls early in disease, presumably via adherence to type II pneumocytes. Progression to pneumonia, however, requires additional events, as suggested by the association of pneumonia with pre-existing viral respiratory infection and the observation that the adherence of pneumococci in vitro is enhanced by viruses and cytokines. Pneumococci, especially transparent variants, bind avidly to interleukin-1-activated pneumocytes. This may involve an interaction between phosphorylcholine of the cell wall and platelet-activating factor (PAF) receptors, the latter upregulated by cytokine stimulation. Although pneumococci are generally not considered invasive for naive endothelial cells, cytokine activation leads to prompt entry. Again, PAF receptors appear to be the target and mechanism of entry.

The lung lesion of pneumococcal lobar pneumonia evolves in four overlapping stages: engorgement, red hepatization, gray hepatization, and resolution. Initially, alveolar capillaries become intensely congested, bacteria and edematous fluid are present in alveolar spaces, and the organism multiples without inhibition (engorgement). The edema-provoking factor consists of a pneumococcal cell wall complex of peptidoglycan and teichoic acid that binds to epithelia and endothelia. It elicits the production of interleukin-1 and the accumulation of a serous exudate.

Activation of procoagulant activity on the surface of endothelial cells leads to further capillary engorgement and diapedesis of erythrocytes into the alveoli (red hepatization). Endothelial activation also leads to accentuated PAF receptor expression, which is the major effector in the lung signaling leukocyte migration. Leukocytes move into the alveolar space by two mechanisms. Half are recruited by the CD18 family of leukocyte-adhesion molecules, and the remainder by a less well-understood CD18-independent pathway that is unique to pneumococcus-induced pulmonary inflammation. As exudate accumulates in the alveoli, capillaries are compressed and leukocyte content increases, giving “gray hepatization.” This leukocyte-rich exudate constitutes the first obstacle to further microbial multiplication. Before the appearance of antibody, extensive phagocytosis is achieved by a phenomenon (surface phagocytosis) in which polymorphonuclear leukocytes compress bacteria against the surface of alveoli or other leukocytes to facilitate ingestion. This defense is markedly enhanced by the appearance of specific antibody, present in detectable amounts between the fifth and tenth days, although more recent findings suggest that smaller amounts of opsonizing antibody may be present as early as 1 or 2 days after initiation of infection. If the patient's defense mechanisms have succeeded in destroying the pneumococci, the stage of resolution is reached, and macrophages can be seen within the alveolar spaces along with cellular debris. There is typically no necrosis of alveolar walls or interstitium, and the architecture of the lung returns to normal.

Traditionally, the capsule of the pneumococcus has been considered its most important virulence factor, in that it protects the organism from phagocytosis. The capsule

itself, however, is not toxic to the host, and at present pneumolysin, an intracellular protein, is the best candidate for a pneumococcus-derived toxin. Pneumolysin is not secreted but is released during bacterial lysis. It has not been identified free in the serum, but serum antibody to pneumolysin has been found after bacteremic pneumococcal pneumonia. The exact mechanism by which this toxin contributes to the virulence of the organism is unclear, but pneumolysin-negative pneumococcal mutants are significantly less virulent in mice. In addition, pneumolysin disturbs the structure and function of ciliated respiratory epithelium *in vitro* and is capable of inducing the salient histologic features of pneumococcal pneumonia.

Clinical Manifestations

Approximately half the patients give a history of upper respiratory tract infection followed in 2 to 14 days by evidence of lower respiratory tract involvement. The three most common early manifestations of pneumococcal pneumonia are fever, cough, and chest pain. Temperature is variable, ranging from 100°F to 106°F. Maximal fever is observed in the afternoon or evening, or it may be sustained with little diurnal change. The cough, which occurs in almost every case, is associated with the production of sputum in approximately 75% of patients. The sputum may have the classic rusty appearance, but just as often it is green (purulent). Frequently, streaks of blood are found in the sputum, and occasionally the cough is productive of frank blood. The chest pain is usually pleuritic, increasing in intensity during inspiration or cough. The pain is least severe when the patient is at rest, but the most comfortable position varies, with some patients preferring to lie with the painful side downward and others noting relief when the involved area is not in contact with any firm surface. Patients commonly feel chilly, and about half experience teeth chattering and shaking chills. Although a single shaking chill is characteristic, it is not uncommon for the patient to experience two to four such chills during a 48-hr period. Myalgia is commonly observed and may extend to tenderness of the thighs and calves. Severe myalgia, particularly that accompanied by vomiting, should strongly suggest the possibility of bacteremia. In approximately 10% of patients, herpes simplex lesions develop during the course of pneumococcal pneumonia.

Classically, physical examination reveals an acutely ill, perspiring patient who describes chest pain and splints on one side of the thorax. Tachycardia is usual in young patients, but in older patients heart rates are frequently between 70 and 100 beats/min. Examination of the chest reveals one of three findings in most patients. In some individuals, especially early in the course of the disease, bubbling rales and dullness to percussion may be the only abnormalities detected, perhaps correlating with the period of outpouring of fluid into the alveoli. A second group of patients shows the classic signs of consolidation: flatness to percussion, egophony, bronchophony, whispered pectoriloquy, and bronchial breathing. In patients with frank consolidation, frequently no rales or only a few crackling inspiratory rales are detected, and they increase as the pneumonia abates and the consolidation diminishes. In this group, a leathery pleural friction rub, heard throughout inspiration or only at the end of inspiration and expiration, may be associated with striking tenderness in the involved area of the chest. Finally, some patients may have one or more areas in which there is moderate dullness to percussion, inspiratory rales, and suppression of the breath sounds, which, although decreased in intensity, still appear harsh. As these patients presumably have mucous plugs in the smaller bronchial radicles and usually produce only scant amounts of sputum, pneumococci may not be detected in sputum cultures but found only in blood cultures. If pneumonia affects the lower lobes, abdominal pain may be a major manifestation and may be of such severity that the patient is admitted to the surgical service with a diagnosis of acute abdominal disease. In such cases, there may be considerable rigidity of the upper abdominal wall.

Laboratory Findings

The majority of patients with pneumococcal pneumonia have leukocytosis, although in 25% of cases the white blood cell count is normal. Leukopenia may be seen in overwhelming infections, and this poor prognostic factor generally occurs in alcoholic, malnourished, or elderly patients. The serum bilirubin may be increased to levels not exceeding 3 to 4 mg/dL. Levels of lactate dehydrogenase may be elevated. Hyponatremia resulting from inappropriate secretion of antidiuretic hormone has been reported. Measurement of arterial blood gases often reveals hypoxemia and occasionally hypocapnia.

Roentgenograms of the chest usually reveal dense homogeneous shadows involving all or part of one or more lobes (Fig. 1) and corroborate the findings of physical examination. If pneumococcal pneumonia is not apparent clinically, it is infrequently detected roentgenographically in an individual without chronic lung disease; however, in those with chronic lung disease, roentgenograms may show infiltrates that are undetectable on physical examination. In some cases, infiltrates are more patchy and less homogeneous. Those over the age of 65 may show more subtle manifestations early in the course of the disease, including less pleuritic pain and a lower incidence of shaking chills. Nevertheless, they are more likely to have multilobar involvement, and the chest x-ray film may show extensive coalescing infiltrates.

FIG. 1. Right middle lobe pneumococcal pneumonia.

Diagnostic Microbiology

A careful study of the sputum is the most important laboratory examination. In pneumococcal pneumonia, unlike most types of viral pneumonia, many polymorphonuclear leukocytes can be readily seen in sputum smears stained with Wright's or Gram's stain. Attempts to make a diagnosis based on an inadequate sputum specimen are largely responsible for studies claiming that sputum Gram's stain and culture are not reliable. To be reliable, sputum specimens must contain areas with at least 15 to 20 white blood cells and no epithelial cells in a standard microscopic field under ×1000 magnification. The characteristic gram-positive diplococci are generally seen in abundance (Plate 1). Results of a Gram's stain of the sputum can be used to guide therapy with considerable confidence, but Gram's stains alone without confirmatory cultures are not adequate. Results of blood cultures are positive in one fourth to one third of patients hospitalized with pneumococcal pneumonia.

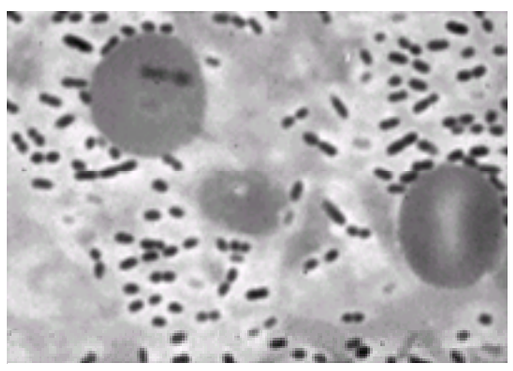

PLATE 1. *Streptococcus pneumoniae* in Gram's stain of sputum. x900. *See color plate 12.*

Therapy

In the pre-antimicrobial era, the “lysis-by-crisis” phenomenon of lobar pneumonia was one of the most dramatic events of clinical medicine. The crisis usually occurred 6 to 10 days after infection. The patient experienced profuse sweating, the temperature could drop 5°F to 6°F, dyspnea and tachypnea disappeared, and dramatic improvement ensued. Currently, this sequence is virtually never seen, because patients are treated with antibiotics as soon as the diagnosis is seriously entertained.

Penicillin remains the drug of choice, with the overwhelming majority of strains of pneumococci being sensitive to small concentrations of the antibiotic. Uncomplicated pneumococcal pneumonia responds to intramuscular penicillin procaine (600,000 units twice daily) or to intravenous aqueous penicillin G (500,000 units every 4 hours), each administered for 7 to 10 days. There is no evidence to suggest that the administration of larger amounts of penicillin effects clinical improvement more rapidly or that larger doses are needed if associated bacteremia or multilobar involvement is present. The administration of higher doses of penicillin or broad-spectrum antimicrobial agents has been shown to increase the likelihood of colonization and superinfection with other pathogens, usually gram-negative bacilli. In patients with meningitis, endocarditis, or arthritis, 20 million units of intravenous aqueous penicillin should be given daily, whereas 5 to 10 million units daily should be adequate for patients with empyema. Oral regimens, including penicillin phenoxyethyl or phenoxymethyl (250 mg every 6 hrs) and amoxicillin (500 mg every 8 hours), are also adequate. Erythromycin, chloramphenicol, vancomycin, imipenem, and many cephalosporins have been shown to be effective in pneumococcal pneumonia, although the response to treatment may be somewhat slower than with penicillin. Tetracycline should be avoided, as 5%–15% of strains are resistant. Pneumococcal meningitis is a well-recognized complication, especially in bacteremic pneumococcal pneumonia, and antimicrobial agents that have good penetration into cerebrospinal fluid should generally be chosen. The optimal duration of therapy is unknown, but therapy for 7 to 10 days, not to exceed 5 days after defervescence, seems appropriate.

Drug-Resistant Streptococcus Pneumoniae

During the past two decades, pneumococci moderately and highly resistant to penicillin alone and pneumococci multiply resistant to various antibiotics have been found throughout the world. By definition, strains with minimal inhibitory concentrations (MICs) of <0.06 mg/mL are regarded as susceptible, those with MICs of 0.1 to 1.0 mg/mL as intermediately resistant, and those with MICs of >1.0 mg/mL as highly resistant. About 2%–25% of strains isolated in the United States show intermediate resistance. The mechanism of resistance involves alterations in penicillin-binding proteins, as the organism does not produce b-lactamase. Mutation to high-grade resistance is thought to involve the acquisition of a packet of genetic material, because resistance to other antibiotics, such as chloramphenicol, erythromycin, and clindamycin, may be present. Of importance, these multiply resistant strains have remained susceptible to vancomycin. Notably, the serotypes accounting for the majority of resistant isolates are included in the currently available pneumococcal vaccine. Serotype 23F has been significantly associated with penicillin-cefotaxime resistance. Most clinical laboratories routinely test pneumococcal isolates for resistance to penicillin using a 1-mg oxacillin disk. As this does not discriminate between intermediately and highly resistant strains, penicillin MICs are required for these oxacillin-resistant pneumococci to determine the appropriate therapeutic agents. Intermediately resistant strains are readily treatable with increased doses of penicillin (150,000 to 250,000 units per kilogram per day), cefotaxime or ceftriaxone, or vancomycin. Ceftazidime is considerably less active and should be avoided. For highly resistant pneumococci, vancomycin should be considered the drug of choice. It is uncertain whether the prognosis of pneumococcal pneumonia is affected by the finding of penicillin resistance.

Prognosis

The mortality associated with pneumococcal pneumonia in a single lobe remains at approximately 1% despite appropriate antibiotic therapy. The majority of deaths are in patients who have severe underlying, concomitant illnesses or who are in the older age groups. The presence of bacteremia, leukopenia, or involvement of two or three lobes is said to increase the mortality to approximately 10%. In older patients with bacteremia, mortality ranges from 30%–60%. Pneumococcal pneumonia in four or five lobes remains a fearful disease, with a mortality rate that approaches 50%. It should be noted that 40% of all deaths caused by pneumococcal pneumonia occur within 24 hours of admission, and antimicrobial therapy does not alter this outcome.

Complications

Empyema

Empyema is now a relatively infrequent clinical complication of pneumococcal pneumonia, but effusions can be found by diligent search in about a third of cases. In patients with empyema, pleural pain continues; fever, which may have diminished initially after penicillin treatment, persists or recurs; and the patient remains toxic. Roentgenograms, especially lateral decubitus films, aid in confirming the diagnosis (Fig. 2).

FIG. 2. Right lower lobe pneumococcal pneumonia and empyema in a 34-year-old man.

In all patients in whom empyema is strongly indicated, a diagnostic thoracocentesis should be performed. Fluid obtained shortly after the onset of empyema is cloudy and may contain 1000 to 600,000 leukocytes per milliliter, virtually all of which are polymorphonuclear cells. If the fluid is infected, its pH is usually <7.30. If empyema is untreated, the fluid subsequently assumes the appearance of frank pus. Initially, treatment may be conservative, consisting of repeated thoracocentesis. If the fluid does not become progressively thinner or if adequate drainage is not achieved, closed or preferably open thoracotomy should be performed.

Collection of sterile fluid. Although the cell count of this fluid may be high, ranging up to 300,000/mm^3, the percentage of mononuclear cells is usually considerably greater than that observed in empyema and the pH is >7.30. Even small effusions of this nature are causes for prolonged fever, and such fluids should be drained by needle aspiration.

Pericarditis

Precordial chest pain, persistent fever, or hypotension suggests the possibility of spread to the pericardium, an infrequent but dangerous complication of pneumococcal pneumonia. The three most reliable early signs in acute purulent pericarditis are the presence of a pericardial friction rub, the development of retrosternal dullness to percussion, and the appearance of Ewart's sign posteriorly at the angle of the scapula on the left or in the left basilar paravertebral area. Cardiac tamponade may develop in patients with pericarditis. Treatment of pericardial effusion is in general similar to that for empyema: aspiration and, if necessary, open pericardial drainage. If only a small effusion is present, no drainage may be needed.

Lung Abscess

Lung abscess following lobar pneumonia is extremely rare and occurs most frequently after infection with type 3 pneumococcus, which has a large capsule that inhibits phagocytosis. Prolonged antibiotic therapy (2 to 4 weeks) is usually required, and lung destruction may be so extensive that subsequent surgical intervention is necessary. There is no evidence that an abscess heals more quickly if the penicillin dose is increased or if multiple antibiotics are administered, but the risk for superinfection is great (Fig. 3). Occasionally, the abscess occurs because of a concomitant aerobic or anaerobic infection; in such cases, a change in the therapeutic regimen is mandatory.

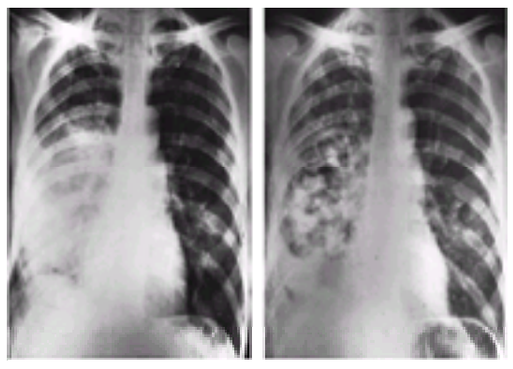

FIG. 3. Right lower lobe pneumococcal pneumonia (*left*) in a 46-year-old alcoholic, with abscess formation (*right*).

Atelectasis

Persistent fever and increasing dyspnea suggest atelectasis, which can usually be confirmed roentgenographically (Fig. 4). Vigorous tracheal suction and forced coughing may clear the mucous plugs, but if these procedures are not successful, bronchoscopy should be undertaken.

FIG. 4. Left upper and lower lobe pneumococcal pneumonia and atelectasis.

Delayed Resolution

Continued low-grade fever, rales, moderate dullness to percussion, and roentgenographic infiltrate may persist as long as 4 to 6 weeks in the absence of evidence of underlying bronchiectasis, obstructing neoplasm, or pulmonary superinfection (Fig. 5). This delayed resolution occurs primarily among older patients, in those suffering from malnutrition or alcoholism, and in some patients with chronic bronchitis, emphysema, and fibrosis. As the healing process cannot be hastened, it is fortunate that this common complication is benign. Repeated bacteriologic studies of sputum should be undertaken, and a single antibiotic agent may be continued at conventional dosage. In addition, bronchoscopy and cytologic examination of the sputum should be performed, as a small but significant number of these patients have obstructing neoplasms.

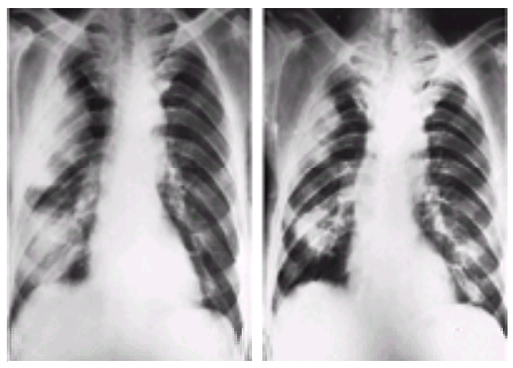

FIG. 5. Pneumococcal pneumonia (*left*) in a 40-year-old alcoholic with slow resolution within a 1-month period (*right*).

Endocarditis

In the course of bacteremia, pneumococci may light on normal or damaged heart valves, chordae tendineae, or papillary muscles. Endocarditis may occur concomitantly with the pneumonia, or there may be an excellent response to treatment of the pulmonary infection, followed by a period without fever and then a recurrence of fever after antibiotics have been discontinued. If endocardial involvement is associated with fever and other evidence of active infection, vigorous treatment should be undertaken: a minimum of 6 million units of penicillin per day for at least 4 weeks. However, when these cardiac complications occur in the absence of fever or evidence of active infection, they probably represent late rupture of a valve, chorda, or papillary muscle that was damaged by infection acquired during the bacteremia accompanying the pneumonia but was bacteriologically sterilized by treatment of the pneumonia. In these patients, a trial of antibiotics is warranted, but there is no evidence that the disease will be modified by such therapy. Surgical intervention may be necessary. Patients in whom pneumococcal endocarditis develops following pneumonia not infrequently have simultaneous evidence of pneumococcal meningitis.

Meningitis

One third to one half of adult patients with pneumococcal meningitis have concomitant or pre-existing pneumococcal pneumonia. Any patient with pneumococcal pneumonia who evidences disorientation, confusion, or somnolence should have a lumbar puncture to evaluate the possibility of pneumococcal meningitis. Although involvement of the meninges is usually apparent clinically, the manifestations can be extremely subtle.

There is some controversy as to the most effective treatment of pneumococcal meningitis, but it is unanimously agreed that an adequate regimen is large amounts of aqueous penicillin administered intravenously (minimal daily adult dose being 10 million units). Alternatives to penicillin include ampicillin, chloramphenicol, and a cephalosporin (cefuroxime, cefotaxime, or ceftriaxone). If moderately resistant strains of *S. pneumoniae* infect the meninges, penicillin is usually not effective.

Gangrene

On rare occasions, pneumococcal sepsis is followed by gangrene involving fingers, toes, nose, lips, and earlobes. In such cases, there is usually evidence of disseminated intravascular coagulation. This complication is particularly prevalent in those who have had a splenectomy.

Jaundice

Modest increases in serum bilirubin concentrations may occur in patients with pneumococcal pneumonia. Transaminase concentrations may be markedly elevated.

The mechanisms underlying the jaundice are not adequately defined, and the bilirubinemia ordinarily disappears in a few days. Physicians often forget that pneumococcal pneumonia may be associated with jaundice; the incorrect diagnosis most often made is Legionnaires' disease, because of the combination of pneumonia and liver dysfunction.

Prevention

The role of polyvalent pneumococcal vaccine is still unsettled. In some studies, it seems to be reasonably effective; in others, it does not. It is not entirely clear who should be vaccinated, although those with gamma globulin deficiencies, alcoholics, those over the age of 60 in institutions for long-term care, patients with sickle cell disease, HIV-infected patients, and those who have undergone splenectomy are certainly prime candidates. Some advocate the vaccine for all persons over the age of 60.

Streptococcal Pneumonia

In the pre-antimicrobial era, pneumonia resulting from group A b-hemolytic streptococci (*Streptococcus pyogenes*) was not uncommon in children after measles or pertussis or in adults after influenza. During the influenza pandemic of 1918–1919, severe streptococcal pneumonia, often culminating in death, assumed epidemic proportions in many areas of the world. The incidence of streptococcal pneumonia and bacteremia decreased markedly after the discovery and use of penicillin, but in recent years there has been an unexplained recrudescence of serious streptococcal disease. Currently, the total number of cases reported still is small, occurring for the most part in the very young, the very old, and the debilitated. Numerous epidemics have been reported in military recruit populations.

Clinical Manifestations

The onset is typically abrupt, with shaking chills, fever, and cough productive of purulent sputum. Hemoptysis and pleuritic chest pain are commonly observed. Cyanosis is noted in more severe cases. Rales and dullness are found on examination, but signs of frank consolidation are detected less frequently. The radiographic picture is that of bronchopneumonia, although one or more focal areas of pneumonitis may be seen. Empyema develops in 30%–40% of cases, and rapid pleural involvement is considered characteristic of this type of pneumonia.

Laboratory Findings

The leukocyte count is characteristically elevated, with a preponderance of mature and immature polymorphonuclear cells. Gram's stain of the sputum shows many polymorphonuclear leukocytes and gram-positive cocci in chains. An increasing percentage of streptococcal pneumonias are caused not by group A organisms, but rather by organisms belonging to groups B through G. Although specific clinical patterns have not been adequately defined for each group, it appears that *Streptococcus agalactiae* (group B) and *Streptococcus milleri* have the greatest propensity for abscess formation. Additionally, microaerophilic or anaerobic streptococci can cause pneumonia; in these cases, necrotizing pneumonia with empyema is frequently found.

In neonates, group B streptococci cause sepsis and diffuse pneumonitis. These infants, who become sick shortly after birth, are frequently very ill, with marked tachypnea and cyanosis. Roentgenograms usually show bilateral alveolar and interstitial infiltrates; in some cases, focal pneumonitis may be seen. Maternal vaginal colonization is the major risk factor for such infections.

Therapy

Penicillin is clearly the antibiotic of choice. Approximately 25% of group A b-hemolytic streptococci are no longer susceptible to tetracyclines. A penicillin dosage of 600,000 units two to four times a day is usually adequate, but some anaerobic streptococci are more resistant, requiring 3 to 6 million units per day. Cephalosporins, semisynthetic penicillins, erythromycin, and vancomycin can be used as alternatives to penicillin. If the infection is caused by group B, C, or G, therapy must depend on in vitro studies. Once severe streptococcal pneumonia is established, it may become a fulminating disease even if adequate amounts of antibiotics are administered. This is particularly true in group B infections in neonates, with mortality in these infants being about 30%. In adults, this characteristic is undoubtedly related in part to its frequent occurrence in persons whose antimicrobial defenses are impaired. In patients with empyema, conservative therapy with repeated thoracocentesis should be tried, especially while the fluid is still thin. Closed or open chest tube drainage may be needed for loculated fluid.

Staphylococcal Pneumonia

In previously healthy, young adults, *S. aureus* rarely causes pneumonia. Local pulmonary or systemic defenses of the host must be compromised before the organism can produce progressive disease. *S. aureus* accounts for 2%–9% of community-acquired pneumonias in the elderly or in patients with concomitant conditions, such as diabetes mellitus, chronic renal failure, bronchiectasis, lung carcinoma, defective polymorphonuclear leukocyte phagocytosis or killing, and intravenous substance abuse, or who are residents in a facility for long-term care. Infections may also occur in previously healthy adults following viral influenza with resultant impairment in bronchopulmonary clearance mechanisms.

Clinical Manifestations

The clinical manifestations of staphylococcal pneumonia vary considerably, depending on the setting in which it occurs. In the majority of patients who acquire the disease outside the hospital, especially those in whom staphylococcal pneumonia develops after viral influenza, the onset is sudden. Fever occurs uniformly and may be remittent or sustained in type. Most patients have pleuritic chest pain, shaking chills, and cough productive of sputum that is usually purulent and on occasion may also be blood-streaked. Gross hemoptysis occurs in a small number of patients. In infants and young children, cough and chest pain may be minimal, and the major manifestations are fever, dyspnea, and cyanosis.

On physical examination, the majority of patients appear extremely ill, with tachypnea, tachycardia, and commonly pleuritic pain. Cyanosis is often found, but hypotension is recorded infrequently. The findings on examination of the chest are generally indistinguishable from those already described for pneumococcal pneumonia. A pleural friction rub may be heard, accompanied by evidence of pleural fluid.

Laboratory Findings

Gram's stain of the sputum shows many polymorphonuclear leukocytes with intracellular and extracellular large, round cocci arranged in clusters. Specimens obtained from patients with staphylococcal pneumonia almost invariably show a heavy and virtually pure growth of *S. aureus.* If only small numbers are present, or if staphylococci are not clearly predominant, then staphylococcal pneumonia is an unlikely diagnosis.

For most adults with staphylococcal pneumonia, blood culture results are negative, the incidence of bacteremia being higher in infants. Leukocyte counts of 1000/mm^3 or less in individuals whose counts were previously normal are associated with a poor prognosis.

Chest roentgenograms typically show consolidation in a lobe or in smaller segments of one or more lobes. In some patients, patchy infiltrates in several areas of the lung suggest diffuse bronchopneumonia, and occasionally what appears to be an interstitial infiltrate is observed. Pleural or interlobar fluid may be detected. Single or multiple radiolucencies are often found in the areas of infiltration. In infants, pneumatoceles occur as frequently as abscesses, whereas in adults the radiolucencies almost invariably represent abscess formation. As cyst and abscess formation are not complications of staphylococcal pneumonia but rather an intrinsic part of the natural history of the disease, their presence does not imply a poor prognosis. Furthermore, the appearance of these lesions on the roentgenogram does not indicate failure of antibiotic therapy and does not necessitate a change in the antistaphylococcal regimen. In successfully treated patients, the vast majority of the abscesses and cysts disappear spontaneously and do not require adjunctive surgical treatment (Fig. 6). The x-ray film should ordinarily distinguish between upper respiratory tract-acquired and embolic staphylococcal pneumonia.

FIG. 6. Right lower lobe staphylococcal pneumonia in a 21-year-old man with prior viral influenza. Note two abscesses in the pneumonic area. These resolved completely in 2 weeks without a change in antistaphylococcal therapy. (Reproduced with copyright permission of The American Society for Clinical Investigation from Louria DB, et al. Studies on influenza in the pandemic of 1957–1958: II. Pulmonary complications of influenza. *J Clin Invest* 1959;38:213.)

Treatment

The mortality among patients who have been treated for staphylococcal pneumonia varies from 15%–50% in different series. Because mortality depends on the virulence of the micro-organism, the ability of the host to mobilize defenses, and the severity of the underlying disease, it is difficult to predict the outcome in any one individual, but it is clear that the presence of leukopenia and the demonstration of bacteremia are ominous prognostic signs.

Therapy should be initiated with large, parenterally administered doses of a penicillinase-resistant semisynthetic penicillin (methicillin, nafcillin, cloxacillin, or oxacillin) or a first-generation cephalosporin. Primarily bacteriostatic agents, including tetracycline, erythromycin, and chloramphenicol, are not advised as initial treatment in seriously ill patients. Clindamycin has significant antistaphylococcal activity but should not be considered a first-line agent. Imipenem also may be effective.

An increasing percentage of both community-acquired and nosocomial cases of staphylococcal pneumonia are caused by methicillin-resistant strains; for these, vancomycin given alone or together with either rifampin or an aminoglycoside is the agent of choice.

In vitro and in vivo animal studies suggest that in severely ill patients, the addition of an aminoglycoside to an agent such as oxacillin or nafcillin results in more rapid killing of the staphylococci. Although convincing clinical data are not now available, the current recommendation is that gentamicin or tobramycin be added to the semisynthetic penicillin for 5 to 7 days if the staphylococcal infection is overwhelming or life-threatening. Rifampicin is an effective intracellular antistaphylococcal agent and may be a useful addition to the antimicrobial regimen in recalcitrant cases.

Treatment should be continued for a minimum of 14 days. Even if adequate and appropriate therapy is given immediately, defervescence may be slow. Persistence of a moderately elevated temperature for 1 to 2 weeks does not in itself necessitate a change in the therapeutic regimen.

Complications

Meningitis

Staphylococcal meningitis with or without clinical evidence of brain abscess may complicate staphylococcal pneumonia. Cerebrospinal fluid examination reveals a variable cell count with a preponderance of polymorphonuclear leukocytes. The protein is elevated, but the glucose level may or may not be reduced. Treatment depends on in vitro susceptibility studies.

Empyema

Empyema develops in 15%–40% of patients with staphylococcal pneumonia, and *S. aureus* still accounts for about one third of all cases of pleural empyema. Acute empyema usually arises by direct extension from pneumonia or lung abscess, and therapy is similar to that described for empyema in pneumococcal pneumonia. Insertion of a chest tube, however, is usually necessary, and the presence of very thick pus makes open surgical drainage advisable early in the course of this disease.

Large Abscesses

Lung abscesses (Fig. 7) or pneumatoceles may become large enough to impair pulmonary function, or they may become secondarily infected. Under such conditions, drainage or excision by lobectomy is necessary.

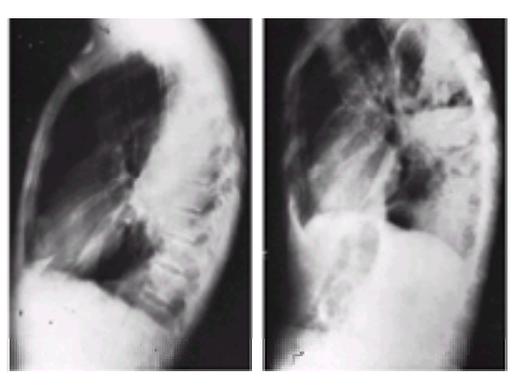

FIG. 7. Staphylococcal pneumonia (*left*) in a 47-year-old man. A large abscess (*right*) developed 1 week later.

Pneumothorax

A not uncommon complication, especially in infants and children, pneumothorax is not usually of grave prognostic import. Treatment depends on the size; a small pneumothorax will resolve spontaneously, but if a large pneumothorax or a tension pneumothorax is present, tube drainage should be used.

Bronchopleural Fistula

This complication usually occurs in patients who have underlying pulmonary diseases. It may be treated by surgical drainage of the empyema and prolonged antimicrobial therapy, but persistent fistulas should be excised surgically.

Miscellaneous Causes of Gram-Positive Pneumonia

Bacillus species can cause severe pneumonia in the compromised host. Only a small number of cases have been reported; most of the patients have had acute or subacute leukemia. However, in one case lethal gram-positive *Bacillus* pneumonia occurred in a previously healthy individual. The organism usually isolated is *Bacillus cereus,* but lethal pneumonia also has been caused by *Bacillus subtilis. B. cereus* multiplies within blood vessels, and as a result wedge-shaped, infarctlike lesions may be seen roentgenologically. Abscesses, cavities, and pneumonic infiltrates also may be found. The sputum is usually bloody, and pleural effusions are found frequently. The antibiotic regimen of choice depends on in vitro sensitivity patterns. The *Bacillus* species isolated from patients with pneumonia have been inhibited by tetracycline,

erythromycin, aminoglycosides, and chloramphenicol.

Corynebacterium (*Rhodococcus*) *equi* is a gram-positive coccobacillus responsible for suppurative bronchopneumonia in horses. In patients who are immunosuppressed, either because of an underlying disease or medications, the organism can cause severe pneumonia, with lobar or lobular infiltrates, infarctlike lesions, abscesses, or cavities. Manifestations include cough, chest pain, and hemoptysis. Pleural effusion may be present, and the organism may be recovered from the sputum or only from bronchial washings and/or pleural fluid. Erythromycin is thought to be the antimicrobial agent of choice (the isolates are also likely to be sensitive to vancomycin, gentamicin, tetracycline, and kanamycin), but too few cases have been reported to make a judgment about an optimal antimicrobial regimen.

Necrotizing pneumonia and empyema may be caused by *Clostridium perfringens.* Some cases follow trauma, surgery, or thoracocentesis, but in others no precipitating event has been noted. Pleural gas may be noted. Hemolysis, renal failure, and profound mental confusion are not present, as they are systemic clostridial infections, and the disease ranges from surprisingly mild to life-threatening. Penicillin, clindamycin, metronidazole, and chloramphenicol appear to be the agents of choice.

PNEUMONIA CAUSED BY GRAM-NEGATIVE BACTERIA

Community-acquired pneumonia is virtually never caused by enteric gram-negative bacilli in previously healthy, young adults. However, these organisms, predominantly Enterobacteriaceae, have been implicated in 3%–15% of cases. This relatively high prevalence of gram-negative bacillary pneumonia in large part reflects the inclusion of debilitated or elderly patients with serious pre-existing diseases. On the other hand, *Haemophilus influenzae* and *Moraxella* (*Branhamella*) *catarrhalis* have been increasingly recognized as pulmonary pathogens and account for 8%–20% and 1%–3%, respectively, of cases of community-acquired pneumonia.

Hemophilus influenzae **Pneumonia**

Because *H. influenzae* is part of the commensal oral flora, this organism was largely unappreciated as a significant pulmonary pathogen until recently. In recent years, there has been a clear increase in the occurrence of *H. influenzae* pneumonia, and it is second only to pneumococcal pneumonia as the most common community-acquired pneumonia in adults. *H. influenzae* pneumonia occurs in perfectly healthy people; in persons with chronic lung disease or other severe, underlying disease; in patients who have undergone splenectomy; and among chronic heavy abusers of alcohol. There is also an increased incidence in patients with disorders of gamma globulin synthesis, including those with chronic lymphocytic leukemia, multiple myeloma, human immunodeficiency virus infection, and the various IgG deficiencies. During epidemics of viral influenza, the incidence of *H. influenzae* pneumonia increases.

Kaplan and Braude, noting that severe infections with bacteremia occurred among adults primarily in alcoholics, performed studies suggesting that serum factors active against *H. influenzae* were less effective in patients with cirrhosis. Reduced effectiveness also was observed immediately after the ingestion of alcohol. These authors postulated that this relationship might be responsible for the enhanced susceptibility of these individuals.

Micro-organism

H. influenzae is a pleomorphic, gram-negative, coccobacillary organism. When grown under unfavorable conditions, it may appear filamentous and elongated and be mistaken for enteric gram-negative rods. It is a fastidious organism requiring special media that supply both X and V factors, such as chocolate or Levinthal agar. It may be recognized in sputum by Gram's stain (Plate 2) or by detection of specific capsular antigen. The encapsulated serotypes of *H. influenzae* (types a through f) can be differentiated by a variety of methods, including slide agglutination, counterimmunoelectrophoresis, and fluorescent antibody techniques. Each method is based on the use of antibodies directed against the capsular polysaccharide, a polymer of ribose and ribitol-5-phosphate.

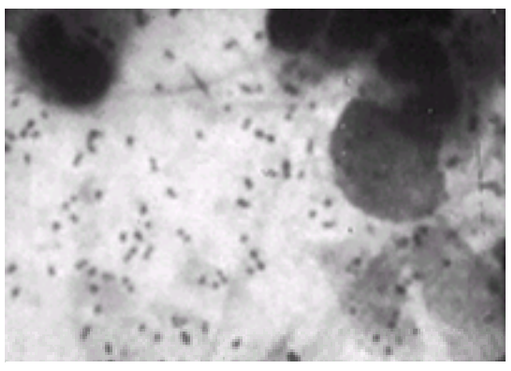

PLATE 2. *Haemophilus influenzae* in Gram's stain of sputum. X900. *See color plate 13.*

Pathogenesis

The development of invasive disease caused by *H. influenzae* follows colonization of the upper respiratory tract. The nasopharyngeal carriage rate for nontypeable strains varies from 50%–80%, in contrast to the carriage rate for type b *H. influenzae,* which is estimated at 3%–5%. Type b *H. influenzae* is responsible for 95% of systemic disease in children and a significant percentage of invasive bacteremic infections in adults. In contrast, nontypeable *H. influenzae* strains generally cause less severe local infection that spreads in a contiguous fashion within the respiratory tract, and these are the most common isolates causing pneumonia in adults.

Clinical Presentation

Two distinct presentations of *H. influenzae* pneumonia are recognized. The first occurs in infants or in patients with alcoholism or underlying immunodeficiency. In these individuals, the onset is typically rapid, with chills, fever, cough productive of purulent sputum, and pleural pain; the clinical features are indistinguishable from those of pneumococcal or other bacillary pneumonias. Bacteremia is common (up to 75% of cases in children), and the causative organism is almost always type b. Type b strains are responsible for about 10%–15% of pneumonias in adults. In contrast, adults with chronic lung disease usually experience a gradual onset, with low-grade fever, cough, increasing sputum production, worsening dyspnea, and occasionally myalgias and arthralgias. Bacteremia is rare in this setting, and the causative strain is invariably nontypeable.

Roentgenograms frequently show segmental lobar consolidation, but patchy bronchopneumonia and multilobular infiltrates may be seen. In patients with chronic lung disease, the initial chest radiographic findings may not be considered abnormal until after therapy, when improvement occurs in an area previously interpreted as chronic interstitial disease. Cavitary disease and empyema occur rarely, but parapneumonic effusions may occur in up to half of patients.

Diagnosis cannot be based solely on isolation of *H. influenzae* from the sputum, because nasopharyngeal carriage rates are so high. In addition, *H. influenzae* can be recovered from the sputum of most patients with chronic bronchitis if serial cultures are performed. Unless the organism is isolated from the bloodstream or pleural space, the diagnosis of *H. influenzae* pneumonia remains probable at best. Serologic methods, measuring antibodies against nonencapsulated *H. influenzae* strains by ELISA (enzyme-linked immunosorbent assay) from paired sera, may increase the ability to diagnose true *Haemophilus* infections. The sensitivity of this specific approach, however, is low.

Therapy

Until the early 1970s, *H. influenzae* was nearly uniformly susceptible to ampicillin, but during the past two decades, plasmid-mediated, b-lactamase-producing, ampicillin-resistant strains have been noted with increasing frequency. These organisms now constitute the majority of isolates in many centers. Chloramphenicol susceptibility has been preserved, however, as very few chloramphenicol-resistant strains have been reported. Ampicillin is not recommended as initial therapy, unless drug-susceptibility profiles confirm sensitivity. Type b *H. influenzae* has a propensity for invading the meninges, and empiric therapy ideally should have good cerebrospinal fluid penetration. Reasonable choices for initial therapy of invasive *Haemophilus* infections would therefore include ampicillin/sulbactam, chloramphenicol, second- or third-generation cephalosporins, and trimethoprim/sulfamethoxazole. Alternative agents include imipenem/ cilastatin, azithromycin or clarithromycin, and the fluoroquinolones, but the cerebrospinal fluid penetration may not be as reliable.

Active immunization against type b *H. influenzae* is now possible, as a vaccine composed of purified type b polysaccharide (PRP) is available. One of these commercially available PRP-conjugated vaccines should be routinely administered to children over the age of 15 months and to adults with conditions predisposing to invasive *Haemophilus* infection.

Outcome

Complications of *Haemophilus* pneumonia include empyema, meningitis, and septic arthritis. All are more likely to occur in the setting of bacteremia, alcoholism, splenectomy, or immunoglobulin deficiency. Mortality rates associated with *Haemophilus* pneumonia are <5% in young, healthy adults, but may be as high as 20%–30% among debilitated, elderly patients.

Moraxella (Branhamella) catarrhalis Pneumonia

Since Osler's time, when the organism was referred to as *Micrococcus catarrhalis,* this gram-negative coccobacillary organism has undergone several name changes. The designation *Neisseria catarrhalis* reflected its resemblance to *Neisseria* in appearance, but DNA homology suggested the genus be transferred to *Moraxella.* In 1970, in honor of Dr. Sarah Branham (for her contributions to the taxonomy of *Neisseria* species), the organism was assigned the genus *Branhamella.* At present, many prefer the designation *Branhamella,* as *Moraxella* implies limited pathogenicity.

This organism has long been recognized as an oropharyngeal commensal, and several studies have established that *B. catarrhalis* colonizes the nasopharynx of up to 7.4% of adults and 30% of children. *B. catarrhalis* is one of the three most common bacteria responsible for exacerbations of chronic bronchitis, and recent studies suggest it is responsible for 1%–3% of community-acquired pneumonias.

Micro-organism

B. catarrhalis is a gram-negative diplococcus shaped like a kidney bean, with its long axes paired side to side. The resemblance of a sputum Gram's stain from a patient with *B. catarrhalis* respiratory tract disease to the urethral smear from a patient with gonorrhea is striking. The organism readily grows on blood agar and can be easily distinguished from *Neisseria* species on the basis of sugar fermentation reactions. At present, 80%–90% of stains produce b-lactamase.

Clinical Manifestations

Chronic obstructive pulmonary disease is the most consistently reported underlying illness associated with *B. catarrhalis* respiratory tract infection, and the mean age of patients exceeds 60 years. Almost three fourths of infected patients are immunocompromised as a consequence of corticosteroid use, diabetes mellitus, or malignancy. Immunoglobulin deficiency is a quantitatively less important risk factor, but the clinical course appears more severe in this setting. More than 85% of cases occur from October through May.

Most cases of *B. catarrhalis* pneumonia are mild and present in a fashion suggesting an exacerbation of chronic bronchitis. There generally is minimal change in the patient's chronic cough, weakness, or dyspnea. In one fourth of patients, chills occur; in one third, pleuritic chest pain is present. Bacteremia, high fever, myalgias, pleural effusion, and empyema are rare. Patchy bronchopneumonia and interstitial or mixed interstitial-alveolar infiltrates are characteristic radiographic features. Lobar consolidation occurs in fewer than one third.

Diagnosis based on the traditional criterion of isolating the organism from blood or pleural fluid is difficult, as bacteremia and empyema are uncommon. A presumptive diagnosis of *B. catarrhalis* pneumonia is suggested by the clinical and radiographic signs of pneumonia, a good-quality sputum Gram's stain showing a predominance of gram-negative diplococci, and heavy growth of the organism on culture. It should be recognized that *B. catarrhalis* is frequently cocultured with other pathogens, especially *S. pneumoniae* and *H. influenzae.*

Therapy

Although 80%–90% of strains of *B. catarrhalis* produce b-lactamase, most of these strains have MICs to ampicillin of 2 mg/mL or less and are not labeled ampicillin-resistant. Clinical evidence suggests that all b-lactamase-producing strains of *B. catarrhalis* be considered ampicillin-resistant. Fortunately, these *B. catarrhalis* b-lactamases are inactivated by clavulanic acid and sulbactam, and have only moderate activity against second- or third-generation cephalosporins. Alternative, non-b-lactam antimicrobial agents include tetracycline, erythromycin, trimethoprim/sulfamethoxazole, and fluorinated quinolones.

Mortality directly attributable to pneumonia caused by *B. catarrhalis* is rare. Recent studies, however, have shown that up to 45% of patients die within 3 months, usually as a result of the underlying disease.

Neisseria meningitidis Pneumonia

Neisseria meningitidis was first reported as a respiratory pathogen after the influenza pandemic of 1918 and 1919. Thereafter, almost half a century elapsed before a renewed interest in the meningococcus as a cause of lower respiratory tract infection emerged in the 1970s. A majority of cases of meningococcal pneumonia have occurred in military populations, but this may only be a consequence of the ongoing surveillance of meningococcal disease by the armed forces. The association of meningococcal disease with antecedent influenza or adenoviral infection is well-known. Although spread of meningococcal infection beyond the nasopharynx almost exclusively requires bloodstream invasion, an inhalational rather than hematogenous pathogenesis is likely for meningococcal pneumonia.

There is nothing distinctive about its clinical presentation, and the onset may be sudden or more indolent. Patchy, lobular, or lobar infiltrates may be found, and in some cases, the pleura is involved. Bacteremia occurs in 15%–26% of cases. The presence of *N. meningitidis* in expectorated sputum may be easily overlooked unless it is specifically sought, and the use of selective culture media, such as Thayer-Martin medium, is helpful.

Confirmation of the meningococcus as the causative organism in bacterial pneumonia can be difficult. *N. meningitidis* can be recovered from the nasopharynx of 7%–13% of asymptomatic outpatients, and up to 30% of patients with acute respiratory infections but no clinical or radiographic signs of pneumonia have meningococcus-positive sputum. Therefore, to assign a causative role for the organism in pneumonia with confidence, it is necessary to isolate it from blood, pleural fluid, or lung aspirate.

The meningococci have remained broadly antibiotic-sensitive, and rapid clinical improvement on therapy is the rule. It should be noted that the administration of antibiotics (as opposed to sulfonamides) does not usually eliminate the carrier state. Rifampin and sulfonamides are effective agents for eradication of the carrier state and for prophylaxis of close contacts, but because of increasing reports of sulfonamide resistance, susceptibility studies should be performed.

Klebsiella pneumoniae (Friedländer's) Pneumonia

Micro-organism

In 1882, Friedländer discovered the organism that came to bear his name. It is a pleomorphic, encapsulated, fat, gram-negative rod that grows rapidly and aerobically on ordinary bacteriologic media. Four years later, in 1886, Escherich described *Aerobacter aerogenes.* Classified as separate species until recently, the two organisms are antigenically so similar that they have been combined into a single *Klebsiella* genus. *Klebsiella* types 1 through 6 are identical to Friedländer's bacillus types a through f, and *Klebsiella* types 7 through 80 are probably members of the old *A. aerogenes* group.

There are certain striking differences between Friedländer's bacillus (*Klebsiella* types 1 through 6) and higher *Klebsiella* serotypes: (1) Colonies of Friedländer's bacillus are far more mucoid and sticky because of their much larger capsules. (2) Differences in virulence for mice are marked. Friedländer's bacillus produces death within 24 to 48 hours after the intraperitoneal inoculation of small numbers of organisms, frequently <100 per mouse. Deaths after intraperitoneal infection with higher *Klebsiella* serotypes, on the other hand, rarely occur even at an inoculum size of a million organisms per mouse; indeed, many strains produce death only irregularly after an injection of 100 million to a billion bacteria per mouse. (3) The settings in which these two organisms cause pulmonary disease are not similar. Friedländer's bacillus characteristically produces pneumonia in men who are >40 years old and who are alcoholics or have chronic underlying disease, usually pulmonary in nature. Most patients with Friedländer's pneumonia enter the hospital with the disease. In contrast, pneumonia resulting from higher *Klebsiella* serotypes is usually acquired within the hospital environment, occurring in patients who are extensively treated with antibiotics and in whom pneumonia subsequently develops.

In the following discussion, the term *Friedländer's pneumonia* refers only to that caused by *Klebsiella* serotypes 1 through 6, most commonly types 1 and 2. Pulmonary infections caused by higher *Klebsiella* serotypes are discussed with pulmonary disease caused by *Escherichia coli*.

Clinical Manifestations

Friedländer's pneumonia, which accounts for <2% of patients hospitalized with bacterial pneumonia, is usually sudden in onset, with fever, cough, and pleuritic chest pain. In a minority of individuals, the cough is productive of the typical thick, gelatinous, red sputum. Most patients expectorate thick, greenish, purulent material that is frequently streaked with blood, whereas in some patients the cough is productive of frankly bloody sputum. On admission, patients may be seriously ill, with severe dyspnea, tachypnea, striking cyanosis, and hypotension, although many persons have considerably milder forms of the disease. Physical examination generally reveals the classic signs of consolidation, but sometimes only dullness to percussion, inspiratory rales, and diminished breath sounds are observed, the latter apparently because of obstruction of the smaller bronchi by plugs of gelatinous material. In some series, as many as one fifth of the patients have visible icterus.

Laboratory Findings

Gram's stain of the sputum shows many polymorphonuclear leukocytes and a myriad of short, fat, gram-negative, heavily encapsulated rods. The pleomorphism of the organism is frequently marked, and it may be so gram-variable that on examination of the sputum smear, a diagnosis of pneumococcal pneumonia may be made, especially by inexperienced observers. The leukocyte count is extremely variable. Although leukocytosis, sometimes with a count of up to 40,000/mm^3, is the rule, normal leukocyte counts or leukopenia may be observed. Frequently, normocytic, normochromic anemia either is present on admission or develops with startling rapidity after hospitalization. Blood culture results are positive in 20%–50% of cases.

The pneumonia more often affects the right side, with a predilection for the lower lobes and the posterior segment of the upper lobes, which suggests that the organisms have been aspirated from the mouth. Roentgenograms characteristically show massive consolidation with a fissure that bulges outward; this is apparently related to the extensive edema observed histologically (Fig. 8). Although the outward-bulging fissure is found frequently in Friedländer's pneumonia, this sign is by no means pathognomonic of infection with the organism that causes Friedländer's pneumonia, as it also may be observed in pneumonia caused by many other organisms. In 25%–50% of patients with acute Friedländer's pneumonia, one or more abscesses, usually not evident by physical examination, appear on the roentgenogram. The presence of abscesses and periodontal disease may tempt the physician to make a diagnosis of primary putrid lung abscess. The separation of the two diseases can often be made by smelling the sputum, which is not foul in Friedländer's disease.

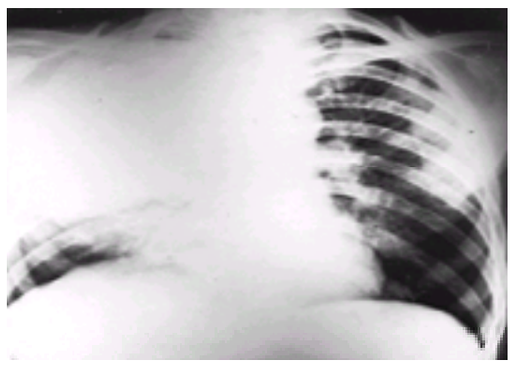

FIG. 8. Friedländer's pneumonia and empyema in a 52-year-old alcoholic. Note the bulging fissure.

Treatment

The micro-organism usually is susceptible in vitro to tetracyclines, chloramphenicol, cephalosporins, aminoglycosides, trimethoprim/sulfamethoxazole, the newer penicillins, such as piperacillin and mezlocillin, and the fluoroquinolones. The treatment of choice consists of a cephalosporin or b-lactam plus an aminoglycoside. Although this combination seems reasonable, there are no satisfactory data showing the advantages of giving both drugs rather than either one alone. Treatment should be continued for a minimum of 2 weeks.

Complications

Complications include empyema, pneumothorax, chronic pneumonia, spread to contiguous tissues, such as the pericardium, and hematogenous dissemination, especially to the meninges. In patients with empyema, open drainage usually is necessary because of the toxemia and thickness of the pus. Chronic Friedländer's pneumonia, which may follow the acute process, is characterized by progressive inanition, abscess formation, and anemia. It usually responds to prolonged antimicrobial therapy combined with careful supportive measures, but in some patients, lobectomy has to be performed for residual abscesses.

Escherichia coli Pneumonia

E. coli ranks after *K. pneumoniae* as the second most common cause of community-acquired gram-negative bacillary pneumonia. The “colon bacillus,” isolated in 1885 by Escherich, is a gram-negative, nonencapsulated bacillus. *E. coli* pneumonia may develop after a bacteremia originating from the genitourinary or gastrointestinal tract or by endogenous aspiration of the organism from a colonized oropharynx.

Patients with community-acquired *E. coli* pneumonia are usually middle-aged to elderly persons with underlying diseases, such as diabetes mellitus, cirrhosis, cardiac disease, and chronic lung disease. Several days of fever, chills, cough productive of purulent sputum, and pleurisy are generally reported. Alcoholics may present after a binge with pneumonia and meningitis. Tachycardia may be out of proportion to fever. Patchy lower lobe bronchopneumonia is typical, but occasionally lobar consolidation with abscess is seen. Parapneumonic effusion is common. The organism is generally readily recovered from blood, sputum, urine, and pleural fluid. Mortality rates vary from 29%–60%, and in survivors, fever ends by lysis.

Pneumonia Caused by *Proteus* Species

Proteus organisms are highly motile, gram-negative bacilli, notable for their characteristic swarming on agar. Patients acquire *Proteus* pneumonias after endogenous aspiration of pharyngeal secretions, and the typical patient is an elderly, alcoholic man with chronic lung disease. Worsening of bronchitic symptoms for several weeks culminates in an acute episode of fever, rigors, cough productive of purulent sputum, chest pain, and dyspnea. Signs of upper lobe consolidation are generally present. Radiographs show dense infiltrates in the posterior segments of the right upper lobe or superior segments of the right lower lobe, frequently with abscess formation. Pleural effusion is unusual, and healing results in a contracted fibrotic lobe. Species of *Proteus* may be cultured from the sputum as the predominant organism for long periods despite the use of antimicrobial agents.

Acinetobacter calcoaceticus Pneumonia

Acinetobacter is a gram-negative coccobacillus that can be easily misinterpreted as *Neisseria, Haemophilus,* or *Branhamella.* Patients with community-acquired *Acinetobacter* pneumonia are usually middle-aged to elderly persons with antecedent alcoholism and tobacco abuse. Occupational exposure to silica particles appears to be an additional risk factor. Patients have been ill for several days before admission with cough, fever, pleurisy, and bloody sputum. They typically present in severe respiratory distress, often sitting “bolt upright,” and half are in shock. Lower lobe consolidation and pleural effusion are common. Leukopenia with an absolute granulocytopenia is present in a majority of cases. Measurement of arterial blood gases shows profound hypoxemia. Blood, sputum, and empyema cultures yield *Acinetobacter.* Pneumonia progresses rapidly despite antimicrobial therapy, and death occurs in <72 hours.

Pseudomonas aeruginosa Pneumonia

Community-acquired *Pseudomonas aeruginosa* pneumonias are rare, accounting for <10% of gram-negative bacillary pneumonias in this setting. Although most patients are elderly with severe, chronic cardiopulmonary disease or malignancy, cases occasionally occur in normal hosts. At presentation, patients are toxic,

apprehensive, and confused, and exhibit chills, fever, and coughs productive of greenish sputum. Relative bradycardia and a reversal of the usual diurnal temperature curve (with elevation primarily in the morning) are typical.

Pulmonary infiltrates may be focal or diffuse, the latter mimicking cardiogenic pulmonary edema. The focal form may involve any part of the lungs, often with roentgenologic evidence of cavitation. Nodular infiltrates may be observed.

The diffuse form is a fearsome disease characterized by necrotizing pneumonia, vasculitis, frequent pulmonary hemorrhage, and abscess formation. Bacteremia is common and often accompanied by marked neutropenia. The nonbacteremic, focal form of *Pseudomonas* pneumonia carries a case fatality rate of 30%–60%. The bacteremic variety, which resembles pulmonary edema, is associated with a case fatality rate in excess of 80% unless treated promptly.

In *Pseudomonas* pneumonia, piperacillin, mezlocillin, ceftazidime, aztreonam, or imipenem combined with aminoglycoside should be adequate therapy.

Miscellaneous Causes of Gram-Negative Pneumonia

Evidence of pulmonary involvement may occur in typhoid fever. Indeed, cough is one of the early manifestations of the disease in as many as 25% of patients. Pulmonary infiltrates in typhoid fever are typically small and fleeting, and the pulmonary involvement is not a significant part of the disease process in the vast majority of patients. However, *Salmonella typhi* infection may be manifested by lobar pneumonia and/or empyema. Pneumonia also may be found in infections caused by *Salmonella* species other than *S. typhi,* especially *Salmonella choleraesuis,* which is the most invasive of the *Salmonella* species. Pneumonia, lung abscesses, and empyema may be the predominant manifestations of this disease.

Melioidosis, an acute, often lethal, disseminated infection acquired from rodents, cats, and dogs, is found primarily in Southeast Asia and the West Indies. The causative organism, *Pseudomonas pseudomallei,* is closely related antigenically to the agent responsible for glanders. Although the acute form of the infection is frequently fatal, there have been a small number of cases of chronic disease. These patients may have systemic disease without pulmonary parenchymal involvement, disseminated disease with secondary involvement of the lung, or primary pulmonary infection. In the lung, focal areas of pneumonic involvement rapidly form abscesses and cavities, followed sometimes by chronic empyema. The onset of the disease may be abrupt or the course may be indolent. Abscesses may appear in virtually any tissue of the body, and osteomyelitis with draining sinuses is observed frequently. Ceftazidime is the drug of choice. Extensive surgical drainage and debridement of diseased areas are also helpful.

Nodular infiltrates and pneumonia, occasionally with cavitation, also have been found in patients with *Yersinia enterocolitica* sepsis.

Legionellosis

In the summer of 1976, an epidemic of pneumonia occurred among persons attending a Legionnaires' convention in Philadelphia, Pennsylvania. In this predominantly older population, the case fatality rate was 16%. Approximately 6 months later, investigators from the Centers for Disease Control identified the causative agent as an aerobic gram-negative rod, *Legionella pneumophila.* It is now known that this organism caused epidemic pneumonia some 30 years before the Philadelphia epidemic. Species of *Legionella* account for 1%–4% of community-acquired pneumonias and rank among the top three microbial causes in several large-scale studies.

Micro-organism

Legionella is a pleomorphic bacillus that stains faintly gram-negative. There are at present >30 species, 20 of which have been implicated in human disease. The two most important are *L. pneumophila* and *Legionella micdadei* (the Pittsburgh agent). Within the species *L. pneumophila,* there are 10 serotypes, and most cases of legionellosis are caused by serotypes 1, 4, and 6. The organism can be seen by special tissue stains (modified Giemsa, Brown-Hopps, or Dieterle's stain), and *L. micdadei* can stain weakly acid-fast. *Legionella* organisms are nutritionally fastidious, and charcoal yeast extract agar is the medium of choice. The organism grows slowly; it takes up to 5 days for macroscopically visible colonies to appear. Aquatic environments are the natural habitat of *Legionella,* and this includes man-made habitats such as cooling towers, evaporative condensers, and potable-water distribution systems.

Epidemiology

Legionnaires' disease occurs in sporadic, endemic, and epidemic forms. Most epidemic Legionnaires' disease is caused by exposure to *L. pneumophila* aerosols in the workplace or in industrial or nosocomial settings. Hospital tap water has been frequently reported as contaminated with *Legionella* organisms—hence the current proscription against the use of tap water for irrigation of nasogastric tubes or any activity related to respiratory therapy. Several epidemics have been associated with retail stores or shopping malls.

Sporadic disease and miniclusters of Legionnaires' disease have been associated with proximity of patients residences to cooling towers. Recent interest has been focused on the home as a source of sporadic legionellosis, as 1%–30% of home heaters harbor *Legionella* organisms. The extent of bacterial colonization varies inversely with tank temperatures in this setting. As the water required to reduce *Legionella* colonization is quite high (55°C to 60°C), the potential risk for scald injuries likely outweighs the benefit in reducing disease.

Susceptibility to Infection

The incidence of legionellosis depends on the degree of contamination of the organism in the aquatic reservoir. Risk factors for the acquisition of disease include cigarette smoking, alcoholism, chronic obstructive pulmonary disease, and age. Immunosuppression is a major risk factor, and corticosteroid use is frequently reported. Transplant recipients appear to be at highest risk. The role of polymorphonuclear leukocytes in host defense is unclear, but patients with granulocytopenia are not at increased risk. Humoral immunity plays only a secondary role. Intracellular multiplication of *L. pneumophila* occurs within human monocytes, and cell-mediated immunity appears to be the primary host defense against *Legionella,* as is true for other intracellular pathogens.

Pathogenesis

Pathogenic organisms can enter the lung by aspiration, direct inhalation, and hematogenous dissemination from another focus. Oropharyngeal colonization with *Legionella* has not been demonstrated, so that subclinical aspiration of contaminated water or direct inhalation of aerosols is the likely mode of entry. The organisms probably are cleared by the mucociliary process, and this would be supported by the consistent epidemiologic association of increased risk for disease with conditions characterized by impaired mucociliary clearance (i.e., cigarette smoking, chronic lung disease, alcoholism). *Legionella* readily undergoes phagocytosis by resident alveolar macrophages, but phagosome-lysosome fusion is inhibited, allowing the organism to multiply and escape the microbicidal mechanisms of this cell. Cell-mediated immunity is the primary host defense against *Legionella,* and lymphocyte proliferation and cutaneous delayed hypersensitivity to *Legionella* antigens develop within the first 2 weeks of infection. Mononuclear cells respond to *Legionella* with the generation of monocyte-activating cytokines, but although the activated monocytes and alveolar macrophage inhibit intracellular multiplication of *Legionella,* killing is not enhanced.

Clinical Manifestations

Legionella infections may vary considerably in presentation, from an acute, self-limited, influenza-like illness (Pontiac fever) to a fulminant pneumonia syndrome with high mortality (Legionnaires' disease). The initial symptoms of Pontiac fever are predominantly malaise, myalgias, headache, and dry cough. The appearance of the chest radiograph is normal, and recovery within a week is the rule.

The incubation period for Legionnaires' disease is apparently 2 to 10 days, and the clinical manifestations vary from mild cough and fever to coma with diffuse pulmonary infiltrates and multiorgan system failure. An antecedent upper respiratory tract infection is reported only infrequently. The respiratory manifestations range from acute, subacute, or even chronic bronchitis to consolidating lobular or lobar pneumonia. Symptoms include malaise, muscle aches, headache, confusion, high fever, chills, and cough that is usually accompanied by some sputum production, with the sputum ranging in quality from serous and thin to thick and purulent. Hemoptysis occasionally may be a prominent manifestation. Pleuritic pain is not infrequent. Early in the course of the disease, there is often a pulse-temperature dissociation with relative bradycardia. This finding may be enormously helpful diagnostically and should not be ignored. Physical examination of the lungs may reveal only a few rales, or there may be more prominent findings, even evidence of frank consolidation.

Pleural effusion occurs in 24%–63% of patients; the fluid may show either a predominance of polymorphonuclear leukocytes or lymphocytes and on rare occasions may be hemorrhagic. Chest x-ray patterns are nondiagnostic. The initial involvement is unilateral in most patients, and the infiltrate is typically alveolar and segmental-lobar or diffuse and patchy. Interstitial infiltrates were described in 25% of patients in the Philadelphia outbreak in 1976. The initial area of infiltration often progresses to more widespread consolidation during the ensuing few days, even in the face of appropriate therapy. The extent of radiographic involvement does not

correlate with the severity of illness or ultimate outcome, but it does correlate with the presence of *L. pneumophila* in sputum. Cavitation of infiltrates occurs almost exclusively in immunocompromised patients. Hilar adenopathy and pneumatocele formation are rare.

The many extrapulmonary manifestations include mild to moderate liver dysfunction, hyponatremia, hypophosphatemia, diarrhea, abdominal pain, splenomegaly, renal dysfunction, pericarditis (with or without effusion), and myocarditis. There is a particular propensity for involvement of the central nervous system, including both the brain and spinal cord. Abnormalities of mentation without focal neurologic findings and aseptic meningitis are the most frequent findings.

It is important to stress that extrapulmonary manifestations suggest but do not document a diagnosis of *Legionella* pneumonia. Although they are common (gastrointestinal, neurologic, and laboratory abnormalities, including liver dysfunction, hyponatremia, hypophosphatemia, and hematuria), such clinical manifestations do not occur more frequently in Legionnaires' disease than in pneumonias of other etiology.

Laboratory Diagnosis

Five techniques are currently available for the specific diagnosis of Legionnaires' disease (Table 7). Sputum findings are variable; there may be few or many polymorphonuclear leukocytes. The organism does not stain well by Gram's method. Culture of the organism on selective media remains the definitive method of diagnosis, and maximal yield depends on specimen collection before antimicrobial therapy. The sensitivity of specimens obtained by bronchoscopy is essentially the same as that for sputum, and bronchoalveolar lavage gives higher yields than bronchial wash specimens. Blood culture results may be positive in up to 20% of cases.

Test	Sensitivity, %	Specificity, %
Culture		
Sputum	75	100
Transtracheal aspirate	90	100
Bronchial washings	75	100
Blood	20	100
Serology (IgG and IgM, acute and convalescent)	30–40	96
Direct fluorescent antibody	40–80	99
Urinary antigen	75–90	100
DNA probe	50–65	99

TABLE 7. *Specialized laboratory tests for the diagnosis of legionellosis*

No test is generally available to detect *Legionella* antigens in sputum, but a test to detect antigen in the urine is commercially available. Advantages include its sensitivity (75%–90%), specificity (99%), and relatively low cost, and the fact that test positivity persists for days, even during antibiotic therapy. The drawback is that only serogroup 1 of *L. pneumophila* is detected. This shortcoming is relatively minor, as this serogroup causes at least 70% of *L. pneumophila* infections.

Antibody estimation is probably the most widely used diagnostic tool. Maximal sensitivity requires both IgM and IgG determinations. Fourfold seroconversion is the definitive criterion, but this may take up to 9 weeks to be detected. In the first week of disease, 25%–40% of patients may have elevated titers.

Immunofluorescence microscopy, more commonly referred to as direct fluorescent antibody (DFA) testing, is an excellent method for detecting *Legionella* species in laboratory tract specimens. The DFA test is more likely to show positive results when multilobar infiltrates are present on chest films. Cross-reactivity with other gram-negative bacilli can give false-positive results.

The DNA probe methods are about as accurate as DFA testing. The DNA probe test may be preferable in high-volume laboratories, as interpretation requires less technical expertise. The polymerase chain reaction has been used experimentally to detect *L. pneumophila* DNA in clinical specimens, but its role is yet to be defined.

Therapy

There are three methods to determine the susceptibility of *Legionella* species to antimicrobial agents: extracellular testing, intracellular testing, and treatment studies of *Legionella*-infected guinea pigs. All three methods have been used to evaluate promising antimicrobial agents, as no controlled trials of treatment for Legionnaires' disease have been performed.

Erythromycin has historically been considered the treatment of choice based on retrospective analysis of outcomes of Legionnaires' disease. The Philadelphia epidemic fatality rates were twofold lower in erythromycin-treated patients than in those who were not treated with erythromycin. Doses of 2 to 4 g/d are advocated, preferably administered intravenously initially. Both clarithromycin and azithromycin are more active in vitro than erythromycin and have been successfully used in the treatment of Legionnaires' disease. They represent attractive agents for the oral treatment of legionellosis. Therapy should be continued for 3 weeks.

Rifampin is active against both intracellular and extracellular *Legionella* organisms. The use of rifampin as sole therapy for Legionnaires' disease has not been reported, and legionellosis has developed in individuals receiving rifampin for tuberculosis. Rifampin may have a synergistic effect when administered with erythromycin, but this benefit may be limited to the initial 3 to 5 days of treatment. Rifampin in doses of 600 mg twice daily should be considered for individuals with more serious disease.

Tetracycline was equivalent to erythromycin in lowering the case fatality rate in the Philadelphia outbreak. Doxycycline and minocycline appear to be more active in vitro than tetracycline, and they would be reasonable alternative agents for patients who cannot tolerate macrolides.

Increasing evidence now exists that fluoroquinolone antimicrobial agentss (ciprofloxacin, pefloxacin, ofloxacin) are superior in activity to erythromycin, and they have been successfully used for the treatment of Legionnaires' disease. There are no clinical data to demonstrate that combining a fluoroquinolone with either rifampin or erythromycin is more effective than the fluoroquinolone alone. Fluoroquinolones have no adverse effect on cyclosporine metabolism and should be considered the drug of choice for immunocompromised patients taking that agent.

Mycoplasma (Primary Atypical) Pneumonia

Micro-organismterm

The term *atypical pneumonia* was first used in 1938 to describe an unusual form of “tracheobronchopneumonia and severe symptoms.” The organism was first isolated in 1944 by Eaton, Meiklejohn, and von Herick from the sputum of patients who had cold agglutinin-positive, atypical pneumonia. Thereafter, the organism was called *Eaton's agent* until 1961, when Chanock identified it as belonging to the genus *Mycoplasma.*

The organisms contain both RNA and DNA, lack a cell wall, and can be identified by direct isolation on highly enriched artificial media. *Mycoplasma pneumoniae* has distinctive properties among human mycoplasmas in that it ferments glucose and causes b-hemolysis of guinea pig red cells, but the final identification is still by serology or specific growth-inhibition tests.

Clinical Manifestations

M. pneumoniae accounts for 2%–15% of all communityacquired pneumonias, but up to 30% of the pneumonias in adolescents and adults younger than 30. Mycoplasmas are of relatively low virulence; pneumonia develops in only 5%–15% of exposed persons.

The onset of the illness may be either insidious or acute. More than 80% of patients have cough and a temperature above 101°F. A persistent, racking, usually nonproductive cough is the hallmark of the disease; before fluorescent antibody techniques were developed, many observers stated that this cough was a uniform finding. More recent evidence, however, suggests that at least 10% of patients with pneumonia and elevated titers of specific antibody do not experience cough. The majority of patients notice pounding headache, usually frontal or generalized, that may be so severe as to be the dominant symptom. Myalgia is common, and coryza,

sore throat, and shaking chills all occur in approximately 25% of patients. Although chest discomfort is reported frequently, frank pleuritic pain occurs in 5% of patients. The pain usually is retrosternal and may be quite severe.

On physical examination, the patient usually appears moderately ill and frequently complains of either cough or headache, the latter markedly accentuated during periods of coughing. The heart rate often appears slow in relation to the degree of pyrexia. The frequent paroxysms of nonproductive cough may at times make the patient virtually incapable of carrying on a prolonged conversation. In patients with extensive pulmonary involvement, moderate or even marked cyanosis may be observed. A clue to the pulmonary diagnosis may be obtained by finding an inflamed tympanic membrane on otologic examination. Bullous myringitis, a frequently emphasized feature of this disease, actually occurs in 5% of patients. Examination of the lungs characteristically reveals fine to medium rales heard early or at the very end of the inspiratory cycle. Early in the course of the disease, physical examination of the lungs may reveal normal findings despite considerable infiltration shown roentgenographically. This discrepancy is notable, especially in the upper lobes, whereas in the lower lobes, which are more commonly involved, physical examination usually shows some abnormality and may give more evidence of pulmonary disease than the roentgenogram. As the disease progresses, dullness to percussion is observed, and the number and intensity of the rales increase so that rales, rhonchi, and wheezes of either a coarse or musical nature are readily detected. Evidence of frank consolidation, pleural friction rubs, and pleural effusion are less frequently found.

Roentgenographic and Laboratory Studies

Roentgenographic study of the chest shows nodular, patchy, or perihilar infiltrates that cannot be distinguished from those of various types of viral pneumonia and on occasion may simulate bacterial lobar pneumonia (Fig. 9). Rarely, *M. pneumoniae* infection has been associated with parenchymal lung abscesses. One or two lobes are involved in the majority of patients, but occasionally pneumonia may occur in four or five lobes. Hilar adenopathy can be found in up to 22% of cases. Roentgenographic findings suggest pleural fluid in <5% of patients. Because stained smears of the sputum show a marked predominance of mononuclear cells, the presence of large numbers of polymorphonuclear leukocytes should suggest another etiology for the pneumonia. However, in a small percentage of cases, the cellular response in the sputum is predominantly polymorphonuclear. During the first week of the disease, the blood leukocyte count is usually <12,000, but in approximately 10% of patients, the count is as high as 20,000/mm^3. During the second to third week of the disease, mild to moderate leukocytosis is common, and on occasion profound leukocytosis has been reported.

FIG. 9. *Mycoplasma* pneumonia in a 23-year-old man who seemed normal on physical examination.

Cold agglutinins appear in the blood 1 to 4 weeks after the onset of illness. Maximum titers are found in the second to sixth week of disease and may persist for several months. Cold hemagglutinins are helpful in the diagnosis of *Mycoplasma* pneumonia but are not diagnostic. Cold agglutinins do not develop at any time during the course of illness in 15%–30% of the patients who have pneumonia and a rising titer of antibody specific for *M. pneumoniae.* Furthermore, a considerable number of patients who have positive results on cold hemagglutinin tests do not show a rise in *M. pneumoniae*-specific antibody, the percentage ranging from 15%–65% in different series. Many other pulmonary and extrapulmonary diseases may produce elevation in the cold agglutinin titers; these diseases include influenza, rubella, cirrhosis, lymphatic leukemia, trypanosomiasis, leishmaniasis, relapsing fever, acute hemolytic anemia, pernicious anemia, paroxysmal cold hemoglobinuria, infectious mononucleosis, and psittacosis. In addition, a small number of patients have persistently high titers for unknown reasons. It has also been shown that certain individuals chronically have low cold agglutinin titers, which may rise to diagnostic levels with virtually any acute infection. Significant titers are at least 1:80, and it is not unusual to see levels of 1:1000 or more. Antibody to streptococcus MG also appears in the blood of 40%–60% of patients with *Mycoplasma* pneumonia. However, both cold agglutinins and streptococcus MG titers are negative in at least 20% of patients with pneumonia caused by *M. pneumoniae.*

Specific serologic tests include growth inhibition, ELISA, radioprecipitation, and complement fixation; a fourfold rise in complement-fixing titers is used most often for establishing a firm diagnosis.

Complications

The major complications of *Mycoplasma* pneumonia are related to the central nervous system and to the effects of cold agglutinins. On the third to thirtieth day of illness, manifestations of nervous system involvement develop in a small number of patients, including papilledema, disorientation, coma, neck stiffness, abnormal reflexes, and transverse myelitis. Lumbar puncture specimens may be entirely normal or may show elevation of the protein to as much as 300 mg/dL and pleocytosis to a maximum of several hundred cells. These may be predominantly polymorphonuclear leukocytes or, more commonly, predominantly mononuclear cells. Central nervous system involvement may be serious. Either meningitis or encephalitis may predominate clinically and result in death or be associated with permanent neurologic residua. Postmortem examination has shown focal hemorrhages, perivascular mononuclear infiltration, and less frequently glial proliferation. Nervous system involvement by *Mycoplasma* also may be expressed as cerebellar ataxia, peripheral neuropathy, or Guillain-Barré syndrome. Cold hemagglutinins in low titer represent no danger to the patient. On the other hand, when titers exceed 1:512, cold hemagglutinemia is potentially dangerous. Peripheral thrombophlebitis, which develops in some patients, may be associated with secondary pulmonary embolism. High-titer cold hemagglutinemia also may be associated with acute hemolysis related either to increased mechanical fragility of antibody-coated cells or to the simultaneous presence of a cold hemolysin. If intravascular hemolysis is rapid, hemoglobinuria may be observed. Occasionally, the use of ice packs, cold oxygen tents, or the administration of cold blood has been associated with arterial occlusion and gangrene, presumably related to intravascular thrombosis induced by cold agglutinins. Dermatologic manifestations usually consist of an erythematous maculopapular or vesicular rash, but the Stevens-Johnson syndrome may occur. Cardiac involvement is infrequent, but myocarditis, pericarditis, and complete heart block have been reported.

Course and Treatment

The course of *M. pneumoniae* pneumonia is variable, although recovery is the rule. Fever may last from 2 days to 2 weeks; it usually subsides by lysis. The cough does not usually subside until at least several days after the fever has disappeared. Malaise, cough, and radiographic abnormalities frequently persist for 2 to 6 weeks. Secondary bacterial infection occurs infrequently in patients with *Mycoplasma* pneumonia. Uncomplicated disease is not fatal in patients who have an inflammatory process in one or two lobes, but it is not generally appreciated that more extensive pulmonary involvement can be associated with some mortality.

In addition to careful supportive therapy, current evidence strongly favors the administration of tetracyclines or macrolides. These antibiotics inhibit the etiologic agent in tissue culture, and well-controlled studies have now demonstrated prompt clinical improvement, defervescence, and more rapid resolution of roentgenographic infiltrates after treatment with one of these drugs. Even after clinical improvement, *M. pneumoniae* may be found in throat cultures for a considerable period.

Chlamydia Infections

Chlamydia pneumoniae *Pneumonia*

C. pneumoniae has only recently been recognized as a pulmonary pathogen. This organism was initially referred to as the TWAR agent, after the laboratory designation of the first two isolates: TW-183 and AR-39.

Serologic studies have demonstrated that *C. pneumoniae* is the most common chlamydial species infecting humans. The prevalence of antibody to *C. pneumoniae* starts to rise in residents of industrialized countries at school age and steadily increases throughout life. Longitudinal studies suggest that only about 10% of infections lead to overt pneumonia. It is estimated that the organism accounts for 2%–10% of community-acquired pneumonias, depending on age and geographic locale.

Micro-organism

C. pneumoniae is an obligate intracellular bacterium having 10% genetic homology with the other *Chlamydia* species. Details of the pathogenesis of *C. pneumoniae* pneumonia are unknown. The agent multiplies in human alveolar macrophages, smooth-muscle cells, and endothelial cells and rapidly induces ciliostasis. Infection with *C. pneumoniae* leads to partial immunity, as reinfections generally do not take the form of pneumonia. When the reinfecting strain, however, is sufficiently different to escape immunologic defense mechanisms, the outcome can be more severe than the illness observed in primary infection. Little is known about the cellular immune response. An IgM response to protein antigens is seen in primary infections but is usually lacking in reinfections. There is also a marked IgA response in reinfections.

Clinical Manifestations

Clinical features of pneumonia attributable to *C. pneumoniae* are similar to those caused by *M. pneumoniae*. The illness is generally mild, but the course may be protracted, with symptoms persisting for 3 to 6 weeks. Severe pharyngitis, hoarseness, and upper respiratory tract symptoms are present in 40%–70% of patients. Fever and cough are common. A biphasic illness is frequently seen; patients seek medical attention with pharyngitis, recover, and then pneumonia develops 1 to 3 weeks later. Rales are almost always present on auscultation. Sputum production is scant and not purulent. In some series, up to 20% of individuals with chlamydial pneumonia are coinfected with other pathogens, such as influenza virus or *S. pneumoniae*. The peripheral blood leukocyte count and differential counts are usually normal, although an elevated erythrocyte sedimentation rate is found in 80% of cases. There are no characteristic radiologic findings. Single, subsegmental alveolar opacities appear frequently, although interstitial infiltrates may be more common in reinfections. Lobar consolidation, hilar adenopathy, and pleural effusion are uncommon.

Diagnosis

Definitive diagnosis requires isolation of *C. pneumoniae* or demonstration of an appropriate antibody response. Cultivation of the organism is difficult, and sensitivity of culture is only 50% in serologically verified cases. Direct antigen detection or fluorescent antibody staining of respiratory tract samples is insensitive. The two primary serologic tests for *C. pneumoniae* are complement fixation and micro-immunofluorescence. Complement fixation is genus-specific and measures antibody against all three *Chlamydia* species (*psittaci, pneumoniae, trachomatis*). The complement fixation test, however, may be useful only in primary infection, as results remains negative in 90% of reinfections. On the other hand, micro-immunofluorescence is specific for *C. pneumoniae* and can distinguish between IgM and IgG antibody. Circulating antibody may not be detectable, however, for 3 to 6 weeks. Criteria for diagnosis using micro-immunofluorescence have been established: a fourfold rise in antibody response, IgM titer ^{3}1:16, or IgG titer ^{3}1:512.

Complications

C. pneumoniae rarely causes life-threatening pneumonia, and most patients do not require hospitalization. Chronic *C. pneumoniae* infection of the lungs has been associated with chronic bronchitis, asthma, and sarcoidosis. Extrapulmonary manifestations include reactive arthritis and erythema nodosum. Dissemination via the bloodstream may explain the recent association of the organism with coronary artery disease and atherosclerotic lesions.

Treatment

Although no clinical studies of efficacy have been performed, tetracyclines, erythromycin, and fluoroquinolones have shown excellent in vitro activity. Tetracycline appears to be the drug of choice, at a dose of 2 g/d. Treatment should be administered for 2 to 3 weeks.

Ornithosis (Psittacosis)

Pathogenesis

Ornithosis is an acute pulmonary infection caused by *Chlamydia psittaci*. These obligate intracellular parasites are larger and more complex organisms than viruses, contain both DNA and RNA, have a cell wall similar in composition to that of some gram-negative organisms, and are stained by Giemsa but not by Gram's stain. Ornithosis is acquired by contact with both psittacine and nonpsittacine birds, including parrots, parakeets, lorikeets, cockatoos, chickens, pigeons, ducks, pheasants, and turkeys. Although the birds are sometimes sick, the disease is frequently acquired from animals that appear to be well. Infection follows inhalation of dried excreta and occurs most often in persons who care for the birds; it is uncommon in persons who visit people with psittacine birds but have no intimate contact with the birds. At least 25% of cases occur without a history of bird contact, and in a small number of cases, human-to-human spread of the disease has occurred.

Clinical Manifestations

After an incubation period, which is usually 7 to 15 days but may occasionally be considerably longer, the patient becomes acutely ill with a mild to moderate cough productive of small amounts of sputum, occasionally blood-streaked. Fever and myalgia are common, and approximately a third of patients experience shaking chills. Pleuritic chest pain occurs relatively infrequently. Hemoptysis also has been described.

The findings on physical examination are extremely variable. In severe cases, consolidation involving several lobes may be accompanied by a pleural friction rub, or examination may show only diffuse, moderate to coarse inspiratory and expiratory rales. In less severe cases, one or two lobes are involved and there are inspiratory rales but no frank consolidation. In some patients with pulmonary involvement, no abnormalities can be detected on physical examination. A few patients have moderate pleural effusion. Not infrequently, the heart rate is slower than expected in a patient with marked elevation in temperature. Splenomegaly is present in 10%–30% of patients. Severe lymphadenopathy, intense pharyngitis, pericardial friction rub, jaundice, evidence of meningoencephalitis, or any combination of these is found occasionally.

Roentgenographic and Laboratory Findings

The variable findings detected on physical examination are reflected in roentgenographic abnormalities. Focal areas of consolidation are seen in 10%–20% of cases. In others, there are small peribronchial or peripheral infiltrates or diffuse, bilateral, confluent pneumonia that is indistinguishable from overwhelming influenza virus pneumonia. Rarely, cavitation may be seen in areas of pneumonia. Mediastinal lymphadenopathy also has been described.

Examination of stained sputum smears usually shows few polymorphonuclear leukocytes, and there is rarely evidence on smear or in culture of secondary bacterial infection. The blood leukocyte count is commonly normal but may be elevated or low. Occasionally, serum titers of cold hemagglutinins rise during the course of ornithosis. The organism can readily be isolated from the sputum or the lungs, and frequently from other tissues at postmortem examination using tissue culture cells or embryonated chicken eggs. Complement-fixing antibodies appear in the serum in the second to fourth week of the disease, but their appearance may be delayed until the fourth to sixth week when patients are treated with antibiotics.

Complications

Complications arising from contiguous or hematogenous spread are reported with increasing frequency; these include pericarditis, myocarditis, hepatitis, meningitis, and encephalitis. If the central nervous system is affected, delirium, stupor, severe headache, and lymphocytic meningitis may be noted, but seizures are extremely uncommon. Hepatic involvement varies from mild to lethal and is characterized by striking hepatocellular abnormalities on liver function studies. Peripheral thrombophlebitis is a not infrequent complication and may cause death by pulmonary embolism.

The mortality associated with ornithosis is currently 2%–10%, with most of the patients dying of respiratory involvement, including the respiratory distress syndrome. In patients who die of ornithosis, the bronchial mucosa is ulcerated.

Treatment

The tetracyclines are the antibiotics of choice and are usually effective in modifying the course of the disease when given in a dosage of 1 to 2 g/d for 10 to 14 days. Chloramphenicol is an equally effective agent, and erythromycin also may be useful. The patient should be placed in strict isolation in view of the well-documented cases of human-to-human spread.

Other* Chlamydia *Infections

Chlamydia trachomatis usually causes conjunctivitis, trachoma, and urethritis. It also can cause interstitial pneumonia in infants. The infection, which usually appears in infants 2 weeks to 3 months old, is characterized by staccato cough, tachypnea, and variable degrees of cyanosis. There is little or no fever. Roentgenograms show alveolar and interstitial infiltrates. The course of the cases is generally protracted, lasting from several weeks to many months. Arterial oxygen saturations are often markedly reduced. The diagnosis is usually made by isolation of the organism from tracheal aspirations and by serologic tests. Genus-specific complement fixation and immunofluorescent antibody tests using lymphogranuloma venereum antigens are available, and there are now specific immunofluorescent antibody tests for *C. trachomatis*. Eosinophilia occurs frequently. In some instances, prolonged erythromycin therapy has appeared to be beneficial, but similar improvement has occurred with supportive therapy alone. If *C. trachomatis* infection is acquired in utero, lethal pneumonia can result. *C. trachomatis* also can cause pneumonia in adults, in both compromised and noncompromised persons, usually characterized by patchy infiltrates without frank consolidations. Mediastinal and supraclavicular lymphadenitis also has been described.

VIRAL RESPIRATORY TRACT INFECTIONS

Viruses may account for 5%–15% of community-acquired pneumonias. Viral respiratory illnesses are caused by >200 serologically distinct viruses, and the clinical manifestations of these illnesses, including rhinitis, tracheobronchitis, bronchiolitis, and pneumonia, are dictated by the principal sites of anatomic involvement. In contrast to bacterial respiratory tract infections, viral infections are transmitted primarily via aerosols or hand-to-hand contact. Although most patients have self-limited symptoms and do not require any specific treatment, some patients, particularly after an influenza illness, have serious secondary bacterial infections.

Influenza

Influenza was undoubtedly known to antiquity. In 1580 and 1782, ravaging epidemics occurred, but the damage therefrom was insignificant in comparison with that observed in the terrifying pandemic of 1918–1919, which struck in three waves, attacked an estimated 20 million persons, and killed 850,000 in the United States alone. Throughout the world, the number of deaths was estimated at 20 million. There is no better or more concise description of the illness produced by influenza viruses than that recorded by Short in 1580:

> “It began with a roughness of the jaws, small cough, then a strong fever with a pain of the head, back, and legs. Some felt as though they were corded over the breast and had a weight at the stomach, all of which continued to the third day at farthest; then the fever went off with a sweat or bleeding at the nose. In some few, it turned to a pleurisy or fatal peripneumony.”

Before 1950, it was never clear whether the pulmonary infection was related to the virus itself or to secondary bacterial invasion. This uncertainty was in large part caused by the absence of a defined etiologic agent, as influenza virus was not recovered from humans until 1933. The first opportunity for accurate assessment of the relative roles of the virus and bacteria in pulmonary complications came during the pandemics of 1957–1958 and 1968–1969. It is now clear that the following pulmonary syndromes may arise in patients infected with an influenza virus.

Lower Respiratory Tract Involvement Without Roentgenographic Evidence of Pneumonia

Within 48 hours after the onset of typical influenza, characterized by fever, dry cough, headache, myalgia, and prostration, the patient notes increased cough, which is at times productive of greenish or blood-tinged sputum. In some patients, this is associated with dyspnea and/or pleuritic chest pain of mild to moderate severity. Physical examination of the lungs reveals unilateral or bilateral inspiratory rales, which may be accompanied by diminished or harsh breath sounds. Occasionally, end-inspiratory wheezes and rales suggest bronchiolitis, and rarely a pleural friction rub can be detected. There is no evidence of consolidation, and roentgenographic findings either appear normal or show accentuation of bronchial markings in the lower lung fields. No evidence of concomitant bacterial infection is obtained. This benign complication of influenza is of importance only in that the patient should be observed closely for development of the more serious pulmonary syndromes detailed below, as well as, rarely, marked stridor resulting from virus-induced laryngitis.

The administration of antibiotics to patients having influenza with no evidence of lower respiratory tract involvement or to those with rales but no evidence of pneumonia is not of benefit and encourages colonization with antibiotic-resistant micro-organisms. These resistant organisms may subsequently be responsible for secondary bacterial pneumonia.

Secondary Bacterial Pneumonia

Secondary bacterial pneumonia is the most common pulmonary complication of influenza. This is not surprising, as the influenza virus damages cilia, delays leukocyte mobilization, promotes adherence of certain bacteria, and interferes with bacterial killing by polymorphonuclear phagocytes. In the majority of patients, the diagnosis can be established by history alone. The patient experiences typical influenza followed by a definite period of improvement. Indeed, such persons may feel well enough to return to their usual occupation. Then, 3 to 14 days after the initial influenza symptoms, the patient's condition worsens precipitously: Recurrence of fever is usually accompanied by shaking chills, pleuritic chest pain, and cough productive of bloody or purulent sputum. In approximately a third of the cases of secondary bacterial pneumonia there is no diphasic course, and pulmonary symptoms blend with the initial influenza.

Physical examination reveals focal involvement of the lung, often with the classic signs of consolidation, and physical findings are confirmed by roentgenogram. Gram's stains of sputum smears show many bacteria and polymorphonuclear leukocytes. Large numbers of bacterial pathogens, most frequently pneumococci, are recovered from cultures. Staphylococci, a rare cause of bacterial pneumonia in healthy adults, are also frequently isolated and are responsible for 15%–30% of bacterial pneumonias in patients who have pre-existing influenza. *Haemophilus influenzae* and *Streptococcus pyogenes* are the responsible micro-organisms in a small number of patients, as are *Escherichia coli*; strains of *Enterobacter, Serratia*, and *Klebsiella*; anaerobic cocci; and species of *Bacteroides*. In these individuals, there is no evidence of serious viral invasion of the lung, and the course and prognosis of this type of pneumonia are related completely to the nature and severity of the bacterial infection.

Primary Viral Pneumonia

A significant number of the deaths related to influenza can be ascribed not to concomitant bacterial infection, but rather to viral invasion of and multiplication within the lungs. These patients have a readily recognized clinical illness. Most have underlying cardiopulmonary disease or are pregnant. The initial symptoms are those of typical influenza, but within 12 to 36 hours the patient notes increasing dyspnea, usually accompanied by a cough productive of scant amounts of bloody sputum. On rare occasions, massive hemoptysis has been noted. Pleural pain is uncommon. At the time of hospitalization, respiratory distress is profound and is accompanied by striking tachypnea, tachycardia, and cyanosis. Abnormalities found on physical examination of the lungs vary with the stage of the disease process. Early in the course of the illness, inspiratory rales and occasional wheezes are heard primarily in the lower lung fields, but as the disease progresses, these findings spread to the entire chest. Evidence of consolidation is uncommonly found, and breath sounds are heard relatively well in the early phases of the infection. Thereafter, as dyspnea and cyanosis increase, breath sounds are suppressed throughout. When the pneumonia reaches its terminal phases, unbearable air hunger is the predominant symptom. Diffuse inspiratory rales, marked expiratory wheezes, and progressive prolongation of the expiratory phase of respiration are observed. The dyspnea and air hunger are frequently so intense and agitation so marked that patients cannot tolerate masks.

Laboratory studies reveal leukocytosis in the majority of patients. The cell count may be as high as 20,000/mm 3, with an increase in the number of polymorphonuclear leukocytes and band forms. Despite the increase in the number of polymorphonuclear cells in the peripheral blood, the sputum shows only a relatively small number, the majority of cells being mononuclear. This relationship in itself serves to distinguish this syndrome from the bacterial complications of influenza. Chest roentgenograms show extensive bilateral infiltrates that radiate from the hilum and simulate the findings in pulmonary edema of cardiac origin (Fig. 10). Occasionally, small pleural or interlobar effusions may be observed.

FIG. 10. Primary influenza virus pneumonia in a 49-year-old man with mitral stenosis. Infiltrates radiating from the hilum simulate the findings in cardiogenic pulmonary edema. (Reproduced with copyright permission of The American Society for Clinical Investigation from Louria DB, et al. Studies on influenza in the pandemic of 1957–1958: II. Pulmonary complications of influenza. *J Clin Invest* 1959;38:213.)

During the pandemic of 1957–1958, the mortality from primary influenza virus pneumonia approached 80%; it was also high in the pandemic of 1968–1969. At postmortem examination, there was evidence of tracheitis, bronchitis, and bronchiolitis, with loss of normal ciliated epithelial cells. The alveolar spaces were frequently filled with edematous fluid, and both mononuclear and neutrophilic infiltrates were found, often accompanied by intra-alveolar hemorrhage. A characteristic finding was the presence of an acellular hyaline membrane lining the alveoli. The virus was readily isolated from these lungs, usually in high titer. There usually was no evidence of congestive heart failure or concomitant bacterial infection.

There is no effective treatment for influenza virus pneumonia. There have been no controlled studies of amantadine treatment, so its use in this setting is based on anecdotal reports of a beneficial effect on peripheral airway resistance in uncomplicated influenza. There is currently no evidence that adrenal glucocorticoids are beneficial. Influenza virus pneumonia can be complicated by renal failure and disseminated intravascular coagulation.

In some cases, the pulmonary disease process produced by influenza viruses has been far milder than that observed during pandemics. Focal pneumonitis and lobular or even lobar consolidation have evidently been caused by the viral infection alone. Consequently, influenza virus infection should be considered in the differential diagnosis of any nonbacterial pneumonia.

Concomitant Influenza Virus and Bacterial Pneumonia

In the disease of combined etiology, there may be an interval as long as 4 days between the initial symptoms of influenza and evidence of pulmonary involvement; during this period, considerable improvement may be noted. In many patients, however, the pulmonary disease blends with the original influenza. Cough productive of bloody or purulent sputum, shaking chills, and pleuritic chest pain are reported in most cases. At the time of admission to the hospital, respiratory distress is usually severe, and most patients are cyanotic. Physical examination of the lungs reveals variable findings. The majority of patients have signs of local consolidation involving one or more lobes, and most of these in addition have manifestations of more extensive disease, evidenced by diffuse inspiratory rales and inspiratory or expiratory wheezes. In a minority of individuals, diffuse inspiratory rales or wheezes are present without evidence of focal consolidation. Roentgenograms show diffuse infiltrates similar to those observed in patients with primary influenza virus pneumonia, or a combination of diffuse infiltrates and areas of focal consolidation may be found.

Blood leukocyte counts vary from <1000 to 30,000/mm 3. If the leukocyte count is normal or elevated, adult and immature polymorphonuclear leukocytes predominate, whereas leukopenia is characteristically accompanied by granulocytopenia. Stained smears of the sputum show a large number of polymorphonuclear leukocytes even in patients who have profound peripheral leukopenia; in addition, myriad bacteria are observed.

In contrast to patients with secondary bacterial pneumonia, in whom the pathogen is usually the pneumococcus, approximately half the patients with combined viral and bacterial pneumonia are infected with S. aureus (Fig. 11). This frequency makes it mandatory that initial treatment be directed against the staphylococcus in patients in whom clinical evidence of influenza is followed by pneumonia that, on the basis of physical examination, roentgenograms, and Gram's stains of the sputum, is suggestive of combined viral and bacterial infection. Even with immediate and appropriate antibiotic therapy, the mortality approximates 50%. The combination of mixed influenza virus and bacterial pneumonia and leukopenia usually indicates staphylococcal infection, and a majority of these patients die. At postmortem examination, both pathogenic bacteria and influenza virus can be cultivated from the lungs. The diagnosis of staphylococcal infection in these patients is so likely, the mortality so high, and the time between initial pulmonary symptoms and death so short that antistaphylococcal therapy should be instituted immediately with antibiotics effective against penicillin-resistant staphylococci, such as nafcillin, oxacillin, or a cephalosporin; in communities where methicillin-resistant strains are common, it would be safer to start treatment with vancomycin.

FIG. 11. Chest roentgenogram of a 21-year-old woman with combined staphylococcal and influenza virus pneumonia. (Reproduced with copyright permission of The American Society for Clinical Investigation from Louria DB, et al. Studies on influenza in the pandemic of 1957–1958: II. Pulmonary complications of influenza. *J Clin Invest* 1959;38:213.)

Several studies have produced additional information on three aspects of influenza infection. First, it has been demonstrated that viremia does occur in influenza, although the data currently available suggest it is infrequent. The virus has been isolated from visceral organs, including the spleen and liver, and has been recovered from the brain. Second, interesting epidemiologic evidence from Great Britain suggests that patients in whom staphylococcal complications of viral influenza develop either have active staphylococcal disease themselves (usually furunculosis) or have close contact with others having active staphylococcal lesions. Third, influenza viruses may cause hospital epidemics in which typical manifestations of influenza occur or in which the disease is manifested primarily by lung involvement in patients compromised by a variety of underlying diseases.

Interferon, arising from virus-exposed cells, appears in the lungs of experimental animals before specific antibody can be detected, but its role in recovery from human influenza is unclear. Amantadine hydrochloride prevents the entry of adsorbed influenza A virus into cells. It is useful prophylactically; it can prevent the clinical manifestations of influenza in about 70% of a population exposed to influenza type A viruses. In patients with influenza A and mild pulmonary involvement, amantadine may result in more rapid return of pulmonary function to normal, but this in itself probably does not justify the use of the drug in such cases. To be effective, amantadine must be given within 48 hours after the onset of clinical illness. Amantadine may be helpful in aborting influenza epidemics within hospitals.

Influenza can be prevented in most cases by immunization with appropriate vaccines. These must be changed constantly to include antigens from newly discovered strains of epidemiologic importance. During periods in which influenza is prevalent, older persons and those with underlying cardiopulmonary disease should be immunized. One problem of growing concern is that the major target group for immunization comprises persons <60 to 65 years old, but this group may show suboptimal antibody response to standard influenza immunization schedules.

Varicella

Epidemiology

Varicella is complicated by pulmonary involvement in the newborn, in approximately 10% of normal adults, in both children and adults who acquire the disease during therapy with adrenal glucocorticoids for another illness, in patients suffering from hematologic malignancy, and in pregnant women. The pulmonary manifestations may be overwhelming. The mortality in adults who are hospitalized ranges from 10%–24%, and in children receiving steroids and in neonates it is even higher. Death in children is often associated with secondary bacterial infection of the lung, especially staphylococcal infection, whereas in adults secondary bacterial infection is unusual and death occurs because of severe hypoxia secondary to the extensive viral pneumonitis. Figure 12 shows the roentgenogram of a 36-year-old woman who died 48 hours after hospitalization despite intensive respiratory care.

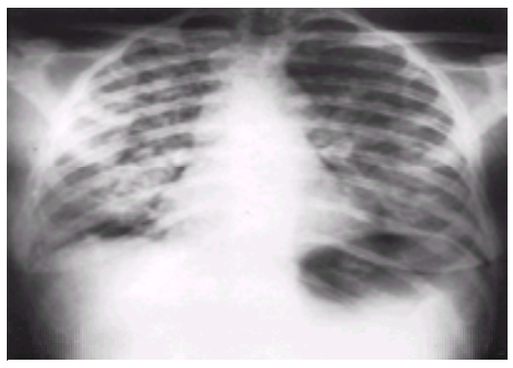

FIG. 12. Fatal varicella pneumonia in a 36-year-old woman. Note the coalescing nodular infiltrates.

Pulmonary involvement is characteristically found 2 to 5 days after onset of the rash. Three types may be distinguished clinically: (1) mild or subclinical disease characterized only by cough; (2) moderate to very severe pneumonia with marked cough and dyspnea, which is usually accompanied by both cyanosis and hemoptysis; and (3) overwhelming and fatal disease with profound cyanosis and shortness of breath. The only findings on physical examination in the patients with milder disease are fine rales and some roughening of the breath sounds. In more severely ill patients, rhonchi, inspiratory and expiratory wheezes, and striking suppression of breath sounds may be detected. In each of the three types, roentgenograms of the chest show diffuse bilateral nodular infiltrates, which in the patients with more severe disease may be coalescent. A small number of patients have pleuritic chest pain, which may be associated with pleural effusions that are occasionally massive. Roentgenographic infiltrates may clear rapidly, but not infrequently they resolve slowly, sometimes persisting for 2 to 4 weeks or longer. Late calcification may occur, and diffusion defects may be demonstrated for a prolonged period following clinical improvement. Examination of sputum smears shows predominantly mononuclear cells and giant cells; characteristic type A intranuclear inclusion bodies can sometimes be seen with Giemsa stain. The blood leukocyte count varies from normal to moderately elevated, usually with a predominance of polymorphonuclear leukocytes. Postmortem examination reveals hemorrhagic, edematous lungs with an interstitial mononuclear infiltrate, alveolar hemorrhage, and sometimes hyaline membranes lining the alveoli. There also may be hemorrhagic pleural blebs and, in the liver, spleen, and occasionally the kidneys, focal necrosis and hemorrhage.

Treatment

Acyclovir given intravenously appears to be effective therapy for varicella pneumonia. Reports documenting the safety and efficacy of acyclovir for varicella pneumonia complicating pregnancy have also appeared. Famciclovir would be a reasonable oral alternative to acyclovir, but its safety in pregnancy has not been established (category B). For individuals intolerant of acyclovir or suspected of having acyclovir resistance, intravenous foscarnet may be used. The safety of foscarnet in pregnancy has not been established (category C). Although varicella pneumonia may be excessively severe in patients receiving adrenal glucocorticoids, these drugs are advocated by many in the treatment of overwhelming pulmonary varicella infection. There are no adequate data to indicate whether such treatment is beneficial. Secondary bacterial infection should be suggested by the sudden appearance in the sputum of large numbers of polymorphonuclear leukocytes. Not only have prophylactic antimicrobial agents failed to prevent the secondary bacterial complications, but there is reason to believe that the bacterial invaders in patients receiving antimicrobial agents prophylactically are more likely to be antibiotic-resistant staphylococci and gram-negative organisms, which are currently considerably more difficult to treat. Antibiotics should therefore be withheld until there is evidence of bacterial superinfection. Patients with varicella pneumonia should be maintained in strict isolation, and special care should be taken to keep them separated from patients who are receiving adrenal steroids or who have hematologic malignancies.

Rubeola (Measles)

Rubeola is associated with three types of pulmonary complications. First, especially if the patient is very young or very old, the virus itself may produce interstitial pneumonia in the absence of bacterial infection. This type of pneumonia is acute and occurs concomitantly while, before, or more often shortly after the rash has reached its peak. Cough and dyspnea are found frequently, but only small amounts of sputum are produced and pleuritic pain is unusual. Roentgenograms show infiltrates radiating from the hilar areas. The blood leukocyte count is characteristically normal or reduced. Although the prognosis is usually good, measles virus pneumonia continues to carry a significant mortality, approximating 5%. In children it may be followed by bronchiectasis.

Second, bacterial pneumonia may complicate rubeola, usually occurring 1 to 7 days after the onset of rash. If the patient has typical measles, improves, and then begins to exhibit pulmonary symptoms, this is virtually pathognomonic of a bacterial superinfection. The bacteria most commonly involved are *Streptococcus pneumoniae, Streptococcus pyogenes, Staphylococcus aureus,* and *Haemophilus influenzae*.

Third, when it is grown in human and monkey renal cell cultures, the measles virus produces multinucleated giant cells with characteristic inclusions. Giant-cell pneumonia apparently caused by the measles virus may follow overt measles in previously healthy children. Furthermore, in children with underlying disease, the measles virus may produce subacute or chronic, usually fatal, giant-cell pneumonia, which may occur with or without clinical evidence of typical measles preceding the pneumonia. Pathologically, giant-cell pneumonia is characterized by an interstitial mononuclear infiltrate, alveolar cell proliferation, and giant cells with intranuclear and intracytoplasmic inclusions.

No treatment other than supportive therapy is available for measles virus invasion of the pulmonary parenchyma. Treatment of secondary bacterial complications depends on the antibiotic susceptibility of the bacterial pathogen.

An additional form of pulmonary disease may occur in patients who have previously received killed measles vaccine and subsequently are given a live measles vaccine or are exposed to wild virus. Rash, lymphadenopathy, and pneumonitis may follow. The pulmonary infiltrate, which may not be accompanied by rash, may be interstitial, locular, lobar, or nodular. Nodular or interstitial infiltrates may persist for weeks or even months.

Adenovirus Infection

These viruses infect 8% of children and 1%–3% of adults annually. Adenovirus infections occur throughout the year, with a peak incidence of respiratory infections occurring in late winter to early spring. Adenoviruses are spread by intimate contact or aerosolization of infected secretions, and serotypes 3, 4, and 7 are more frequently associated with lung disease. The first isolation of adenoviruses from diseased patients occurred in a study of military recruits in 1954; these individuals had a variety of influenza-like syndromes, referred to as *acute respiratory disease*. In that report, one fifth of infected individuals required hospitalization.

Fever, headache, nasal congestion, hoarseness, and paroxysms of cough are the most common symptoms and usually last 3 to 5 days. On examination, cervical lymphadenopathy, laryngitis, and rales are common. Sputum examination may reveal either mononuclear cells or a predominance of polymorphonuclear leukocytes. The appearance of the latter does not in itself connote secondary bacterial infection, but bacterial superinfection does occur in a significant percentage of patients with adenovirus pneumonia. Although patchy or lobular infiltrates are found most frequently, there may be extensive consolidation. There are no specific drugs or therapeutic measures available for the treatment of adenovirus infections.

Hantavirus Infection

Hantaviruses are RNA viruses belonging to the family *Bunyaviridae*. Rodents are the primary reservoir for all hantaviruses and shed the virus in their saliva, urine, and feces. Humans acquire infection most often by inhalation of aerosols from rodent excreta. Person-to-person transmission does not occur. Hantaviral disease first became a public health concern in the United States in the 1950s, when soldiers serving in Korea were afflicted with an illness referred to as *Korean hemorrhagic fever* or *hemorrhagic fever with renal syndrome*. Only rarely have there been prominent pulmonary signs or symptoms. However, a new hantavirus was isolated in the southwestern United States in 1993 that caused hantavirus pulmonary syndrome. The deer mouse (*Peromyscus maniculatus*) has been determined to be the vector for this syndrome.

The mortality of hantavirus pulmonary syndrome is 10 times higher than that associated with Korean hemorrhagic fever. The syndrome is manifested by (1) a febrile illness (temperature ³101°F) occurring in a previously healthy person, characterized by unexplained adult respiratory distress syndrome or bilateral interstitial pulmonary infiltrates developing within 1 week of hospitalization with respiratory compromise requiring supplemental oxygen, or (2) an unexplained respiratory illness resulting in death in conjunction with an autopsy examination demonstrating noncardiogenic pulmonary edema without an identifiable, specific cause of death. The agent of the syndrome is the first hantavirus to cause disease in North America. Now named *sin nombre virus*, it closely resembles a Prospect Hill strain of hantavirus

that is found in voles but is not pathogenic in humans.

The diagnosis is largely based on epidemiologic circumstances and a clinical triad of interstitial infiltrates with adult respiratory distress syndrome, hemoconcentration, and marked elevation of lactate dehydrogenase. Anecdotal evidence suggests ribavirin may be beneficial.

Respiratory Syncytial Virus Infection

Perhaps the most frequently involved virus in young children is the respiratory syncytial virus. Respiratory syncytial virus infection is seasonal, occurring from November through March. The frequency with which infant pneumonia or bronchiolitis is related to this agent obviously depends on the prevalence of the virus in the environment, but current data suggest that respiratory syncytial virus is responsible for 10%–40% of lower respiratory tract disease in infants and children. During epidemics, it may account for 50% of all pediatric hospital admissions.

The virus is most likely spread by aerosol or direct contact with infected specimens, and inoculation routes include the eyes, nasopharynx, and oropharynx. Incubation lasts 2 to 8 days. Respiratory syncytial virus may cause croup, bronchiolitis, or pneumonia, and the latter is more frequent with primary infection. Respiratory syncytial virus infection among adults is usually mild, but severe disease may be seen among institutionalized persons, the elderly, and patients with underlying cardiopulmonary disease. Abnormal roentgenographic findings may include interstitial infiltrates, bronchopneumonia, and diffuse pneumonia. A specific diagnosis can be made by obtaining nasopharyngeal secretions for viral culture. In addition, respiratory syncytial virus infection can be diagnosed rapidly by antigen detection using immunofluorescence techniques or ELISA. Although aerosolized ribavirin showed promise for respiratory syncytial virus pneumonitis in children, there is no convincing evidence for its benefit. Most authorities now recommend ribavirin only for severe respiratory syncytial virus disease in immunocompromised patients, but experience is anecdotal and efficacy has been dismal.

RICKETTSIAL DISEASE

Q Fever

Q (query) fever was first described in 1937 by Derrick, who detailed an acute febrile illness involving abattoir workers in Brisbane, Australia. Subsequently, Burnet in Australia and Cox in the United States isolated the causative organism and demonstrated that it was one of the rickettsiae. In honor of these investigators, the micro-organism is called *Coxiella burnetii*. *C. burnetii* is worldwide in distribution, the most common reservoirs being sheep, goats, cattle, and ticks. The organism is frequently shed in cows' milk, and the disease may spread by consumption of raw milk, by inhalation of contaminated dust, and occasionally by tick or animal bites. Recent outbreaks have been associated with infected parturient cats. Human-to-human transmission has been reported.

Clinical Manifestations

After an incubation period that ranges from 2 to 4 weeks, clinical evidence of disease appears, usually abruptly. Fever occurs in almost all patients, is frequently of considerable degree, and in untreated cases usually persists for a period of 10 days to 3 weeks, but it may remain for as long as 3 months. It then resolves by lysis. Severe headache, marked sweats, shaking chills, and diffuse myalgia are found in the majority of patients. One third to two thirds of patients report cough that, in contradistinction to that observed in primary atypical pneumonia, is usually not severe. It is typically nonproductive, although occasionally a small amount of sputum is expectorated, infrequently blood-tinged. From 10%–40% of patients experience mild to moderate chest pain that may be pleuritic in nature. Dyspnea is noted in a minority of cases, and vomiting, confusion, and abdominal pain occur uncommonly.

Although the patient usually appears acutely ill on physical examination and is markedly febrile, the pulse is relatively slow. The abnormalities in the lungs, ordinarily consisting of unilateral or bilateral fine inspiratory rales, are often confined to the lower lobes. On occasion, dullness to percussion, evidence of frank consolidation, a pleural friction rub, and signs of pleural effusion are noted. Splenomegaly occurs in 5%–10% of cases, and hepatomegaly, cyanosis, a maculopapular rash, and stiffness of the neck with resistance to flexion may be observed in a small number of individuals.

Roentgenographic and Laboratory Findings

The leukocyte count is usually normal or slightly elevated, with a moderate increase in the number of polymorphonuclear leukocytes. Stained smears of the sputum show predominantly mononuclear cells. The radiographic picture is variable. Segmental and subsegmental pleura-based opacities are common. Multiple rounded opacities have been reported following inhalational exposures. Pleural effusions are usually small but may be present in up to one third of cases. Hilar adenopathy may occur. Time of resolution ranges from 10 to 90 days. By injection of infected material into the peritoneal cavity of guinea pigs, *C. burnetii* can be isolated from the blood, sputum, or pleural fluid during the acute phase of the illness. Specific complement-fixing and agglutinating antibodies appear in the blood during the second to third week of illness and in most cases establish the diagnosis. The Weil-Felix reaction is invariably negative.

Complications

The pulmonary lesions heal without residua, and the complications of Q fever are found in extrapulmonary sites. The hepatitis may be severe and prolonged, even fatal, with marked icterus and derangement of liver function. Arthritis, iritis, pericarditis with pericardial friction rub, myocarditis, otitis, epididymitis, esophagitis, neuropathy, and radiculitis have all been reported. Although the lumbar puncture usually yields normal results despite the severe headache, the micro-organism has been isolated from the spinal fluid, and on rare occasions spinal tap has revealed lymphocytic meningitis. A small number of cases of endocarditis caused by *C. burnetii* have been described, most of them in the United Kingdom; in 80%, the aortic valve is involved with aortic regurgitation. Perhaps the most frequent complication is thrombophlebitis, which may be accompanied by pulmonary emboli. A significant number of patients in whom well-documented Q fever develops have persistent, vague aches and pains and fail to return to their original state of health for a substantial period of time. The mechanisms underlying these prolonged and at times incapacitating features have not been established, but they are not associated with demonstrable persistence of the micro-organism.

Treatment

Q fever is rarely a fatal disease. The micro-organism is susceptible in vitro to tetracyclines and chloramphenicol, and administration of one of these antibiotics in a dosage of 2 g/d in adults is usually associated with rapid defervescence and clinical improvement. However, in some patients treated with a tetracycline or chloramphenicol, improvement may be surprisingly slow, and relapse may occur after the antibiotics have been discontinued. These relapses usually respond promptly to reinstitution of the same antimicrobial regimen.

Scrub Typhus

Scrub typhus, a rickettsial disease caused by *Rickettsia tsutsugamushi*, is endemic in Japan, Southeast Asia, the southwestern Pacific, and Australia. It is transmitted to humans by mites, and after a 4- to 10-day incubation period a primary eschar appears at the site of the mite bite. The eschar and regional adenitis are found in at least 60% of patients with scrub typhus.

There are three potentially severe complications of the disease: myocarditis, encephalitis, and pneumonitis. Lung involvement, which varies considerably in its manifestations, is said to occur in 40%–50% of patients. Cough, the most frequent pulmonary symptom, may be productive of small amounts of blood-streaked sputum. Extensive pulmonary disease may cause dyspnea and cyanosis. The pneumonia is primarily interstitial in nature, and may be either localized or diffuse. Chest radiographs usually show patchy infiltrates, but lobar consolidation may be seen.

The average mortality is approximately 5% in untreated patients. Tetracyclines are the treatment of choice.

Rocky Mountain Spotted Fever

In Rocky Mountain spotted fever, chest complaints may be the presenting manifestations. Lung involvement is at first characterized by patchy pneumonitis or pleural effusion accompanied by nonspecific symptoms, including chest pain and cough. As the disease progresses, the local vasculitis and systemic thrombocytopenia may result in lung edema and/or hemorrhage. In some cases, the respiratory distress syndrome supervenes. Additionally, Rocky Mountain spotted fever myocarditis can result in congestive heart failure. Roentgenograms vary depending on the pathophysiology: There may be focal infiltrates, dense consolidation from hemorrhage or secondary bacterial infection, or diffuse bilateral infiltrates. In some cases, the lack of a rash and the prominence of pulmonary manifestations result in a substantial delay in establishing a correct diagnosis. Occasionally, myalgias involving thoracic muscles are so severe that a diagnosis of bacterial pneumonia or pulmonary embolus is mistakenly made.

ZOONOTIC PNEUMONIAS

Bacteria associated with domestic and wild animals are often capable of producing disease in humans, and spread may occur by direct contact, inhalation or ingestion, or animal bites or insect intermediates. These zoonotic bacterial infections have few unique clinical characteristics, and the diagnosis is often first considered after a provocative interrogation including travel history, occupation, hobbies, and contact with animals and insects. Although the diseases reviewed here are rare causes of respiratory infections in the United States, they can be severe, life-threatening, and contagious illnesses for which effective antimicrobial therapy is available.

Anthrax

Micro-organism

Bacillus anthracis, a large, aerobic, gram-positive, sporule-forming micro-organism, has played a major role in the history of microbiology. Isolated by Robert Koch in 1877, it consistently produced fatal infections in laboratory animals, and Koch's now famous postulates for determining whether an organism is a pathogen were based on his studies with anthrax.

Epidemiology

Pulmonary anthrax has never been a common disease. Some 200 cases were reported before 1900, and only a small number of cases have been reported since that time, with most of the patients having some contact with wool and wool processing. However, direct contact with wool or hides during processing procedures is not necessary; anthrax has occurred in persons who lived or frequently walked near tanneries but never had direct contact with such procedures. It should be emphasized that finished rugs and carpets are not a source of the infection.

The thoracic form of the disease is not ordinarily pneumonia. After spores have been inhaled, they are carried to the pulmonary parenchyma, where they undergo phagocytosis by macrophages and then are transported to regional lymph nodes, where they germinate. The germination of the spores produces a violent reaction in the host: Necrosis, hemorrhage, and edema lead to acute hemorrhagic mediastinitis. Subsequent pulmonary involvement is secondary to hematogenous spread of the bacteria. Like mediastinitis, this type of pneumonia is characteristically hemorrhagic. Although parenchymal lung involvement usually follows bloodstream dissemination, there have been reports of pneumonia with necrosis of alveolar walls that apparently occurred as a primary phenomenon following spore inhalation.

Clinical Manifestations

The course of the disease is usually diphasic. The patient initially experiences chills, fever, and myalgia. These symptoms are followed by a 1- or 2-day period during which there is either no change or some improvement; then, progressive disease ensues abruptly and is characterized by tachypnea, dyspnea, cyanosis, and cardiovascular collapse. Rales, and at times rhonchi and wheezes, may be heard in focal areas or diffusely throughout the lung fields. In some patients, dullness to percussion and altered breath sounds suggest consolidation. Chest roentgenograms show congestion, patchy infiltrates, areas of consolidation, and mediastinal widening. While the disease is fulminating, pleural effusion, subcutaneous edema of the chest and neck, splenomegaly, and meningitis may be observed. Most of the patients reported have died.

Therapy

As the anthrax bacillus is susceptible to penicillin and streptomycin, the treatment of choice for adults is 3 to 10 million units of penicillin per day. Some give streptomycin together with penicillin. Erythromycin, chloramphenicol, and tetracycline are alternate agents.

Brucellosis

Brucellae are small, gram-negative, coccobacillary aerobes that can be separated into four major species: *Brucella abortus, Brucella melitensis, Brucella suis,* and *Brucella canis.* Brucellosis occurs in susceptible individuals who deal with animals and animal products, veterinarians, farmers, and persons ingesting unpasteurized dairy products. The organism is acquired through ingestion or, rarely, contact. No human-to-human transmission has been reported.

The clinical presentation of brucellosis involves a variety of nonspecific constitutional symptoms, including relapsing fever and headache. Cough occurs in one fourth of cases, but other respiratory symptoms are notably absent. The most characteristic radiographic findings include perihilar thickening and peribronchial infiltrates, although nodular lesions and miliary infiltrates may be seen.

No data are available on sputum bacteriology, and blood culture findings are rarely positive. Cultures of biopsy specimens of granulomas are frequently positive, and the *Brucella* agglutination test is confirmatory. The most effective therapy is with tetracycline (1.5 to 2.0 g orally) and streptomycin (1.0 g intramuscularly) daily for 1 month.

Pasteurella multocida Pneumonia

Pasteurella multocida is the causative agent of hemorrhagic septicemia in animals and can be isolated from the respiratory tracts of a variety of domestic and wild animals. The organism is a small, gram-negative, bipolar-staining, nonmotile rod that grows well on blood agar, but its growth is inhibited on MacConkey media. In humans, three clinical patterns of disease are observed: (1) local suppuration or cellulitis following a bite or scratch; (2) meningitis or bacteremia; and (3) acute or subacute lung infection, sometimes accompanied by empyema. Although respiratory disease is rarely reported, sputum is the most common source of isolates in cases of animal-bite cellulitis.

Most cases of *Pasteurella* pneumonia occur in individuals with underlying chronic lung disease, including bronchiectasis, emphysema, and carcinoma. Spread to humans is probably from animals, but in only half the cases is there an exposure history. Lung involvement is probably initiated by aspiration of the oropharyngeal flora. Radiographic findings include lobar, multilobar, or diffuse patchy infiltrates with a tendency to spare the upper lobes. Pleural effusions are found in 20% of cases. Empyema and abscess formation occasionally occur. Diagnosis depends on isolation of the organism from sputum, pleural fluid, or blood. Penicillin is the drug of choice, as the majority of strains are exquisitely sensitive. Alternative choices include chloramphenicol, cephalosporins, and tetracycline.

Tularemia

Francisella tularensis is a tiny, gram-negative, pleomorphic, coccobacillary organism that grows poorly on artificial medium unless supplemented with serum, glucose, and cystine. There are approximately 150 cases of tularemia per year in the United States, and pulmonary disease occurs in 10%–15% of these cases. Tularemia can be transmitted to humans by wood ticks, dog ticks, the deer fly, and a variety of wild animals, notably the rabbit. Punched-out skin lesions with secondary lymph node involvement, the so-called ulceroglandular type, is the most common form of the disease; although pneumonic tularemia often arises from hematogenous dissemination from cutaneous foci, as many as 50% of patients with pleuropulmonary tularemia have no demonstrable disease of the skin or lymph nodes.

Respiratory disease often begins with a poorly productive cough, chest pain, and dyspnea. In airborne tularemia, sore throat has been observed in about one third of patients, and a similar proportion exhibit a skin rash, either erythema nodosum or erythema multiforme. The roentgenographic appearance varies from small areas of bronchopneumonia to extensive lobar or lobular consolidation, often with hilar adenopathy. Extension to the pleura is common. Only rarely are organisms seen on sputum Gram's stain, and because of the potential for laboratory-acquired infection, isolation should be reserved for special reference laboratories. The diagnosis can be established by demonstrating a rise in serologic agglutinations. The micro-organism is susceptible to streptomycin (or gentamicin), tetracycline, and chloramphenicol. Streptomycin remains the mainstay of therapy, with a dramatic response usually being observed within 24 to 48 hours of initiation of the antibiotic, in a dosage of 1.5 to 2.0 g/d.

Plague

Yersinia pestis remains a problem in China, India, Vietnam, and certain areas of the Middle East and Africa. In the past 15 years, a very small number of cases have been reported in the United States, most of these in California and New Mexico; in one case, a domestic cat was the source. Although the bacillus, first isolated by Yersin in 1894, has now been relegated to secondary importance among organisms parasitic to humans, its importance in medical history and perhaps in the course of our civilization is undeniable. During the plague epidemic of the fourteenth century, when many cases were pneumonic, the disease acquired its macabre figurative name, the Black Death. During that epidemic, it is estimated that one half to two thirds of the people in Great Britain died of this infection. In the sixteenth century,

ravaged the world for 30 to 60 years, “depopulated towns, turned the country into a desert, and made the habitations of men to become the haunts of wild beasts,” and during this period it is said to have killed some 100 million persons. During the seventeenth to nineteenth centuries, there was a striking decline in the incidence of the disease, and subsequently, because of higher standards of living, greater attention to personal hygiene, and vigorous efforts to control rat populations, plague virtually disappeared from many areas of the world.

Pneumonic plague is not the natural form of the infection in humans. Ordinarily, plague acquired from wild rodents through infective fleas occurs initially in the bubonic form. Progressive bubonic disease is associated with bacteremia in as many as 70%–85% of patients, and secondary lung involvement ensues in some. As in the epidemic of the fourteenth century, these individuals may spread the disease by the airborne route to other persons, in whom the lungs may become the initial site of invasion. Such patients usually have shaking chills and high fever. Their sputum varies from gelatinous to rusty, and on occasion there is profuse hemoptysis. Most striking in these patients is profound dyspnea and air hunger. Physical examination and chest roentgenograms show lobar pneumonia or diffuse involvement simulating pulmonary edema. The lung may be heavy, mimicking the roentgenogram of Friedländer's pneumonia. The disease is characteristically fulminating. The average survival time among untreated patients is 1.8 days. Postmortem examination of the lungs shows severe hemorrhage, coagulation necrosis, and infiltration by large numbers of polymorphonuclear leukocytes.

Treatment, which must be immediate if the patient's life is to be saved, consists of oxygen and antibiotics. The micro-organism is usually susceptible to streptomycin, other aminoglycosides, tetracyclines, and chloramphenicol, and the therapeutic regimen of choice appears to be one of the last two in combination with streptomycin or gentamicin. Patients with bubonic plague should probably be isolated, as some may have throat cultures positive for *Y. pestis.* Strict isolation precautions should be observed in cases of pneumonic plague, as the dangers to those attending such patients are great.

PARASITIC DISEASE

Three types of pulmonary disease are associated with protozoal or helminthic infection:

1. Loeffler's syndrome with no evidence of invasion of the pulmonary parenchyma
2. Parasitic disease with direct lung invasion
3. Pulmonary involvement resulting from direct spread from subdiaphragmatic lesions

Loeffler's Syndrome

In 1936, Loeffler described a series of cases characterized by pulmonary infiltrates and mild illness lasting for 3 to 8 days and accompanied by striking peripheral eosinophilia, with the peak of the increase in eosinophils usually following the maximal pulmonary infiltration. Roentgenographic abnormalities were patchy and fleeting. Moderate cough was noted, but most of the patients remained afebrile and sputum was ordinarily not produced. A great number of infections and drugs have been associated with the syndrome. Pulmonary eosinophilia has been observed in patients with certain bacterial and mycotic infections, including tuberculosis, brucellosis, coccidioidomycosis, aspergillosis, and histoplasmosis; in patients with allergic asthma; in individuals exposed to certain drugs, especially antibiotics; and in patients with intestinal parasitism by the following protozoa, nematodes, and trematodes: *Entamoeba histolytica, Trichinella spiralis, Trichuris trichiura, Enterobius vermicularis, Fasciola hepatica, Necator americanus, Taenia saginata, Ancylostoma braziliense, Ancylostoma duodenale, Toxocara canis, Toxocara mystax, Ascaris lumbricoides*, and *Strongyloides stercoralis.* The last four perhaps do not belong in this category, as there is considerable evidence to suggest that the pulmonary disease with eosinophilia is related to direct invasion of lung tissue. Because Loeffler's syndrome is benign, no specific therapy is required.

Parasitic Disease with Direct Lung Invasion

Schistosomiasis

Micro-organism

Pulmonary schistosomiasis, which may be caused by *Schistosoma mansoni, S. japonicum,* or *S. haematobium,* is a problem of considerable magnitude in areas of the Middle East, Asia, Africa, and Latin America. Free-swimming cercariae infect humans by penetrating the skin. The larvae (schistosomulae) gain access to the circulation, pass through the lungs, and eventually reach the portal and mesenteric vessels. During the period in which the larvae pass through the pulmonary vasculature, asthmatic symptoms may occur, but the major pulmonary involvement occurs later and is related to metastatic spread of ova produced by the adult worms through the systemic circulation to pulmonary vessels. The ova obstruct the arterioles, penetrate the arteriolar walls, and become the focus of obliterative granulomatous arteritis.

Clinical Manifestations

During the larval migration phase, symptoms include wheezing, dyspnea, and nonproductive cough. In a small number of cases, acute pneumonic schistosomiasis occurs 3 weeks to 3 months after the initial cercarial penetration. This is apparently related to an intense inflammatory response to invasion by ova. In such cases, schistosomiasis may be manifested as overwhelming, diffuse disease characterized by severe respiratory distress, productive cough, hemoptysis, cyanosis, and bilateral rales on physical examination of the chest, or there may be signs of focal consolidation. Pulmonary involvement in those in whom symptoms develop is usually chronic and accompanied almost uniformly by extensive extrapulmonary schistosomal involvement, including hepatosplenomegaly. Dyspnea is the most common symptom, and the majority of patients also have a cough that is ordinarily nonproductive. Both cyanosis and hemoptysis are rare.

Roentgenographic and Laboratory Findings

In those with symptoms related to larval migration, the chest roentgenogram appears normal or shows some nonspecific increase in markings. Some degree of eosinophilia is usually found, and this may be marked. In patients with acute pulmonary schistosomiasis, areas of consolidation or coalescing nodular infiltrates are found. The lung fields may appear normal roentgenographically, or there may be a diffuse fibrotic or nodular infiltrate. The vascular dilatation may be marked, as shown in Fig. 13, the roentgenogram of a 16-year-old girl with schistosomal cor pulmonale. Many, but not all, patients with acute pulmonary schistosomiasis have significant peripheral eosinophilia, but eosinophilia is ordinarily absent in patients with chronic obliterative arteritis. The stools of most are positive for *Schistosoma* ova. In addition, in as many as a third of patients who have a productive cough, *Schistosoma* ova may be demonstrated in the sputum.

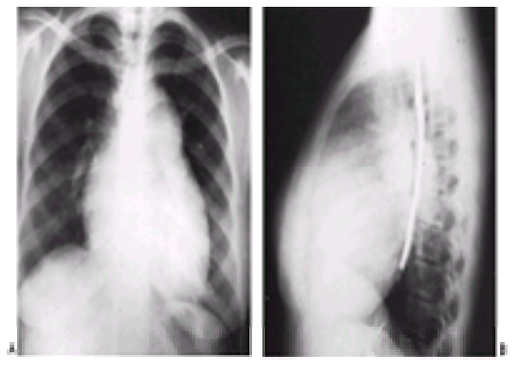

FIG. 13(A,B). Schistosomal cor pulmonale in a 16-year-old girl. Note the marked dilatation of the pulmonary artery segment.

Once cor pulmonale has appeared, antischistosomal therapy is ineffective. If ova are found in the sputum or if the patient has acute pulmonary schistosomiasis, praziquantel in a single oral dose of 40 mg/kg is now considered to be the drug of choice. It is uncertain whether therapy actually alters the natural course of acute schistosomal pneumonia.

Echinococcosis

Epidemiology

Hydatid disease of the lung is caused by infection with the larval form of *Echinococcus granulosus,* a small tapeworm of the dog. Human infection is especially prevalent in the Middle East, Australia, New Zealand, central Europe, and parts of Latin America, areas in which sheep are an important part of the economy. Hydatid disease is uncommon in North America, except in certain areas of Canada and Alaska.

The incidence of lung involvement in human echinococcosis ranges from 5%–25% in different series. Although pulmonary infection usually arises from primary hematogenous dissemination, it may be secondary to metastatic spread from a ruptured abdominal cyst. Almost all the pulmonary cases are caused by *E. granulosus* (*unilocularis*); only rarely is a case caused by the more malignant *E. multilocularis.* There is a clear predilection for the lower lobes, especially the right lower lobe. Approximately one third of patients with pulmonary echinococcosis also have clinical evidence of extrapulmonary hydatid disease.

Clinical Manifestations

Initial symptoms consist most commonly of cough, hemoptysis, and pleuritic pain. Sputum production is usually sparse, and characteristically there is little fever. Physical examination is frequently unrewarding. Clubbing of the fingers and toes is detected infrequently. Chest roentgenography shows one or more discrete, round lesions that typically are sharply defined with little surrounding inflammatory response and are sometimes calcified. These lesions are frequently mistaken for metastatic carcinoma.

Hydatid involvement of the thoracic cavity also may take the form of primary mediastinal disease (Fig. 14), which occurs most commonly in the posterior mediastinum. Anterior mediastinal involvement may be associated with Horner's syndrome (miosis, ptosis, and diminished sweating ipsilaterally).

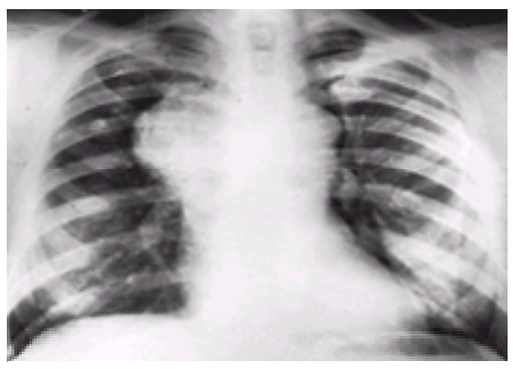

FIG. 14. Mediastinal echinococcosis. Note the thin rim of calcium in the cysts.

Laboratory Findings

Laboratory analysis in patients with echinococcosis reveals a normal total leukocyte count. Eosinophilia, generally moderate, is found in 50% of patients. Careful examination of sputum or of the sediment from material aspirated from the thoracic cavity may reveal hooklets or scoleces. Precipitin, complement fixation, indirect hemagglutination, and bentonite flocculation tests are available, and the results are positive for the majority of patients with echinococcal disease. The most reliable test is an enzyme immunoassay utilizing partially purified hydatid antigen.

Treatment

Surgical removal of the cyst, the treatment of choice, is often not technically feasible, and chronic disease is frequent even after apparently complete extirpation of the cyst. However, despite the persistence of chronic hydatid disease of the lungs or abdomen for many years, the patient may lead a relatively normal life. Secondary infection of the cyst should be treated with appropriate antimicrobial agents and surgical drainage. Medical therapy with mebendazole or albendazole may be effective.

Ascariasis

Ascariasis is a common intestinal nematode infection caused by *A. lumbricoides.* It is worldwide in distribution, and in the United States is found particularly in the southeastern section of the country. After ingestion, the embryonated ova hatch into larvae that penetrate the intestinal wall, reach the circulation, and subsequently arrive in the lungs. During pulmonary migration, fever is commonly of considerable magnitude. Cough, hemoptysis, inspiratory rales, and evidence of focal consolidation are the other common manifestations, but on rare occasions the lesions can be diffuse and produce death either directly or through the development of severe, superimposed bacterial infection. Peripheral eosinophilia is often found during pulmonary migration but may not become evident until late in the course of the pulmonary disease. In addition to pneumonitis with fever, cough, and hemoptysis, there is considerable evidence to suggest that migration of the larvae through the lungs produces a milder illness that is consistent with Loeffler's syndrome.

The diagnosis of pulmonary ascariasis may be established by finding the larvae in the expectorated sputum or in gastric aspirates. The role of *A. lumbricoides* also should be suspected in patients with pneumonitis or Loeffler's syndrome if ova or adult worms are found in the stool. Serologic tests, including agar gel diffusion and immunoelectrophoresis, are available. Treatment of the pulmonary disease is usually not necessary, and in any case it is not known whether any of the currently available antihelminthic agents are beneficial in lung ascariasis. If pulmonary disease persists, a trial of mebendazole might be considered.

Visceral Larva Migrans

Visceral larva migrans results from the ingestion of embryonated ova of the dog or cat roundworm *T. canis* or *T. cati.* The disease occurs predominantly in young children who have close contact with dogs or cats and eat dirt. The larvae hatching from the ova penetrate the intestinal wall and migrate widely. Hepatomegaly is noted frequently. During pulmonary migration, wheezing, cough, cyanosis, or dyspnea may occur in association with roentgenographic evidence of diffuse or focal pneumonitis. The diagnosis can be established best by liver biopsy, with histologic sections of the specimen showing eosinophilic granulomas with larvae. The blood leukocyte count is usually markedly elevated, often reaching 40,000/mm^3 or higher, and eosinophilia of >30% is present in 85% of patients. The available serologic tests, indirect fluorescent antibody and indirect hemagglutination, are sensitive but lack specificity. The prognosis is usually good. Thiabendazole, the present drug of choice, can be given orally in a dosage of 25 mg/kg of body weight twice a day for 5 days (maximal daily dose, 3.0 g).

Strongyloidiasis

An estimated 35 million persons in the world suffer from infection with *Strongyloides stercoralis.* The majority of cases in the United States are confined to the southern parts of the country. Pneumonitis may occur during pulmonary migration of larvae, characterized by fever, wheezes, productive cough, and patchy or diffuse infiltrates on chest roentgenogram. Blood and sputum eosinophilia are found frequently, and typical larvae may be detected in the expectorated sputum.

Pulmonary manifestations are usually transient but may be chronic or recurrent. Recurrence is perhaps related to repeated bouts of endogenous dissemination to the lungs from established foci in the small intestines.

In the normal host, rhabditiform larvae are passed in the stool but can reinvade through the perianal area. This is called *exoautoinfection.* In patients with immunologic defects, in particular resulting from hematologic malignancies, large numbers of filariform larvae may penetrate the intestinal wall and invade various tissues, including the lungs (*endoautoinfection*). In almost all cases, corticosteroids and/or immunosuppressive agents have been administered. As a consequence of the penetration, gram-negative septicemia may occur, involving one or more enteric organisms. Larval meningitis may occur, and the pulmonary involvement varies from small pneumonic patches to massive infiltrates of five lobes. Larvae can usually be seen in expectorated sputum. Findings on stool examination are usually positive but in some cases may be negative, and jejunal intubation is necessary to establish the diagnosis. In the hyperinfection syndrome, eosinophil counts range from normal to markedly elevated. Immunofluorescence, complement fixation, and indirect hemagglutination tests for antibody determination are available, but more data are needed

to define their usefulness.

Thiabendazole is the drug of choice in intestinal strongyloidiasis. Whether it is beneficial in acute or chronic pulmonary disease caused by *S. stercoralis* is unknown.

Paragonimiasis

Pulmonary paragonimiasis is found commonly in Southeast Asia, the Philippines, and less frequently in the South Pacific, Africa, India, and Latin America. The etiologic agent is the oriental lung fluke *Paragonimus westermani.*

The pulmonary manifestations vary considerably and depend on the number of parasites involved. Most patients have little fever or prostration. Cough is usually not marked but may be productive of thin sputum with globules of tenacious gelatinous material, or there may be small amounts of blood-stained sputum. Occasionally, the symptoms may be more severe, consisting of prostration and dyspnea. Pleuritic pain is noted infrequently. In most patients, the only findings are inspiratory rales, sometimes accompanied by dullness to percussion and roughened breath sounds. Less frequently, areas of focal consolidation or pleural effusion or pneumothorax may be detected. Roentgenograms of the chest usually reveal linear or patchy infiltrates in the lower lung fields or nodular densities in which there may be areas of rarefaction. Cystlike lesions may be found and may be as large as several centimeters, and on rare occasions thick- or thin-walled cavities may be present. Pleural effusion and pneumothorax are each observed in <10% of cases.

In most cases of paragonimiasis, the blood leukocyte count is normal and eosinophilia is inconstant. The diagnosis can be made only by finding the characteristic ova, which can usually be seen readily on examination of the sputum or stool.

Paragonimus westermani infection frequently produces chronic disease that is sometimes incapacitating, and occasionally, in patients experiencing very heavy infestation, it is fatal. The treatment of choice is 25 mg of praziquantel per kilogram of body weight, given three times in a 1-day course.

INTRODUCTION

Hospital-acquired pneumonia is the second leading cause of nosocomial infection, accounting for 13%–18% of all nosocomial infections. It is the leading cause of death among patients with hospital-acquired infections, and the cost of therapy for this problem exceeds $2 billion annually. This chapter focuses on the epidemiology, risk factors, pathogenesis, diagnostic strategies, and preventive measures related to hospital-acquired pneumonia. As many of the infective etiologies of pneumonia are reviewed in other chapters, only those organisms and/or features unique to the hospital setting are discussed here. The chapter concludes with a section on pneumonia in the immunocompromised host.

EPIDEMIOLOGY

Lower respiratory tract infection is not a reportable illness, but available data suggest it occurs at a rate of 5 to 10 cases per 1000 hospital admissions. This incidence may be 6 to 20 times higher in patients who are being ventilated mechanically. Nosocomial pneumonia has occurred in as many as 70% of patients with the adult respiratory distress syndrome (ARDS). Crude mortality rates for hospital-acquired pneumonias of 20%–50% have been reported, but they may be as high as 90% when pneumonia occurs in patients with ARDS. Although all these deaths are not the direct result of infection, the attributable mortality of hospital-acquired pneumonia is estimated to account for one third to one half.

RISK FACTORS

Although many of the variables predisposing to the development of hospital-acquired pneumonia are likely to be interrelated, several studies using regression analysis have identified independent risk factors. These include the following: (1) host factors, such as extremes of age and underlying disease; (2) conditions favoring aspiration; (3) surgical procedures, especially thoracic or upper abdominal surgery; (4) colonization of the oropharynx with gram-negative bacilli; and (5) continuous mechanical ventilation. More than 85% of patients in whom a nosocomial pneumonia develops have a serious underlying disease. Patients with chronic lung disease may have altered mucociliary clearance, and those with neurologic disorders may be predisposed to aspiration because of an impaired gag reflex.

Colonization of the oropharynx with gram-negative bacilli is an important risk factor because most cases of nosocomial pneumonia result from aspiration of contaminated oropharyngeal secretions into the tracheobronchial tree. Approximately 45% of healthy adults aspirate during sleep, and aspiration is even more frequent in patients with altered consciousness, abnormal swallowing, depressed gag reflexes, delayed gastric emptying, or decreased gastrointestinal motility. Intubation compromises the natural barrier to aspiration, and the entry of bacteria into the lung may also be facilitated through pooling and leakage of secretions around the endotracheal tube cuff. In the normal respiratory tract, the oropharynx is colonized, but not with enteric gram-negative bacilli. When serious illness of any type is present, enteric gram-negative bacilli can replace the normal flora and become the colonizing bacteria in the oropharynx. Patients receiving antibiotics or acid-neutralizing medications also have a higher incidence of colonization. When the time course of colonization was examined, most patients had acquired gram-negative bacteria by the third hospital day.

Gastric colonization as a source of oropharyngeal and tracheal colonization in mechanically ventilated patients has been suggested by studies dating from 1978 and later. These studies have emphasized gastric overgrowth with aerobic gram-negative bacilli and increased rates of pneumonia in patients who have received agents that alter gastric pH. Several meta-analyses found that administration of sucralfate (which does not increase gastric pH) was associated with a reduced incidence of pneumonia when compared with the use of either antacids alone or in combination with H_2 antagonists. In all studies, gastric colonization has correlated best with gastric pH (increasing as pH exceeds 4.0), and rates of pneumonia increase accordingly.

The lower respiratory tract is ordinarily sterile in healthy nonsmokers. Smoking increases the likelihood that the tracheobronchial tree has lost its sterility, and half of patients with chronic bronchitis have a colonizing tracheobronchial microflora, but enteric gram-negative bacilli are not present. Oropharyngeal and tracheobronchial colonization patterns in intubated patients reveal that gram-negative bacteria usually enter the trachea after first colonizing the oropharynx. The exception to this finding is *Pseudomonas aeruginosa,* which can colonize the tracheobronchial tree as a primary event without first becoming established in the oropharynx. Colonization of gram-negative bacteria in the tracheobronchial tree occurs in 50%–100% of intubated patients, and more than one potential pathogen may be present. The relationship of airway colonization to the subsequent development of pneumonia is well-known, as respiratory infection develops in 13%–23% of colonized patients.

In addition to aspiration and colonization, one of the most important risk factors is tracheal intubation and mechanical ventilation, with the incidence of pneumonia rising as the duration of intubation increases. The risk for pneumonia is seven to 21 times greater in intubated patients than in other hospitalized patients, and pneumonia develops in as many as two thirds of patients with tracheostomy who require mechanical ventilation. The relationship of nosocomial pneumonia to the duration of mechanical ventilation was demonstrated by Fagon and colleagues; the risk for pneumonia was found to be 6.5% after 10 days of ventilation, 19% at 20 days, and 28% at 30 days. The endotracheal tube itself is not routinely changed. In one report, 95% of the tubes examined by scanning electron microscopy had partial bacterial colonization, and 84% were covered by bacteria in a biofilm or glycocalyx. Whether this is clinically relevant remains to be seen.

PATHOGENESIS

Nosocomial pneumonia develops when organisms reach the lung and overcome the pulmonary host defenses. Illness results if the inoculum is sufficiently large, if the organism is virulent, or if host defenses are malfunctioning. Organisms may reach the lung via aspiration of oropharyngeal secretions colonized with pathogenic bacteria, aspiration of esophageal/gastric contents, inhalation of contaminated aerosols, hematogenous spread from a distant infected site, exogenous penetration from a pleural infection, or by direct inoculation into the airways of intubated patients. Not all routes, however, are equally effective in precipitating infection. Of these routes

of entry, aspiration of oropharyngeal flora is recognized as the predominant mechanism in both intubated and nonintubated patients. Although microaspiration is a frequent event, reportedly occurring in as many as 45% of healthy adults during sleep, the critical event is the presence of pathogenic bacteria that are able to overwhelm the lower respiratory tract defenses. If organisms reach the lung as a liquid bolus, fewer organisms are needed to cause infection than if they are delivered as an aerosol. In the mechanically ventilated patient, sources of a liquid bolus of organisms include aspiration from a previously colonized oropharynx, aspiration from a colonized stomach to the oropharynx and then to the lung, leakage of pooled subglottic secretions above the inflated endotracheal tube cuff, or direct instillation of colonized ventilator tubing condensate into the lung via the endotracheal tube.

The aerosol route is an effective method for the spread of *Legionella* species, certain viruses, *Mycobacterium tuberculosis,* and fungi, such as *Aspergillus* species. Hematogenous spread from distant sites of infection is especially noted in postoperative patients and in patients with indwelling intravenous or genitourinary catheters.

The initial step in oropharyngeal colonization is the adherence of bacteria to mucosal cells, an interaction dependent on both host and microbial factors. The usual local respiratory tract chemical (salivary proteases, secretory IgA) and physical (mucociliary escalator) barriers to infection may be overcome by bacteria after tracheal intubation or large-volume aspiration. Systemic illness can result in an increase in the number of airway cell receptors and in a loss of surface fibronectin, thereby promoting bacterial adherence. Mucous glycoproteins that trap bacteria may act as actual surface receptors for these gram-negative organisms if they are not cleared as a result of faulty ciliary function. If the airway has been injured, underlying connective tissue and basement membrane, to which bacteria readily bind, can be exposed. Pili or fimbriae act as bacterial adhesions for many enteric gram-negative bacilli; other bacteria secrete exoproducts that promote airway colonization by impairing ciliary function, degrading fibronectin, stimulating excessive mucin production, or degrading mucin. Bacterial adherence has been shown to mediate tracheobronchial colonization and correlate with the subsequent development of pneumonia in mechanically ventilated patients in the intensive care unit (ICU).

It is unlikely that an increase in adherence by itself leads to colonization and infection unless other host defenses are impaired. However, many of the same clinical factors that can cause a rise in adherence can also impair mucociliary clearance and interfere with the cellular and humoral immune functions of the lung. For instance, malnutrition is associated with airway colonization, and this is likely the result of increased buccal and tracheal cell adherence, impaired cell-mediated immunity, decreased neutrophil migration, impaired recruitment of alveolar macrophages to the lung, complement deficiency, and diminished airway levels of IgA.

DIAGNOSIS

Several criteria have been used to establish a clinical diagnosis of nosocomial lower respiratory tract infection; these include fever, leukocytosis, purulent tracheobronchial secretions, and the radiographic appearance of a new or progressive pulmonary infiltrate. The development of these clinical manifestations in a previously healthy individual without underlying lung disease almost invariably indicates pneumonia. When these criteria have been applied to mechanically ventilated patients, however, they have been quite sensitive but not very specific, as a variety of noninfectious causes may lead to pulmonary infiltrates in this setting. Fagon and colleagues prospectively evaluated 147 consecutive patients suspected of having ventilator-associated pneumonia, and three of the usual clinical criteria were met in 93% of the patients and all four criteria were present in 51%. The diagnosis was definitely excluded in 49% of the patients, and no combination of 16 clinical variables was useful in distinguishing patients with bacterial pneumonias. In studies of patients with ARDS, pneumonia was falsely diagnosed using these clinical criteria in 19%–36% of patients but was unrecognized in up to 62%. Whereas overdiagnosis of pneumonia is the problem in mechanically ventilated patients in general, those with ARDS have not only the problem of overdiagnosis but also that of underdiagnosis. The remainder of this section reviews the diagnostic tools that may be useful in the diagnosis of both hospital- and ventilator-associated pneumonia.

General Evaluation

All patients with suspected hospital-acquired pneumonia require certain diagnostic evaluations. A careful history and physical examination can identify the presence of specific risk factors or conditions that may suggest the likely etiologic pathogens (Table 1). Chest radiography is imperative and can be used to define the presence and location of infiltrates, cavitation, and complications such as pleural effusion, and the severity of the process. Diagnostic thoracocentesis should be performed in individuals with parapneumonic effusions, especially if the effusion is 10 mm thick on a lateral decubitus chest x-ray film, if the individual has had chest trauma, or if a chest tube has been placed previously. A complete blood cell count and serum electrolyte levels should be determined, and arterial blood gas analysis and renal and liver function tests should be routinely performed. Although these do not contribute to the identification of a specific etiology, the tests help to define severity of illness and guide appropriate antimicrobial dosing. Serologic studies are of little use in the initial evaluation and should not be routinely performed.

Organism	Risk factor
Anaerobes	Abdominal surgery, poor dentition, witnessed aspiration
Staphylococcus aureus	Antecedent influenza, coma, head trauma, diabetes mellitus, renal failure
Legionella	Corticosteroids
Pseudomonas aeruginosa, Acinetobacter	Prolonged ICU stay, prior antimicrobial therapy, chronic lung disease

TABLE 1. *Hospital-acquired pneumonia: pathogens associated with specific patient risk factors*

Blood Cultures

Blood cultures can isolate the causative organism in almost one fourth of all cases of hospital-acquired pneumonia. In patients with ARDS, bacteremia has been documented in 27% of those with pneumonia and 67% of those with an abdominal focus of infection. A positive blood culture result in patients with respiratory failure, the appearance of a new pulmonary infiltrate, and the presence of purulent tracheal secretions are not necessarily conclusive evidence of pneumonia, as an additional source of infection may be present in up to 50% of these patients.

Sputum/Tracheal Aspirate

Gram's stain and culture of the respiratory tract secretions are the time-honored methods of microbiologic evaluation but are of limited diagnostic value in ventilator-associated pneumonia. Cultures of expectorated sputum in patients with nosocomial pneumonia in whom the etiologic diagnosis was based on cultures from uncontaminated specimens (blood, transtracheal aspirate, pleural fluid) yielded the implicated bacterial pathogen in up to 80% of patients if *Staphylococcus aureus* was involved. On the other hand, gram-negative bacilli were recovered from sputum in 45% of patients who did not have these organisms as the etiologic agent. The absence of gram-negative bacilli in purulent secretions usually excludes their presence in the lower airways. Quantitative culture of expectorated sputum specimens is of no value diagnostically.

Microscopic examination of respiratory tract secretions is of limited usefulness. Grading of Gram's stains for neutrophils, bacteria, and percentage of intracellular organisms has correlated with quantitative tracheal aspirate colony counts, but overlap with results from patients who do not have infection makes this method less reliable.

The presence of elastin fibers in sputum or tracheal aspirates after digestion with potassium hydroxide is a very reliable indication of the diagnosis of hospital- or ventilator-associated pneumonia (Plate 1). The microscopic finding of elastin fibers is indicative of pulmonary parenchymal destruction or necrosis and was first described in 1846 as pathognomonic for tuberculosis. The demonstration of elastin fibers has subsequently been associated with necrotizing bacterial pneumonia, with a sensitivity of 52% and specificity and positive predictive value of 100% for infection. Recovery of elastin fibers from bronchial aspirates of patients with ARDS has a lower positive predictive value (50%), as noninfectious lung necrosis may occur in that setting. Elastin fibers are more likely to be seen in nosocomial pneumonia caused by gram-negative bacilli than in that caused by gram-positive bacteria, and the presence of elastin fibers may actually precede radiographic evidence of pulmonary infiltrates by a few days.

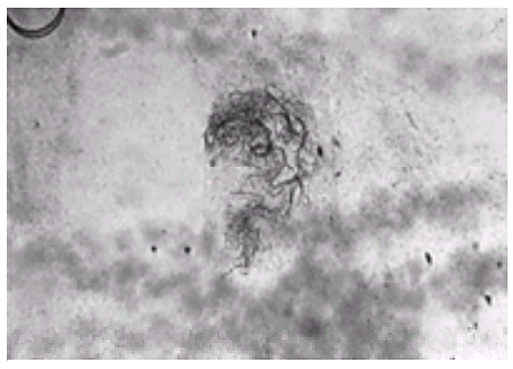

PLATE 1. Elastin fibers in a potassium hydroxide preparation of sputum. *See color plate 14.*

Qualitative cultures of tracheal aspirates have a high false-positive rate, frequently contain more than one potential etiologic pathogen, and are the least reliable method of diagnosis. Studies evaluating quantitative cultures of tracheal aspirates have yielded inconsistent results, with thresholds for the diagnosis of pneumonia ranging from 10^5 to 10^7 colony-forming units (CFU) per milliliter. The specificity of quantitative culture of tracheal aspirates has been best at higher cutoff points, but at the expense of decreasing sensitivity.

Transthoracic Lung Aspiration

Transthoracic lung aspiration for the diagnosis of bacterial pneumonia is of limited applicability for patients in the ICU, and it is contraindicated in patients receiving mechanical ventilation. Sensitivities as high as 79% have been reported in community-acquired pneumonias, but series dealing with more complex pneumonias have revealed sensitivities of 35%–56%. Because of the high incidence of pneumothorax associated with this procedure and its limited sensitivity, transthoracic lung aspiration is not recommended as a diagnostic procedure for patients in the ICU.

Bronchoscopy

Fiberoptic bronchoscopy has become an increasingly valuable tool for the diagnosis of lower respiratory tract infection. To reach the bronchial tree, however, the bronchoscope must traverse the oropharynx or the endotracheal tube, and colonization of these sites with pathogenic bacteria has been reported in up to 90% of patients receiving mechanical ventilation. Bronchoscopic aspirates in patients undergoing bronchoscopy are frequently contaminated by oropharyngeal bacteria, and as a result routine bacterial cultures obtained through the bronchoscope are unreliable for the diagnosis of pneumonia.

Two diagnostic techniques that have been recently described make it possible to acquire lower respiratory tract specimens for bacterial culture without oropharyngeal contamination. One technique uses a double-sheathed protected specimen brush (PSB), and the second involves bronchoalveolar lavage (BAL) of radiographically involved portions of the lung. Both methods rely on quantitative bacterial cultures to differentiate between infection and colonization.

Accordingly to a meta-analysis, the use of a predetermined threshold concentration for either PSB or BAL may not be appropriate in all clinical settings. Quantitative cultures of PSB and BAL specimens should be interpreted according to the pretest likelihood of pneumonia and how information gained from the procedure will influence management. Because pretest probability, risks of therapy, and likelihood of benefit vary widely among patients, a single value that defines an abnormal PSB or BAL culture result for all patients cannot be defined.

Bronchoalveolar Lavage

BAL refers to the sequential instillation and aspiration of a physiologic solution into the lung through a bronchoscope that has been wedged into an airway and so is subject to contamination with oropharyngeal flora. Quantitative cultures of BAL fluid have yielded growth in excess of 10^5 CFU/mL in the majority of patients with pneumonia, and the presence of 1% squamous epithelial cells in the BAL sample accurately predicts the presence of heavy contamination by oropharyngeal flora. A growth of 10^5 CFU/mL in a BAL specimen with at most 1% squamous epithelial cells has a diagnostic sensitivity of 88% and a specificity of 100%. Unprotected BAL, however, does not discriminate pneumonia from acute bacterial bronchitis. More recently, the technique of protected BAL has been described for diagnosing ventilator-associated pneumonia. Using a threshold of 10^4 CFU/mL, quantitative bacterial cultures of protected BAL samples had a sensitivity of 92% and a specificity of 97%, with a positive predictive value of 97% and a negative predictive value of 92%.

Microscopic analysis of cytocentrifuged BAL fluid may be useful in the diagnosis of pneumonia. Whereas total and differential cell counts are not helpful, the presence of intracellular organisms in 7% of cells (sensitivity of 86%, specificity of 96%) and the presence of bacteria on BAL specimen Gram's stain correlate closely with the results of both BAL and PSB quantitative cultures.

Protected Specimen Brush

The feasibility of obtaining uncontaminated specimens from the lower respiratory tract through a contaminated bronchoscope with a double-sheathed catheter was demonstrated in 1979. The technique has been described in detail and requires that a catheter containing a PSB be passed under direct visualization into the area of lung involvement as defined radiographically. Using a cutoff of 10^3 CFU/mL, quantitative cultures of samples obtained by PSB can separate patients with lower respiratory tract infection from those with airway colonization. Quantitative PSB cultures correlate well with histologic and bacteriologic features of tissue obtained at autopsy in mechanically ventilated patients and have a positive predictive value of 75% in ventilated patients who meet the standard clinical criteria for nosocomial pneumonia. Antecedent use of antibiotics diminishes the diagnostic efficacy of PSB cultures. In general, the sensitivity and specificity of PSB quantitative cultures are cited as 70%–90%. Studies comparing the efficacy of PSB and BAL quantitative cultures for the most part support the concept that these techniques are complementary. In patients with clinically suspected pneumonia in whom quantitative culture of PSB samples yields organisms in a concentration of 10^2 CFU/mL but $<10^3$ CFU/mL, PSB sampling should be repeated if pneumonia continues to be suspected clinically. In one third to one half of these patients, follow-up PSB quantitative culture will yield organisms in a concentration exceeding the diagnostic cutoff of 10^3 CFU/mL.

Plugged Telescoping Catheters

Because the routine use of the PSB technique is time-consuming and requires the use of a fiberoptic bronchoscope, an alternative, simpler technique using a plugged telescoping catheter (PTC) has been presented. Blind PTC sampling is as accurate as directed sampling via the bronchoscope, with a sensitivity of 100% and specificity of 82%. The accuracy of undirected PTC sampling is not unexpected. Pathologic examination of the lungs of intubated patients dying with nosocomial pneumonia has shown that bronchopneumonia is predominantly found in the lower and posterior parts of the lung, and chest radiographs taken during blind BAL via PTC have shown that 95% of catheters are lodged in the distal airways of the lower lobes. PTC sampling thus appears to be a useful tool for the diagnosis of ventilator-associated pneumonia as long as the radiographically defined area of involvement is limited to the lower lung fields.

PROPHYLAXIS

Given the fact that nosocomial pneumonia is the most common fatal nosocomial infection, an effective prophylactic regimen could have a significant impact on survival of hospitalized patients. To date, no single specific measure for pneumonia prevention has been proved to be beneficial, but several techniques currently under investigation may emerge as useful in the future.

Conventional Infection Control

Conventional infection control strategies have focused on identifying reservoirs of infection, interrupting transmission among patients, preventing progression from colonization to infection, and improving host defenses. Conventional infection control practices may fail to prevent nosocomial infection in the ICU, because many patients arrive already colonized with nosocomial bacteria; hand washing and barrier precautions are abandoned during crisis situations; and health care personnel may fail to adhere to traditional measures aimed at preventing infection in colonized patients, such as changing intravenous catheters routinely, discontinuing bladder catheters, suctioning with careful aseptic techniques, and removing ventilator circuit tubing condensate frequently to minimize exposure to the patient. The use of gloves by health care workers, as advocated under universal precautions guidelines, can lead to inadvertent transmission of pathogens (*Acinetobacter, Pseudomonas*)

if they are not changed between patients.

Enteral Nutrition

Enteral nutrition is the method of choice for nutrient administration, as it is less invasive, more physiologic, and less expensive than total parenteral nutrition. In one study of patients with abdominal trauma, enteral feeding with a jejunostomy tube was not accompanied by pneumonia in any of the 29 patients treated in this manner, whereas pneumonia occurred in 6 of the 30 patients receiving parenteral nutrition. Although nutrition is an important therapeutic modality used to counteract the adverse effects of malnutrition on lung defense mechanisms, enteral feeding produces a definite risk for infection. The most significant risk of enteral feeding results from gastric colonization and the subsequent transmission of gastric organisms to the trachea, with resultant nosocomial pneumonia. Pingleton and colleagues evaluated simultaneous daily gastric, tracheal, and oropharyngeal cultures in mechanically ventilated patients not receiving antacids or H_2 antagonists, and they demonstrated that the number of gastric gram-negative isolates increased significantly after enteral feeding began. In their study, 36% of patients had gram-negative bacilli recovered first in the stomach that were later recovered in the trachea. The mechanism of transfer of gastric organisms into the trachea appears to be aspiration. Important factors implicated in aspiration associated with enteral feeding are the size and location of the feeding tube. Clinically significant aspiration is infrequent when enteral feeding is administered continuously via a small-bore nasoenteral tube in intubated patients. Feedings delivered directly to the stomach, as opposed to distal enteral feeding, increase the likelihood of aspiration and pneumonia, especially if the patient is being kept supine rather than semi-erect.

Antimicrobial Prophylaxis

Antibiotic prophylaxis of nosocomial pneumonia can be administered systemically, topically, by aerosol, or by a combination of these methods.

Systemic Antibiotic Prophylaxis

Systemic antibiotic prophylaxis has clearly been unsuccessful. In the 1950s, trials of systemic antibiotic prophylaxis involving patients with poliomyelitis who have undergone tracheotomy, comatose patients in the ICU, and patients with congestive heart failure failed to demonstrate a significant reduction in tracheal colonization or frequency of pneumonia. Furthermore, prophylaxis actually increased the risk for resistant gram-negative bacillary pneumonia, cutaneous infection, and bacteremia. Based on data that 50% of pneumonias appear within 4 days of ICU admission, a more recent multicenter survey readdressed the issue of systemic prophylaxis. In that study of 570 patients in 23 ICUs, antibiotic prophylaxis did not result in a statistically significant decline in rates of early-onset pneumonia or death.

Aerosolization

The delivery of aerosolized antibiotics directly into the tracheobronchial tree has had minimal success as prophylaxis for ventilator-associated pneumonia. Polymyxin B was selected in several studies because it is bactericidal against a broad range of gram-negative bacilli, including *P. aeruginosa,* and it adsorbs well to epithelial surfaces without being absorbed systemically. Although aerosol polymyxin B can clearly reduce the occurrence of *P. aeruginosa* colonization and pneumonia when it is administered for prolonged periods, it results in the emergence of resistant organisms, and overall mortality rates have not been improved. Similarly, the endotracheal administration of gentamicin has been shown to decrease the rate of pneumonia, but overall mortality and infection-related mortality were unchanged. In addition, patient colonization with gentamicin-resistant organisms increased.

Selective Decontamination

Selective decontamination of the oropharynx is a prophylactic technique in which nonabsorbable antibiotics are applied directly to the oropharynx, in either a liquid or paste form. Parenteral antimicrobial agents are not administered. Prospective trials comparing topical nonabsorbable antibiotics with placebo have demonstrated decreased incidence of nosocomial pneumonia, but overall mortality rates were unchanged. Despite promising early results of selective oropharyngeal decontamination trials, flaws in study design have made these results largely unreliable.

Selective digestive decontamination as a method of pneumonia prevention was initially investigated in Europe. It is based on the use of orally administered, nonabsorbable antibiotics that eliminate aerobic gram-negative bacteria from the gut while sparing anaerobes. With time, selective digestive decontamination has been gradually modified. Fungal overgrowth often followed prophylaxis with polymyxin E and tobramycin, so amphotericin B became a standard part of the regimen. Because lower respiratory tract infection occurring within 5 days after ICU admission cannot be prevented solely by the topical administration of antibiotics to the oropharynx and stomach, intravenous cefotaxime given for several days was added to the regimen. Early nonblinded trials of selective digestive decontamination demonstrated reductions in rates of pneumonia, but for the most part no improvement in overall mortality or length of stay. More recent prospective, randomized, double-blinded, placebo-controlled studies using invasive methods to define the presence of pneumonia, however, have failed to demonstrate a benefit of selective digestive decontamination in decreasing the incidence of nosocomial infections (including pneumonia), length of stay, duration of mechanical ventilation, or mortality rates.

Gastric pH and Bacterial Overgrowth

Many studies have correlated high levels of gastric pH with logarithmic increases in the concentrations of gram-negative bacteria in the stomach and demonstrated the development of retrograde colonization from the stomach to the oropharynx and trachea. Several investigators reported increased rates of pneumonia in patients who received agents that alter gastric pH. Meta-analysis has consistently demonstrated that sucralfate (which does not alter gastric pH) is associated with a reduced incidence of pneumonia in comparison with antacids alone or combined with H_2 antagonists. There is disagreement, however, about whether the use of H_2 antagonists alone is associated with a higher rate of pneumonia in comparison with sucralfate or placebo. Nevertheless, it is overly simplistic to say that any intervention that raises gastric pH is undesirable. Other factors, especially gastric volume and the route of enteral feeding (gastric vs. distal) influence gastric bacterial growth, and analyses have not consistently considered the impact of these concomitant risk factors.

Management of Equipment Used for Respiratory Therapy

Bacteria can proliferate in the equipment used during respiratory therapy, and the incidence of pneumonia is increased if the tubing is manipulated frequently rather than infrequently. When tubing is handled, the condensate should always be drained away from the patient, as it can contain large concentrations of bacteria. Although many hospitals have a policy to change ventilator tubing every 48 to 72 hrs, there are no data showing that any particular frequency of circuit changes, compared with no circuit changes, lessens the incidence of pneumonia. The use of heat and moisture exchangers to lessen ventilator tubing contamination may decrease bacterial colonization of the circuit but has no effect on the incidence of pneumonia.

Aspiration of subglottic secretions is achieved with the use of a special endotracheal tube, designed with a suction port above the endotracheal tube cuff, in the subglottic area. The removal of contaminated respiratory secretions pooling above the endotracheal tube cuff reduces the incidence of some forms of ventilator-associated pneumonia. Once endotracheal tubes allowing the aspiration of subglottic secretions become more widely available, this approach may be used more regularly.

Continuous Postural Oscillation

Many years ago, it was recognized that prolonged recumbency increases the risk for pulmonary complications after operation, and for that reason early ambulation after surgery has become standard practice. For many critically ill patients in the ICU, however, ambulation is impossible, and the use of oscillating beds has been advocated as a means of avoiding the adverse pulmonary consequences of prolonged immobilization. Continuous postural oscillation (CPO) has been studied in patients bedridden with acute stroke, immobilized head-injured patients in traction, and victims of blunt trauma, and pneumonia occurred in significantly fewer patients randomized to CPO than to a conventional bed. Other studies, however, have not supported the benefit of CPO. Postoperative chest physiotherapy has failed to affect the incidence of pneumonia after gastric bypass surgery, and the use of CPO in medical patients in the ICU did not reduce overall mortality or the incidence of pneumonia. Although CPO may have a valid role in the care of certain critically ill patients, studies to date can be faulted for relying on clinical criteria for the diagnosis of pneumonia, and future trials are warranted.

MICROBIAL ETIOLOGIC AGENTS

Most reported cases of nosocomial pneumonia are caused by bacteria, and the time of onset of pneumonia after hospitalization is related to the bacterial etiology. Early-onset pneumonia, defined as pneumonia developing within 2 to 4 days after admission, occurs in anywhere from 8%–60% of patients requiring prolonged intensive care and accounts for up to 50%–60% of all cases of nosocomial pneumonia in some series. Early-onset pneumonia may be caused by community-acquired flora, including *S. aureus, Streptococcus pneumoniae,* and *Haemophilus influenzae.* After this initial time period, gram-negative bacteria become the major etiologic agents, coinciding with the time frame of oropharyngeal and tracheal colonization described earlier. Gram-negative bacilli account for 50%–80% of all nosocomial

pneumonias, and 10%–20% of cases are polymicrobial.

Among the gram-positive bacteria, *S. aureus* is by far the most common, accounting for at least 10% of all nosocomial pneumonias. *S. aureus* is the gram-positive organism most often responsible for bacteremic nosocomial pneumonia. Staphylococcal pneumonia is more common in individuals with recent influenza, head injury, coma, a history of injecting drug use, chronic renal failure, or diabetes mellitus. Chest radiographs usually reveal multilobar infiltrates, predominantly in the lower lobes, often bilaterally. Pleural involvement is common, but cavitation and abscess formation infrequently occur. Infection caused by methicillin-resistant organisms is more likely in persons who have previously received antibiotics.

Although *S. pneumoniae* is the most common bacterial cause of community-acquired pneumonia, it accounts for less than 3% of all nosocomial pneumonias but up to 12% of bacteremic nosocomial pneumonias. Pneumococcal nosocomial pneumonia usually occurs within the first few days of hospitalization. Enterococcal nosocomial pneumonia has been associated with antecedent cephalosporin therapy and enteral alimentation.

Pseudomonas, Klebsiella, Enterobacter, Escherichia coli, and *Serratia* species are the most commonly reported causes of gram-negative bacillary pneumonias. *Pseudomonas* and *Serratia* are the most common pathogens causing bacteremic nosocomial pneumonia, whereas *E. coli, Klebsiella,* and *Enterobacter* are more frequently associated with nonbacteremic cases. Patients with ventilator-associated pneumonias who have received antibiotics before the onset of pneumonia are especially likely to be infected by *P. aeruginosa* or *Acinetobacter* species. Bacteremic nosocomial pneumonia caused by gram-negative bacteria is more likely to occur in elderly patients with debilitating underlying diseases, and mortality rates of 58%–82% are typical. *P. aeruginosa* is the most common pathogen, accounting for almost 17% of all nosocomial pneumonias. Oropharyngeal colonization by the organism with subsequent spread to the lower respiratory tract, as is typical for most gram-negative bacillary pneumonias, commonly occurs with *P. aeruginosa* but is not the sole mechanism of pathogenesis. Primary tracheal colonization with *P. aeruginosa* without antecedent oropharyngeal colonization has been described, and for this reason attempts at topical oropharyngeal decontamination would be unlikely to prevent primary colonization of the lower respiratory tract. In addition, hematogenous or bacteremic *Pseudomonas* pneumonia, with a presentation that mimics cardiogenic pulmonary edema, can occur and is nearly universally fatal.

Bacteremic *Pseudomonas* pneumonia is more common in patients with leukemia, lymphoma, solid tumor neoplasms, or chemotherapy-induced granulocytopenia (Plate 2), whereas nonbacteremic disease is seen more frequently in debilitated elderly patients with underlying cardiopulmonary disease. Radiographically, *Pseudomonas* pneumonia may be focal or diffuse. The focal form characteristically involves a lower lobe, although multilobar involvement has been the usual finding in patients with terminal infection. Infiltrates are usually alveolar, often with radiologic evidence of cavitation or abscess formation. Occasionally, a peculiarly nodular bronchopneumonia of the lower lobes, with multiple small, thin-walled radiolucent cystic lesions, is seen. The diffuse form is a fearsome disease having an early radiographic presentation that mimics cardiogenic pulmonary edema. Bacteremia and leukopenia are common. If the patient survives beyond 48 hours, the chest radiograph demonstrates evolution into a necrotizing bilateral bronchopneumonia, often with pleural effusion and abscess formation. Histologically, this form is characterized by necrotizing pneumonia, vasculitis, pulmonary hemorrhage, and abscess formation. Mortality rates of 30%–60% have been reported for nonbacteremic *Pseudomonas* pneumonia, whereas the bacteremic variety is associated with case fatality rates invariably exceeding 80%. Treatment, which depends on in vitro sensitivities, is ordinarily with ceftazidime, aztreonam, imipenem, ciprofloxacin, or extended-spectrum penicillins plus an aminoglycoside. In many series, mortality has been independent of the effectiveness of the antimicrobial regimen applied, correlating mostly with the underlying disease process and degree of immunosuppression.

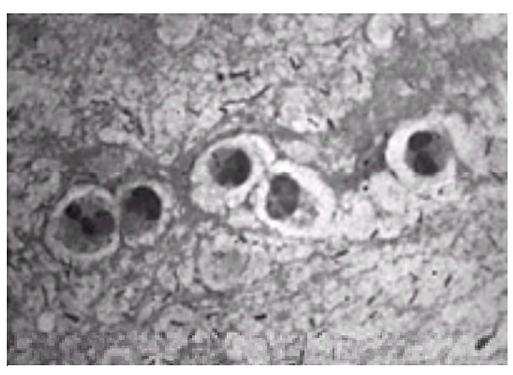

PLATE 2. *Pseudomonas* in sputum of a neutropenic patient. ×900. *See color plate 15.*

E. coli is the third most frequently isolated gram-negative organism responsible for hospital-acquired pneumonia, following *Pseudomonas* and *Klebsiella.* Pneumonia caused by *Klebsiella* is discussed in chapter 24. *E. coli* may colonize the oropharynx and subsequently invade the lower respiratory tract, but bacteremic invasion may occur from a distant focus in the genitourinary or gastrointestinal tract. The presence of serious underlying disease is a major factor leading to *E. coli* pneumonia, and two thirds of the patients have had been receiving broad-spectrum antibiotics, corticosteroids, or cytotoxic chemotherapy before the onset of pneumonia. Multilobar involvement is as common as disease localized to one lobe, and parapneumonic pleural effusion occurs frequently. Bacteremic *E. coli* pneumonia is associated with a normal or elevated white blood cell count, unlike bacteremic *Pseudomonas* pneumonia, in which leukopenia is a major predisposing factor. Mortality rates of 60%–80% are reported, with the worse outcomes associated with bacteremia.

Legionellosis may account for up to 30% of nosocomial pneumonias in hospital settings where potable water is contaminated, but because the diagnosis requires special serologic and microbiologic techniques, the true incidence is unknown. The presentation of nosocomial *Legionella* pneumonia may be sporadic or epidemic. Clinical diagnosis in an outbreak setting is not difficult; however, differentiating *Legionella* pneumonia from other types of pneumonia in a nonepidemic setting can be troublesome. Risk factors for nosocomial legionellosis include malignancy, renal failure, neutropenia, cytotoxic chemotherapy, and corticosteroid therapy. Factors such as altered consciousness, prior antibiotic therapy, and intubation, which are known to be associated with other types of pneumonia, have a negative association with *Legionella* infection. There are no pathognomonic radiologic findings. Initial infiltrates are usually patchy, alveolar, and unilobar, with a predilection for the lower lobes. Generally, the infiltrate spreads locally within a lobe and then to contiguous lobes (Fig. 1). Pleural effusion may occur, and cavitation is seen in 10% of patients, usually in an immunosuppressed host receiving corticosteroids. Diagnosis and therapy are similar to those previously described for community-acquired disease.

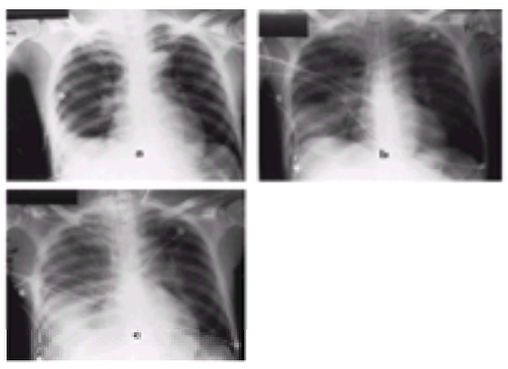

FIG. 1. A,B,C: Nosocomial legionellosis appearing as a patchy infiltrate in the right lower lobe with rapid progression during a period of 4 days.

Nosocomial viral lower respiratory tract infections are particularly common in children, and in one survey viral agents accounted for 20% of all hospital-acquired pneumonias. Respiratory syncytial, influenza, and parainfluenza viruses are important causes of viral nosocomial pneumonia, but only with prospective monitoring using specialized virologic diagnostic methods can the true incidence of nosocomial disease be determined. Nosocomial viral pneumonias are dissimilar to bacterial infections in several respects. Whereas bacterial nosocomial pneumonias tend to reflect the environmental flora of the hospital, nosocomial viral disease generally parallels activity of these agents in the community. Transmission of respiratory viruses involves active infection of hospital personnel in addition to passive transfer of virus on fomites or hands. Finally, whereas nosocomial bacterial infections are most likely to occur in individuals at high risk, viral diseases may occur in any exposed, nonimmune individual.

Herpes simplex virus (HSV) has been identified as a cause of nosocomial lower respiratory tract infection, but because endogenous reactivation is the likely mechanism leading to disease, the term *hospital-acquired* may be inaccurate. Most of the cases reported to date have involved patients with alterations of

cell-mediated immunity, severe underlying disease, or diffuse lung injury, including ARDS. It should be borne in mind, however, that HSV infection of the lower respiratory tract has occurred in apparently normal, immunocompetent hosts. Chronic lung disease and tobacco abuse have been reported by some authors as predisposing factors. Aspiration or contiguous spread from the oropharynx to the respiratory tract is the predominant pathogenic mechanism, but hematogenous seeding may occur in cases characterized with diffuse interstitial infiltrates (Plate 3). Aspiration as a mechanism is supported by the fact that in most patients, HSV infection of the lower respiratory tract is accompanied by oral or pharyngeal sores.

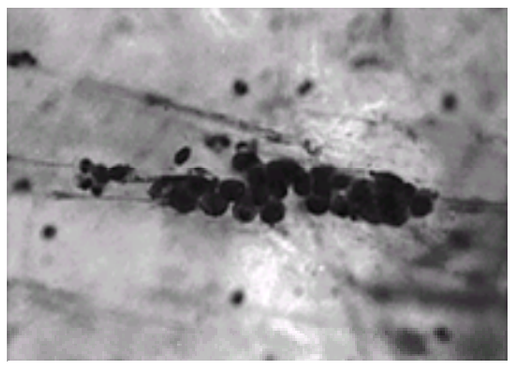

PLATE 3. Giemsa stain of endotracheal secretions showing intranuclear inclusions of HSV. Fever and diffuse interstitial pneumonia developed in this patient after coronary bypass surgery. *See color plate 16.*

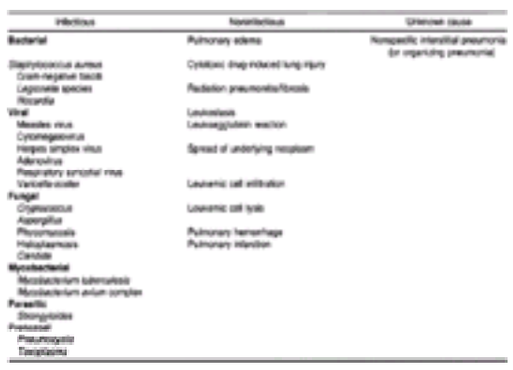
Clinically, the disease process is variable, and in its mildest form nothing more than the extension of an oropharyngitis occurs. HSV infection can be localized to the trachea and large bronchi, or a more generalized tracheobronchitis with extension into the bronchioles and alveoli can occur. HSV tracheobronchitis usually presents acutely with substernal pain, bronchospasm, and bloody respiratory secretions, and it may progress to respiratory failure, with the need for intubation and mechanical ventilation. When HSV tracheobronchitis arises in the intubated patient, it may manifest as bronchospasm, and weaning from mechanical ventilation is difficult. Localized or diffuse pneumonia can also be seen. Bacterial and fungal superinfections occur frequently.

HSV can be cultured from the mouth of 1%–5% of asymptomatic adults, and with any respiratory illness, the carriage rate rises to 2.7%–11.5%. For this reason, viral cultures of respiratory secretions are nondiagnostic unless supported by cytologic or histologic evidence of infection. Cytologic preparations typically reveal multinucleated giant cells and Cowdry type A intranuclear inclusions in patients with HSV infection of the lower respiratory tract. Bronchoscopy has been particularly useful in the diagnosis of HSV tracheobronchitis, as it allows for direct visualization of the characteristic punctate mucosal ulcerations and fibrinopurulent tracheal membrane. Direct immunofluorescent staining of HSV-infected tissue may be useful in obtaining a rapid diagnosis.

Acyclovir is the drug of choice, administered in a dose of 5 mg/kg intravenously every 8 hours for 10 days. In patients who fail to respond, an acyclovir-resistant HSV strain may be present, and intravenous foscarnet should be substituted. Mortality rates of 30%–70% have been reported.

PNEUMONIA IN THE IMMUNOCOMPROMISED PATIENT

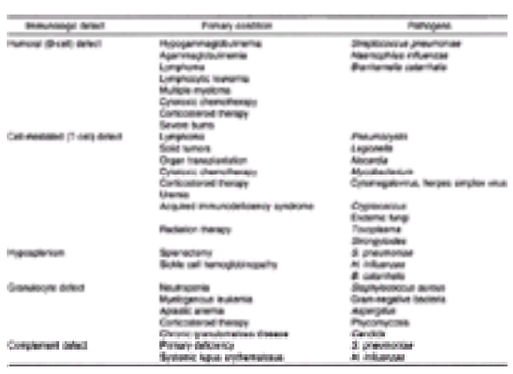
Pulmonary infiltrates occurring in the immunocompromised host may have a myriad of causes, both noninfectious and infectious (Table 2). The differential diagnosis in any given patient can be narrowed by employing a systematic approach in which the clinician categorizes the nature of the underlying immunodeficiency, the onset of disease relative to hospitalization or immunosuppressive therapy, the tempo of the disease process, and the radiographic pattern of involvement. This section focuses on the diagnostic approach to the infectious etiologies, and only those etiologic agents unique to a particular clinical situation are discussed. Pulmonary infections complicating the acquired immunodeficiency syndrome (AIDS) are reviewed in Chapter 26. This chapter concludes with a discussion of the pulmonary infectious complications of transplantation.



Infectious	Noninfectious	Unknown cause
Bacterial	Pulmonary edema	Nonspecific interstitial pneumonia (or organizing pneumonia)
Staphylococcus aureus	Cytotoxic drug-induced lung injury	
Gram-negative bacilli		
Legionella species	Radiation pneumonitis/fibrosis	
Nocardia		
Viral	Leukostasis	
Measles virus	Leukoagglutinin reaction	
Cytomegalovirus		
Herpes simplex virus	Spread of underlying neoplasm	
Adenovirus		
Respiratory syncytial virus		
Varicella-zoster	Leukemic cell infiltration	
Fungal		
Cryptococcus	Leukemic cell lysis	
Aspergillus		
Phycomycosis	Pulmonary hemorrhage	
Histoplasmosis	Pulmonary infarction	
Candida		
Mycobacterial		
Mycobacterium tuberculosis		
Mycobacterium avium complex		
Parasitic		
Strongyloides		
Protozoal		
Pneumocystis		
Toxoplasma		

TABLE 2. *Pulmonary infiltrates in the immunocompromised host*

The differential diagnosis of pulmonary pathogens in a particular patient is influenced in part by the nature of the immunologic defect (Table 3). Patients with abnormalities of immunoglobulin synthesis, hyposplenism, or complement deficiencies are uniquely predisposed to infections with encapsulated bacteria, especially *S. pneumoniae, H. influenzae,* and *Branhamella catarrhalis.* Quantitative or qualitative defects in neutrophil function primarily predispose patients to both bacterial and fungal pathogens, whereas cellular immune dysfunction can lead to infection by a variety of opportunistic organisms. The clinical situation is seldom so easily defined, and coexistent immune defects may be present. For example, although Hodgkin's disease is classically associated with cell-mediated immune dysfunction, both humoral and granulocytic immune dysfunction may also develop in these patients secondary to cytotoxic chemotherapy, radiation therapy, and splenectomy.



Immunologic defect	Primary condition	Pathogens
Humoral (B-cell) defect	Hypogammaglobulinemia	*Streptococcus pneumoniae*
	Agammaglobulinemia	*Haemophilus influenzae*
	Lymphoma	*Branhamella catarrhalis*
	Lymphocytic leukemia	
	Multiple myeloma	
	Cytotoxic chemotherapy	
	Corticosteroid therapy	
	Severe burns	
Cell-mediated (T-cell) defect	Lymphoma	*Pneumocystis*
	Solid tumors	*Legionella*
	Organ transplantation	*Nocardia*
	Cytotoxic chemotherapy	*Mycobacteria*
	Corticosteroid therapy	Cytomegalovirus, herpes simplex virus
	Uremia	
	Acquired immunodeficiency syndrome	*Cryptococcus*
	Radiation therapy	Endemic fungi
		Toxoplasma
		Strongyloides
Hyposplenism	Splenectomy	*S. pneumoniae*
	Sickle cell hemoglobinopathy	*H. influenzae*
		B. catarrhalis
Granulocyte defect	Neutropenia	*Staphylococcus aureus*
	Myelogenous leukemia	Gram-negative bacteria
	Aplastic anemia	*Aspergillus*
	Corticosteroid therapy	Phycomycosis
	Chronic granulomatous disease	*Candida*
Complement defect	Primary deficiency	*S. pneumoniae*
	Systemic lupus erythematosus	*H. influenzae*

TABLE 3. *Immunologic defects and associated pathogens*

The time of onset of the pulmonary illness relative to the underlying immunodeficiency or immunosuppressive therapy may help to focus the differential diagnosis (Table 4). A retrospective review of patients with acute leukemia found that focal infiltrates occurring before initiation of therapy were likely to represent bacterial infections, whereas diffuse infiltrates were never caused by opportunistic pathogens and were usually noninfectious in etiology. In contrast, once patients had received chemotherapy, the occurrence of pulmonary infiltrates was usually secondary to opportunistic infections. Nodular or patchy alveolar infiltrates developing after prolonged periods of granulocytopenia are likely to represent invasive pulmonary aspergillosis. Lastly, pulmonary infectious complications of organ transplantation

commonly follow characteristic temporal patterns, and this is discussed at the end of the chapter.

Before immunosuppressive therapy	Bacterial, viral
	Pulmonary hemorrhage
	Neoplasia
	Primary bronchogenic carcinoma
	Metastatic carcinoma
	Lymphangial spread
	Leukemic cell infiltration
During chemotherapy	Opportunistic pathogen
	Leukoagglutination reactions
	Leukemic cell lysis pneumonopathy
	Pulmonary edema
Late or delayed	Cytomegalovirus
	Radiation pneumonitis/ fibrosis
	Cytotoxic drug-induced

TABLE 4. *Time of onset of pulmonary infiltratein relation to etiology*

The rate of disease progression varies according to etiology and helps in narrowing the differential diagnosis (Table 5). Acute illnesses of 24 hours' duration suggest a bacterial pneumonia, whereas subacute presentations spanning several days are more consistent with infectious processes such as cytomegalovirus (CMV), *Pneumocystis carinii,* nocardiosis, or fungi. Lastly, chronic illnesses occurring during a period of weeks are more typical of mycobacterial or endemic fungal pathogens.

Rapid	Subacute	Insidious
Infectious		
Bacterial	Cytomegalovirus	Nocardia
Gram-negative organisms	Fungi	Fungi
Staphylococcus aureus	Aspergillus	Cryptococcus
Legionella	Cryptococcus	Histoplasmosis
Viral	Phycomycosis	Mycobacterium
Herpes simplex virus	Pneumocystis carinii	
Measles virus		
Noninfectious		
Pulmonary edema	Leukemic cell infiltration	Cytotoxic drug-induced
Leukoagglutination reaction		Radiation pneumonitis/fibrosis
Pulmonary hemorrhage		
Leukemic cell lysis pneumonopathy		

TABLE 5. *Time course of pulmonary disease in immunocompromised patients*

The radiographic pattern of involvement is rarely pathognomonic, but classification into diffuse, nodular, or focal infiltration is useful (Table 6). A definitive diagnosis cannot be established on the basis of the radiographic presentation alone, as more than one etiology may be present and progression of infiltration from a focal to a diffuse pattern may occur. The air-crescent sign, however, is virtually pathognomonic of invasive pulmonary aspergillosis and is perhaps the only diagnostic radiographic pattern (Fig. 2). In addition, a characteristic halo sign, or zone of lower attenuation surrounding a pulmonary mass, has been observed on computed tomography in patients with invasive pulmonary aspergillosis.

Diffuse	Nodular or cavitary	Focal
Common		
Bacteremia	Bacterial lung abscess	Bacteria
Pneumocystis carinii	*Nocardia*	*Nocardia*
Cytomegalovirus	*Staphylococcus aureus*	*Cryptococcus*
Herpes simplex virus	*Cryptococcus*	*Aspergillus*
	Aspergillus	Phycomycosis
Uncommon		
Candidemia	Tuberculosis	Tuberculosis
Miliary tuberculosis	*Legionella*	Histoplasmosis
Disseminated histoplasmosis	*Pneumocystis carinii*	*Legionella*
	Septic emboli	

TABLE 6. *Radiographic patterns of pulmonary infiltrates in immunocompromised patients*

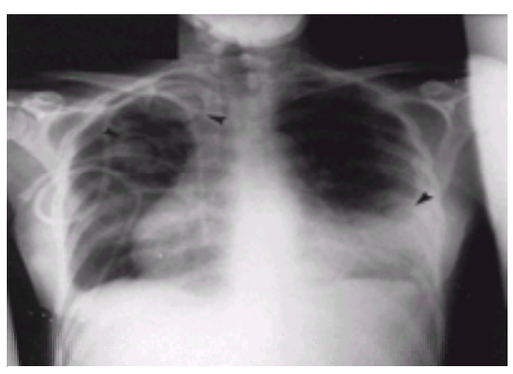


FIG. 2. Multiple air-crescent signs (*arrowheads*) in the lingula, right upper lobe, and right lower lobe in a patient with refractory acute myelogenous leukemia and invasive pulmonary aspergillosis.

Diagnostic techniques, including sputum examination and fiberoptic bronchoscopy with BAL, are similar to those described for the diagnosis of hospital-acquired pneumonia. In addition, transbronchial biopsy may be necessary for the diagnosis of pulmonary infiltrates in the immunocompromised host. Unfortunately, a significant number of transbronchial biopsies fail to establish a definitive diagnosis. For example, a specific diagnosis was made in only 45% of nearly 600 procedures reported in 18 studies. Furthermore, at least 11% of the transbronchial biopsy results in those studies were falsely negative, largely attributable to sampling error. It should also be borne in mind that the addition of transbronchial biopsy to fiberoptic bronchoscopy increases the risk of the procedure 20-fold, with a resultant 14% complication rate. Open lung biopsy remains the definitive diagnostic procedure. In the critically ill immunosuppressed patient, frequently with a bleeding diathesis, it offers the additional advantage of direct control of complications resulting from the tissue biopsy. Complication rates vary from 8%–20%, with 3% of them major. Procedure-related mortality is estimated at 1%. The highest diagnostic yield of open lung biopsy in general is in patients with pulmonary nodules, masses, and cavities. It has been useful in patients with diffuse infiltrates who have had previous bronchoscopic evaluation. Overall diagnostic yields range from 44%–94%, and the incidence of missed diagnoses is about 6%.

Lower respiratory tract infection in the immunocompromised host may be caused by a variety of microbes, including bacteria, *Legionella,* viruses, and opportunistic fungi. The clinical manifestations of these etiologic agents have been reviewed earlier in this chapter, as well as in Chapter 24, Chapter 26, and Chapter 27. The reader

is referred to the respective sections for details. *P. carinii* and CMV, however, are uniquely pathogenic to the immunocompromised host and warrant further discussion.

P. carinii has been recognized as a cause of pneumonia for 30 years, and through the 1970s the majority of cases occurred in patients with lymphocytic leukemia, lymphoma, or congenital T-cell deficiencies, or those receiving chronic corticosteroid therapy. In the 1980s, *P. carinii* emerged as the most common cause of pneumonia in patients with human immunodeficiency virus (HIV) infection, accounting for thousands of cases annually in the United States (Chapter 26). Nevertheless, *P. carinii* continues to cause considerable morbidity and mortality in non-HIV-infected immunocompromised patients, and this discussion focuses on such individuals.

Not all patients with neoplastic disease are at risk for *P. carinii* infection. Attack rates of 20%–40% have been reported in children with acute lymphocytic leukemia, and patients with underlying hematologic neoplasm, especially lymphoma, account for the majority of cases. Cases in patients with underlying solid tumors have become more common, now accounting for approximately 40% of the cases complicating neoplastic disease. Treatment with corticosteroids represents the main chemotherapeutic risk in most series, a risk factor noted in 80%–90% of all cases. Interestingly enough, in 80% of patients, the corticosteroid dose was being tapered at the time of diagnosis.

The clinical presentation is marked by fever, dry cough, and dyspnea of several days' duration. Chest radiographs disclose bilateral interstitial infiltrates, and arterial blood gas determination shows hypoxia. Serum lactate dehydrogenase levels may be elevated. There are dissimilarities in the clinical presentation of *P. carinii* pneumonia between patients with AIDS and those without AIDS (Table 7). The onset of illness is typically more acute in the non-HIV-infected host, and a more fulminant presentation mimicking that of bacterial pneumonia may be seen. The *Pneumocystis* cyst burden seen on microscopic examination of the respiratory tract secretions is generally much lower than that encountered in AIDS patients. Recurrence is rare, as is the development of extrapulmonary pneumocystosis in the non-AIDS host. Although adverse reactions to trimethoprim/sulfamethoxazole are uncommon in patients without AIDS, the overall mortality rate is consistently higher than in patients with AIDS (50% vs. 10%–15%, respectively). The diagnostic methods, therapeutic aspects, and prophylactic strategies are similar to those in AIDS patients (Chapter 26). It should be noted, however, that no trials have assessed the utility of adjunctive corticosteroid therapy for *P. carinii* pneumonia in non-AIDS patients.

Clinical feature	AIDS	Non-AIDS
Mean duration of symptoms, days	28	5
Cyst load in secretions	High	Low
Recurrences	Common	Rare
Side effect to trimethoprim-sulfamethoxazole	Common	Rare
Mortality rate, %	10–15	50

TABLE 7. *Clinical features of Pneumocystis carinii pneumonia: AIDS versus non-AIDS patients*

CMV is ubiquitous among organ transplant recipients and has been referred to as the “troll of transplantation.” CMV infection is associated with increased susceptibility to bacterial, fungal, and protozoal superinfection; increased risk for chronic transplant rejection; and increased overall mortality. CMV-seronegative recipients of marrow or granulocyte infusions or organs from seropositive donors are at the greatest risk for development of serious CMV disease. CMV infection typically occurs 2 to 12 weeks after transplantation, with a mean time to diagnosis of primary disease of 3 to 4 weeks and to discovery of reactivation/reinfection of 6 weeks. Fever occurs in 90% of patients and is frequently prolonged. Headache, arthralgias, myalgias, fatigue, and diarrhea may antedate the onset of pneumonitis. Neutropenia, anemia, and hepatitis are frequent accompanying abnormalities. Diffuse interstitial and/or alveolar infiltrates are the most common radiographic findings, although focal infiltrates, nodules, discoid atelectasis, and normal findings have been reported.

The diagnosis of CMV pneumonitis requires cytologic or histologic confirmation of positive CMV cultures, titers, or antigen detection. Conventional culture of BAL fluid has a high sensitivity and negative predictive value; however, the cultures must be incubated for several weeks, and a positive culture lacks specificity. The BAL fluid may also be cultured in the shell-vial method and stained after 24 to 48 hours of incubation for expression of early CMV antigen. Although more rapid than conventional culture techniques, an analogously high sensitivity and low specificity are expected. Standard cytologic examination of BAL fluid for cells with viral inclusions has had a low sensitivity (21%) but a high specificity (98%). Immunocytochemical staining of BAL cells to detect the presence of CMV antigen has a higher sensitivity (86%), lower specificity (84%), and a good negative predictive value (96%). The sensitivity of transbronchial biopsy for the diagnosis of CMV pneumonia cannot be readily ascertained; it remains the diagnostic procedure of choice, however, and open lung biopsy is rarely necessary. Coinfection with other opportunistic pathogens, particularly *P. carinii,* is common. Ganciclovir or foscarnet is the drug of choice, and outcome is much better in recipients of solid organ transplants than in bone marrow transplant recipients.

ORGAN TRANSPLANTATION

Largely as a result of improvements in immunosuppressive therapy, 1-year survival rates among recipients of livers, kidneys, hearts, and lungs now approach 70%–80%, and in 1990 it was estimated that 9560 kidney, 2656 liver, 2085 heart, 262 lung, 50 heart-lung, and 2200 allogeneic bone marrow transplantations were performed in the United States. Transplantation of any organ is often followed by a variety of complications, prominent among which are pulmonary disorders, both noninfectious and infectious. This section reviews the pulmonary infectious complications as they pertain to the specific organ transplanted.

Liver Transplantation

Orthotopic liver transplantation was first performed by Starzl in 1963, and 1-year survival rates now exceed 70%. The early postoperative course is marked by the development of pleural effusions, atelectasis, and diaphragmatic dysfunction. Infection is the most important postoperative pulmonary complication, and it is the principal source of morbidity and mortality from pulmonary disease in orthotopic liver transplant recipients. Risk factors for infection after transplantation include prolonged operating time, prolonged postoperative antibiotic therapy, renal failure, and gastrointestinal or vascular complications, and overall, the incidence of bacteremia and fungemia is 70%. The critical time period for the development of infection after orthotopic liver transplantation is the first 2 months.

Bacterial pneumonia occurs in 2%–25% of recipients and accounts for almost 50% of all pulmonary infections. The majority of cases of bacterial pneumonia develop in intubated patients and are not usually associated with bacteremia. A decline in the incidence of pneumonia has been reported when selective bowel decontamination is employed, although gram-positive organisms then become more frequent etiologic agents. Case fatality rates approach 40%.

CMV is the most common infectious agent in this patient population, with an incidence 60%. Symptomatic disease occurs in 20%–70% of infected individuals, and augmentation of immunosuppression for treatment of allograft rejection often precedes the onset of CMV disease. In particular, treatment of allograft rejection with OKT3 has been associated with an increased incidence of disseminated disease. Ganciclovir is effective therapy, with complete clearing of virus occurring in 75%–100% of patients.

The majority of fungal pneumonias occur within the first month of transplantation, and are usually caused by *Candida* species and *Aspergillus.* Disseminated infection with these organisms is associated with 70%–100% mortality. *P. carinii* pneumonia usually occurs 3 to 5 months after transplantation, and prophylaxis with trimethoprim/sulfamethoxazole is recommended.

Renal Transplantation

Both patient and renal allograft survival rates have improved during the past decade, such that transplantation now compares favorably with dialysis as a therapeutic modality for end-stage renal disease. More than 95% of renal transplant patients are alive at 1 year, and graft survival rates of 70%–90% are expected. Infections account for 65% of all pulmonary complications after renal transplantation, and the incidence of pneumonia has ranged from 8% to 16% in recent surveys.

Bacterial nosocomial pneumonias usually develop within the first month of transplantation, and the clinical presentation may be quite fulminant. The administration of steroid boluses for the treatment of allograft rejection is associated with an increased risk for hospital-acquired pneumonia. The incidence of fungal pneumonia may be directly related to the number of treated rejection episodes, and fungal infections that are superimposed on CMV infection have an especially poor prognosis.

Aspergillus is the most frequent and most serious of the pulmonary mycoses described, and infection usually occurs within the initial 4 months. Amphotericin B is the treatment of choice, and the response is variable. The presence of copathogens significantly affects outcome. Eighty percent of those with primary *Aspergillus* infection respond to therapy, whereas none of those with *Aspergillus* infection superimposed on another pulmonary infection survive.

The incidence of mycobacterial infection in renal transplant patients is several times higher than that in the general population, occurring in 0.6%–2.3% of patients. Pulmonary involvement is the most frequent clinical manifestation, although an increased incidence of joint and skin disease occurs. The onset of infection is usually late, often developing a year or more after transplantation. Respiratory symptoms are often minimal, and an unexplained fever or abnormal-appearing chest radiograph may be the only clue to the infection. Dissemination is common, and ARDS has occurred. Response to standard antituberculous therapy is good.

The incidence of *P. carinii* pneumonia was 5% in the early experience with renal transplantation, but a striking increase in incidence of disease followed the introduction of cyclosporine. The onset of illness is typically acute, with fever and respiratory symptoms evolving within several days. Illness usually develops 2 to 4 months after transplantation, and prophylaxis with trimethoprim/sulfamethoxazole for 12 months after transplantation is recommended.

CMV infection is the most common infectious complication after renal transplantation, with an incidence of 75% consistently reported. Overall, symptomatic disease develops in 20%–40% of infected patients. The majority of patients have either asymptomatic or mildly symptomatic disease that usually appears within the first 2 months after transplantation. Before the availability of ganciclovir, CMV pneumonia in the renal transplant patient carried a 48% mortality, and 90% of patients requiring mechanical ventilation died. Ganciclovir is effective therapy for CMV pneumonia in renal transplant patients, and the survival rate approaches 78%, including a 39% survival rate in patients requiring mechanical ventilation. Complete virologic clearing is seen in 70%–90% of treated patients.

Bone Marrow Transplantation

Bone marrow transplantation has been successfully applied to a growing list of hematologic and malignant diseases, and 2-year, disease-free survival rates exceed 60% for some forms of leukemias and aplastic anemia. Pulmonary complications occur in 40%–60% of marrow recipients, and particularly prominent among the infectious pulmonary complications are the respiratory viral and fungal infections.

Bacterial pneumonia is infrequently diagnosed during the early period after marrow transplantation, primarily because of the early empiric use of broad-spectrum antibiotics during episodes of fever. Nevertheless, a recent publication reported a 12%–60% incidence of bacterial pneumonia in this population, with gram-negative organisms as the predominant cause. Most of the late bacterial infections occurring after marrow transplantation involve the respiratory tract, are associated with chronic graft-versus-host disease, and are caused predominantly by gram-positive organisms, including *S. pneumoniae.*

The incidence of CMV infection after allogeneic bone marrow transplantation ranges from 50%–70%, and CMV pneumonia develops in one third of infected patients. Overall, CMV pneumonitis occurs in 15% of all bone marrow recipients, and an increased incidence has been observed among older patients, seropositive patients, those who have received total-body irradiation, those with severe graft-versus-host disease, and seronegative recipients of marrow from seropositive donors. The single feature that distinguishes CMV pneumonia in bone marrow recipients from CMV pneumonia in recipients of solid organ transplants is the high mortality. Despite the significant antiviral action of ganciclovir in vitro, its clinical efficacy for CMV pneumonia in bone marrow recipients has been variable. When used alone, ganciclovir has resulted in 17%–48% survival rates. The combination of ganciclovir with high-titer, CMV-specific immune globulin has proved beneficial, with survival rates ranging from 52%–70%. Relapses occur, however, in nearly one third of these patients.

Recent studies have demonstrated the efficacy of antiviral agents for the prophylaxis of CMV infection. In one study, high-dose, intravenously administered acyclovir reduced the incidence of both CMV infection (from 75% to 59%) and pneumonia (from 31% to 19%). In addition, survival was greater in the acyclovir-treated patients. Even better results have been found with ganciclovir. Schmidt and co-workers randomized recipients of allogeneic bone marrow who had CMV detected in BAL fluid at day 35 after transplantation to receive full-dose ganciclovir versus observation. The incidence of CMV pneumonia or death was reduced from 70% in the control group to 25% in the prophylaxis group. Based on these findings, ganciclovir should be considered for prophylaxis in asymptomatic bone marrow recipients shedding CMV in BAL fluid or blood.

In the absence of acyclovir prophylaxis, HSV is excreted by 80% of seropositive bone marrow recipients, usually between the second and third week after transplantation. Most of these infections represent viral reactivation and involve the oropharyngeal mucosa. The clinical features are nonspecific, and two forms of HSV pneumonitis exist. Focal or multifocal pulmonary involvement usually arises from direct, contiguous spread from the oropharynx, whereas diffuse pulmonary involvement represents hematogenous dissemination from oropharyngeal or genital sites. Virtually all patients have mucocutaneous involvement, and copathogens are frequent.

Respiratory syncytial virus may cause interstitial pneumonitis in bone marrow recipients. Patients present with fever, cough, and signs of ear or sinus involvement before the onset of clinical and radiographic pulmonary disease. The majority of cases occur during the winter and spring. Therapy with aerosolized ribavirin and intravenous immunoglobulin has been advocated. Mortality rates exceed 80%.

Although pulmonary infection with *Candida, Cryptococcus, Histoplasma,* and *Coccidioides* are described, *Aspergillus* species are the most common cause of invasive fungal disease in bone marrow transplant recipients. Recipients of bone marrow are the most susceptible of all transplant patients to invasive pulmonary aspergillosis because of the nature of their immunosuppression. The duration of granulocytopenia and the administration of high-dose corticosteroids are well-recognized risk factors for the development of invasive pulmonary aspergillosis, and these factors concomitantly exist in the majority of bone marrow transplant patients. Treatment of invasive pulmonary aspergillosis is unsatisfactory, and outcome is best determined by the recovery of the granulocyte count. Mortality rates are high, approaching 80%–90%.

The incidence of *P. carinii* pneumonia has dropped significantly since the routine introduction of prophylaxis with trimethoprim/sulfamethoxazole, and cases are now limited to those patients who either cannot tolerate sulfa drugs or are noncompliant. The median time to onset of *P. carinii* pneumonia is 2 months after transplantation. Response to therapy is good if it is started early.

Heart Transplantation

In the United States, approximately 2500 heart transplantations are performed annually, with a 5-year actuarial survival rate of 72%. Pulmonary infections are by far the leading infectious complication after heart transplantation, occurring in 40%–60% of patients in the era before cyclosporine and in 24%–40% of patients in recent years. The majority of infections occur within the first 3 to 4 months, and multiple pathogens are present in 20%–25% of patients.

Most episodes of bacterial pneumonia occur within the first few weeks after transplantation and are usually caused by the aerobic gram-negative bacteria present in the hospital environment. *Legionella pneumophila* may cause up to 5% of bacterial pneumonias after heart transplantation, and unlike immunocompetent patients, organ transplant recipients may present with nodular infiltrates that progress to necrotizing pneumonia with cavitation. Treatment with erythromycin is usually successful, but 6 to 12 months of therapy may be required, because relapse is common. The incidence of nocardial pulmonary infection varies from 0–6% following cardiac transplantation. Fever and cough are the most common clinical features, and in 80% of patients the radiographic presentation is a solitary nodular lesion. The lung is the only site of involvement in about 80% of patients; the remainder, with disseminated disease, often exhibit skin or bone involvement. Treatment with trimethoprim/sulfamethoxazole is universally successful.

In approximately 30% of heart transplant recipients, invasive fungal disease develops, and the reported incidence of *Aspergillus* infection ranges from 0–24%. The clinical presentation is similar to that previously described, and mortality rates of 50%–86% are typical.

The use of prophylactic trimethoprim/sulfamethoxazole has reduced the incidence of *P. carinii* infection substantially. Mortality rates of 34% in heart transplant recipients have been reported, but outcome is generally good if the disease is diagnosed and treated early.

CMV infection after heart transplantation occurs in 67%–100% of patients, and CMV pneumonia develops in up to 16% of infected patients. Before the advent of effective antiviral therapy, mortality ranged from 46%–75%. Ganciclovir has proved to be effective in this patient population, and mortality rates have been reduced to 14% with this antiviral agent.

Of special concern to the heart transplant recipient is pulmonary infection by *Toxoplasma gondii.* Twelve percent to 17% of heart transplant recipients have had no previous exposure to this organism and receive a heart from a seropositive donor. A symptomatic primary infection develops in more than half of these patients. The most frequent clinical manifestations include fever, chorioretinitis, encephalitis, myocarditis, and pneumonitis. The diagnosis of toxoplasmosis requires the demonstration of tachyzoites in body fluids or tissues. Serologic studies may be useful, and titers begin to rise 4 to 12 weeks after transplantation. Prophylaxis with pyrimethamine or trimethoprim/sulfamethoxazole is recommended for patients at risk for primary infection.

Heart-Lung Transplantation

Infection is the leading cause of mortality after heart-lung transplantation, accounting for 48% of early postoperative (30 days) deaths and 73% of the late deaths. The lung as an allograft is more vulnerable to infection, as ischemia, handling, preservation, and reimplantation alter local pulmonary defenses. In addition, the normal cough reflex has been ablated by denervation, and mucociliary clearance has been markedly reduced.

Bacterial pneumonia is common after heart-lung transplantation. An overall incidence of 66% during the early experience with heart-lung transplantation has been reduced to only 13% by administering antibacterial prophylaxis with ceftazidime and clindamycin and by promptly adjusting the drug regimen to treat any bacteria isolated from airway secretions during the first 7 to 10 days. As with most hospital-acquired infections, gram-negative organisms, *S. aureus,* and *L. pneumophila* have been the most frequent causes.

CMV pneumonitis poses a special problem, as its clinical presentation is similar to that of acute rejection. Fiberoptic bronchoscopy with BAL and transbronchial biopsy, as described earlier in this chapter, have a good diagnostic yield and a low complication rate in this setting. There are no controlled trials evaluating the efficacy of ganciclovir in such patients; however, other treatment modalities have been disappointing. Therefore, ganciclovir should be considered the treatment of choice, and immune globulin can be considered in refractory or severe cases.

Before the routine administration of prophylactic therapy, *P. carinii* pneumonia developed in 75% of heart-lung transplant recipients at risk, although the majority of cases were subclinical. The diagnosis, therapy, and prophylactic regimen are similar to those already described.

Deep-seated fungal infections have been uncommon following heart-lung transplantation. *Candida* infection has been the most frequent, and these infections are usually disseminated. Although isolation of *Candida* species from respiratory tract specimens is not unusual, true *Candida* pneumonitis occurs infrequently. Only a few cases of *Aspergillus* infection after heart-lung transplantation have been reported, and mortality rates have been high.

Respiratory disease in the immunosuppressed patient. *Ann Intern Med* 1992;117:415. *A summary of a National Institutes of Health consensus conference on pulmonary disease in immunocompromised patients, emphasizing predisposing immunologic factors, differential diagnosis, diagnostic procedures, therapy, and prevention.*

Tenholder MF, Hooper RG. Pulmonary infiltrates in leukemia. *Chest* 1980;78:468. *In 98 episodes of pulmonary infiltrates developing in hospitalized patients with leukemia, infiltrates appearing before treatment or within 72 hours of initiation of therapy were not opportunistic. Local disease during treatment was infectious in 74%, diffuse disease was noninfectious in 65%, and opportunistic infection was more likely if diffuse rather than local infiltrates were seen.*

Whimbey E, et al. Respiratory syncytial virus pneumonia in hospitalized adult patients with leukemia. *Clin Infect Dis* 1995;21:376. *Among hospitalized adult patients with leukemia who experienced an acute respiratory illness, 10% of cases were attributed to respiratory syncytial virus infection, and 75% of these progressed to pneumonia. Mortality rate, despite therapy with ribavirin and intravenous immunoglobulin, was 83%.*

CHAPTER

26 Pulmonary Complications of HIV Infection

Mark J. Rosen · Roslyn F. Schneider

M. J. Rosen and R. F. Schneider: Department of Medicine, Albert Einstein College of Medicine, New York, New York 10461.

INTRODUCTION

The AIDS epidemic, now in its second decade, is one of the most important global health problems of the twentieth century. In many urban communities in the United States, AIDS-related disorders are the leading causes of death among adults 25 to 44 years of age. By June 1996, 548,000 cases of AIDS had been reported in the United States, about half of them since 1993, and 343,000 had died. The worldwide impact is even more devastating: some sub-Saharan countries could lose a quarter of their adult population to AIDS, and without a cure, an estimated 10 million Asians will die of AIDS-related illnesses before the year 2015.

Since the beginning of the epidemic, lung diseases have been among the most important causes of illness and death. The first cases of AIDS were described in homosexual men in Los Angeles who had *Pneumocystis carinii* pneumonia (PCP) without a known reason for immunodeficiency. Lung diseases were later recognized not only in HIV-infected patients with full-blown AIDS, but in others with less severe immune compromise. Over the years, shifts in the demographics of HIV-infected populations and advances in the prophylaxis of HIV-associated infections have profoundly influenced the types of lung diseases in these patients.

PATHOGENESIS

Human immunodeficiency virus type 1 (HIV-1), the etiologic agent of AIDS, is a cytopathic RNA virus in the lentivirus subfamily of retroviruses. HIV-2, a retrovirus endemic in West Africa, also causes an immunodeficiency syndrome. In almost all cases, the virus is transmitted by sexual contact, by exposure to blood or blood products (most often among injection drug users), or from mother to child during childbirth.

The pathogenesis and immunologic effects of HIV infection involve a complex interplay of persistent viral replication, immune activation, and dysregulation of cytokine secretion. After primary infection, HIV disseminates widely through the blood. The virus is initially contained within follicular dendritic cells in the germinal centers of lymphoid tissue, and the number of $CD8^+$ T lymphocytes increases, opposing the progression of infection. Humoral responses, with antibodies directed against HIV proteins, may also reduce the severity of viremia. However, proinflammatory cytokines (interleukin-1b, interleukin-6, tumor necrosis factor, granulocyte-macrophage colony-stimulating factor) are overexpressed, upregulating HIV expression.

HIV causes disease mainly by infecting cells that express the CD4 molecule. Infection of $CD4^+$ (helper) T lymphocytes usually leads to progressive depletion of this cell line and immunosuppression, but some nonprogressors remain well, with stable CD4 cell counts for at least 10 years. $CD4^+$ T lymphocytes also regulate immune responses mediated by B cells, suppressor T cells, natural killer cells, monocytes, and macrophages, so the effects of HIV infection on immune responses are far more profound than simple T-cell depletion.

HIV may be identified in alveolar macrophages and lymphocytes early in the course of HIV infection, and the function of these cells may become impaired. Initially, the $CD8^+$ alveolitis may protect against immune killing of HIV-infected cells. Release of proinflammatory cytokines may be directly toxic to pulmonary epithelium, activate neutrophils, or facilitate HIV replication.

DEFINITION OF AIDS

In 1983, the Centers for Disease Control (CDC) established a case definition of AIDS to track the epidemic. AIDS was defined by the presence of specific opportunistic infections and neoplasms that occurred with advanced immunosuppression, and PCP was the most common AIDS-defining disorder. Since the purpose of surveillance is to describe the affected populations so as to anticipate trends and guide public health planning and responses, the case definition was revised in 1987, and again in 1993. The current definition includes recurrent pneumonia, pulmonary tuberculosis, and carcinoma of the cervix in HIV-infected persons. Advanced immunosuppression, defined as a CD4 count of 200/μL, was also included in the case definition, even in the absence of opportunistic infections or neoplasms. The expanded case definition of AIDS led to a 111% increase in reported cases from 1992 to 1993, and new case reports increased disproportionately in women, racial/ethnic minorities, and injection drug users.

Knowledge of the types of pulmonary disorders that are associated with HIV infection are reflected in the updated case definitions. In October 1983, the National Heart, Lung, and Blood Institute Workshop on Pulmonary Complications of HIV Infection found that 41% of the 1067 patients in whom AIDS was diagnosed in the participating institutions had serious pulmonary disorders, and PCP was by far the most common, occurring in 85% of the patients with lung disease. For years, PCP was considered the predominant pulmonary disease in HIV-infected patients. However, the early reports of pulmonary disorders associated with HIV infection considered only patients who met the case definition for AIDS, and almost all had advanced immunosuppression. We now recognize that other common respiratory illnesses develop in patients with less severe immunologic impairment, and the full range of pulmonary disorders associated with HIV infection is wide. Table 1 lists the infectious, neoplastic, and inflammatory diseases that occur in patients with HIV infection, and their typical radiographic patterns are summarized in Table 2.

TABLE 1. *HIV-associated respiratory disorders*

Focal opacification	**Mediastinal lymphadenopathy**
Bacteria	*M. tuberculosis*
Mycobacterium tuberculosis	*M. avium-intracellulare*
Pneumocystis carinii	Kaposi's sarcoma
	Lymphoma
	Fungi
Diffuse opacification	**Pleural effusion**
P. carinii	Bacteria (parapneumonic effusion, empyema)
M. tuberculosis	*M. tuberculosis*
Kaposi's sarcoma	Kaposi's sarcoma
Bacteria	Lymphoma
Fungi	Fungi
Cytomegalovirus	Cardiomyopathy
	Hypoproteinemia
Diffuse nodules	**Cavitation**
Kaposi's sarcoma (large nodules)	*M. tuberculosis* (high CD4)
M. tuberculosis (miliary)	*P. carinii* (low CD4)
Fungi (small nodules)	*Pseudomonas aeruginosa* (low CD4)
	Rhodococcus equi
Pneumothorax	Fungi
P. carinii	Lymphoma
	Cytomegalovirus

TABLE 2. *HIV infection: chest radiographic patterns and common etiologies*

RISK FACTORS FOR SPECIFIC PULMONARY DISEASES

The pulmonary disorders associated with HIV infection range from mild abnormalities in pulmonary function unaccompanied by respiratory symptoms to fatal opportunistic infections. The risk for each of these disorders is strongly influenced by the severity of immunosuppression, the patient's demographic characteristics and place of current or prior residence, and whether the patient is using prophylaxis against common HIV-associated infections. Genetic factors are probably also important but less precisely defined.

Influence of Immune Function

The severity of the abnormality in host defense is a primary determinant of the risk for specific pulmonary disorders. Early in the course of HIV infection, when the immune system is not severely compromised, respiratory disorders may occur that are similar to those in the general population; opportunistic infections occur only with severe immunodeficiency. The CD4-lymphocyte count is used most often as a surrogate marker for severity and progression of HIV disease, and the probability of specific diseases developing can be estimated by this measurement. Assessment of HIV load by measurement of the number of HIV-1 viral RNA copies in the blood also correlates strongly with disease progression.

The spectrum of disease in patients with severe immunosuppression was well-described early in the epidemic, but more recent studies have confirmed the relationship of immune function to the risk for common problems like upper respiratory infection, bacterial pneumonia, and pulmonary tuberculosis. In the Pulmonary Complications of HIV Infection Study, 1353 subjects were followed prospectively in six U.S. cities to determine the prevalence, incidence, and types of lung diseases that occur in persons in selected HIV transmission categories. To describe the types of disorders that occur in early HIV infection, patients with an AIDS-defining diagnosis (1987 case definition) were excluded from enrollment. After 18 months of follow-up, the most frequent respiratory diagnoses in the HIV-seropositive subjects were upper respiratory infection (33.4%), acute bronchitis (16%), and acute sinusitis (5.3%). Although these disorders were also common in a control group of HIV-seronegative homosexual men and injection drug users, the incidence of acute bronchitis and sinusitis was significantly higher in the HIV-infected subjects. Surprisingly, upper respiratory infection (defined as a mild, self-limited illness with coryza and sometimes sore throat and cough) occurred less frequently in subjects with a baseline CD4 count of 250/µL than in those with higher lymphocyte counts. The reason for this is not known, but it is possible that patients with severe immunosuppression may have a less vigorous immune response and milder symptoms with this self-limited illness. In the same study, bacterial pneumonia and PCP occurred more frequently in subjects with baseline CD4 lymphocyte counts of 250/µL than in those with higher counts.

The association between reduction in the CD4 lymphocyte count and the risk for specific diseases was explored in a survey of the medical records of more than 18,000 HIV-infected subjects who received care at more than 100 sites in 10 U.S. cities (Table 3). Common disorders like sinusitis, bronchitis, and pharyngitis occurred at all strata of CD4-cell counts. With lower counts, different pulmonary infections occurred with increasing frequency: 80% of cases of bacterial pneumonia and pulmonary tuberculosis occurred with CD4 counts of 400/µL; recurrent pneumonia and nontuberculous pulmonary mycobacterioses at CD4 counts of 300/µL; and PCP, Kaposi's sarcoma (KS), and disseminated *Mycobacterium tuberculosis* infection at CD4 counts of 200/µL. More than 80% of cases of disseminated nontuberculous mycobacteriosis, including *M. avium-intracellulare* infection, disseminated fungal infection, central nervous system toxoplasmosis, and cytomegalovirus (CMV) disease occurred in patients with the most severe immunosuppression (CD4 count of 100/µL).

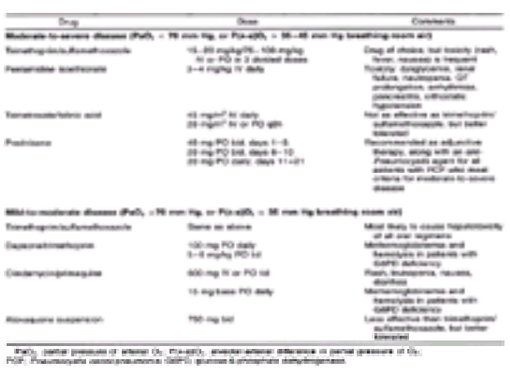

TABLE 3. *Treatment of Pneumocystis carinii pneumonia*

Therefore, common respiratory problems like sinusitis and bronchitis may occur at any CD4 count, and bacterial pneumonia and tuberculosis often occur before AIDS-defining opportunistic infections and neoplasms. Declining immune function increases the risk for all HIV-associated respiratory disease, except for mild upper respiratory tract infections.

Demographic Factors

The demographic characteristics of persons with HIV infection also have a major impact on the incidence of specific pulmonary disorders, and demographic shifts were accompanied by a changing spectrum of disease. Persons who acquired HIV infection through injection drug use and heterosexual contact represent an increasing proportion of new cases of AIDS. From 1981–1987, 64% of cases of AIDS were in homosexual men, compared with 45% of new cases from 1993–1995. In the early

years of the epidemic, most patients with AIDS were white. Now, the majority are black and Hispanic.

These demographic trends are reflected in the recognition of bacterial pneumonia and pulmonary tuberculosis as important HIV-associated infections. CDC surveillance data in the 1980s showed a doubling of mortality rates for pneumonia among persons ages 25 to 44 years in cities with a high prevalence of injection drug use and AIDS. Selwyn et al. found that the incidence of bacterial pneumonia was five times greater in HIV-infected than non-HIV-infected injection drug users, and that bacterial infections accounted for substantial mortality. In the cohort followed in the Pulmonary Complications of HIV Infection Study, bacterial pneumonia occurred more frequently than PCP, and the risk for bacterial pneumonia was significantly higher in injection drug users than in others.

Race and ethnicity may also influence the risk for bacterial pneumonia and tuberculosis, but these associations are confounded by differences in access to health care, the higher prevalence of tuberculosis in minority communities, and the disproportionately high numbers of injection drug users who are black or Hispanic. Nevertheless, the risk for tuberculosis is higher in blacks and Hispanics than in whites, whereas whites have a higher risk for HIV-associated malignancies and CMV disease.

Residence

A person's place of residence strongly influences the risk for acquiring specific infections. The high incidence of PCP in the United States and Europe contrasts sharply with that in Africa, where it is much less common. It is still unknown whether genetic or environmental factors account for the lower incidence of PCP in Africa. In the United States, the incidence of HIV-associated tuberculosis is highest in the Northeast. The geographic distribution of endemic fungi is a strong determinant of risk for those infections; disseminated histoplasmosis and coccidioidomycosis are common in patients with AIDS who live in endemic areas. These infections may also occur as reactivation disease after HIV-infected persons move to other areas and become immunocompromised.

Use of Prophylaxis

The risk for specific opportunistic infections declines with the use of prophylaxis. This is reflected in studies that document a declining incidence and mortality of PCP and a declining case rate for tuberculosis despite the relatively constant number of persons in the United States who are immunocompromised by HIV infection.

PULMONARY FUNCTION TESTS

Pulmonary function tests are usually not performed in the evaluation of patients with suspected HIV-associated pulmonary disorders, as no pattern of abnormality is specific for any disease and precise measurement of severity of physiologic derangements in patients with acute illnesses is usually not helpful in management. The common disorders (PCP, pulmonary KS) may reduce the vital capacity (VC), and they consistently reduce the single-breath carbon monoxide diffusing capacity (D_LCO). Measurement of D_LCO is sometimes used in the diagnostic evaluation of patients with normal chest radiographic findings who are suspected of having PCP; a normal value is interpreted as strong evidence against this infection.

Persons with HIV who have no apparent lung disease may also have abnormalities in pulmonary function. Values for forced vital capacity (FVC), forced expiratory volume in 1 second (FEV_1), and FEV_1/FVC are usually normal, but FVC and FEV_1 may be reduced in injection drug users compared with other HIV-infected persons, perhaps related to their high prevalence of cigarette smoking. The D_LCO is often reduced in asymptomatic persons with HIV infection, especially in those with advanced immunosuppression. In the Pulmonary Complications of HIV Infection Study, asymptomatic HIV-infected subjects with CD4-lymphocyte counts of 400/µL and/or HIV-associated symptoms had small but significant reductions in D_LCO compared with HIV-infected persons with higher CD4 counts. Perhaps subclinical inflammatory pulmonary processes such as nonspecific interstitial pneumonitis and lymphocytic interstitial pneumonitis occur in asymptomatic HIV-seropositive patients, reflected by a reduction in D_LCO. In many patients, D_LCO may be reduced by factors unrelated to HIV infection, including race, cigarette smoking, and injection drug use.

PNEUMOCYSTIS CARINII PNEUMONIA

Despite the development of effective prophylaxis against *P. carinii,* PCP remains the most common AIDS-defining infection. Until recently, *P. carinii* was assumed to be a protozoan, but recent molecular studies classify it as a fungus. Whether the organism is acquired from an environmental source or by person-to-person transmission is unknown.

Clinical, Radiographic, and Laboratory Features

The presenting features of PCP are nonspecific; they include dyspnea, dry cough, and fever that usually progress gradually during several weeks. However, it may occasionally present as an acute illness with rapid deterioration within a few days. The chest radiograph usually reveals diffuse granular opacities, which strongly suggests the diagnosis (Fig. 1), but sometimes patients with PCP have nodular densities, lobar consolidation, or normal radiographic findings. All of these radiographic patterns may also occur with other infections and neoplasms. Cystic abnormalities and spontaneous pneumothorax in patients with known or suspected HIV infection are usually caused by PCP (Fig. 2).

FIG. 1. Typical radiographic appearance of PCP, with diffuse granular opacifications.

FIG. 2. Chest radiograph of a patient with cystic pulmonary lesions caused by PCP.

The diagnosis of PCP may be supported by adjunctive testing. This infection is unlikely in a patient who had a CD4-cell count of 200/µL in the preceding 2 months in the absence of other HIV-associated symptoms. Approximately 90% of patients with PCP have an elevated serum lactic dehydrogenase level, but this may occur with other pulmonary diseases. Oxygen desaturation with exercise is a relatively sensitive and specific test in patients suspected to have PCP, but it is not diagnostic.

Gallium 67 and indium 111 lung scans are highly sensitive indicators of PCP, but isotope uptake also occurs in other pulmonary infections, so they are seldom useful in a diagnostic algorithm. One of these tests could be used in patients with normal chest radiographic findings in whom an opportunistic infection is suspected. If the scan shows abnormal uptake in the lungs, further diagnostic studies may be appropriate, whereas most patients with a negative scan can be observed. The lesions of KS do not take up gallium 67 or indium 111, and lymphoma does not take up indium 111, so the scans may be useful adjuncts in the noninvasive diagnosis of these malignancies in patients with abnormal chest radiographic findings.

Microbiologic Diagnosis

P. carinii cannot yet be cultured in vitro; therefore, infection and the diagnosis of PCP can be confirmed only by demonstrating organisms in a lung-derived specimen. The least invasive test is the analysis of sputum induced with 3% saline solution delivered by ultrasonic nebulization. By means of modified Giemsa, methenamine silver, or immunofluorescent staining, the organism can be identified in up to 80% of cases, depending on the experience of the laboratory. Other pathogens, especially *M. tuberculosis* and fungi, may also be found in induced sputum by using appropriate staining and culture techniques.

Whether to proceed routinely with fiberoptic bronchoscopy to confirm the diagnosis of PCP in patients suspected of having the disease but whose sputum specimens are nondiagnostic is controversial. Some prefer to treat these patients empirically for PCP and establish a diagnosis only if no clinical response occurs within 5 days. Proponents of empiric therapy hold that a presumptive diagnosis of PCP is usually accurate and that the procedure usually carries unnecessary inconvenience, risk, and discomfort to patients, as well as expense. A decision analysis supporting initial empiric therapy indicated that the expected 1-month survival rate was identical whether patients received early bronchoscopy or whether the procedure was offered only to nonresponders, and that bronchoscopy was associated with greater costs and effort.

Proponents of early bronchoscopy maintain that routinely using an empiric approach subjects many patients to treatment and its attendant toxicity for a disease that they do not have, and nonresponders may be too ill to undergo bronchoscopy after several days of inappropriate therapy. Coinfection with other pathogens is common and may not be diagnosed in patients treated empirically. Also, adjunctive corticosteroid therapy may transiently improve symptoms in patients with other pulmonary disorders and contribute to the emergence of other opportunistic infections, such as aspergillosis and CMV disease.

In any case, fiberoptic bronchoscopy with bronchoalveolar lavage (BAL) is the next procedure in the diagnostic algorithm for PCP when sputum specimens are nondiagnostic. The complication rate is very low, and the yield is 90% in most centers. This yield is optimized by performing lavage in more than one lobe, and the yield is higher in the upper lobes than the lower. All lavage specimens should be examined for the presence of acid-fast bacilli, fungi, and viral cellular inclusions, as patients with suspected PCP may have another infection or may be coinfected with other pathogens. The use of BAL in the diagnosis of bacterial pneumonia in HIV-infected persons is not generally indicated.

When bronchoscopy with BAL is carried out in patients with HIV-associated pulmonary disorders, it is also controversial whether to perform bronchoscopic lung biopsies routinely. Because the diagnostic yield of BAL in PCP is so high, some authors recommend that biopsy be omitted initially and performed during a second bronchoscopy if the lavage specimen is nondiagnostic. However, biopsy specimens are occasionally diagnostic of PCP and other pathogens when the lavage result is negative, and it is the least invasive means of diagnosing other pulmonary conditions that require histologic interpretation. Transbronchial biopsies are contraindicated in the presence of bleeding disorders, and the high risk for pneumothorax usually precludes biopsies in patients undergoing mechanical ventilation. Diagnosing PCP by video-assisted thoracoscopy or an open procedure is rarely necessary, as almost all cases are confirmed using sputum induction or bronchoscopy.

Treatment

The drugs used to treat PCP are outlined in Table 3. Trimethoprim/sulfamethoxazole (T/S) is the agent of choice, regardless of the severity of disease. It is consistently the most effective in comparative studies and also inexpensive and available in both oral and intravenous preparations. Although it is usually well tolerated, many patients are unable to tolerate the drug for a full course. The optimal duration of treatment is unknown, but most clinicians treat for 14 to 21 days, followed by prophylaxis for life.

The choice of anti-*Pneumocystis* treatment depends on the severity of disease and how the patient tolerates the medication. Outpatient treatment with oral agents is an option for patients with mild to moderate episodes whose arterial oxygen tension (PaO_2) while breathing room air is 70 mm Hg. In a comparison of oral T/S, trimethoprim/dapsone, and clindamycin/primaquine, all three had similar efficacy and rates of treatment-limiting toxicity. Atovaquone is available as second-line treatment for mild to moderate PCP, defined as a PaO_2 of 60 mm Hg and an alveolar-arterial oxygen difference [$P(A\text{-}a)O_2$] of 45 mm Hg, in patients who cannot tolerate T/S. This drug is administered orally and is associated with fewer adverse reactions than T/S, but it is also less effective.

T/S is the treatment of choice of patients with moderate to severe PCP. However, the high rate of toxicity limits or precludes its use in many. Adverse effects include fever, rash, stomatitis, nausea, vomiting, neutropenia, nephritis, and elevated serum aminotransferase concentrations. For unknown reasons, persons with HIV infection are more likely than others to have adverse reactions to T/S.

Patients with PCP who cannot tolerate T/S are usually given intravenous pentamidine isethionate. This drug is as effective as T/S, but severe adverse effects are also common with pentamidine, including nephrotoxicity, pancreatitis, hyperglycemia, hypoglycemia, leukopenia, hypotension, and ventricular arrhythmias. Trimetrexate/leucovorin is also an alternative for patients who cannot tolerate or who do not respond to T/S. It not as effective as T/S but is associated with fewer side effects. Whether trimetrexate should replace pentamidine as second-line treatment of moderate to severe PCP is unknown, because comparative trials of these two drugs have not been performed.

Adjunctive therapy with corticosteroids at the start of anti-*Pneumocystis* treatment reduces the likelihood of respiratory failure, deterioration of oxygenation, and death in patients with moderate to severe infection. The precise mechanisms of the beneficial effects of corticosteroids in patients with PCP are unknown. An inflammatory response in the lung occurs at the start of anti-*Pneumocystis* treatment in patients who do not receive corticosteroids, probably in response to components of killed organisms and manifested by deteriorating gas exchange. Corticosteroids modify this inflammatory response, prevent the initial worsening of gas oxygenation, and allow the patient to receive more antimicrobial treatment.

The patients with PCP most likely to benefit from adjunctive corticosteroids have a PaO_2 of 70 mm Hg or a $P(A\text{-}a)O_2$ of 35 mm Hg. Patients with less severe abnormalities of gas exchange usually do not benefit, mainly because their outcomes are very good with anti-*Pneumocystis* treatment alone. Benefit is also questionable when corticosteroids are administered 72 hours after anti-*Pneumocystis* treatment has begun.

The optimal dosage and duration of corticosteroid treatment are unknown, but the largest controlled trial that showed benefit used oral prednisone in the following regimen: on days 1 through 5, 40 mg was given twice daily; on days 6 through 10, 40 mg was given daily; on days 11 through 21, 20 mg was given daily. Adverse reactions occur infrequently, and although life-threatening superinfections have been described, they are uncommon. Patients in whom pulmonary disorders develop shortly after apparently successful treatment of PCP should be evaluated for another opportunistic infection, especially CMV disease.

Prophylaxis

The prevention of PCP with drugs has reduced its incidence, and PCP-associated mortality in HIV-infected persons has fallen dramatically (Fig. 3). Although anti-*Pneumocystis* prophylaxis may prevent this infection and prolong life, longevity is usually accompanied by progressive immunosuppression, rendering patients susceptible to other potentially fatal infections. While the percentage of HIV-related deaths in the United States caused by PCP declined, deaths caused by nontuberculous mycobacteriosis, CMV disease, bacterial infections, non-Hodgkin's lymphoma, and tuberculosis increased. In an analysis of 844 HIV-infected homosexual men enrolled in the Multicenter AIDS Cohort Study, those who received prophylaxis for PCP before being given a diagnosis of AIDS had a lower incidence of PCP and lower mean CD4 count at the time of the AIDS diagnosis than those who did not. However, they had a higher incidence of *M. avium* disease (33.4% vs. 24.8%), wasting syndrome (18.4% vs. 6.4%), and esophageal candidiasis (21.3% vs. 12.8%). PCP prophylaxis also appeared to delay the time to the first AIDS-related illness by 6 to 12 months.

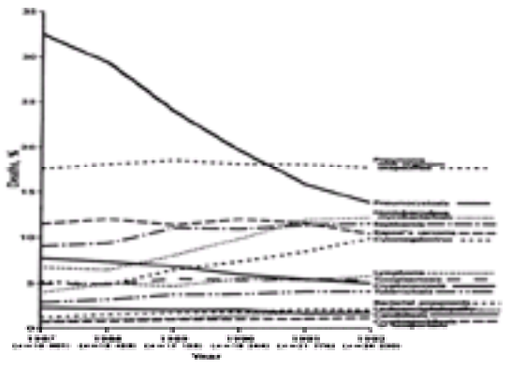

FIG. 3. Trends in the prevalence of infectious diseases and cancers reported among persons dying of HIV infection in the United States from 1987 to 1992. (Reproduced with permission from Selik RM, Chu SY, Ward JW. Trends in infectious diseases and cancers among persons dying of HIV infection in the United States from 1987 to 1992. *Ann Intern Med* 1995;123:933–936.)

Lifelong prophylaxis against *P. carinii* infection is recommended for all HIV-infected persons with CD4-cell counts of 200/µL, and for patients with HIV-related symptoms, including unexplained persistent fever (100°F) for 2 weeks, oropharyngeal candidiasis unrelated to antibiotic or corticosteroid therapy, and unexplained weight loss. Oral T/S, dapsone, and aerosolized pentamidine are the drugs most extensively studied and used.

The preferred regimen is one double-strength tablet of T/S (160 mg trimethoprim, 800 mg sulfamethoxazole) daily. In addition to its superior efficacy against *P. carinii,* this drug may also prevent toxoplasmosis and bacterial infections. However, the high rate of intolerable side effects limits its application. Lower doses (one single-strength tablet daily, or one double-strength tablet thrice weekly) appear to be almost as effective and more likely to be tolerated. Desensitization to T/S may be attempted in patients allergic to the drug who have not had life-threatening reactions. Failure of T/S prophylaxis is associated with noncompliance and with CD4-lymphocyte counts of 50/µL.

Patients who cannot tolerate T/S should take 100 mg of dapsone daily, in single or divided doses. Fifty milligrams of dapsone daily, along with 50 to 75 mg of pyrimethamine weekly and 25 mg of leucovorin weekly, also confers protection against toxoplasmosis. Pentamidine administered by aerosol has the potential advantages of high drug levels in the lung and minimal systemic absorption and toxicity, but it is less effective than T/S and dapsone. The only aerosolized pentamidine regimen recommended by the CDC is 300 mg administered monthly using the Respigard II nebulizer (Marquest, Englewood, Colorado). Other doses and delivery systems are under investigation.

When PCP occurs in patients using aerosolized pentamidine, it is associated with atypical clinical and diagnostic features. Normal regional differences in ventilation deposit the drug preferentially in the lower lung zones, accounting for a higher rate of predominantly upper lobe involvement. These patients are also more likely to have cystic lung lesions and pneumothorax. Extrapulmonary *P. carinii* infection may occur in patients receiving prophylaxis with aerosolized pentamidine, as the drug is delivered only to the lung.

Other agents have been used to prevent PCP in patients who cannot tolerate standard treatments, or in whom PCP develops despite prophylaxis. These include clindamycin/primaquine, atovaquone, pyrimethamine/sulfadoxine, alternative aerosol pentamidine regimens, and intermittent parenteral pentamidine or trimetrexate. Their efficacy is not known, and they should not be used unless recommended drugs cannot be given.

Respiratory Failure Caused by *Pneumocystis carinii* Pneumonia

Despite the use of prophylaxis and declining mortality rates associated with PCP, the infection is still the most common cause of respiratory failure and admission to intensive care units (ICUs) in patients with AIDS. When treatment of PCP is postponed or ineffective, a clinical syndrome develops that resembles the acute respiratory distress syndrome (ARDS), with severe hypoxemia, intrapulmonary shunt, reduced pulmonary compliance, and the radiographic appearance of diffuse opacities. Just as severe PCP clinically resembles ARDS, the supportive treatment, including intubation, mechanical ventilation, and application of positive end-expiratory pressure, is similar. Continuous positive airway pressure (CPAP) delivered by face mask may improve gas exchange without endotracheal intubation, but its usefulness is limited in patients with severe disease. However, it may afford the patient and physician more time to consider whether mechanical ventilation is desirable.

As changes in therapy modified the prognosis, three distinct eras of critical care for patients with PCP and respiratory failure were identified. Initially, the outlook for survival was dismal. In the 1984 National Institutes of Health Workshop, 88 of the 102 patients with AIDS who received mechanical ventilation died, and nearly all had PCP. Other studies from individual centers confirmed that survival after respiratory failure was about 15%. In some centers, ICU utilization declined because physicians did not recommend aggressive interventions, and patients were more likely to decline ICU care. After 1986, mortality rates seemed to decrease to about 50%, with the decline attributed to the selection of patients with a better prognosis and the benefits of adjunctive corticosteroid therapy.

We are now in a third era of outcomes, when patients who require mechanical ventilation for PCP again have a very high mortality rate. At San Francisco General Hospital, mortality increased from 61% in the period from 1986–1988 to 76% in the next 2 years. At the same time, the proportion of patients who were injection drug users and who had recurrent episodes of PCP increased. Mortality was strongly associated with a CD4-lymphocyte count of 50/µL (94%) and with the development of a pneumothorax (100%). Recent patients who require mechanical ventilation for PCP are also more likely to have failed prophylaxis, anti-*Pneumocystis* treatment, or adjunctive corticosteroid therapy and therefore are expected to have a poor prognosis. Recent studies show that when respiratory failure follows several days of appropriate therapy for PCP, the probability of survival is only 10%–20%.

The prospects for long-term survival following PCP and respiratory failure are better than earlier in the epidemic. Prolonged survival is probably related to the selection of patients with a better prognosis for mechanical ventilation, and to improvements in prophylaxis and treatment of subsequent infections.

BACTERIAL PNEUMONIA

The importance of bacteria as HIV-associated pulmonary pathogens was established by investigations in patients who did not have advanced immunosuppression. HIV infection impairs humoral immunity through quantitative and functional defects in CD4 lymphocytes. This increases the risk for bacterial infections, including sinusitis and pneumonia. Although a first episode of bacterial pneumonia usually occurs before the diagnosis of AIDS, the risk for pneumonia increases as the CD4-lymphocyte count declines. Injection drug users are at higher risk than other groups, and neutropenia is an independent risk factor. Prophylaxis with T/S appears to reduce the risk for bacterial pneumonia. Bacterial pneumonia may also accelerate the course of HIV disease, as it is an independent predictor of progression to AIDS and mortality.

In early HIV infection, the pathogens that cause pneumonia are similar to those in the general population. Encapsulated organisms, especially *Streptococcus pneumoniae* and *Haemophilus influenzae,* are the most frequent etiologic agents. Although pneumonia caused by atypical pathogens like *Mycoplasma* and *Legionella* is described, it is relatively uncommon. However, in a careful prospective analysis of 149 episodes of pneumonia in HIV-seropositive former injection drug users, *Chlamydia pneumoniae* was confirmed serologically as the second most common cause of pneumonia (after *S. pneumoniae*), and infection occurred at higher mean CD4-cell counts than infection caused by other pathogens.

Pathogens that rarely cause community-acquired pneumonia in the general population occur more frequently in HIV-infected persons. *Rhodococcus equi,* an aerobic, gram-positive, acid-fast bacillus, may cause focal consolidation, endobronchial disease, and cavitation, usually in patients with advanced HIV disease. Pneumonia caused by *Pseudomonas aeruginosa* was rare in the early years of the AIDS epidemic but is now emerging as an important entity. It usually follows another opportunistic infection or occurs when the CD4-cell count is 50/µL. Although many patients have histories of recent hospitalization, this infection usually presents as community-acquired pneumonia and is not necessarily associated with neutropenia or the use of corticosteroids. Cavitation is common, and the infection is often recurrent or chronic. *Nocardia asteroides* may cause nodules, consolidation, cavitation, pleural effusions, empyema, and intrathoracic lymphadenopathy in patients with HIV infection.

Bacterial pneumonia usually presents in a typical fashion, with fever, chills, productive cough, and localized areas of consolidation on chest radiograph. Although this clinical picture strongly suggests bacterial pneumonia, it may also occur with tuberculosis and fungal infection. Conversely, patients with bacterial pneumonia may have diffuse pulmonary opacities that resemble those of PCP. HIV-infected patients with bacterial pneumonia may be bacteremic and critically ill, but overall mortality is similar to that of HIV-seronegative persons with comparable severity of illness.

The approach to diagnosis and treatment of bacterial pneumonia is the same as that for HIV-negative patients. Because bacterial pneumonia is so common, it should be suspected in any patient with a compatible clinical syndrome and abnormal chest radiographic findings. The routine evaluation includes blood cultures, and if pleural fluid is present, it should be cultured and stained for bacteria, fungi, and mycobacteria. Patients with a productive cough should always have sputum specimens examined for acid-fast bacilli, but the usefulness of sputum Gram's stain and culture in the diagnosis of bacterial infection is controversial.

Empiric coverage for common bacterial pathogens should be started promptly after specimens are obtained. The initial antibiotic regimen should always cover *S. pneumoniae* and *H. influenzae,* and empiric treatment of *P. aeruginosa* should be considered in patients with advanced HIV infection or CD4-lymphocyte counts of 50/µL. Bronchoscopy should be performed in patients who do not respond to empiric therapy without an established diagnosis, to determine whether they have mycobacterial or fungal infection. Occasionally, pulmonary involvement with KS or lymphoma may resemble bacterial infection and can be diagnosed with bronchoscopy.

The polyvalent pneumococcal vaccine is recommended for all HIV-infected people, although persons with low CD4 counts are unlikely to mount an adequate antibody response. A vaccine against *H. influenzae* type b is available, but its usefulness in patients with HIV infection is questionable, as most of these infections are caused by nontypeable strains. Although influenza vaccine is also recommended, there are no data to show that persons with HIV infection are at increased risk for contracting influenza, or that the illness is more severe than in the general population.

TUBERCULOSIS

Modest reductions in cell-mediated immunity increase the risk for reactivation of latent tuberculosis, and the risk increases as CD4-cell counts decline. In HIV-infected persons, tuberculosis often occurs before opportunistic infections, probably because *M. tuberculosis* is more virulent. In patients with mild immunodeficiency, the clinical presentation is similar to that of tuberculosis in HIV-negative patients. Atypical pulmonary presentations, including diffuse infiltrates, miliary patterns, intrathoracic lymphadenopathy, or normal chest radiographic findings, occur more frequently in patients with advanced immunosuppression (Table 3). These patients also have a high incidence of extrapulmonary infection affecting the pleurae, lymph nodes, gastrointestinal tract, bone marrow, and blood.

The diagnosis of tuberculosis may be difficult in HIV-infected persons. Cutaneous anergy is more prevalent as CD4-cell counts decline, making tuberculin skin tests less useful. Radiographic clues to the diagnosis include cavitation, hilar and mediastinal lymphadenopathy, and pleural effusions. When cavitation is present, results of acid-fast smears and cultures of sputum are usually positive. In patients who do not expectorate spontaneously, sputum may be induced with hypertonic saline solution. Results of bronchoscopy with BAL, transbronchial biopsy, and analysis of postbronchoscopy sputum specimens are often diagnostic. Biopsies enhance the immediate diagnostic yield of bronchoscopy in the diagnosis of pulmonary tuberculosis, in comparison with BAL alone.

Despite an appropriate evaluation, results of acid-fast smears of sputum and bronchoscopic specimens may be negative, and cultures may not yield positive results for several weeks. Early treatment of tuberculosis improves the outcome and reduces transmission of the disease to others, so initial empiric therapy is warranted for patients with radiographic abnormalities consistent with tuberculosis unless another disorder is identified.

ATYPICAL MYCOBACTERIAL INFECTION

M. avium-intracellulare causes devastating complications and death in patients with AIDS. In HIV-infected persons with severe immunosuppression, *M. avium-intracellulare* usually causes bacteremia and disseminated infection with fever, weight loss, diarrhea, and anemia. However, *M. avium-intracellulare* is rarely a pulmonary pathogen in patients with AIDS. It is usually isolated from pulmonary specimens in patients with symptomatic pulmonary disease along with another pathogen (such as *P. carinii*) that accounts for the clinical picture. When *M. avium-intracellulare* is isolated from asymptomatic persons, it is strongly predictive of the later development of disseminated infection.

Other nontuberculous mycobacteria may cause pulmonary infection in patients with HIV infection. Like tuberculosis, atypical mycobacterial infections are usually diagnosed first by direct microscopy of smears of any specimen, and the species is then identified by nucleic acid probe or culture. However, if acid-fast bacilli are identified from sputum or bronchoscopic specimens, patients should be treated presumptively for *M. tuberculosis* infection until the species is identified, mainly because tuberculosis is more common and responds better to treatment, and because early treatment of active tuberculosis is an essential public health measure.

CYTOMEGALOVIRUS INFECTION

In patients with CD4-lymphocyte counts of 50/µL, CMV commonly causes retinitis, esophagitis, gastritis, colitis, hepatitis, encephalitis, pneumonia, and death. Patients with AIDS may also have CMV pneumonitis, but uncommonly. Although the virus can often be isolated in cultures of BAL fluid, it is not usually pathogenic. Pulmonary infection can be inferred when typical intranuclear or intracytoplasmic inclusions are found in BAL fluid or biopsy material. The likelihood that CMV is a pulmonary pathogen is also greater when CMV infection is found at other sites.

CMV pneumonitis usually occurs in patients who have had prior AIDS-defining illnesses. They present with a clinical syndrome similar to that of PCP, with dyspnea, nonproductive cough, fever, and diffuse pulmonary opacities. Unilobar radiographic involvement, cavitation, nodules, and pleural effusions are also described. It is treated in the same way as infection in other sites, with intravenous gancyclovir or foscarnet, and the response to therapy is similar to that of CMV retinitis or gastrointestinal disease. As CMV infection occurs only in patients with very severe immunosuppression, the long-term prognosis is very poor.

FUNGAL PNEUMONIA

Life-threatening fungal disease may occur in HIV-infected patients, either by new infection or reactivation of latent disease. The types of fungal infections depend on the severity of immunodeficiency and whether the patient has lived in endemic areas.

Cryptococcosis

Cryptococcus neoformans is distributed throughout the world and is the most common fungus causing life-threatening illness in patients with AIDS. The meninges are the most common site of infection, and cryptococcal meningitis is often the first manifestation of AIDS. With cryptococcal pneumonia, the chest x-ray film usually shows diffuse infiltrates, similar to those of PCP, but localized infiltrates, nodules, cavitation, pleural effusions, miliary patterns, and lymphadenopathy are also seen. Almost all patients with cryptococcal pneumonia have meningitis and disseminated disease, and CD4-lymphocyte counts are typically 100/µL. The diagnosis is established by identification of the organism from sputum, BAL fluid, pleural fluid, or lung biopsy specimens. A high titer of cryptococcal antigen in serum is strongly suggestive, and an antigen titer of 1:8 in BAL fluid is diagnostic of cryptococcal pneumonia.

Because most patients with HIV and cryptococcal pulmonary infection have disseminated disease, 0.5 to 1.0 mg of amphotericin B per kilogram of body weight daily is usually the therapy of first choice. Four hundred milligrams of fluconazole daily is a reasonable alternative in patients who are less ill. After the patient improves and the cerebrospinal fluid is sterilized, lifetime prophylaxis with 200 mg of fluconazole daily is indicated.

Histoplasmosis

Histoplasma capsulatum is endemic in the Ohio and Mississippi River valleys, Central and South America, and the Caribbean Islands. Disseminated disease may develop in patients with HIV infection who come from endemic areas when immunodeficiency permits reactivation of latent infection. The clinical presentation is usually subacute, and the chest roentgenogram typically shows a diffuse or miliary pattern, although localized infiltrates may occur. The diagnosis is established by identification or culture of the organism from blood, lung-derived specimens, bone marrow, or liver.

Amphotericin B is the treatment of choice for most cases of HIV-associated histoplasmosis. An alternative in patients with milder disease is 200 mg of itraconazole daily, and it should be used as suppressive therapy for life after the primary infection has been controlled.

Aspergillosis

Life-threatening pulmonary aspergillosis may develop in patients with advanced immunosuppression. Two common patterns of disease are identified: an invasive parenchymal infection, which is usually fatal, and a predominantly bronchial disease with initial symptoms of dyspnea and airway obstruction. The classic risks for *Aspergillus* infection—namely, prolonged neutropenia and treatment with high-dose corticosteroids—are often absent. Aspergillosis probably develops in patients with advanced AIDS because of defects in neutrophil or alveolar macrophage function. The CD4-lymphocyte count is typically 30/µL, and the prior use of corticosteroids

and neutrophil counts of 500/µL increase the risk. Disseminated disease is common, especially to the brain.

Clues to the diagnosis of invasive pulmonary aspergillosis include upper lobe disease with cavitation and hemoptysis (Fig. 4). Histologic proof has traditionally been required for this diagnosis, because *Aspergillus* is ubiquitous and its presence in nasopharyngeal secretions, sputum, and BAL fluid may represent contamination or colonization. However, recent studies in patients with severe immunosuppression, including AIDS, indicate that the isolation of *Aspergillus* in BAL fluid correlates strongly with histologic proof of tissue invasion.

FIG. 4. Chest radiograph of a patient with invasive pulmonary aspergillosis. Diffuse cavitary lesions are present, especially in the upper lung fields.

Invasive aspergillosis is usually treated with amphotericin B, and itraconazole is a reasonable alternative. Despite treatment, most patients die within a few weeks.

Other Fungal Infections

In endemic areas, disseminated coccidioidomycosis and blastomycosis may occur in patients with AIDS, usually as a complication of advanced immunosuppression. In some patients, a prior infection may become reactivated after they have moved from an endemic area. These infections usually involve the lung; the presentation includes cough, fever, dyspnea, and the appearance of nodular, focal, cavitary, or diffuse disease. The diagnosis is established by demonstrating the organism by microscopy or culture in respiratory specimens.

Patients with disseminated disease should be treated with amphotericin B, and if they respond, suppressive treatment is indicated for life. Fluconazole is recommended for coccidioidomycosis, and itraconazole for blastomycosis.

NEOPLASTIC DISEASES OF THE LUNG

Kaposi's Sarcoma

KS is the most common malignancy in persons with HIV infection, and the skin is the major site of involvement. KS is believed to be caused by a herpesvirus that infects many healthy adults and may be isolated commonly in saliva, prostate tissue, and semen. The virus is probably transmitted by sexual contact, and it causes disease when activated during HIV-associated immunosuppression. This hypothesis helps to explain why KS is much more common among HIV-infected homosexual men than in other transmission groups.

KS may involve many organs, including the lung. Patients with pulmonary KS usually have obvious mucocutaneous lesions, but the lung may be the only site of disease in up to 15% of cases. Involvement of the airways, parenchyma, pleurae, and intrathoracic lymph nodes causes a diverse range of symptoms and radiographic findings. The majority of patients with pulmonary KS diagnosed ante mortem have cough, dyspnea, and fever.

In the airways, KS lesions are usually asymptomatic, but sometimes cause obstruction or hemoptysis. The finding of typical lesions on inspection of the airways is usually considered diagnostic. Histologic diagnosis may be difficult, because the yield of forceps biopsy is low. Some authors believe that forceps biopsy of KS lesions places the patient at significant risk for bleeding, but this is controversial.

Parenchymal involvement with KS is suggested by bronchial wall thickening, nodules, Kerley B lines, and coexisting pleural effusions, especially in patients with cutaneous disease (Fig. 5). Bronchoscopy may be performed to determine whether diffuse radiographic opacities are caused by KS or an opportunistic infection. The yield of bronchoscopic lung biopsy in the diagnosis of KS is low, and even open lung biopsy is nondiagnostic in approximately 10% of cases because of the focal distribution of lesions. Therefore, the diagnosis of pulmonary parenchymal KS is usually inferred in patients with cutaneous disease, chest radiographs that suggest this disorder, visual confirmation of airway lesions, and no evidence of opportunistic infection on BAL or bronchoscopic lung biopsy. Patients with parenchymal opacities who have typical lesions in the airways and no identified pulmonary infection are assumed to have parenchymal KS.

FIG. 5. Chest radiograph of a patient with pulmonary parenchymal KS. The nodular densities suggest this diagnosis, especially in patients with cutaneous disease.

When KS involves the pleurae, effusions are usually exudative and sanguinous, but the cytologic examination is nondiagnostic. Results of closed pleural biopsy are rarely positive because of the focal nature of pleural lesions and predominant involvement of the visceral, rather than parietal, pleura. Because establishing a diagnosis usually necessitates a thoracoscopic or open pleural biopsy, the presence of pleural involvement with KS is usually inferred in a patient with cutaneous disease and a serosanguinous effusion without any reasonable alternative explanation.

Other Malignancies

Non-Hodgkin's B-cell lymphoma is associated with HIV infection. Although pulmonary involvement is usually clinically innocuous, the lung is a common site of extranodal disease. If symptoms occur, they usually do so late in the course of HIV disease and simulate common opportunistic infections. Even in patients with an established diagnosis of lymphoma, lung involvement is usually a late feature of disease. It may present with lobar consolidation, nodules, reticular opacities, and masses. The diagnosis is established by bronchoscopic or open biopsy; BAL has a very low diagnostic yield.

Radiographically, intrathoracic lymph node involvement is manifested by lymphadenopathy, pleural involvement by effusions and pleural thickening, and airway involvement by atelectasis. The diagnosis is established by biopsy or cytologic analysis of pleural fluid.

Carcinoma of the lung has been reported in patients with HIV infection. Although reports emphasize the relatively young age of these patients and aggressive nature of

their disease, it is not established that HIV infection increases the risk for lung cancer.

OTHER PULMONARY DISORDERS

For unknown reasons, patients with advanced HIV infection may have chronic bronchitis and bronchiectasis, even if they do not smoke. These patients usually have CD4 counts of 100/µL. Standard antimicrobial agents are usually effective, but symptoms are likely to recur, especially when *P. aeruginosa* is isolated from the sputum. The role and efficacy of bronchodilators and anti-inflammatory agents in HIV-associated airway disease have not been studied.

Pulmonary disorders without a defined infectious or neoplastic etiology occur in HIV-infected persons. Lymphocytic interstitial pneumonitis and nonspecific interstitial pneumonitis are believed to comprise a spectrum of inflammatory changes in response to HIV infection of the lung itself. Lymphocytic interstitial pneumonitis is most common in HIV-infected children and African-Americans. It may occur as part of a systemic CD8 lymphoproliferative syndrome, with lymphadenopathy, blood lymphocytosis, and involvement of other organs. Nonspecific interstitial pneumonitis is very common in persons with low CD4 counts but is rarely diagnosed because it usually causes no symptoms. When symptomatic, both lymphocytic interstitial pneumonitis and nonspecific interstitial pneumonitis are treated with corticosteroids.

Bronchiolitis obliterans organizing pneumonia is also described in patients with HIV infection, but the reasons for this association are unknown. The manifestations are similar in patients with and without HIV infection. Lung biopsy is necessary for the diagnosis. This disorder often improves dramatically with corticosteroids.

Pulmonary hypertension occurs more commonly in HIV-infected patients than in the general population. It may occur without a prior AIDS diagnosis or severe immunosuppression, and the clinical and histologic features of this disorder are indistinguishable from those of primary pulmonary hypertension. The etiology is unknown, no effective treatment is available, and the prognosis is dismal.

INTRODUCTION

Infection by fungi generally occurs by inhalation. Thus, the lungs are the organs most frequently encountering these microorganisms and the organs that most often demonstrate the pathologic changes of fungal disease. Generalized dissemination of the fungus may cause spread of the infection from the lungs to the rest of the body as part of a process that has been called *primary infection and postprimary dissemination,* in which the immune system is involved in a complicated series of reactions reflecting innate factors as well as humoral and cell-mediated immunity.

In general, the resistance of the body to infection by fungi characterized as saprogphytic is excellent; in fact, these fungi rarely cause significant infection in healthy humans. A group of more aggressive fungi regularly causes primary infection in healthy human subjects, but this infection is limited and not associated with significant disease, even when postprimary dissemination occurs. In this respect, these fungi behave similarly to *Mycobacterium tuberculosis,* but they are considerably less prone to produce active disease. The fungi making up this group include *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis, Sporothrix schenckii, Paracoccidioides brasiliensis,* and *Cryptococcus neoformans.* There is also evidence that species of *Nocardia* can cause disease when inhaled.

Special consideration for *Aspergillus* species is warranted, as this genus represents one of the common environmental organisms that rarely, under circumstances not clearly understood, may cause progressive infection in ostensibly normal humans. In addition, this organism may elicit a syndrome of hypersensitivity in the human airways, and it may lodge as a commensal organism in pre-existing cavities and produce a mat of tissue called a *fungus ball* or *mycetoma.* Other fungi have been found to cause fungus balls, but this is rare.

Another special situation relates to organisms normally found within the body, such as *Candida* species and *Actinomyces israelii,* that normally do not produce disease. *Candida* is a normal commensal of the gastrointestinal tract, and it is extremely rare for it to cause progressive systemic disease in immunocompetent persons. *Actinomyces* is likewise a friendly inhabitant of the body but may produce disease in the presence of local trauma to the mouth and throat, where the organism is found, especially in tonsillar crypts and tooth sockets.

When the human immune system is suppressed, any microorganism may cause progressive disease, and fungi are clearly part of this threat. Thus, in any consideration of the impact of fungi on the body in general and the lungs in particular, the state of the immune system must be accounted for.

Although fungi are the subject of this chapter, *Actinomyces* and *Nocardia* species, which are bacteria, are included for two reasons: They have traditionally been dealt with in this manner, and many of the characteristics of diseases caused by these organisms are similar to those of true fungal diseases.

FUNGAL DISEASES

Histoplasmosis (Fig. 1, Fig. 2, Fig. 3, Fig. 4 and Fig. 5)

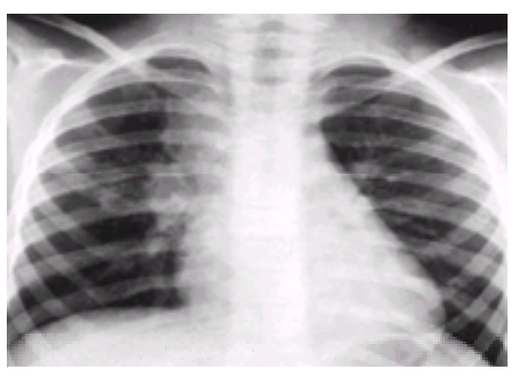

FIG. 1. Primary histoplasmosis with peripheral pneumonia and hilar adenopathy.

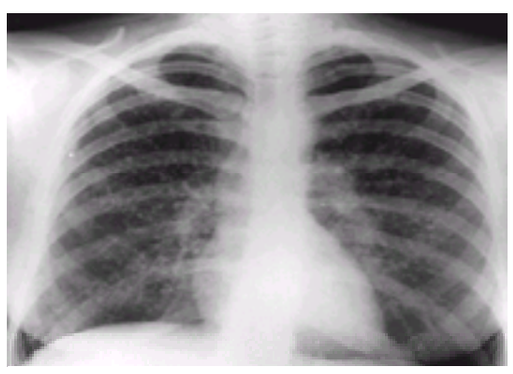

FIG. 2. Multiple primary lesions in acute histoplasmosis simulating hematogenous dissemination.

FIG. 3. Healed lesions of pulmonary histoplasmosis.

FIG. 4. Large cavity of the left upper lobe resulting from histoplasmosis. Diffuse disease is seen throughout the lung.

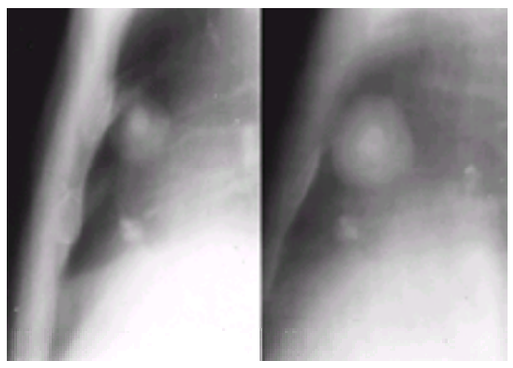

FIG. 5. Enlarging histoplasmoma with central and peripheral laminated calcifications.

Originally thought to be a rare, disseminated, tropical disease, infection with *H. capsulatum* has been found to be very common in endemic areas (the Mississippi and Missouri River valleys in the United States, and isolated areas elsewhere in the world), and sporadic but not rare in other areas. The first patients were found in Panama and described by Darling in 1905. Although he was able to differentiate the organism in tissues from *Leishmania,* which it closely resembles, he nonetheless thought it was a parasite. The fungal nature of the organism was clarified by da Rocha-Lima in 1913. Most infected persons have asymptomatic infections. Humans have excellent resistance to the organism, and despite uniform dissemination in the bloodstream at the time of primary pulmonary infection, progressive disease is uncommon. Healing is associated with massive production of scar tissue and frequently with florid calcification.

Organism

H. capsulatum variety *capsulatum* is a dimorphic fungus that occurs in nature as a mold with septate hyphae bearing tuberculate macroconidia and infectious microconidia. When the microconidia are inhaled, they convert into small budding yeasts (3 to 5 µm) that are found as intracellular pathogens of mononuclear phagocytes.

Pathology

After the microconidia are inhaled and reach the respiratory parenchyma of the lungs, a transient purulent exudate is produced, quickly followed by the sequence of T and B lymphocytes as well as circulating macrophages. This evolution is characteristic of a cell-mediated immune response and is often accompanied by caseous necrosis in the center of the granulomatous focus (or foci) of primary infection. Shortly after infection, a local lymphangitis and lymphadenitis with similar characteristics occur, which may involve the lymph system in progressive fashion until the bloodstream is invaded, with dissemination of the organism throughout the body. The organ most frequently demonstrating foci of infection outside the lungs and thorax is the spleen. This may be a consequence of the large concentration of reticuloendothelial cells found in the spleen. The liver is much less frequently involved. The adrenal glands, bones, gastrointestinal tract, and central nervous system may also host foci of infection. In all, the process is mainly granulomatous in nature.

The healing tendency is remarkable, and the formation of large amounts of scar tissue and calcification, especially in the mediastinal nodes and spleen, may be seen on x-ray films. In fact, scarring and calcification are so prominent that syndromes caused by obstruction and penetration of mediastinal structures, with no evidence of active infection, are part of the clinical spectrum of histoplasmosis. The question of exogenous reinfection occurring in normal hosts is moot, but a few case reports have suggested that it occurs. Much more problematic is whether endogenous reinfection occurs when the primary encounter has ended in clinical healing.

In immunosuppressed humans, primary infection with *H. capsulatum* is associated with much more active dissemination than in immunocompetent hosts. The granulomatous reaction does not develop as well or as typically, and frequently, depending on the degree of lowering of the CD4-lymphocyte count, the reaction to infection may be primarily neutrophilic. Exogenous reinfection almost certainly occurs, and there is evidence to suggest that endogenous reinfection may occur in immunosuppressed hosts.

Immunopathology of *Histoplasma* infection is mainly manifested by activation of the cellular immune system and associated delayed hypersensitivity. The role of humoral immunity is unclear, and the presence of antibodies of both IgG and IgM types appears to be merely a marker of infection.

Epidemiology

The central United States, especially the southern half, is probably the most highly endemic area in the world. Populations of Eastern Europe, South Africa, and parts of

South America and China have shown higher than average rates of skin test positivity. Sporadic cases of infection and disease have been found all over the world, which may reflect the increase in worldwide travel. High concentrations of the organism are found in specific regions outside the endemic areas, and persons who travel to these locales may be subjected to massive exposure. Most dramatically, closed areas, such as caves, abandoned chicken houses, and places where common house bats tend to congregate, may contain very large numbers of infectious conidia in the soil. *H. capsulatum* is a normal inhabitant of the bat colon and is expelled in the feces. Exposure to bat guano is often associated with massive pulmonary infection. Association with starling roosts has been reported.

Clinical Manifestations

Primary histoplasmosis of the lungs is usually clinically silent. If the dose of inhaled conidia is large or if the infection occurs in a young child or weakened adult, there may be flulike symptoms, including fever and chills. These persist for a few days at most unless the host is immunosuppressed from any cause, in which case the symptoms may continue and progress. Cough and scanty sputum production are evanescent. Symptoms clear spontaneously and the diagnosis is usually overlooked. Associated clinical and roentgenographic findings seen in the course of primary infection include pericardial effusion and erythema nodosum. The latter clears spontaneously, as does the former, which rarely persists as chronic constrictive pericarditis. If the infection is massive, the infected person is under 1 1/2 years of age, or immunosuppression is present, blood pancytopenia and more severe signs of systemic organ involvement, affecting the liver and kidneys, may appear. Disseminated infection may be devastating in patients with AIDS, as no effective cell-mediated immunity remains to resist infection.

Healing of the primary infection is almost always associated with massive formation of scar tissue and accompanying calcification. In the lung itself, this leads to a dramatic chest radiographic pattern that has little or no clinical significance. In the mediastinum, however, the results of this process may be devastating. The spectrum includes mild bronchial obstruction (in young patients an enlarged node may cause narrowing from pressure alone); broncholithiasis; esophageal obstruction and formation of diverticula; obstruction of various vascular structures, including the aorta, pulmonary arteries, and most frequently the superior vena cava; bronchiectasis; and lobar or whole-lung collapse. In extreme cases, fibrosing mediastinitis may develop. The signs and symptoms are related only to the anatomic abnormality and usually not to any activity of the infection.

Acute eosinophilic pneumonia caused by *H. capsulatum* has been described with typical clinical characteristics. If indeed this exists, it is a self-limited syndrome; if severe, it responds well to steroid treatment.

Solitary (occasionally multiple) pulmonary nodule may be caused by *H. capsulatum* (histoplasmoma) and appears to be a remnant of the primary focus. It is imperative to differentiate between carcinoma and inactive *Histoplasma* infection as the cause of the nodule. In many instances this requires resection, although the presence on chest x-ray films of a diffuse, “popcorn” kind of calcification in the lesion, especially when the patient is asymptomatic, strongly suggests histoplasmosis as the cause.

Chronic granulomatous disease of the lungs may result from *Histoplasma* infection. There are no clinical or roentgenographic criteria to differentiate between mycobacteria, *Histoplasma,* or for that matter *C. immitis* as a cause of the syndrome, which usually occurs in men of middle age or older and is associated with progression to death if not treated. There is disagreement as to the pathogenesis of this form of histoplasmosis. It would appear to develop in patients with an active cell-mediated immune system, as seen in patients with cavitary tuberculosis. On the other hand, it has been suggested that this form of histoplasmosis represents superinfection of previously existing emphysematous areas in the lung. If this is true, it is hard to explain the very typical pathology of chronic granulomatous infection that is routinely seen. The possibility of endogenous reinfection exists.

Epidemic histoplasmosis is an acute, multifocal bronchopneumonia caused by a massive inhalation of conidia of *H. capsulatum.* Such cases frequently occur in clusters, as numbers of persons may be exposed at the same time or in the same area during a prolonged period of time. Such highly contaminated areas are often inhabited by bats. Roosts of starlings have also been associated with these outbreaks. Exploration of caves containing large quantities of bat guano (spelunkers' disease), use of an abandoned chicken house for storage or playing (chicken house disease), and acute exposure to highly contaminated soil in a central city play area have all been associated with such outbreaks. Patients have an acute febrile illness beginning between 7 and 14 days after exposure, characterized by toxemia, dry cough, and often chest muscular pains. Extensive lung involvement may lead to adult respiratory distress syndrome (ARDS). Only in immunosuppressed patients does the infection progress to extrapulmonary dissemination and death if not treated. In immunocompetent patients, respiratory support may be needed but recovery is almost universal. Of interest is the appearance of multiple parenchymal calcifications in the lungs of persons initially exposed to the fungus. In persons previously infected, the multiple lesions usually heal with no or minimal radiographic findings.

In infants under 1 1/2 years of age or persons over the age of 65 to 70, a first encounter with *H. capsulatum* almost always leads to widely disseminated infection that may be accompanied by miliary pulmonary histoplasmosis. This is potentially fatal and requires treatment. In infants the infection progresses rapidly, whereas in the elderly it may progress slowly and be accompanied by painful mucosal ulcerations.

Cases of typical sarcoidosis have been described from which *H. capsulatum* has been isolated. It is assumed that the fungus triggers the massive granulomatous reaction, noted particularly in the lungs and mediastinal lymph nodes. The principles for treating sarcoidosis are generally adhered to in these cases, and the presence of the organism does not change the therapy.

Diagnosis

Chest x-ray films may show the peripheral focus and enlarged regional and hilar nodes of a typical primary complex. The lymph node enlargement may not be as obvious in adults as in children under the age of 16 years.

Chronic granulomatous disease is associated with characteristic radiographic changes in the lungs, details of which are shown best by computed tomography (CT). Although little used currently, classic tomography is also helpful if CT is not available. Histoplasmomas show solitary or multiple well-circumscribed homogeneous densities anywhere in the lung fields, but most typically in the periphery. The presence of single or multiple calcifications strongly suggests a granulomatous etiology, but a single calcification is not totally reliable. In so-called epidemic cases, multiple, poorly defined densities are seen, usually bilaterally, and there may be associated hilar adenopathy. The parenchymal shadows may simulate miliary disease. Again, the x-ray picture is not specific, but with an appropriate history it can be highly suggestive. In true disseminated disease, miliary lesions may be seen in the lungs, and other organs and systems may be involved by inflammatory changes, including liver, kidneys, bones, and central nervous system.

In epidemiologic surveys, the presence of splenic calcifications, especially more than two, has been found to be a reliable indicator of previous infection with *H. capsulatum.* These may also be seen in patients with active lung disease, but their significance in this setting is no greater than that of any other indicator of previous infection.

Except for pancytopenia, seen in disseminated active infection, and nonspecific signs of inflammatory liver involvement, general laboratory findings are not helpful.

Definitive diagnosis of histoplasmosis is made by isolation of the organism from bronchoalveolar lavage (BAL) fluid, bone marrow, blood, or biopsy material. Although the organism may require 7 to 21 days for initial growth, rapid confirmation may be obtained within 24 hours using a commercially available DNA probe for colony hybridization. A presumptive diagnosis of histoplasmosis is frequently made by direct microscopic examination of clinical material using the Grocott silver stain in tissue or a Giemsa stain of bone marrow or buffy coat. Culture of peripheral blood by the lysis-centrifugation technique has been shown to have equivalent sensitivity to bone marrow culture in HIV-positive patients. Serologic tests for antibody include complement fixation, immunodiffusion, and an enzyme-linked immunosorbent assay (ELISA). In immunocompetent patients, a complement fixation titer ^{3}1:16 is highly suggestive of histoplasmosis. The presence of an M band on immunodiffusion suggests a previous infection with the organism, but the H band is diagnostic of active infection. ELISA has shown promise as a screening test, with greater sensitivity than immunodiffusion. Testing for antigenuria and antigenemia is the serologic procedure of choice in immunocompromised patients; the tests are very sensitive for the diagnosis of disseminated disease, and changes in titer in serial specimens appear to be prognostic. Skin testing with the reagent histoplasmin is useful for epidemiologic investigation, but it is not recommended for diagnosis because of the high incidence of skin test positivity in endemic regions and the propensity of a positive response to modulate antibody responses in subsequent tests using mycelium-derived antigens.

Prognosis and Treatment

In immunocompetent patients over the age of 1 1/2 years who are not elderly or otherwise ill, the prognosis in primary infection is excellent without any specific treatment. This is also true in cases of eosinophilic pneumonia caused by *Histoplasma* and histoplasmoma. The prognosis is grave in chronic granulomatous histoplasmosis and in disseminated active infection. Without treatment, almost all such patients die of their disease.

Thus, antibiotic therapy is indicated in these two forms of histoplasmosis. The antibiotic of choice is amphotericin B. The total dose is between 30 and 40 mg/kg of body weight, given as 1.0 mg/kg/dose intravenously. The dose is smaller at first and increased gradually to the maximum. The drug is administered daily in more acutely ill patients and then continued 2 to 3 times per week. There are many side effects, especially retention of urea and creatinine, which is generally completely reversible if the total dose is 45 to 50 mg/kg. Hypokalemia may also develop, as well as mild hematologic abnormalities. The almost uniform chills, fever, and nausea that occur at

the time of drug infusion are treated symptomatically but are less troublesome if the daily dose is given within 1 1/2 hours. Liposomal/lipid-complexed drug has been used to avoid side effects. The decreased efficacy of these preparations requires the administration of increased total doses to achieve similar clinical results.

Itraconazole is the one azole antibiotic that has shown significant activity in potentially fatal histoplasmosis. It should be considered as an alternative in patients who cannot tolerate amphotericin B therapy. The dose is 200 to 400 mg/day, and the therapy should be continued for 2 months or more. Use of this drug has been recommended for life to prevent recurrences of active infection in HIV-positive patients. The maintenance dose is 200 mg/day.

Coccidiodomycosis (Fig. 6, Fig. 7, Fig. 8 and Fig. 9)

FIG. 6. Acute coccidioidomycosis with bilateral upper lobe infiltrates.

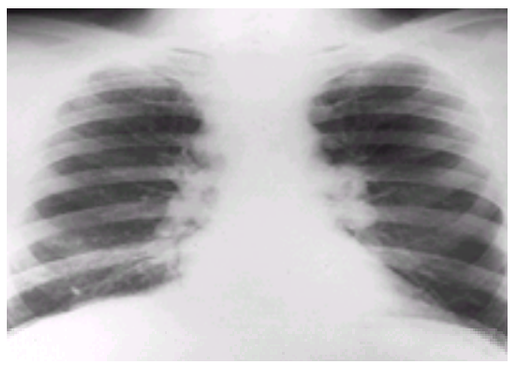

FIG. 7. Acute coccidioidomycosis with bilateral hilar adenopathy.

FIG. 8. Thin-walled cavity of the right lower lobe in a patient with chronic coccidioidal infection.

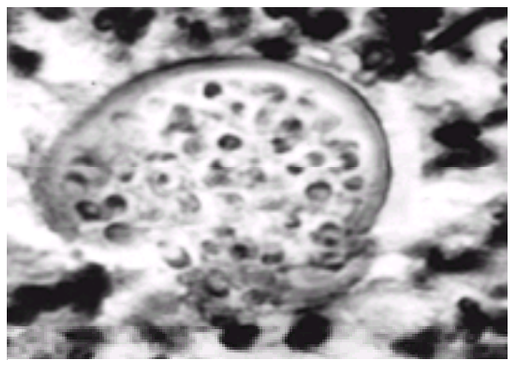

FIG. 9. Spherule of *C. immitis* seen with endospores in tissue section. (Reproduced with permission from Straub M, Schwarz J. Coccidioidomycotic thoracic lesions in dogs in Tucson, Arizona. *Arch Pathol* 1956;62:479. Copyright 1956 by the American Medical Association.)

Described in South America by the young Posadas and his pathologist teacher Wernicke in 1892, this disease was thought to be exclusively a tropical protozoan disease until the work of Dickson and Gifford in the 1930s uncovered a mild pulmonary form of the infection. As with histoplasmosis, natural resistance to the infection is high, but certain ethnic groups appear to have increased susceptibility to the development of active disseminated infection. The clinical spectrum of the disease is broad, and in certain situations curative treatment does not exist.

Organism

C. immitis is another of the dimorphic fungi. It is present in the soil as a mold with septate hyphae that form alternating, barrel-shaped arthroconidia. These arthroconidia are easily aerosolized and highly infectious. Following inhalation, the conidia round up and convert into the tissue form, referred to as *spherules.* Spherules are round, thick-walled structures averaging 30 to 60 µm in diameter. When mature, they are filled with 2- to 5-µm endospores that develop into spherules after being released in the tissue.

Pathology

In most infections, the portal of entry is the lung. After sufficient conidia are inhaled to reach the respiratory tissue, acute inflammation occurs, followed quickly by lymphocyte/macrophage infiltration and the development of a granulomatous process. As in histoplasmosis, caseous necrosis takes place. The lymph system is involved concurrently, with lymphangitis and local lymphadenitis and early dissemination. The pattern is similar to that of other granulomatous infections. The differences are that the degree of scarring and calcification is less than in histoplasmosis, and in a significant fraction of cases the organism clearly remains viable,

even if not actively replicating, after the primary infection has healed. This makes subsequent endogenous reinfection a real possibility. Exogenous reinfection has been seen.

In addition to the T lymphocyte/macrophage-associated delayed hypersensitivity response, antibodies of both the IgG and IgM types develop. They may be demonstrated by a variety of techniques, such as complement fixation, immunodiffusion, and latex agglutination. If the cell-mediated immune system fails to react, active dissemination is common. The active role of the antibodies is unknown at present.

Epidemiology

The endemic areas of infection with *C. immitis* are referred to as the *Lower Sonoran Life Zone,* an area encompassing western Texas, New Mexico, Arizona, southern California, and northwestern Mexico. In addition, the disease has been seen in Central America, Venezuela, Colombia, Paraguay, and Argentina. Other regions have been investigated, but the organism has not been found. Support for this localization has come from widespread skin testing programs using spherulin and coccidioidin. A confounding factor has been the increasing number of people who travel.

Because the organism is present in relatively superficial soil layers in its highly infectious mold form, massive exposure may occur during wind storms in endemic areas, especially during dry weather, or when the infected soil is disturbed by digging. Outbreaks have even occurred after the organism was introduced into an air-conditioning system!

Clinical Manifestations

Primary infection with *C. immitis* is usually silent. Occasionally, nonspecific symptoms of a flulike illness may be accompanied by fever, most often in children. On chest x-ray films, a typical primary complex may be seen that includes both peripheral lung infiltrate(s) and accompanying enlarged regional hilar and/or mediastinal lymph nodes. There may be an associated pleurisy with fluid, an event that usually clears spontaneously. This is almost always a self-limited illness, but in certain ethnic groups (nonwhites in general but especially Filipinos) the likelihood of active disseminated disease developing at the time of primary infection is much higher. If dissemination occurs, it is fatal unless treated.

As in histoplasmosis, there may be dramatic occurrences of widespread bronchopneumonia resulting from exposure to high concentrations of fungus in the soil. Many such events have been described, and the associated syndrome, which has been called *desert fever,* is an acute febrile episode with respiratory symptoms that is usually self-limited. It may be associated with erythema nodosum and other allergic skin manifestations as well as migratory arthopathy, known as *desert rheumatism.* All these symptoms may occur with primary coccidioidomycosis, even if not so dramatically. The symptoms spontaneously resolve. The chest x-ray film shows widespread areas of bronchopneumonia that may simulate miliary lung disease. Potentially, this could cause ARDS. The need to treat with antifungal antibiotics is questionable, but in any case careful clinical follow-up is indicated.

Cavitary coccidioidomycosis is seen both as an asymptomatic surprise finding on chest x-ray films or as part of the syndrome of chronic granulomatous disease of the lungs. Although the so-called typical coccidioidal cavity is described as thin-walled, cavities characteristic of any granulomatous disease are the rule rather than the exception. This form of the disease occurs more frequently in adults than in children and has been ascribed to endogenous or exogenous reinfection. In fact, the pathogenesis is not well understood. Whether asymptomatic individuals require treatment is a controversial point, but currently it is felt that antibiotic therapy is indicated. Clinically, a stable cavitary lesion may not progress and appear to represent localized disease. More frequently, there is true progressive disease. In fact, if the so-called stable lesions are followed long enough, clinical and roentgenologic progression is often noted. Complications of a cavity include hemorrhage, pneumothorax, and the development of a fungus ball. Although fungus balls are usually caused by *Aspergillus* species, there have been rare instances of coccidioidal mycetomas. The presence of the mold form of the fungus within a cavity suggests possible person-to-person transmission of the disease, which does not happen in other forms of active coccidioidomycosis.

Other syndromes may occur. Coccidioidomas are seen, often as a direct result of the primary infection. They are often found on a routine x-ray film. Of importance is that within these lesions as well as within cavitary lesions the organism may remain viable for many years. This is in contrast to the rare positive culture from histoplasmomas. Disseminated disease, which may occur as noted above or in immunosuppressed patients, is rapidly progressive and fatal unless treated, and even then the prognosis is guarded. The most dramatic form of disseminated disease is coccidioidal meningitis, which is a chronic and ultimately fatal disease unless treatment is maintained for life!

Diagnosis

Chest x-ray findings in pulmonary coccidioidomycosis are characteristic of the syndrome but not specific. Radiographic features of primary infection include peripheral foci, hilar node enlargement, and occasionally the accumulation of pleural fluid, findings that in no way differ from those associated with a variety of agents, including mycobacteria or other fungi. The same is true for the cavitary form of the disease, except for the suggestive nature of a thin-walled cavity associated with little or no pericavitary infiltrate. This is usually localized to the upper zones. Fluid levels may be seen. When a fungus ball is present, there are no roentgenologic methods to differentiate between the fungi that can cause this entity.

General laboratory findings include leukocytosis, elevated erythrocyte sedimentation rate, and possible mild liver enzyme abnormalities, but in general they are not pathognomonic for this specific infection.

Microbiologic examinations and immunologic testing are critical in diagnosis and prognosis. The large, endosporulating spherules of *C. immitis* are easily visualized in BAL fluid or biopsy tissue specimens with routine hematoxylin and eosin staining or any of the special stains for fungi. Culture of the organism provides definitive diagnosis; the organism grows relatively rapidly, with most cultures becoming positive within 7 to 10 days, often within 48 hours. Confirmation of the identification of cultures is most rapidly made by utilizing the DNA probe hybridization that is commercially available. Serologic diagnosis of coccidioidomycosis is available as a tube precipitin test for early (IgM) response and as a complement fixation test for IgG response. Immunodiffusion screening tests are available that correlate with both the precipitin and complement fixation tests. The titers of complement-fixing antibodies are prognostic. The diagnosis of coccidioidal meningitis is almost always made by the demonstration of complement-fixing antibodies in cerebrospinal fluid; only in highly immunocompromised patients are spherules seen in or organisms grown from cerebrospinal fluid. Two skin-testing reagents are available, coccidioidin and spherulin, for epidemiologic investigations; the latter is a newer reagent of greater sensitivity and specificity.

Prognosis and Treatment

Most cases of primary coccidioidomycosis clear spontaneously and leave minor residua. Calcification of peripheral foci and hilar and mediastinal lymph nodes is much less pronounced than in histoplasmosis. Chronic cavitary disease may persist with no activity for years and then either slowly progress or, if some associated stress to the body occurs, rapidly disseminate. In cases of progressive cavitary or disseminated disease, only extended treatment prevents mortality. Meningitis may persist with many exacerbations and remissions before causing death, and treatment needs to be lifelong for death to be prevented or significantly delayed.

The drug of choice in serious progressive disease is amphotericin B. Treatment needs to be prolonged, and a total dose of about 60 mg/kg is required. This large dose may cause permanent renal damage. Some cases of meningitis have required even larger doses, but such treatment is rarely permanently effective. As an alternative, up to 50 to 60 mg/kg may be given in one prolonged course of 8 to 12 weeks, after which the drug may be given once a year 3 to 5 times during one week in separate doses of 1 mg/kg. This regimen must continue for the life of the patient. In addition, intrathecal amphotericin B is frequently given. There are numerous side effects, and treatment must be continued intermittently for life.

Alternatively, the drug ketoconazole has been used as extended treatment of pulmonary coccidioidomycosis at a dose of 200 mg/d for as much as a year or more in addition to amphotericin B. More recently, both fluconazole and itraconazole have been found effective and show particular promise for the treatment of coccidioidal meningitis. Amphotericin B, however, remains the major drug for treatment of serious, life-threatening disease.

In cases of skin test-negative coccidioidomycosis, treatment was previously given with transfer factor. This substance, the crude extract of polymorphonuclear leukocytes taken from persons with a strongly positive spherulin skin test, seems to increase the body's immune response, but the effect is temporary and repeated injections of the material are required every 4 to 6 weeks. It is not generally used.

There is increasing experience with a vaccine against *C. immitis* infection, and it may be indicated in persons from nonendemic areas who anticipate exposure for significant periods of time or to possibly high concentrations of the organism.

Blastomycosis (Fig. 10, Fig. 11 and Fig. 12)

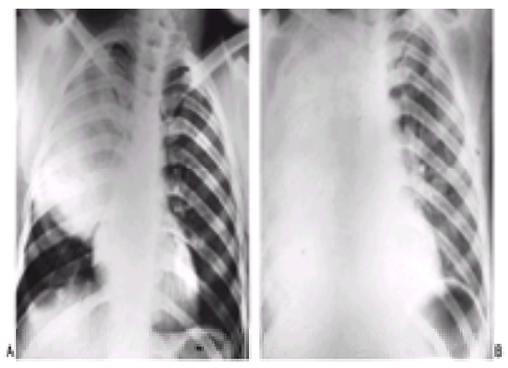

FIG. 10. A,B: Acute blastomycotic pneumonia with consolidation of most of the right upper lobe.

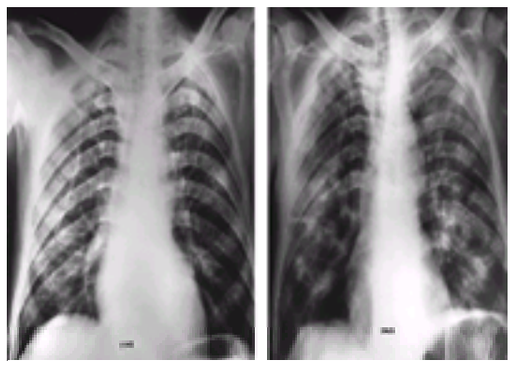

FIG. 11. Chronic pulmonary blastomycosis characterized by linear infiltrates with slow but relentless progression during an 8-year period.

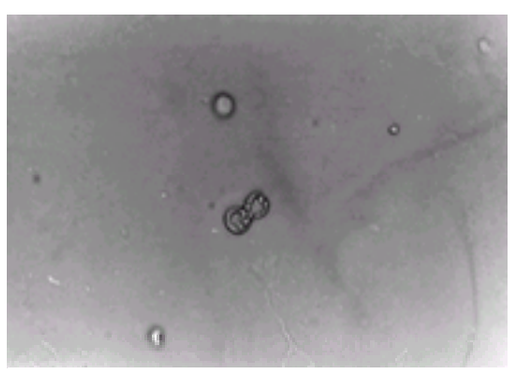

FIG. 12. Yeast-phase *B. dermatitidis* showing characteristic single bud and presenting a “figure 8” appearance.

North American blastomycosis was first described by Gilchrist in 1894 as a disseminated skin disease, and it was considered to be mainly an inoculation infection with ABoccasional instances of dissemination to the lungs and the rest of the body. In the early twentieth century, a group of cases was reported from Chicago, which gave the city's name to the disease. In 1951, it was proposed that the primary infection was almost always pulmonary and that skin lesions represented dissemination of the organism. In the late 1940s, the first effective chemotherapeutic agent for blastomycosis, stilbamidine, was reported, soon to be followed by 2-hydroxy-stilbamidine and subsequently amphotericin B.

Organism

B. dermatitidis is the etiologic agent of North American blastomycosis. The septate hyphae of this dimorphic fungus occur transiently in the soil, where they produce small, round to pyriform conidia, the infectious form of the organism. On inhalation, the conidia are transformed into large (8 to 12 µm), thick-walled, budding yeast cells that are characterized by single buds, separated from the mother cell by a wide isthmus.

Pathology

The classic pathology of blastomycotic lesions of the skin is a combination of pseudoepitheliomatous hyperplasia of the epidermis with microabscess formation in the dermis breaking into the epidermis. In the lung, there may be an acute inflammatory response with primarily polymorphonuclear leukocytes and abscess formation. A granulomatous response is seen in blastomycosis, but almost always in combination with a suppurative reaction. Alternate inflammation and scarring are seen in the same areas of involvement in skin, lung, and other organs. All organs in the body may be involved, but the development of pleural lesions is seldom accompanied by fluid formation. Hilar and mediastinal lymph node enlargement can be found, even in the presence of minimal pulmonary parenchymal involvement. This speaks for the primary pulmonary nature of most infections.

Immunopathology has not been well defined, but the development of delayed skin hypersensitivity suggests that the cell-mediated immune system plays a role. This is supported by the combination of suppuration with granulomatous inflammation seen in most cases. Specific antibody formation is not consistent, and the role of this factor is not clear.

Epidemiology

This infection has been mainly localized to North America, cases having been described in Canada as well as the United States and Mexico. Dogs in these areas have been infected, indicating the localization of the fungus in soil. In the latter part of the twentieth century, cases have been described in natives of central Africa.

Although once known as *Chicago disease,* it is now felt that the endemic area of the infection, if indeed one exists, is in Wisconsin. Outbreaks have been described in other areas as well, but in general the infection has been found east of the Mississippi River. Sporadic cases have been found in the southeastern United States especially. The absence of a reliable skin test or other tools useful in widespread testing for symptomless infection has hindered the collection of accurate epidemiologic data.

Ethnic factors do not appear to influence resistance to the infection or its dissemination. Because of the significantly higher prevalence of the disease in men than in women, there is a question of some genetic determinant of susceptibility. Immunosuppression from any cause favors more malignant dissemination, but blastomycosis is not a special problem of AIDS patients.

Clinical Manifestations

Few cases of clinically diagnosed primary pulmonary infection have been reported. Most of those appear to have been part of so-called mini-epidemics in which acute bronchopneumonia was seen in association with hilar lymph node enlargement. Isolated cases have been reported and support the presence of a definite hilar lymph node component. These cases have been associated with mild flulike symptoms that clear spontaneously within a week to 10 days. Careful history reveals the critical fact of exposure to *B. dermatitidis.* Only if the possibility of the diagnosis is entertained will the critical diagnostic tests be carried out.

ARDS has been described in 10 patients with blastomycotic pneumonia. It was not clear whether these cases were primary infections, but the clinical picture was one of severe acute pneumonia. No underlying immunosuppression was found in any of the patients. Mortality was high despite amphotericin treatment.

Healed primary infection may be encountered, usually on a chest radiograph taken for other reasons. The pulmonary parenchymal and hilar elements of the primary complex are identifiable on x-ray films in such cases, but in contrast to healed primary histoplasmosis, the scarring rarely causes mechanical problems of mediastinal structures. Solitary pulmonary nodules have been described as being caused by *B. dermatitidis,* and almost certainly these are remnants of healed primary pulmonary parenchymal blastomycosis.

Disseminated blastomycosis may present clinically with isolated, chronic skin lesions that exhibit peripheral extension and central scarring, resemble basal cell or even squamous cell carcinomata of the skin, and are associated with peculiarly characteristic microabscesses, typically at the periphery of lesion. This appearance should alert the physician to the possibility of blastomycosis. Patients may present with chronic cough, production of mucopurulent sputum, weight loss, low-grade fever, and many of the symptoms associated with chronic granulomatous disease of any etiology. Chest x-ray findings are nonspecific but indicate a destructive inflammatory process of the lungs. Involvement of the pleurae may occur but is rarely associated with pleural effusion. Lesions may be found in any organ system but rarely in the gastrointestinal tract. The urinary tract in men and women is a common site. Blastomycotic prostatic abscesses have been seen as a cause of urinary obstruction. Occasionally chronic widely disseminated disease is enountered, and such patients are clearly cachectic.

Acute blastomycotic pneumonia has been described in immunosuppressed patients; the only distinguishing characteristic is the presence of the organism in secretions obtained from the tracheobronchial tree or lungs. The clinical picture is that of an acute lower respiratory tract infection modified by the immune suppression of the patient.

Diagnosis

The chest x-ray film in primary pulmonary blastomycosis may show poorly defined infiltrates associated with lymph node enlargement in the hilar/mediastinal areas, or there may be few findings in the pulmonary parenchyma, with nodal enlargement as the only finding. Rarely, bilateral hilar node enlargement may be seen, suggesting the diagnosis of sarcoidosis. In progressive chronic pulmonary disease, most frequently associated with dissemination, typical changes of chronic granulomatous inflammatory disease with cavitation may be seen. There is nothing to distinguish these changes from those caused by *M. tuberculosis* or other fungi.

Results of general laboratory tests add little other than to confirm the debilitating nature of the chronic disseminated infection. Involvement of liver and kidneys may be expressed by abnormalities of function studies.

The diagnosis of blastomycosis is made by the demonstration of the typical, thick-walled, single-budding yeast in sputum, BAL fluid, or tissue. The organism is easily visualized using any of the special stains for fungi. Definitive identification depends on culture of the organism, and confirmation of the morphologic identification may be made by DNA hybridization with the colonies. The organism often requires 7 to 14 days or longer to grow in culture. Serologic testing for blastomycosis rarely is useful. The immunodiffusion test for antigen A is specific but lacks sensitivity. Recent work with an ELISA to detect antibody to an antigen termed *WI-1* shows promise.

Prognosis and Treatment

Based on experience, particularly with epidemics of blastomycosis, prognosis is excellent for spontaneous remission of primary infections in immunocompetent persons. In cases of progressive disease, mortality is high unless the patient is treated with specific antibiotics. Skin lesions tend to recur even after local therapy has been apparently effective. As noted, the mortality in ARDS, even with treatment, is high.

Amphotericin B given intravenously is effective in all types of cases. The total dose is between 20 to 40 mg/kg given as single doses of 1 mg/kg. Therapy is given daily for acutely ill patients, then 2 to 3 times per week according to the clinical situation. Itraconazole (200 to 400 mg/d) may be used as an alternative to amphotericin B in patients not judged to be critically ill.

Paracoccidioidomycosis (South American Blastomycosis)

This disease was first described by Adolfo Lutz in 1908 and has been identified in areas localized to Central and South America. At first thought to be acquired by extrinsic inoculation into the skin and/or mucosae, it is now recognized to be a primary pulmonary infection in almost all cases. Just how common the asymptomatic infection is has not been clarified, but almost certainly the number of active cases seen represents a small fraction of persons infected with *P. brasiliensis.*

Organism

The dimorphic fungus *P. brasiliensis* is found in the soil as a mold with septate hyphae that produce small, round to pyriform conidia, resembling those of *B. dermatitidis.* The yeast cells of *P. brasiliensis* are extremely variable in size, with an average of 10 to 20 µm and a range of 2 to 30 µm. The yeast cells are characterized by multiple buds separated from the mother cell by a narrow isthmus. A specialized form of the budding cells, called a *mariner's wheel,* features a large, 20- to 30- µm mother cell surrounded by many 2- to 3-µm daughter cells.

Pathology

Grossly, the pathology of this infection is most obvious on skin and mucosal surfaces. The cutaneous lesions seen resemble those of blastomycosis and leishmaniasis. Tumorlike growths of granulomatous tissue frequently involve the gastrointestinal tract, as opposed to the lesions of blastomycosis, which are rarely seen in this area. Areas of localized inflammation may be seen in the lungs; interstitial thickening is found in disseminated disease, and cavities may form. This infection involves the lymph system particularly, and nodes are enlarged and necrotic in all areas of the body, but especially in the mediastinum and hilar areas, when the infection is widespread. Histopathology is characterized by the combination of granulomatous inflammation and suppuration, a similarity with blastomycosis. This is noted in all organs involved.

The presence of delayed hypersensitivity skin reactions and the above noted histopathology suggest that the cellular immune system is an important but not the only element in natural resistance to *P. brasiliensis.* There is little information relating to the impact of AIDS or other causes of immune suppression on this infection.

Epidemiology

Paracoccidioidomycosis is encountered almost exclusively in Central and South America but is not seen in areas of rain forest or desert. Up to a few years ago, no cases had been reported from Chile, Guyana, Surinam, or Nicaragua. Southern Brazil is the area of highest prevalence. The definition of the areas in which the organism is found includes elevation of 500 to 1800 m, 800 to 2000 mm annual rainfall, average yearly temperature of 18° to 23°C, and acid soil.

A skin test has been used to identify endemic areas, and to the extent that it has been used the results correlate with the distribution of active cases and with the area defined above.

Clinical Manifestations

This disease is seen mainly in male patients, the estimate being about 90%. Skin test surveys, however, demonstrate a 50:50 relationship between men and women infected with the organism. This is a rare disease in persons under the age of 10 years but may occur in a fulminant form in childhood.

Generally, the disease presents with mucocutaneous lesions, especially in the oropharynx and gingivae, and also in the gastrointestinal tract. The port of entry is the respiratory tract, the extrapulmonary lesions being metastatic, as in blastomycosis.

Pulmonary disease may be localized to the lung parenchyma and the hilar and mediastinal lymph nodes or be part of progressive disseminated disease. The acute

limited disease is manifested by nonspecific symptoms and x-ray findings of multiple foci of infiltrates in both lungs. These may recede spontaneously and the enlarged nodes calcify. The primary infection may occur without symptoms. Minimal parenchymal fibrosis occurs as a residual. Immune factors that determine the outcome of this disease have not been well defined.

A chronic progressive form of the disease seen in adults resembles tuberculosis in all its manifestations. Without effective treatment, it leads to cachexia and death. Cavities are seen in the lungs in only 15% of such cases. Often, extrapulmonary lesions involve the pleurae and all extrathoracic organs.

Diagnosis

A history of residence in the endemic area is the most important diagnostic finding. As the clinical manifestations are nonspecific, awareness of the possibility of this disease is an indication for appropriate diagnostic tests.

Chest x-ray films demonstrate parenchymal infiltrates and hilar node enlargement if the infection is primary. In chronic progressive pulmonary disease, the findings are similar to those of tuberculosis, histoplasmosis, and coccidioidomycosis. Cavities are seen in only 15% of such patients. Geographic prevenience of the patient determines the likelihood of this disease.

Laboratory diagnosis of paracoccidioidomycosis is based on demonstration of the characteristic multiple budding yeast form in respiratory secretions or tissue. The organisms stain readily with any of the special stains for fungi. Confirmation by culture requires patience, as *P. brasiliensis* is one of the most slowly growing of the dimorphic fungi, usually requiring 3 to 6 weeks of incubation. Identification is based on the morphology of the organism and confirmed by in vitro conversion to the yeast forms or an immunologic procedure referred to as the *exoantigen test.* The serologic tests that show the most promise for the diagnosis of paracoccidioidomycosis are the immunodiffusion test for band 1 and an ELISA directed at antigen E2.

Prognosis and Treatment

Most cases of primary pulmonary infection clear spontaneously. Acute pulmonary infection, primary or not, in adults up to about 60 years of age also tends to clear, but chronic pulmonary disease is progressive and fatal unless treated. Disseminated disease, including lesions on skin and mucosae, is progressive and requires treatment; otherwise it progresses, albeit slowly, to a fatal end.

Treatment with sulfadiazine is effective. Other antibiotics have been used also, but sulfadiazine is still considered the drug of choice. Treatment must continue for up to a year at a dosage of 4.0 g/d. Amphotericin B is also effective and used in disseminated cases. The dosage is the same as for chronic histoplasmosis, up to 2 to 3 g per total dose. Ketoconazole has been found effective at a dosage of 200 mg/d for at least 1 year.

Sporotrichosis (Fig. 13)

FIG. 13. A: Cavity of the left upper lobe in a young adult with pulmonary sporotrichosis. **B:** Linear tomogram of the cavity. Diagnosis was proved by sputum cultures and by culture of material from resected cavity.

This disease is much better known as a skin disease than as a pulmonary disease, as the majority of cases have localized skin ulcerations and the route of infection is by direct inoculation. The organism was discovered by a medical student, Schenck, in 1898, and the pulmonary form of the infection was recognized much later. Animal infection was noted for the first time in 1907 in Brazil, and since then the presence of the organism in soil has been demonstrated repeatedly.

Organism

S. schenckii is another of the dimorphic fungi. The mold form of the organism features delicate septate hyphae bearing pyriform conidia arranged like petals on a ABdaisy. The yeast cells are small (2 to 5 µm), round to cigar-shaped cells that are difficult to visualize in tissue.

Pathology

Skin lesions appear grossly as induration with or without ulceration, and usually they occur in line with the associated lymphatic channels. Histologically, granulomas and suppuration are seen along with dystrophic changes of the skin that resemble carcinoma. Organisms are rarely demonstrated in tissues, even with the use of special stains.

The lung shows nodular lesions that are occasionally plaquelike and tend to occur in the upper lobes more than in other areas of the lung. Cavities are frequently seen and often are thin-walled. Necrotic lining of the cavities is the best place to look for organisms. Histologically, the lesions are similar to the skin lesions in that both granulomas and purulent exudate are present. The cavities are usually limited by scar tissue, which is also found in the areas of noncavitary pulmonary lesions.

Epidemiology

The organism is found worldwide in soil and on the leaves of a variety of plants. In particular, rose and burberry bushes host the fungus, and it is also found on hedge bark, reeds, potting soil, sphagnum moss, grasses, and tree bark. It has been isolated from timbers used to shore up a mine in South Africa, and this source infected more than 3000 miners in the largest outbreak of the skin disease that has been reported. The skin disease is an occupational risk for gardeners and soil workers.

The distribution of pulmonary cases is sporadic and probably more related to the interest and diagnostic capability of the involved physicians than to the distribution of the fungus! There is no diagnostic skin test to identify asymptomatic infected persons.

Clinical Manifestations

The disease is best known as a skin problem. The distribution of the lesions tends to follow the lymphatic channels, but lymph nodes are involved infrequently.

Pulmonary sporotrichosis appears to be a separate form of the disease, in which the primary encounter with the fungus is through inhalation. Little is known about early events. The patients usually have cough, sputum production, rarely hemoptysis, and occasionally weight loss and weakness, depending on how long they have been ill. There is nothing to differentiate this chronic lung infection from tuberculosis, histoplasmosis, or coccidioidomycosis.

Dissemination is a rare event and is usually associated with immunosuppression. Lesions may appear in any organs and clinically resemble disseminated infection caused by any fungal organism.

Diagnosis

The history of occupational exposure to potential sources of the fungus may be diagnostically important in evaluating the skin lesions, but not in pulmonary sporotrichosis.

Chest x-ray films reveal localized infiltrates, usually in the upper lobes and often associated with cavities, possibly thin-walled. There may be pericavitary spread of the infection. Findings are nonspecific.

In the laboratory, the organism is readily isolated when cultures are held for at least 2 weeks. The morphologic identification of the mold form is confirmed by in vitro conversion of the organism to its yeast form. The organisms are difficult to see in tissue, even when special stains for fungi are used. Although a number of serologic tests for sporotrichosis have been proposed, none is widely used or commercially available.

Prognosis and Treatment

The skin lesions of sporotrichosis progress slowly but inexorably. Dissemination is rare, as is spontaneous cure of the lesions. The pulmonary lesions progress slowly, and all the reported cases have improved only after treatment.

Iodides are the treatment of choice for skin lesions. Why this very old treatment works is a mystery. It is not because of a direct effect on the fungus. Usually, a saturated solution of potassium iodide is used and continued until all lesions have healed. As a matter of interest, this is the only fungal disease in which iodides are effective, although they have been used in the treatment of all.

Pulmonary sporotrichosis is unaffected by iodides; amphotericin B is required for effective treatment. The exact dose is unknown, but if a total of 1 to 2 g is given according to the usual dosage schedule, results are excellent, with disappearance of pulmonary lesions, conversion of sputum to negative, and clinical improvement. Occasionally, surgery may be necessary to eradicate large cavities.

Itraconazole, which has been successfully used for cutaneous sporotrichosis, has been shown to control systemic disease at a dosage of 600 mg/d for a few weeks and then 400 mg/d for up to a year in patients unable to tolerate amphotericin B.

Cryptococcosis (Fig. 14)

FIG. 14. Chronic pulmonary cryptococcosis in a 66-year-old man with multiple nodular lesions simulating metastatic carcinoma.

This yeast infection was first described in 1894 by Busse and later by Buschke in a patient with involvement of the tibia. Early on, the organism was considered to be a cause of lymphoma, as it was found as a coexisting infection is such patients. A variety of names was given to the organism, but finally it was recognized as a member of a separate genus and the confusion with *B. dermatitidis* was resolved. The major clinical form of the infection, the one most feared because of its high mortality, is meningitis, and to this day the differential diagnosis between cryptococcal and tuberculous meningitis is a challenging one.

Organism

C. neoformans varieties *neoformans* and *gattii* occur as budding yeast cells (2 to 10 µm) with distinctive polysaccharide capsules. The two varieties correspond to the serotypes A/D and B/C, respectively. The yeast cells of variety *neoformans* are typically rounder, whereas those of variety *gattii* tend to be more oval to lemon-shaped. Infrequent isolates of *C. neoformans* have been reported that demonstrate the presence of hyphae in tissue or culture; these are now believed to be the result of failure of haploidization during the sexual reproductive cycle.

Pathology

In humans, this organism may be found in any organ system. Entrance to the body, however, is almost certainly through the respiratory tract. Desiccation of the organism in pigeon fecal material allows for aerosolization of particles of appropriate size to be inhaled and transported to the respiratory areas of the lungs and there cause the initial infection. Dissemination from such primary foci occurs regularly, with special tropism to the central nervous system.

The tissue response to the organism is quite varied, ranging from acute suppuration to practically no response at all. Lesions may display a variety of inflammatory components, including granuloma formation and proliferation of scar tissue. In some cases, significant accumulations of organisms are found with almost no tissue reaction whatsoever. Grossly, such lesions, especially in the skin, look like blisters full of mucus that on microscopic examination demonstrate countless organisms, with the mucinous capsule being responsible for the gross appearance.

The special relationship between infection with *C. neoformans* and immunosuppression, either from lymphomatous disease, AIDS, or immunosuppressive therapy, demonstrates a varied pathology microscopically. There may be a severe, acute, purulent inflammatory response when cell-mediated immunity is suppressed, as in AIDS; there may be granuloma formation (if the T lymphocytes are functional) in lymphomatous disease, or there may be little cellular response in cases in which the immune system has been overwhelmed. Combinations of the above may be seen in a single patient. The clear lack of a granulomatous reaction in patients with AIDS reflects the basic immune pathology of AIDS.

Epidemiology

Infection with *C. neoformans* occurs worldwide, although the occurrence of the various serotypes of the yeast is area-related. Variety *neoformans* is found in Austria, Belgium, Denmark, France, Holland, Switzerland, Italy, and Japan as well as Argentina, Canada, the United Kingdom, and the United States. Variety *gattii* is found in Australia, California, Brazil, Cambodia, Hawaii, Mexico, Paraguay, Thailand, Vietnam, Nepal, and central Africa. The factor that seems to determine the presence of human infection by variety *neoformans* is contamination of the environment by pigeon feces. Variety *gattii* is found in association with the red gum eucalyptus tree.

From early in the history of this infection, clinical disease has been related to the presence of lymphomatous disease, especially Hodgkin's disease. The disease was also described in patients receiving immunosuppressive therapy. Since the early 1980s, cryptococcosis has been identified as the most common life-threatening fungal infection of AIDS patients.

Clinical Manifestations

The most dramatic clinical presentation of cryptococcosis is meningitis, which is very similar in character to tuberculous meningitis. The course is usually protracted in the immunocompetent patient but may be fulminant in the immunosuppressed patient.

Pulmonary cryptococcosis is most frequently encountered as asymptomatic single or multiple pulmonary nodules found by routine chest x-ray examination. The

diagnosis is most often made in these situations by the histology of the resected lesion.

Acute progressive pneumonia may occur, with symptoms of cough, sputum production, fever, and weakness. The clinical picture is not pathognomonic. The progression to abscess formation is more common than in pneumonias caused by bacteria and viruses. Failure of the patient to respond to routine treatment should lead to a search for the causal fungus.

Rapidly progressive infection is most frequently encountered in the immunosuppressed host, especially the AIDS patient. There is often widespread dissemination with involvement of extrathoracic organs. A unique form of the infection consists of multiple superficial mucosal ulcers in the airways, visible on fiberoptic bronchoscopy.

Pleural involvement may occur in all types of pulmonary cryptococcosis, and the resulting pleural exudate is an excellent source for obtaining a culture of the organism. Chronic pleuritis has not been described.

Diagnosis

In the most common clinical presentation of pulmonary cryptococcosis, chest radiography demonstrates single or multiple nodules, well defined and rarely calcified. These may occur in any location. There is nothing to distinguish these nodules from those caused by other fungi, tuberculosis, or tumor. Frequently, only histology is diagnostic. In acute respiratory infection, there may be infiltrates that resemble those of any acute bronchopneumonia. Cavitation may appear, resembling lung abscess. When the lungs are involved as part of a progressive dissemination, there may be multiple foci of infiltration and involvement of lymph nodes in the mediastinum. In all forms of cryptococcosis, CT adds to the exactness of the anatomic diagnosis but not the specificity. It also may reveal enlargement of mediastinal lymph nodes not seen on regular chest x-ray films.

General laboratory findings in all the above presentations are nonspecific and may indicate an underlying lymphomatous process or suggest AIDS. In the asymptomatic syndromes, usually no abnormalities are present.

The diagnostic findings come from the microbiology and pathology laboratories. Culture of bronchoalveolar fluid, cerebrospinal fluid, blood by lysis centrifugation, or tissue readily yields the organism, usually after 24 to 72 hours of incubation. Presumptive identification of *C. neoformans* is obtained within 24 hours by testing for the presence of the enzyme phenoloxidase in any urease-positive yeasts. Although a DNA probe for colony hybridization is commercially available, the sensitivity and specificity of the tests for phenoloxidase render it a less cost-effective procedure than its counterparts for the dimorphic fungi. Confirmation then depends on traditional biochemical testing, using any of the numerous commercially available systems. Rapid diagnosis of *C. neoformans* may also be obtained by the finding of soluble cryptococcal polysaccharide antigen in cerebrospinal fluid or serum, using either a latex agglutination test or an ELISA. Testing of BAL fluid has shown some promise but has a high false-positive rate. Finally, cryptococci are easily visualized in clinical specimens. The India ink preparation is positive in 50%–75% of cerebrospinal fluid specimens from patients with cryptococcal meningitis. The yeasts are stained well by any of the special stains for fungi; cryptococci may be presumptively identified by the intense staining of their polysaccharide capsules by the mucicarmine stain.

Prognosis and Treatment

Asymptomatic pulmonary cryptococcosis appears to be of little threat to an immunocompetent person. This is said with some hesitation, because prolonged follow-up of a significant number of patients in whom the diagnosis was established by resection of a nodule, even a single one, revealed active cryptococcosis in other locations—either the lung or extrathoracic organs, including the meninges—in almost 20% of a total of 60 patients. This included meningitis in almost 10% of them! Thus, the prognosis must be guarded.

In disseminated disease, the outcome is death, but this may not occur until after a long course. If immunosuppression is present, especially if caused by AIDS, the prognosis is for relatively rapid progression to death. All this is without treatment. Of special concern is cryptococcal meningitis. In the days before effective treatment, it was known that exacerbations and remissions could occur spontaneously. This gave rise to stories of spontaneous cures, which merely represented premature conclusions being drawn about remissions in a uniformly fatal disease.

Treatment is now indicated for all cases given a diagnosis of cryptococcosis, even if the diagnosis has been made by resection of a solitary, asymptomatic pulmonary nodule. In the case of an immunocompetent patient with an asymptomatic nodule, the treatment is 2 to 400 mg of fluconazole per day for a minimum of 6 weeks. The basic regimen used for meningitis is applicable to all other cases of pulmonary cryptococcosis. This includes amphotericin B given intravenously at a dose of 0.3 to 0.5 mg/kg per day to a total of 15.0 mg/kg. Initially, treatment is given daily, but if the patient is not seriously ill, this can be quickly reduced to three times per week. Accompanying treatment may be given with 5-fluorocytosine at a dosage of 150 mg/kg daily in four divided doses for a total of 6 weeks. This treatment is 80% effective in meningitis in immunocompetent patients and even more so in pulmonary disease. In immunosuppressed patients, maintenance therapy is required, and this may take the form of 30 mg of amphotericin B every 2 weeks in one intravenous dose. This continues for a year or two, and in the experience of several observers, it is effective on condition that response to the active treatment has been good. In addition to this treatment, it is possible to administer amphotericin B intrathecally in patients with meningitis. The side effects of amphotericin B include decreased clearance of urea and creatinine, anemia, fever, electrolyte abnormalities, and nausea. All these clear when treatment is stopped and can be reduced by giving premedication with antihistamines and antipyretics and by limiting the infusion to no more than 1 1/2 hours. 5-Fluorocytosine is cleared by the kidneys and causes very few side effects. If renal function is already restricted, the amount of 5-fluorocytosine administered each day is reduced in relation to the creatinine clearance.

Liposomes have been used to deliver amphotericin B, but it is necessary to increase the dose to achieve adequate coverage. As of this writing, liposomal treatment is not generally accepted.

Fluconazole is now an accepted treatment alternative, especially for maintenance therapy after completion of amphotericin B treatment of the acute disease. Itraconazole shows promise but is not yet recommended. Two hundred milligrams of either drug daily is continued for a year or more and is well accepted by the patients.

Dosages of fluconazole as high as 800 to 1200 mg/d have been used in the treatment of immunosuppressed patients. The success rate is considerably less than the 80%–90% seen in immunocompetent patients, but it is still significant and worth pursuing. In immunosuppressed patients, maintenance therapy is of critical significance, as the primary treatment is not totally fungicidal and the possibility of a relapse is very high.

Candidiasis

In 1839, the German surgeon Langenbeck described *Candida* in mucosal lesions in a patient with typhus. Actually, the clinical manifestations of candidiasis had been described by both Hippocrates and Galen some 2000 years before. Because the orifices of the body, where the organism normally is found, are readily accessible, *Candida* has been accused of causing many diseases, but as our sophistication has grown it has become clear that even though the surface of the body may suffer insults by *Candida,* the internal organs are extremely well protected by an intact immune system. When the internal milieu of the body is upset by antibiotics, steroids, or other factors, then the normally diminutive organism overgrows and clinical problems ensue.

Organism

Candidiasis is caused by numerous species of *Candida;* the most common include *C. albicans, C. tropicalis, C. parapsilosis, C. krusei,* and *C. (Torulopsis) glabrata.* All species of *Candida* form round to oval budding yeast cells in the size range of 3 to 7 µm. In addition, the first four species listed also form pseudohyphae (elongated yeast cells attached like strings of sausages) in tissue.

Pathology

The normal presence of the yeast *Candida* on mucosal surfaces of healthy persons does not provoke any reaction. When skin surfaces become macerated by moisture or when disease or antibiotic or steroid treatment upsets the ecologic balance of mucosal surfaces, an acute and subacute inflammatory reaction occurs that leads to local irritation. Microscopically, the inflammatory reaction is neutrophilic and lymphocytic. The same basic pathology is found in the esophagus and throat when the infestation progresses to the clinical syndrome of thrush and esophagitis, but a pseudomembrane is added consisting of fungal elements, cell detritus, and fibrin.

Lung involvement almost always occurs in the presence of immunosuppression or cachexia. There may be multiple foci of neutrophilic inflammation with necrosis that may evolve into abscesses. In severely weakened patients, little inflammatory response may be associated with the large collections of yeast cells in lung tissue. Extrathoracic organ tissues are often involved by a similar process, especially the renal cortices. Demonstration of the yeast cells or pseudohyphae of *Candida* is easily

done with regular tissue stains or the special fungal stains.

Special consideration must be given to the possibility of *Candida* pneumonia occurring in otherwise normal hosts. *Candida* may undoubtedly gain entrance to pulmonary tissue via contaminated intravenous needles or tubing, and in such situations blood cultures may well be positive for the yeast. It is highly unlikely, however, that the presence of organisms in the lungs on this basis alone is a threat to an otherwise normal person. The body has excellent defenses against this infection, probably because the organism is normally present on body surfaces. Serum from normal persons inhibits growth of *Candida* in culture. The organisms are subjected to efficient phagocytosis and killing by neutrophils, T lymphocytes and macrophages recognize *Candida* yeast cells, and at least three clones of antibodies are found in serum—IgA, IgM, and IgG. Thus, adequate means are available to control the organism. Entrance of *Candida* to the lungs via aspiration of mouth or nose contents may occur in normal persons, but this is probably quite rare. If it does happen, the same efficient defense takes over, so that finding *Candida* in sputum collected from normal persons almost certainly represents a mouth contaminant of the specimen and not active *Candida* infection of the lungs or airways.

One other expression of altered immune responsiveness is the occurrence of chronic mucocutaneous candidiasis, which is characterized by granulomatous lesions on the skin. This pathologic entity, often associated with various endocrine deficiencies in children, has not been described in the lung.

Epidemiology

The occurrence of systemic candidiasis and candidiasis of the lung as a unique entity is related primarily to immunosuppression and neutropenia. Other factors are associated with a higher incidence of systemic candidal disease are prematurity of infants, chronic cachexia, immunosuppressive therapy for any cause, and long-term steroid therapy. Interestingly, although local candidal involvement of the mouth and esophagus is associated with AIDS, true systemic candidiasis is almost never seen.

Clinical Manifestations

Pulmonary candidiasis occurs for all practical purposes only in immunosuppressed patients, and the only open question is whether the disease is part of a generalized systemic candidiasis. The patients are almost always acutely ill and clearly seriously weakened by their underlying conditions. There may be spiking fever, or in the case of a prolonged underlying illness, the fever may be low-grade. The entire clinical picture is one of overall deterioration. In the most confusing situation, a patient has multiple foci of bronchopneumonia and is unresponsive to antibiotic therapy, and *Candida* is found in the sputum. Even more compelling is the concurrent finding of *Candida* in a blood culture. Clinical judgment is difficult, but careful evaluation of all relevant factors in the case, such as the presence of a long-standing intravenous line or chronic ulcerative skin lesions (foci for dissemination of *Candida*) and the underlying status of the immune system, usually leads to a correct assessment of the need to treat.

Of special concern are patients undergoing bone marrow transplantation. These patients are almost completely depleted immunologically and are extremely susceptible to all types of infections. *Candida* is a significant threat in this situation. It is recommended that preventive therapy be given.

If pulmonary and/or generalized candidiasis has been diagnosed, the clinical situation is grave and treatment is urgently indicated.

If an immunocompetent patient presents with a pneumonia that does not respond to the usual treatment and *Candida* is found in sputum, it is unlikely that the presence of *Candida* is significant.

Diagnosis

The most helpful diagnostic tool is awareness of the overall clinical situation of the patient, especially the immune status, and of whether systemic candidiasis is a likely possibility.

Chest x-ray films demonstrate single or multiple foci of bronchopneumonia, in which radiolucencies often develop. This is a highly suggestive finding, but not specific.

The general laboratory findings are a reflection of the overall clinical situation and not diagnostic.

Specific diagnosis of pulmonary candidiasis depends on the demonstration of yeasts and pseudohyphae consistent with *Candida* in tissue, and the diagnosis is confirmed by the subsequent isolation and identification of the organism from the specimen. Because *Candida* is found as a commensal and a colonizer of mucosal surfaces, identification of the organism from sputum or BAL fluid may be suggestive, but mucosal contamination should always be suspected. The organism is easily cultured from blood, tissue, or respiratory tract specimens; identification depends on demonstration of defined morphologic and biochemical properties. Serologic tests for antibody to *Candida,* such as the immunodiffusion test, lack sensitivity and specificity because of the high prevalence of antibodies in the normal population. Tests for circulating antigen, either mannan or enolase, show promise, but the first generation of commercially available antigen assays has been disappointing.

Prognosis and Treatment

Untreated pulmonary or systemic candidiasis is fatal. In an immunocompetent patient with a positive blood culture resulting from a long-standing intravenous needle or cannula that has become contaminated, the prognosis is excellent if the offending needle or cannula is promptly removed. No other treatment is necessary. Otherwise, serious disease is a possibility, although not a certainty.

Amphotericin B is the treatment for life-threatening candidiasis. The total dose in adults is 15 to 20 mg/kg administered daily (at first) and then three times weekly in intravenous infusions of 0.75 to 1.0 mg/kg per dose. Premedication with antihistamine and antipyretic medication is indicated, and the instillation of 50 mg of hydrocortisone in the infusion helps to minimize side effects. Also, the administration of the entire infusion in 1 1/2 hours is advisable. Almost all species of *Candida* are sensitive to amphotericin B, so that resistance is not a problem. Most cases respond to this treatment. If the immunosuppression that so often underlies the problem can be dealt with, the prognosis is improved. The prognosis is not good for cachectic patients who are deteriorating progressively, even with treatment. In cases of bone marrow transplantation, this treatment should be effective.

Use of the imidazoles and triazoles in life-threatening situations is not recommended at this time. These drugs are effective in various forms of skin and mucosal candidiasis and are indicated as prophylaxis in patients undergoing bone marrow transplantation, but they are not effective in life-threatening candidiasis. Fluconazole has been shown to have the same efficacy in treating candidemia in patients who are not neutropenic as amphotericin B. For preventive therapy, fluconazole is the preferred drug; the dose is 200 mg/d and should be continued until all signs of immunosuppression have disappeared.

Aspergillosis (Fig. 15)

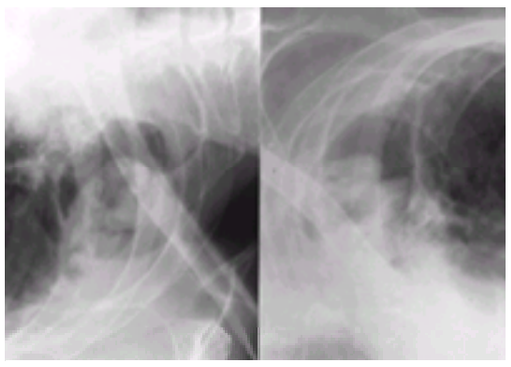

FIG. 15. Cavity in a 68-year-old man containing a fungus ball caused by organisms of a species of *Aspergillus.* Two positions show movement of the ball with change in position of the downward side of the patient.

Aspergillus species have been observed in nature for several hundred years. The name *Aspergillus* is based on the similarity of the spore head of the fungus, first noted by Micheli in 1792, to an aspergillum, the instrument used for sprinkling holy water on supplicants. The fungus was found to cause disease in jays by Mayer and

Emmert in 1815 and was suspected as the cause of human disease later in the nineteenth century. The spectrum of disease caused by this fungus became clear only in the middle of the twentieth century.

Organism

Invasive aspergillosis is caused most frequently by *A. fumigatus* and *A. flavus. A. niger* is often the cause of aspergilloma. Allergic bronchopulmonary aspergillosis (ABPA) is almost always caused by hypersensitivity to *A. fumigatus.* The two species causing invasive disease are heat-tolerant organisms. All species form septate hyphae in tissue; in culture and in nature, millions of conidia, the infectious propagules, are formed on aspergillum-shaped heads produced by the hyphae.

Pathology

The presence of the fungus on the intact skin produces no reaction, and even if there are breaks, there is almost never any inflammatory reaction. On mucous surfaces, the fungus may induce an immediate allergic reaction in persons previously sensitized. The presence of specific IgE seems to be the mediator of the reaction, which is similar to immediate hypersensitivity caused by any allergen. In the airways, there may be an immune response in sensitive individuals that is mediated by IgM and especially IgG antibodies. An acute inflammatory reaction characterized mainly by lymphocytic exudate, edema, and local vasodilation occurs in response to the presence of antigen-antibody complexes lodged in the mucosa at the site of the *Aspergillus* residence. This in turn may result in necrosis locally in the airway, with the development of local bronchiectasis. If the individual colonized with the fungus is allergic, the resulting exudation is characterized by the presence of eosinophils and neutrophils and the hypersecretion of mucus. In such cases, mucous plugs containing inflammatory cells and often hyphae may obstruct airways. The presence of hyperreactive airways and asthma may be suggested pathologically by hypertrophy and hyperplasia of smooth-muscle cells in the bronchial wall.

In the pulmonary parenchyma, *Aspergillus* is seen in at least three circumstances. In the case of hypersensitivity, as described above, in which the lymphocytic infiltrate predominates in the bronchial wall, similar infiltrates may be seen in the pulmonary parenchyma, characterized also by the presence of macrophages and generally similar to those of typical hypersensitivity pneumonitis.

Disseminated aspergillosis may occur in immunosuppressed patients, especially those with leukopenia (granulocytic leukemia, either in an aleukemic phase or being treated with chemotherapy) who are cachectic. This is characterized by widespread dissemination of the fungus in the body, especially in the lung. The pulmonary lesions may demonstrate a lymphocyte/macrophage exudate with few neutrophils associated with necrosis, or in an overwhelmed patient, there may be almost no cellular reaction whatsoever. The fungi may be demonstrated easily by all stains. Similar pathologic changes may occur in all other organs.

It is not clear whether progressive, necrotizing aspergillosis of the lung can occur in patients who are not immunosuppressed. Cases have been reported with localized, acute inflammatory lesions in the lung, suppurative and necrotic in nature, in patients with no obvious underlying disease. This is rare.

In pre-existing cavities with an underlying cause that is usually not active, *Aspergillus* may enter and grow rapidly. The abundance of nutrients in the cavity and the narrow bronchial exit lead to the development of an aspergilloma (fungus ball). Little or no pericavitary invasion by the fungus is seen, but there may be an intense inflammatory reaction caused by the presence of antigen–anti-*Aspergillus* antibody complexes in the wall of the cavity, with associated dilatation of the blood vessels supplying the cavity. As these usually come from the high-pressure bronchial circulation, bleeding into the cavity occurs and may be identified histologically.

Epidemiology

The presence of *Aspergillus* in the environment is the primary factor in determining where various forms of aspergillosis will be encountered. The fungus occurs more frequently in temperate areas of the world, especially if the annual rainfall is more than 25 in (650 mm). The prevalence of the fungus in the air in any given area is relevant in that it increases or reduces the likelihood of contamination of sputum cultures.

Clinical Manifestations

Disseminated aspergillosis is a ravaging disease, seen especially in neutropenic patients and cachectic patients who have leukopenia. Patients with abnormalities of other branches of the immune system seem less prone to the infection. With the advent of treatment for acute leukemia and the use of bone marrow transplantation in a variety of situations, and the associated therapeutic pan-immunosuppression, the physician must be alert for the development of this specific infection.

Acute necrotizing pneumonia has been diagnosed in immunocompetent patients when there has been no response to routine antibiotic therapy and an invasive procedure has been performed that reveals *Aspergillus* species on culture. These cases are similar clinically to any other acute necrotizing pneumonia and are rare.

A fungus ball may first be revealed on chest x-ray films. On the other hand, hemoptysis may be the symptom that calls attention to the mass. Systemic symptoms of fever and muscle aches may be associated with evanescent pulmonary infiltrates in hypersensitive patients. The cavity may have been caused by histoplasmosis, tuberculosis, coccidioidomycosis, or even sarcoidosis, and the underlying process is usually not active at the time the fungus ball is discovered.

ABPA is characterized usually but not always by severe attacks of asthma, fever, cough with scanty sputum and the production of mucous plugs, the appearance of pulmonary infiltrates in varying locations, and proximal bronchiectasis that may be associated with normal bronchi more peripherally in the same bronchial branch. The serologic and skin test findings are described below. The fungus may be found in the sputum of the patient, but this is not essential to the diagnosis. The sedimentation rate is usually greatly elevated, and values for specific anti-*Aspergillus* IgE are high. The active disease waxes and wanes spontaneously but may ultimately lead to localized pulmonary fibrosis.

The above description relates to pure syndromes, but in fact cases are encountered in which a fungus ball may be associated with locally invasive, albeit limited, disease, symptoms of ABPA may be appear in association with a “quiet” fungus ball, and a local necrotizing lesion may be associated with dissemination or aggressive local progression.

In AIDS patients, treatment-induced neutropenia is often the predisposing factor for disseminated aspergillosis with pulmonary manifestations. The use of steroids is also associated with the development of widespread disease. Cavities containing fungus balls tend to bleed and thus pose an added threat to patients.

Patients with cystic fibrosis are at greater risk for ABPA than the general population. The reason for the relationship is not clear. The course and treatment are the same as for patients without cystic fibrosis, and the response to therapy is good. The ultimate impact of ABPA on the course of cystic fibrosis is not clear.

Diagnosis

A clinical picture of periodic worsening of underlying asthma is suggestive of the diagnosis of ABPA. The coming and going of pulmonary infiltrates seemingly not related to other events and without the usual allergic seasonal connection is also suggestive of the diagnosis, especially in asthmatic patients. The sudden onset of hemoptysis in a patient known to have a cavity caused by one of the usual granulomatous infections should arouse suspicion of a fungus ball.

In ABPA, the x-ray film demonstrates the infiltrates as noted. Bronchiectasis proximally located may be seen by high-resolution CT and, in rare cases these days, bronchography. The presence of an intracavitary mass, especially one that moves when the patient changes position, is clear evidence of a fungus ball. CT makes the picture even prettier, but no more accurate. In disseminated aspergillosis, poorly defined focal infiltrates may be seen that are nonspecific. Small radiolucencies may be seen.

Diagnosis of ABPA is aided by the demonstration of elevated titers of anti-*Aspergillus* IgE and IgG and the presence of a wheal-and-flare reaction following skin testing with *Aspergillus* antigen. Specificity of these tests has been improved with the introduction of a purified antigen, Asp f1. In cases of aspergilloma, cultures of sputum and BAL fluid are usually positive, and precipitin tests for IgG antibodies often demonstrate numerous positive bands.

Diagnosis of invasive aspergillosis is the most difficult. Because the organisms are ubiquitous, positive cultures of respiratory secretions do not always indicate the presence of invasive disease. Therefore, definitive diagnosis often depends on the demonstration of septate hyphae in biopsy material (easily seen in tissue stained with any of the fungal stains), with the subsequent isolation of the organism in culture. Isolation of the organism is necessary, as many organisms with the same morphology have been described as opportunistic pathogens of profoundly neutropenic patients. The organism is rapidly growing; cultures are positive in 24 to 72 hours. Identification is based on morphologic criteria. Antibody-based serologic tests are of little value in the diagnosis of invasive aspergillosis. Antigen tests show great promise, but those currently available lack sensitivity, in part because of the transient nature of the antigenemia.

Prognosis and Therapy

Disseminated aspergillosis is a fatal disease unless the underlying immunosuppression and/or cachexia can be reversed. Even with antibiotic treatment, death is almost certain. Fungus ball is a benign syndrome and is not threatening to the life of the patient except when hemoptysis is significant. ABPA is very disturbing to the patient but rarely if ever life-threatening unless the asthma that usually accompanies the syndrome becomes very severe. The syndrome does not spontaneously disappear permanently, but it may be in remission for prolonged periods.

Treatment of disseminated disease is ineffective unless the underlying depression of the immune system is repaired. Amphotericin B, which is the antibiotic most frequently used, is relatively ineffective in this situation. There is still a possibility that one of the newer triazole drugs will prove useful against *Aspergillus* species, although itraconazole at a dosage of 600 mg/d for the first few days and then 400 mg/d continued for months has shown limited effectiveness.

It is not necessary to treat a fungus ball unless hemoptysis or recurrent systemic symptoms that have been proved to be caused by the fungus ball are present. If treatment is required, resection is indicated. Inhaled amphotericin B has been suggested for this condition, but it is ineffective as a systemically administered drug. The reason is that the bleeding and other symptoms are caused by the inflammatory reaction in the wall of the cavity, as a consequence of the large quantity of antigen present. Antifungal therapy has no effect on that.

Treatment of ABPA is aimed at two different aspects of the problem. In the first place, the asthma that so frequently accompanies ABPA is usually severe and thus requires the use of b_2-adrenergic agonists, inhaled steroids, and in certain cases oral theophylline. Systemic steroids, usually oral prednisone, may be required on the basis of the severity of the asthma. The other role of steroids is to reduce the immunologic response to the specific fungal immunogen that is the basis of the syndrome. The dose is about 1.0 mg/kg daily at the outset, with slow tapering of the dose guided by both the clinical condition and the level of specific IgE in the serum. In cases with pulmonary infiltrates only and no asthma, steroids are the only therapy indicated.

PULMONARY DISEASE CAUSED BY ACTINOMYCETACEAE

This group of organisms is identified with fungi, although taxonomically they are bacteria closely related to *Mycobacteria.* In some respects they resemble fungi (e.g., staining and behavior within the body), but they resemble bacteria morphologically and in their characteristics on culture. They have traditionally been considered with the fungi, and we shall do so in this chapter.

Actinomycosis (Fig. 16)

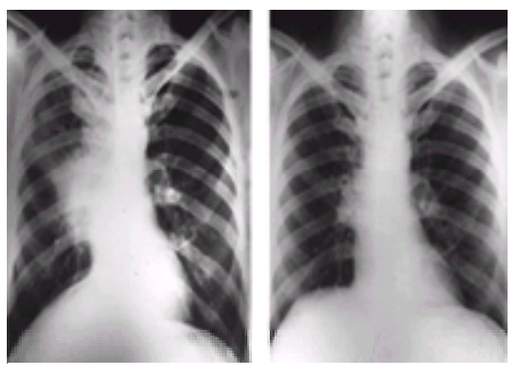

FIG. 16. Acute actinomycosis with focal infiltrates in a 40-year-old man (**A**) before and (**B**) 9 months after initiation of penicillin therapy.

This infection was first recognized in cattle in 1826, and in humans in 1845. The localization of the disease to the mouth in both mammalian species was a frequently observed clinical characteristic. The advent of sulfonamides and antibiotics changed the perception of this disease, and also its frequency.

Organism

The most common cause of actinomycosis in humans is *A. israelii,* an anaerobic, non–spore-forming, gram-positive rod. It is catalase-negative, and succinic acid and lactic acid are its two major metabolic products in culture. Its historical inclusion with the fungi can be attributed to its propensity to form filamentous rods, especially in tissue.

Pathology

This organism is found in the mouth normally, and in otherwise healthy persons there is no reaction to its presence. When local trauma or aspiration of mouth contents containing the organism occurs, the body reacts and disease develops. The response under these conditions is acute inflammation with suppuration and necrosis of tissue. The suppurative process is inexorable in its progression unless treated and has the tendency to cross tissue boundaries that usually limit inflammatory processes caused by bacteria, even mycobacteria. This process leads to fistula formation wherever the infection is found: in the facial tissues, in the lung and pleurae, and in the abdominal organs and peritoneum. Pleurocutaneous fistula (empyema necessitatis) may occur. The disease has been identified in all body organs, implying hematogenous spread.

The characteristic tissue finding in this disease is the so-called sulfur granule, which is a collection of filaments radiating out from a central necrotic core. These may be up to 5.0 mm in diameter and can be recognized grossly in pus. In fact, collections of pus should be routinely examined for sulfur granules. They characterize this disease in tissues, although they are not absolutely pathognomonic, as they may be found in nocardiosis and less frequently in pus associated with staphylococcal infection. In tissues, the sulfur granules take the hematoxylin-eosin stain and are dramatic findings.

A chronic form of this infection is seen in which localized, slowly progressive granulomatous lesions are associated with a plethora of scar tissue. These may be seen on skin, in mediastinal lymph nodes, and in other locations of the body.

Epidemiology

The distribution of cases in the world is related more to clinical awareness of the possibility of the disease than to any external characteristic such as climate, terrain, or living conditions. This is because the organism can be found in the mouths of almost everyone in the world! The wide use of sulfonamides and antibiotics has reduced the incidence of this disease, as this organism is exquisitely sensitive to most of them.

Clinical Manifestations

Actinomycosis most commonly appears in a localized, maxillofacial form. Swellings and distortion of tissues in the maxillofacial area result in fistula formation unless the disease is diagnosed and treated. There is often a history of mouth or face trauma before the development of clinical actinomycosis of this type. In the abdomen, fistula formation is disastrous, and the diagnosis is usually made late in the course of the disease.

Pulmonary actinomycosis is almost certainly secondary to aspiration of mouth contents containing the organism. Also, mouth or facial trauma have frequently occurred before the onset of pulmonary disease. The clinical presentation may be acute and characteristic of pneumonia caused by any organism. It may also be more chronic in onset, with a course similar to the development of aspiration lung abscess of any cause. In fact, a diagnosis of actinomycosis should be considered in any case of lung abscess in which aspiration is a possible factor, and the organism should be specifically looked for. The course of the disease is prolonged and downhill if it is not appropriately treated. Suppuration is extensive, with all the associated toxic systemic signs as well as increasing shortness of breath, cough, production of large quantities of purulent sputum, and chest pain if the pleurae become involved. Empyema may develop, and if untreated it may be complicated by the formation of a

pleurocutaneous fistula.

Lesions of the chronic form of actinomycosis are quite rare in the pulmonary parenchyma. There are usually no acute symptoms; rather, the patient is chronically mildly ill. The course may be many years long before a specific diagnosis is made.

Diagnosis

A history of mouth trauma or of aspiration should arouse suspicion of this disease. Chest radiography is helpful if pulmonary infiltrates cross natural tissue boundaries, such as pleural borders, or chest wall structures. The picture of lung abscess is nonspecific, but again attention should be paid to the anatomic configuration of the lesions.

Laboratory diagnosis begins with clinical suspicion, so that material for culture is collected and transported to maintain anaerobiosis. Collections of pus may be examined for sulfur granules; if found, these should be rinsed in sterile saline solution before culture. Cultures must be incubated anaerobically and held for at least 7 to 10 days; they should be examined every other day for the presence of the characteristic molar tooth colonies. Identification of the organism depends on demonstration of appropriate morphology on Gram's stain and characteristic reactions to a panel of biochemical tests. Direct microscopic examination of sulfur granules or tissue often provides a presumptive diagnosis. The granules are irregular in size (0.1 to 5 mm) and shape and may have a slightly yellow hue. They are made up of filamentous bacteria in a radial array; the exterior ends of the rods are coated with eosinophilic material in hematoxylin and eosin. Serologic testing does not play a role in the diagnosis of actinomycosis.

Prognosis and Treatment

All forms of actinomycosis are rapidly or slowly inexorably progressive and potentially fatal if untreated.

Treatment of actinomycosis is preferably penicillin given in doses of 2 to 10 million units, at first systemically and then continued by mouth. The response is usually prompt, but the treatment must be continued for a minimum of 6 to 9 months, preferably a year. The rationale for this is based, in part at least, on the presence of a great deal of necrotic and fibrotic tissue in the lesions and the persistent viability of the organism residing in this tissue. Results with prolonged treatment are excellent, even in the chronic form of the disease.

If the patient is hypersensitive to penicillin, sulfonamides may be given as well as tetracyclines and many other antibiotics. The emphasis is on length of treatment, regardless of which antibiotic is used.

Treatment of empyema with adequate drainage is mandatory. It is important to prevent the spontaneous formation of a pleurocutaneous fistula, as this increases morbidity significantly.

Nocardiosis (Fig. 17)

FIG. 17. Acute, fatal pulmonary nocardiosis occurring during steroid therapy in a 73-year-old man with lymphatic leukemia. Note the diffuse infiltrates.

Infection with this organism was first described by Nocard in 1888. Its place in the spectrum of suppurative diseases became clearer in the mid-twentieth century, especially when it was noted to be an accompaniment of alveolar proteinosis. This organism has been found in soil all over the world. There are many confusing elements to this infection, not the least being the weak acid-fast nature of the hyphae and their tendency to fragment and resemble bacilli. The organism has many cousins that cause a variety of serious skin lesions.

Organism

Pulmonary nocardiosis is most commonly caused by *N. asteroides; N. brasiliensis, N. otitidis-caviarum,* and *N. farcinica* represent the etiologic agents of the majority of the remaining cases. All are aerobic, non–spore-forming, gram-positive, branching filamentous bacteria that stain weakly acid-fast. The filaments (1.5 mm) tend to break into coccobacillary forms; aerial filaments are formed in culture. The cell wall of the genus is characterized by the presence of meso-diaminopimelic acid.

Pathology

This is a suppurative disease in whatever organ it is found. The lung is the most common site, as the route of infection appears to be by inhalation of the organism, with primary lesions in the lung. Other sites in which the disease may be found include the central nervous system, skin, and urinary system, especially the kidneys. Histologically, the characteristic inflammation is neutrophilic, and only rarely are granulomatous changes seen. There may be scarring, but it is less pronounced than that seen in actinomycosis. The sulfur granules that may be found in actinomycotic pus may also be found in nocardial suppuration. The tendency for crossing tissue barriers noted in actinomycosis is also present in nocardiosis, although it is less dramatic. The frequency of extrapulmonary suppurative and fibrotic lesions is estimated to be close to 50%, but accurate figures are not available.

Epidemiology

Nocardiosis is found all over the world. In the United States, 90% of cases are caused by *N. asteroides* and the rest by the other *Nocardia* species. There is an association with certain underlying conditions, such as malignant disease, cachexia, alveolar proteinosis, and immunosuppression from diseases or treatment, but about 20% of cases have been found in patients with no identifiable predisposing factor. There appears to be no association with occupation, season, sex, or ethnic origin.

Clinical Manifestations

Pulmonary nocardiosis is almost always an acute or subacute pneumonia that progresses to abscess formation. There is nothing specific about the clinical picture, but the frequency of extrapulmonary lesions is high. There may be pleural involvement with empyema. Of the extrathoracic sites, the central nervous system and the skin are most frequently involved. In fact, the syndrome of multiple subcutaneous abscesses, pulmonary lesions, and possibly pleural effusion is very suggestive of nocardiosis. Cases of chronic brain abscess have been seen. The course of the untreated disease is progressively downhill, and death is inevitable. The disease progresses much more rapidly in patients with immunosuppression.

The association between alveolar proteinosis and nocardiosis was reported in the 1960s, but the reason for the association is not known. The course of the combined diseases is more malignant than the course of either one alone. Treatment of the nocardial infection with antibiotics is not hindered by the proteinosis.

There appears to be a chronic form of nocardiosis that resembles cavitary pulmonary tuberculosis; only the microbiologic findings differentiate between disease caused

by two different agents.

Diagnosis

The clinical syndrome noted above of subcutaneous and pulmonary lesions is suggestive of the diagnosis, as is a complicated course of alveolar proteinosis. In malignant disease with complicating pulmonary, subcutaneous, or central nervous system lesions, nocardiosis must be considered among other opportunistic infections.

Chest radiography shows focal bronchopneumonia frequently associated with abscess formation. Empyema is present in a significant percentage of the patients. None of these findings is specific, however. The typical lesions of proteinosis, widespread alveolar or interstitial shadows, are not modified by the superinfection by *Nocardia.* The brain abscesses that may develop are well demonstrated by standard radiography, CT, and magnetic resonance imaging (MRI), but the lesions are not diagnostic.

Laboratory diagnosis of nocardiosis depends on the isolation of the organism from BAL fluid, pus, or tissue. Clinical suspicion of the diagnosis must be communicated to the laboratory to ensure appropriate handling of the cultures. The organism grows slowly for a bacterium, requiring 5 to 10 days to become positive on culture; because it is sensitive to many antibiotics, it may not grow on the selective media used for routine isolation of fungi. The organism is identified by morphology, staining characteristics, and biochemical profile; analysis of cell wall components by chromatography may also be used. A presumptive diagnosis based on the appearance of filamentous, branching, gram-positive bacteria in clinical material is strengthened if the filaments are determined to be weakly acid-fast (i.e., require the use of dilute mineral rather than acid alcohol for decolorization). In tissue, the filaments may be stained with Brown and Brenn, Grocott, or the Fite modification of the acid-fast stain. Granules are rarely seen in pulmonary disease but may be present in infections acquired by the direct inoculation of the organism into skin.

Prognosis and Therapy

The disease progresses without treatment, with dissemination throughout the body in immunosuppressed cases especially. A fatal outcome occurs in a large fraction of cases. Even with response to therapy, significant scarring may occur.

Effectiveness of therapy varies based on the sensitivity of various strains of *N. asteroides* and other *Nocardia* species to antibiotics, and on the underlying condition of the patient. The most frequently effective antibiotic or chemotherapeutic agent is trimethoprim/sulfamethoxazole. Other effective antibiotics are amikacin and to some extent the tetracyclines. In any case, treatment should be continued for at least half a year and perhaps longer, depending on the clinical course. In the case of brain abscess, surgery may be necessary, and when collections of pus are present subcutaneously, in the pleurae, or elsewhere in the body, adequate drainage is essential.

In the case of a patient who has AIDS or is HIV-positive, it is especially important to test for drug sensitivity, as the organism is more often resistant to the above-mentioned antibiotics in this situation, possibly because of the use of sulfa drugs as chemoprophylaxis against *Pneumocystis.*

MISCELLANEOUS FUNGAL DISEASES

The following infections are rare indeed and almost always associated with some underlying factor that renders the patient more susceptible.

Trichosporonosis

This infection caused by *Trichosporon* species was extremely rare as a cause of human systemic disease until the advent of immunosuppression as a relatively common clinical situation. Involvement of the lungs is seen almost always as part of disseminated disease. There may be superinfection of chronic inflammatory lesions of the lung caused by other conditions. Treatment with a variety of antibiotics, including 5-fluorocytosine and amphotericin, is not very effective but should be tried.

The majority of cases are caused by *T. beigelii.* Regardless of the species involved, infection is characterized the presence of budding yeast cells, hyphae, and arthroconidia in tissue.

Pseudoallescheriasis

Pulmonary involvement includes the formation of a fungus ball, colonization of the tracheobronchial tree, and invasive parenchymal disease. This latter is almost always associated with immunosuppression, and the lesions occur as foci of bronchopneumonia. Treatment is indicated only in the pneumonic form of the infection; the imidazoles have been reported to be effective. Colonization of the airways alone is not a threatening condition, and the fungus ball is dealt with in the same way as an *Aspergillus* fungus ball.

Pseudoallescheria boydii (*Scedosporium apiospermum*) is the most frequent cause of this infection. Rarely, cases are caused by *Scedosporium prolificans.* The organisms appear identical in tissue and must be differentiated in culture.

Zygomycosis

This infection is caused by several fungi belonging to the order Mucorales, including *Mucor, Rhizopus,* and *Absidia* species. Infection with these organisms is associated with diabetes mellitus and neutropenia. Pulmonary disease is rare and is usually seen as a progressive pneumonia that is resistant to usual antibiotic therapy. More frequent is the syndrome of rhinocerebral disease, in which the paranasal sinuses are involved and there may be spread to the major venous sinuses of the head. The pathology in all forms of the infection is acute inflammation associated with a prominent amount of tissue necrosis. Underlying pathology is nonspecific except that the fungi tend to invade blood vessels and thus cause intravascular thrombosis. This phenomenon may be the factor responsible for the prominent necrosis. Treatment is inconsistently effective with amphotericin B. Surgical debridement is often necessary to remove necrotic bone or other tissues.

Rhinocerebral mucormycosis is caused by *Rhizopus* species in 90% of cases. Although *Rhizopus* is also the most common cause of pulmonary disease, species of *Mucor* and *Absidia* are seen more frequently. In tissue, all appear identical, and differentiation is made by identification of the organism in culture.

ABPA Syndrome of Various Causes

Clinically and roentgenographically, typical ABPA has been described infrequently as caused by a variety of fungi, many of them known as saprophytes. These include *Aspergillus* species other than *fumigatus, Candida albicans, Pseudoallescheria boydii, Fusarium vasinfectum, Curvularia lunata, Rhizopus, Helminthosporium, Penicillium, Stemphylium, Candida glabrata, Bipolaris,* and *Drechslera hawaiiensis.* The diagnosis is made only by means of serology, skin tests, and finding the specific fungus in culture, the finding of lesser frequency. The treatment is mainly with steroids using the same criteria for length of treatment as in ABPA.

CHAPTER

28 Tuberculosis

Reynard J. McDonald · Lee B. Reichman

R. J. McDonald and L. B. Reichman: Department of Medicine, New Jersey Medical School National Tuberculosis Center, University of Medicine and Dentistry of New Jersey, Newark, New Jersey 07107.

INTRODUCTION

Does it not seem reasonable that if a new infectious epidemic were to emerge that annually infected one third of the earth's population (1.7 billion people), causing sickness in 8 million new victims, striking 20 million people at any one time, and killing 3 million, then scientists and policy makers would work overtime to highlight the problem, identify the cause, and find a cure to eliminate this scourge rapidly?

Tuberculosis is an ancient disease that fulfills all the above descriptions regarding its infection prevalence, incidence of morbidity, and mortality. The disease is quite common, its cause is well characterized, and it is by current state of the art both preventable and curable with inexpensive, nontoxic medications.

Yet, embarrassingly, tuberculosis still kills more people than any other infectious disease. Even though its cause and methods of cure are well established, the global health organizations have never put enough political pressure on governments to apply the practical solutions that would eliminate this disease from the world.

By all rights, when the first edition of Baum's *Textbook of Pulmonary Disease* was published, anybody would have predicted that by the sixth edition tuberculosis would have been considered as a rare, historic curiosity. In the sixth edition, however, we are still considering a disease that now affects and kills more people worldwide than at any time in history.

This chapter presents a 1997 view of an ancient killer and includes current information regarding its epidemiology, transmission, pathogenesis, prevention, and treatment. The medical community and world governments merely need to exert the political will necessary to ensure that by later editions, tuberculosis will rightfully have become the curiosity it deserves to be.

EPIDEMIOLOGY

Ever since Robert Koch's remarkable discovery of the tubercle bacillus in 1882, many mycobacterial species have been identified. Pulmonary disease caused by atypical mycobacterial infection, which frequently is clinically indistinguishable from tuberculosis, is now recognized as being caused by several different nontuberculous mycobacteria, most often *M. avium* complex and *M. kansasii*.

Tuberculosis in humans is caused by infection with the *Mycobacterium tuberculosis* complex of organisms. *M. tuberculosis, M. bovis,* and *M. africanum* are mammalian tubercle bacilli that are included in this group.

It is estimated that 1.7 billion persons—one third of the global population—are infected with mammalian tubercle bacilli. Annually, on a worldwide basis, 20 million prevalent active cases occur, including 8 million new cases, with an incidence of approximately 160 cases per 100,000 population. This disease is the leading infectious cause of death in the world, with approximately 3 million people worldwide dying yearly of tuberculosis.

It was estimated in 1990 that 3 million people worldwide are coinfected with the tubercle bacillus and human immunodeficiency virus (HIV). More recent estimates (1994) place this figure closer to 5.5 million. Because of the increased numbers of tuberculosis cases that will likely occur from this cohort of dually infected patients, it is projected that global rates of tuberculosis will rise in the decade ahead, particularly in sub-Saharan Africa and perhaps most seriously in Southeast Asia.

Tuberculosis has re-emerged as a very important public health problem in the United States. It is estimated that 10 to 15 million people are infected with the tubercle bacillus in this country and that most new cases of tuberculosis come from this infected cohort. It should be pointed out, however, that recently there have been increasingly frequent reports, primarily in persons coinfected with the tubercle bacillus and HIV, of clusters of new tuberculosis cases documented by DNA fingerprinting to have resulted from recent infection.

The number of tuberculosis cases declined approximately 5%–6% per year from 84,304 cases in 1953, when nationwide reporting began, to 22,255 cases in 1984 (Fig. 1). However, from 1985, when the number of reported tuberculosis cases reached its lowest point (22,201), through 1992, tuberculosis morbidity in the United States increased by almost 20%, to 26,673 cases (Fig. 1). Since 1992, largely because of an unprecedented expenditure of resources designed to re-establish the public health infrastructure for tuberculosis prevention and control, the number of reported tuberculosis cases has begun once again to show a downward trend, although sustaining this reduction in an era of budget cuts and health care reform may be difficult.

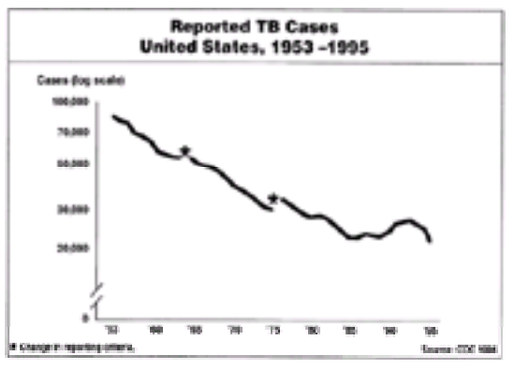

FIG. 1. Reported tuberculosis cases in the United States, 1953–1995.

In 1993 and 1994, and again in 1995, reported tuberculosis cases declined in the United States from 25,287 to 24,361 (3.7% reduction) to 22,812 (6.4% reduction). However, the number of reported cases in 1995 still represents a 2.8% increase over 1985. During the period from 1985 through 1995, it is estimated that >75,000 excess cases of tuberculosis were reported in this country than would have been reported if the trend of a 5%–6% decline per year, as from 1953 to 1984, had continued.

Of the main factors that contributed to the increase in the number of reported tuberculosis cases in the past decade, first and foremost is the deterioration of the infrastructure of the health care system that was allowed to occur. Other contributing factors include coinfection with tubercle bacilli and HIV, transmission of infection in congregate settings, and immigration from countries where tuberculosis is common. The reason that the infrastructure is so important is that all the other factors can be successfully managed in the presence of a proper infrastructure for tuberculosis control.

In 1994, the number of tuberculosis cases reported in persons born in the United States decreased in all age groups except young children (<15 years of age), in whom a 0.4% increase was noted. In foreign-born persons that year, the number of reported tuberculosis cases increased in all age groups except children <15 years of age, in whom a 7.5% decrease was noted. The number and percentage of tuberculosis cases that have been reported in the United States since 1985 in foreign-born persons have progressively increased, and in 1994 they represented almost one third of the cases of tuberculosis reported in this country (Table 1).

Year	Cases, No.	Percentage
1986	4925	22
1987	5025	22
1988	4868	22
1989	5411	23
1990	6262	24
1991	6982	27
1992	7270	27
1993	7354	29
1994	7627	32

TABLE 1. *Reported tuberculosis cases in foreign-born persons in the United States, 1986–1994*

Tuberculosis occurs across racial and ethnic lines and among all age groups. However, case rates are higher among racial and ethnic minorities in the United States than among non-Hispanic whites. In 1994, the risk for tuberculosis was eightfold greater for blacks, sixfold greater for Hispanics, fivefold greater for Native Americans, and 13-fold greater for Asian and Pacific Islanders than for non-Hispanic whites in this country.

Among all age groups, regardless of sex, race, or ethnicity, tuberculosis case rates are highest in the elderly, but they have been declining for several years (Table 2). The largest increase in the number of reported cases of tuberculosis occurred primarily in the younger groups, particularly the 25- to 44-year-old age group; this is in large part a consequence of the increase in tuberculosis morbidity in persons who are coinfected with HIV.

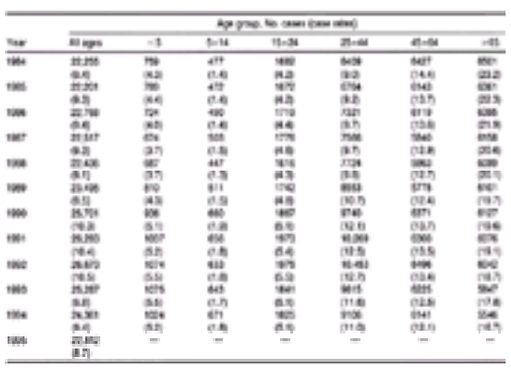

TABLE 2. *Tuberculosis cases and case rates per 100,000 population by age in the United States, 1984–1995*

In a general sense, in the non-Hispanic white population in the United States, tuberculosis is primarily a disease of the elderly (³65 years of age), whereas among minorities, tuberculosis morbidity primarily affects younger age groups (Fig. 2). In 1989, the Centers for Disease Control and Prevention (CDC) reported that the median age of members of minority groups with tuberculosis was 39 years, compared with 61 years in non-Hispanic whites.

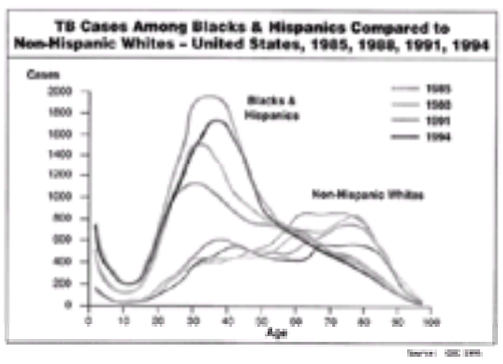

FIG. 2. Cases of tuberculosis among blacks and Hispanics compared with non-Hispanic whites in the United States: 1985, 1988, 1991, and 1994.

Between 1989 and 1992, multiple outbreaks of multidrug-resistant tuberculosis (MDRTB) were reported. These outbreaks were associated with HIV infection, high mortality rates, and evidence of transmission to health care workers. In response to this threat of MDRTB, the CDC began to monitor the number of reported cases of MDRTB each year. For the first quarter of 1991, the percentage of tuberculosis cases that were reported to be resistant to both isoniazid (INH) and rifampin (RIF) was approximately 3.4%. This represented approximately a sevenfold increase over the percentages in 1984, when only 0.5% of reported cases were resistant to both INH and RIF.

One of the most constant aspects of tuberculosis epidemiology has been the dictum that 90% of cases arise in persons previously infected. Recent studies utilizing DNA fingerprinting for tracking infection by the same strain reveal that 33% or more of tuberculosis cases in several areas represent recent infection. By the same technique, HIV-infected patients have been shown to be at high risk for reinfection with new organisms that may be responsible for apparent relapses.

TRANSMISSION AND IMMUNOPATHOGENESIS

Tuberculosis in humans is caused by infection with one of four closely related mycobacterial species that collectively make up the *M. tuberculosis* complex of organisms, which includes *M. tuberculosis, M. bovis, M. africanum,* and the bacillus Calmette-Guérin (BCG), which is a modified strain of *M. bovis. M. microti,* the vole bacillus, is an infrequently encountered mycobacterial species that is also included in the *M. tuberculosis* complex by some mycobacteriologists but does not cause disease in humans.

In the United States, tuberculosis caused by the *M. tuberculosis* complex of mycobacteria is almost always caused by infection with *M. tuberculosis.* However, in this country *M. bovis* has not been completely eliminated as a cause of tuberculosis, and in third world nations, where the pasteurization of milk is less common, *M. bovis* is a prominent source of tuberculosis morbidity. In rare instances, the administration of BCG to victims of bladder cancer and HIV-infected persons has led to reported tuberculosis outbreaks. Cases of tuberculosis in patients from equatorial Africa caused by *M. africanum* were initially reported in 1969 and are presumed to be spread via airborne transmission.

Infection with *M. tuberculosis* is almost exclusively spread from person to person by airborne transmission. The studies of Riley clearly demonstrated airborne transmission of *M. tuberculosis* from humans to guinea pigs, and Houk's studies of an airborne tuberculosis outbreak on the USS Richard E. Byrd strongly support this principle.

Tiny particles containing tubercle bacilli (droplet nuclei), 1 to 5 µm in size and enveloped in an aerosol droplet, are expelled into the air primarily when someone with pulmonary or laryngeal tuberculosis coughs or sneezes. These microscopic infectious particles can remain suspended in air for extended periods of time (several hours). If a new host inhales the air contaminated by these droplet nuclei, transmission may occur. Larger particles fall out of suspension and are deposited on the mucociliary escalator lining the airways and are simply expectorated or swallowed. Smaller droplet nuclei are not deposited on the airway mucosa but are transported by air currents primarily to the periphery of the lower lung zones and deposited on the surfaces of alveoli, where they may be ingested by alveolar macrophages and destroyed, or, as happens in certain instances, the tubercle bacillus may multiply.

Following inhalation, any one of several outcomes is possible. The tubercle bacillus can be eliminated immediately (no infection) or can remain dormant in the host indefinitely (infection without disease), as occurs in the majority (90%) of persons, who are free of disease but remain infected with *M. tuberculosis* for the rest of their lives. The organism can immediately or rapidly cause tuberculosis (primary tuberculosis), as occurs in approximately 5% of persons, in whom tuberculosis develops in the first or second year following infection. Finally, the tubercle bacillus can cause disease many years after infection has occurred (recrudescent tuberculosis), as occurs in approximately 5% of patients. Thus, disease develops at some point during their lifetime in only about 10% of persons infected with *M. tuberculosis.*

Despite recent advances in molecular biology that have greatly increased our knowledge of the immunopathogenesis of tuberculosis, the complex interactions (checks and balances) that occur between the tubercle bacillus and the human immune system remain incompletely understood. Lurie's studies on the histopathology of tuberculosis using immune-competent and immune-incompetent rabbit models were seminal. Dannenberg's subsequent observations, based on Lurie's work, pointed out the importance of the interaction between delayed-type hypersensitivity (DTH) and cell-mediated immunity (CMI) in determining what form tuberculosis takes and greatly aided our understanding of these complex events. Dannenberg proposed that both CMI and DTH inhibit growth of *M. tuberculosis.* CMI enhances the ability of macrophages to destroy tubercle bacilli, causing little tissue damage, whereas DTH destroys nonactivated macrophages that are laden with tubercle bacilli, causing tissue damage. Nardell, in a review of Dannenberg's analysis of the pathogenesis of tuberculosis, outlines four stages (Fig. 3): onset, logarithmic growth, immunologic control, and liquifaction.

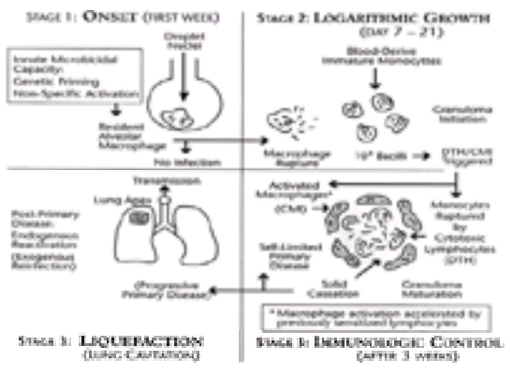

FIG. 3. Four stages in the pathogenesis of tuberculosis in the normal host. See text for detailed description. (From Nardell 1993, with permission. Based on Dannenberg 1991.)

Stage 1: Onset

Following ingestion of droplet nuclei by nonspecifically but highly activated alveolar macrophages, the mycobacterial inoculum is either destroyed (90%) or inhibited or may multiply, depending on the innate mycobactericidal ability of the macrophage and the innate resistance of the tubercle bacilli to the defenses of the host.

Stage 2: Logarithmic Growth

Intracellular multiplication of tubercle bacilli occurs when the innate mycobactericidal ability of the macrophage is inadequate to destroy the initial inoculum of mycobacteria. *M. tuberculosis* organisms not destroyed by alveolar macrophages are released when the macrophages die and lyse, attracting inactivated monocytes from the bloodstream to form an early primary tubercle (initial granuloma formation). Although these monocytes are capable of ingesting the released tubercle bacilli, they do not have the ability to destroy them or inhibit their growth, which increases logarithmically during this stage (7 to 21 days).

Stage 3: Immunologic Control

By 3 weeks, CMI and DTH have developed, as can be demonstrated by intradermal injection of purified protein derivative (PPD), resulting in tuberculin reactivity at 48 to 72 hours. During stage 3, tubercle bacilli have multiplied in many of the inactivated macrophages to a number far in excess of what can be destroyed by immune cellular mechanisms (CMI), and only cytotoxic lymphocytes carrying the CD8 marker (DTH) can limit further logarithmic growth by killing the *M. tuberculosis*-laden macrophages. The destruction of these tubercle bacilli results in the formation of the caseous necrotic center of the granuloma. This necrotic, soft, cheeselike center is surrounded by an accumulation of partially and highly activated macrophages and lymphocytes that have organized to form a granuloma.

The tubercle bacillus is an obligate aerobe and is unable to multiply in solid necrotic granulomas, which contain toxic fatty acids and are very acidic and anoxic. The organism either dies or becomes dormant. Tubercle bacilli that are released from destroyed macrophages within the granuloma are also ingested and destroyed during stage 3 by highly activated macrophages that are specifically activated by helper T lymphocytes (Th1 subset).

Released tubercle bacilli as well as those in infected macrophages are transported via peribronchial lymphatic channels to regional lymph nodes. If infection is not contained (stage 4), ultimately it spreads to the hilar and mediastinal lymph node chains, from which entrance to the systemic circulation via the thoracic duct is

possible.

Stage 4: Liquifaction (Lung Cavitation)

The causes of liquifaction are incompletely understood; however, the release of hydrolytic enzymes that liquefy solid caseum and DTH to tuberculin proteins are thought to be contributing factors. Liquifaction of the solid, necrotic, caseous center of the granuloma kills macrophages but provides a favorable environment for abundant multiplication of tubercle bacilli. The large antigenic load that is created triggers a DTH response, causing extensive tissue damage. Erosion of the liquefied caseous material into adjacent airways, lymphatics, and blood vessels leads to pulmonary spread via the bronchial tree and extrapulmonary spread by lymph and hematogenous dissemination.

Immunologic Mechanisms

Several cell types—including helper (CD4) T cells (subsets Th1 and Th2), cytotoxic (CD8) T cells, and gd T cells as well as natural killer (NK) cells, alveolar macrophages, and monocytes—play an important role in regulating CMI and DTH. However, the actual roles that these cells play in producing and regulating the various cytokines, the most important of which include interleukin-2 (IL-2), tumor necrosis factor (TNF), and interferon-g (INF-g), is not well understood.

DIAGNOSIS

Clinical Presentation

Important components of a complete diagnostic evaluation for tuberculosis are an accurate medical history and physical examination. Particular care should be taken in determining tuberculosis exposure, prior treatment for the disease, concurrent medical problems, including HIV infection, and use of medications that affect host immunity.

The presenting symptoms of tuberculosis may differ depending on the site affected. In most cases—approximately 85%—the lung is the site of disease, and respiratory symptoms predominate. The clinical presentation of pulmonary tuberculosis may include nonspecific cough, chest pain, and hemoptysis. At its onset, the cough is usually nonproductive but persistent, and it may become productive of mucopurulent or blood-streaked sputum; occasionally hemoptysis can be moderate to severe. Chest pain may occur and often is described as dull and aching or pleuritic in nature. The latter may frequently be associated with the presence of a pleural effusion. Dyspnea is an uncommon feature; when present, it is usually caused by extensive parenchymal disease or a large pleural effusion.

Chills, fever, night sweats, fatigue, and loss of appetite and weight are systemic symptoms consistent with both pulmonary and extrapulmonary tuberculosis. Approximately 15% of tuberculosis cases are extrapulmonary (the percentage is higher when coinfection with HIV is present). The clinical symptoms of extrapulmonary tuberculosis also depend on the site affected. Headache, back pain, swelling of the neck, and blood in the urine may be the presenting symptoms in patients with tuberculosis of the central nervous system, spine, lymph nodes, and kidneys, respectively.

Unfortunately, in elderly patients many of the classic clinical features that many physicians rely on to diagnose tuberculosis may be absent. Frequently in this group, symptoms are nonspecific or atypical. The presence of concurrent illnesses, such as chronic obstructive pulmonary disease (COPD) or lung cancer, in an elderly person may obscure the diagnosis of tuberculosis, delaying therapy, or tuberculosis may be completely missed, only to be found at autopsy. The physical examination may provide important information regarding the patient's overall medical condition and guide the physician in choosing appropriate diagnostic and therapeutic approaches.

Tuberculin Skin Testing

The tuberculin skin test is a useful diagnostic test for evaluating persons who have symptoms of tuberculosis or who are suspected of being infected with *M. tuberculosis.* It is the standard test for detecting tuberculosis infection before progression to disease occurs. The tuberculin test may also be of particular assistance in evaluating patients with extrapulmonary tuberculosis, who may have normal findings on chest roentgenograms.

A negative tuberculin skin test reaction *never* excludes the diagnosis of tuberculosis. Normally, a period of 2 to 10 weeks is required after infection for a DTH response to tuberculin to develop. Infants <6 months of age may have a false-negative tuberculin skin test reaction because their immune systems have not yet fully developed. False-negative tuberculin skin test reactions may occur in persons with severe illness, HIV infection, sarcoidosis, and uremia, and in those receiving therapy with immunosuppressive drugs.

Overall, approximately 10%–25% of person with tuberculosis will have a false-negative reaction when given a tuberculin skin test. Although infected with *M. tuberculosis,* 30% of patients who are HIV-seropositive may have false-negative tuberculin skin tests (<5 mm) when tested. Thus, a positive tuberculin skin test reaction supports the diagnostic possibility that a suspected illness is tuberculosis; however, a negative tuberculin skin test reaction by no means excludes the diagnosis of tuberculosis.

Two preparations, purified protein derivative (PPD) and to a much lesser extent old tuberculin (OT), are currently used clinically. Robert Koch in 1890 first used the filtered and concentrated heat-sterilized broth in which tubercle bacilli had been grown as a therapeutic agent, and designated the concentrated extract *old tuberculin.* OT was later adopted as a diagnostic tool but proved to be a crude, nonspecific preparation containing extraneous antigenic substances that caused skin test reactions that were not always diagnostic of infection with *M. tuberculosis.* In the United States, OT is used primarily as an antigen in multiple puncture screening tests, in which the exact antigen dose introduced into the skin cannot be standardized. Therefore, these multiple puncture devices should not be used as diagnostic tests.

In the early 1930s, Florence Siebert isolated a protein from filtrates of OT, which she called *purified protein derivative.* PPD-S (Siebert's lot 49608) has subsequently been adopted as the international standard for purified protein derivative of mammalian tuberculin by the U.S. Public Health Service.

In the United States and Canada, the potency of PPD preparations is measured in tuberculin units (TU); a TU is defined as 0.00002 mg of PPD-S. The dose that best separates true-positives from false-positives is the 5-TU (standard in the United States) dose of prepared PPD, which produces a skin reaction equivalent in size to one produced by using PPD-S, regardless of the actual amount of tuberculin used. Because tuberculin is absorbed by glass and plastics, a detergent, Tween 80, has been added to prevent loss of potency of tuberculin during storage.

The standard for diagnosing infection with mammalian tubercle bacilli is the Mantoux test, performed by the intracutaneous injection of 0.1 mL of Tween-stabilized liquid PPD into the dorsal or volar surface of the forearm. In 48 to 72 hours, the area of induration (not erythema) is measured and recorded in millimeters. If a delay occurs in reading, a positive test reaction, if present, may be valid up to 1 week following placement of a Mantoux test. A negative test reaction must be confirmed by 72 hours.

A Mantoux skin test reaction size of ³5 mm is interpreted as positive in the following cases:

1. Persons having or suspected of having HIV infection
2. Close contacts of a person with infectious tuberculosis
3. Persons with abnormal chest radiographic findings suggestive of old healed tuberculosis who have not been previously appropriately treated
4. Persons who inject drugs and whose HIV status is unknown

A tuberculin skin test reaction size of ³10 mm is considered positive in the following cases:

1. Persons with certain medical conditions, excluding HIV infection
2. Persons who inject drugs (if HIV-negative)
3. Medically underserved, low-income populations, including racial and ethnic groups at high risk
4. Residents of long-term care facilities
5. Children <4 years of age
6. Locally identified high-prevalence groups (e.g., migrant farm workers or homeless persons)

A Mantoux skin test reaction of ³15 mm is considered positive in all persons with no known risk factors for tuberculosis.

Anergy testing, although currently recommended by the U.S. Advisory Council for the Elimination of Tuberculosis (ACET) in the evaluation of immunosuppressed

persons suspected of having tuberculosis but whose tuberculin skin test reaction is negative, is a controversial point. Recent studies suggest that anergy is a complex, unstable process that varies dramatically within short periods. A recent study of anergy in HIV-positive persons found that the degree of anergy was best defined by the helper lymphocyte count. Clearly, to recommend routine evaluation of CD4 counts and placement of antigens, such as mumps virus or *Candida,* in all immunosuppressed patients who are suspected of being anergic, adds substantially to patient care cost without evidence of definite benefit. Anergy testing should not be used for individual patient decisions.

Roentgenographic Examination

Historically, the chest roentgenograph has been an important diagnostic tool in evaluating patients, particularly for pulmonary tuberculosis. The chest x-ray film can be used to rule out tuberculosis in a person with a positive tuberculin skin test reaction and no symptoms of tuberculosis. A posteroanterior projection is the standard view needed for the detection of chest abnormalities. Lateral, lordotic, oblique, and decubitus views may be helpful, depending on the location or nature of the suspected lesion.

In some instances, newer imaging techniques, such as computed tomography (CT), may be helpful. CT of the chest is particularly helpful in evaluating hilar and mediastinal adenopathy, pleural effusion, and calcifications of the visceral and parietal pleural surfaces, and may also be helpful in evaluating patients with extrapulmonary tuberculosis. Tuberculosis involving the vertebrae, with paravertebral abscess formation, and lesions of the central nervous system may be evaluated using CT with or without contrast. Magnetic resonance imaging (MRI) may also be helpful in evaluating tuberculous lesions of the central nervous system.

Although certain abnormalities on chest x-ray films are highly suggestive of tuberculosis, it should be remembered that they are *never* diagnostic. Parenchymal infiltration and cavitation changes involving the apical or posterior segments of the upper lobes and less commonly the superior segments of the lower lobes are compatible with postprimary tuberculosis.

The manifestations of primary tuberculosis of the lungs include hilar and mediastinal adenopathy, pleural effusions, and infiltrates in the lower lung fields. However, the lung changes associated with pulmonary tuberculosis can vary and include consolidation (as occurs in endobronchial spread of disease) and miliary nodules, in addition to the previously described changes. Some elderly patients and those with HIV infection may have unusual chest x-ray findings, which may be normal or compatible with primary tuberculosis (adenopathy, lower lung infiltrates).

It has been reported that 60% of patients with advanced AIDS have hilar or mediastinal adenopathy, compared with 3% of non-AIDS patients; 29% have localized middle or lower lung field infiltrates, compared with 3% of non-AIDS controls; and 12% have normal chest x-ray findings, compared with none of the non-AIDS patients. In one study, none of the AIDS patients had chest cavitary lesions, compared with 67% of the non-AIDS patients, and 97% of the non-AIDS patients had upper lobe disease, compared with 18% of the AIDS patients.

Laboratory Evaluation

Specimen Collection

A joint statement of the American Thoracic Society (ATS), the CDC, and the Infectious Disease Society of America states that an important feature in the diagnostic evaluation for tuberculosis is ". . . to obtain appropriate specimens for bacteriologic and histologic examination." Depending on the location of the disease, sputum, bronchial washings, lung tissue, lymph node tissue, bone marrow, liver, blood, urine, stool, and cerebrospinal fluid may be examined.

Because most cases of tuberculosis are pulmonary, examination of sputum is of primary importance. The yield of positive sputum smears in patients with pulmonary tuberculosis when three sputum specimens are collected has varied from approximately 50%–80%, depending on the study. The specificity of a positive smear has remained high (>99%). Some of the variability in studies reporting the sensitivity of positive sputum smears in patients with pulmonary tuberculosis may be explained by differing clinical presentations. In one review, 52% of patients with cavitary tuberculosis and only 32% of patients with local infiltrates had positive smears; similarly, only 45% of AIDS patients (noncavitary disease) with tuberculosis had positive sputum smears, compared with 81% of non-AIDS patients.

Patients who are suspected of having pulmonary tuberculosis should have 10 mL of an early morning sputum specimen submitted to an appropriate laboratory for smear and culture for tubercle bacilli. Several methods exist for obtaining specimens from patients who have difficulty producing sputum spontaneously (i.e., after inhalation of a saline aerosol). Transmission of tuberculosis, especially in HIV-infected populations, may occur in association with sputum induction, so special precautions should be taken by using portable hoods and sputum induction chambers that are appropriately vented. Gastric lavage fluid may be used for culture of tubercle bacilli but not smears as saprophytic mycobacteria are normally found in the stomach. Fiberoptic bronchoscopy with bronchoalveolar lavage (BAL) and/or biopsy has a high yield and may be useful in such patients or in those whose initial sputum specimens are negative for acid-fast bacilli (AFB) on smear. These procedures also may generate hazardous aerosols. The yield of bronchoscopy specimens in the demonstration of AFB is extremely high.

Invasive procedures beyond bronchoscopy to obtain diagnostic specimens are warranted when other techniques fail. Body fluid specimens should always be analyzed for differential cell count and glucose and protein content. In tuberculosis, lymphocytosis and elevated protein and low glucose levels are usually present in infected body fluid. Tissue biopsy (needle aspiration biopsy, transbronchial biopsy, biopsy of bone marrow, lung, liver) specimens should be divided and a portion sent to the laboratory for culture and another sample placed in formalin for histologic examination. Histologic changes characteristic of tuberculosis include granuloma formation and caseation necrosis.

Acid-Fast Bacillus Stains

Although far less sensitive than culture, the AFB smear is an important diagnostic aid for tuberculosis. AFB stains may be done quickly and provide the physician with the first preliminary confirmation of a clinical diagnosis of tuberculosis. AFB smears do not actually confirm tuberculosis, because nontuberculous mycobacteria and nonmycobacterial organisms such as *Nocardia* and some species of *Legionella* may produce positive stains.

The fluorescent staining technique that utilizes fluorochrome dyes (auramine/rhodamine) is now the preferred staining method for AFB. When the fluorochrome stain is viewed with fluorescence microscopy, AFB stain bright against a dark background and are more easily detected than when conventional AFB staining techniques are used. Because of the shortened amount of time needed to review a slide, fluorescent stains are considered more sensitive for detecting AFB. Until recently, the conventional Ziehl-Neelsen stain or one of its modifications, the Kinyoun stain, viewed under a light microscope were the conventional stains of choice for AFB, and positive smears correlated closely with infectiousness.

Mycobacterial Identification

Digestion and Decontamination

Sputum contains numerous microbes and various types of organic debris that interfere with mycobacterial growth on culture medium. Raw sputum specimens, therefore, must undergo a process of digestion and decontamination before being cultured for mycobacteria. The digestion and decontamination method most widely used in the United States utilizes *N*-acetyl-L-cysteine (NALC) and sodium hydroxide (NaOH). Raw sputum samples contain mucus and other proteinaceous materials that surround microbial contaminants and mycobacteria. NALC is used to liquify the debris that surrounds and protects these microbes from the decontamination effects of NaOH. Liquification of the debris also gives surviving mycobacteria freer access to the nutrients of the medium into which they are subsequently inoculated.

Raw sputum contains numerous bacteria that grow more rapidly (doubling time of <1 h) than tubercle bacilli (doubling time of 18 to 24 h), and these will quickly overgrow the mycobacteria if a raw sputum specimen is inoculated directly onto culture medium. To prevent this occurrence, decontamination of the raw specimen is accomplished by adding NaOH. Because of the high lipid content of the cell wall, mycobacterial growth is less inhibited by NaOH than is the growth of normal bacterial flora. However, some mycobacterial growth is inhibited by the chemical. Normally sterile fluids like blood, cerebrospinal fluid, and pleural fluid should therefore not be decontaminated for fear of further decreasing the small number of mycobacteria present.

Conventional Growth Techniques

Culture of specimens containing tubercle bacilli is a much more sensitive method of detecting mycobacteria than are direct smears. It is estimated that ³10,000 AFB must be present per milliliter of sputum for a sputum smear to give a positive result, whereas a culture of sputum can detect as few as 10 AFB per milliliter of a digested, concentrated specimen. Culture of AFB also allows speciation of the organism and recognition of its drug susceptibility pattern.

Two types of solid media have traditionally been used: an egg-based medium (Lowenstein-Jensen) and an agar-based medium (Middlebrook 7H10 and 7H11). A liquid

medium (Dubos Oleic-Albumin) that requires incubation in 5%–10% carbon dioxide (CO_2) for 3 to 8 weeks is also available. The principal drawback to the use of solid culture media is that cultures grow slowly, and the process requires highly skilled personnel and is labor-intensive.

Because all mycobacterial strains cannot be grown on a single substrate, it is a common laboratory practice to inoculate both egg and agar media to obtain the initial isolate. Following growth of the mycobacteria, colony morphology, growth rate, and pigment production should be determined and tested biochemically to identify the organism completely. When sufficient mycobacterial growth has occurred, evaluation of colony morphology is helpful. Colonies of *M. tuberculosis* are typically rough with irregular edges when viewed on translucent Middlebrook 7H10 agar with a stereo-optic microscope.

Most mycobacteria, including *M. tuberculosis,* require >1 week for growth. Notable exceptions to this observation are the rapid growers, such as *M. fortuitum* complex, which often produces mature colonies on Lowenstein-Jensen media in 3 to 5 days, and *M. marinum* (5 to 7 days). *M. tuberculosis, M. avium* complex, and *M. fortuitum* usually do not have significant pigment and are buff-colored. This contrasts sharply with the highly pigmented (orange) scotochromogens, such as *M. scrofulaceum,* and the highly pigmented photochromogens, such as *M. kansasii* and *M. marinum,* which become bright yellow when exposed to light. The bacteriology of nontuberculous mycobacteria is discussed in Chapter 29.

Nearly 99% of the strains of *M. tuberculosis* are niacin-positive. However, some strains of *M. simiae* and *M. kansasii* may also be niacin-positive. In biochemical testing, the combination of a positive niacin test, positive nitrate reduction test, and negative heat-stable catalase test is diagnostic of *M. tuberculosis.*

The Bactec system is an automated radiometric culture method, introduced in the late 1970s, that can detect the growth of mycobacteria more quickly than can other conventional culture methods using solid media. The system uses a liquid Middlebrook 7H12 medium containing radiometric palmitic acid labeled with radioactive carbon (^{14}C). Growth of mycobacteria within the system is measured as a daily growth index that represents the production of carbon dioxide ($^{14}CO_2$) by the metabolizing organisms. The detection of ($^{14}CO_2$) allows early recognition of mycobacterial growth, even before there is visible evidence of growth. The growth of *M. tuberculosis* complex is inhibited by *p*-nitro-L-acetylamino-b-hydroxypropiophenone (NAP), but NAP does not impede the growth of nontuberculous mycobacteria. When an increase in the growth index indicates that AFB are growing in a Bactec system, confirmation by a positive stain of the specimen is usually carried out. Samples of the specimen can then be subcultured in Bactec bottles with and without NAP. If the growth index value of each Bactec bottle is monitored daily, it is easy to tell whether *M. tuberculosis* complex or nontuberculous bacteria are growing in the sample. Results are usually available in 5 to 7 days.

DNA Probe

A significant advancement in the ability to identify mycobacteria rapidly and precisely occurred in the late 1980s, when nucleic acid hybridization assays were introduced. A complementary DNA (cDNA) probe is labeled with acridinium ester as a detector, and most commonly is directed at ribosomal RNA (rRNA) of the target mycobacteria in the sample. When the cDNA probe reacts with the target rRNA, a DNA-RNA hybrid is formed, producing light (chemiluminescent assay) that can be measured with a luminometer. This detection method is very sensitive; chemiluminescence is 10^6-fold more sensitive than fluorescence. Commercially available probes can react specifically with *M. tuberculosis* complex, *M. avium, M. intracellulare, M. kansasii, M. gordonae,* and *M. avium-intracellulare* complex. The sensitivities and specificities of these assays are >95% for these species.

At least 10^5 to 10^6 organisms must be present for best results; thus, the probes require cultures. A DNA probe can be completed in a matter of hours and can be used in combination with the Bactec system. When an increase in the growth index is noted in a Bactec system, a sample of the broth culture medium is stained, and if AFB are observed, a DNA probe is performed on the medium. It is estimated that by using this method the time required for identification of *M. tuberculosis* can be reduced to 1 to 2 weeks.

Both high-performance liquid chromatography (HPLC) and gas-liquid chromatography are used to identify mycobacterial species, with HPLC perhaps enjoying wider use. However, although HPLC provides a rapid and sensitive means of detecting mycobacteria, this technique has been used preferentially in level III reference laboratories because of its high cost. Because substantial growth of the mycobacteria is required for analysis, HPLC is not applicable for direct detection of mycobacteria in clinical specimens. HPLC is based on the observation that each species of mycobacteria produces specific fatty acids in its cell wall. These mycolic acids are extracted from the cell wall and methylated to form a methyl ester; when analyzed by chromatography, the methyl ester produces a characteristic pattern that can be used to differentiate the various species of mycobacteria. This test provides a specific diagnosis for most species in <4 hours. Detection of tuberculostearic acid by gas-liquid chromatography has proved to be a very sensitive and rapid method of detecting *M. tuberculosis* and may be particularly useful in the diagnosis of tuberculous meningitis. However, this test is still in a developmental stage.

Drug Susceptibility Testing

A drug susceptibility test should be obtained for all initial isolates, and whenever patient response to treatment is inadequate or cultures remain positive for ³2 months after initiation of treatment. Drug susceptibility testing may be performed using the conventional method or Bactec system; both methods have advantages and disadvantages.

Conventional Method

The conventional method for drug susceptibility testing uses solid media (Middlebrook-Cohn 7H10) that can be impregnated with antituberculosis drugs, depending on the desired test. The proportion method is most commonly used in the United States. An isolate of *M. tuberculosis* is considered drug-resistant if the number of colonies on the drug-containing medium is >1% of the number of colonies on the drug-free control plate.

Direct and Indirect Methods

Drug susceptibility tests can be carried out directly or indirectly. A direct test can be performed on a digested and decontaminated specimen with a smear positive for AFB. A direct test provides results faster (21 days) and gives a truer picture of the population of mycobacteria in the isolate.

Indirect tests are usually performed when the smear of the clinical specimen is negative for AFB or when significant contamination with pyogenic bacteria or other non-AFB is present. The inoculum for indirect drug susceptibility tests is obtained from the culture of the initial isolate. When indirect tests are performed, there is a risk of inadvertently selecting a predominant population of susceptible or resistant mycobacteria that are not truly representative of the population of organisms in the isolate that is being subcultured. This bias may be lessened by preparing a dilution of the entire subcultured population of mycobacteria. Because it is more difficult to avoid contamination and adjust the inoculum size when using the Bactec system, conventional drug susceptibility testing using solid media is the suggested method for performing direct drug susceptibility testing. The Bactec system (see above) is more applicable to indirect drug susceptibility testing using solid culture media or Bactec broth media. The Bactec method is best suited for testing first-line drugs and is preferable for pyrazinamide (PZA) testing. PZA susceptibility testing requires a very low pH (5.5) in conventional solid media, which prevents the growth of some strains of *M. tuberculosis.*

Newer Laboratory Methods

Polymerase Chain Reaction

The polymerase chain reaction (PCR) is a laboratory method for amplification of the amount of DNA in a specimen. The technique can be used on raw (uncultured) clinical specimens and theoretically is capable of detecting a single mycobacterium in a biologic sample. The process requires initial denaturation of double-stranded DNA by heating the specimen. Highly specific oligonucleotide primers—synthetic, short, single-stranded DNA probes—are added and attach only to cDNA sequences of the target mycobacteria. A DNA polymerase then enzymatically extends the primers to make a complete strand of cDNA. Multiple cycles of this process repeated sequentially create millions of identical copies of target DNA sequences of mycobacteria. These markers are specific for *M. tuberculosis* complex or other species of mycobacteria and can be detected by gel electrophoresis. If the target mycobacteria are absent from the sample, the primer has nothing to bind to, and amplification of the target DNA sequence does not occur. Although available in many laboratories, PCR is so far not generally used for the routine diagnosis of tuberculosis. It is highly sensitive, and contamination must be rigorously controlled. However, it is a promising tool for the rapid diagnosis of tuberculosis and may prove to be particularly helpful in the diagnosis of smear-negative tuberculosis.

Ligase Chain Reaction

Like PCR, ligase chain reaction (LCR) is a recently developed target amplification system used for the detection of species of mycobacteria. In research laboratories, the test has been demonstrated to have very high sensitivity and specificity and can be performed rapidly. However, it is still in the developmental stage.

Restriction Fragment Length Polymorphism or DNA Fingerprinting

DNA fingerprinting is not a diagnostic test but is a recently developed epidemiologic tool used primarily to evaluate the transmission of tuberculosis and identify cross-contamination of specimens within the laboratory. Restriction fragment length polymorphism (RFLP) subtypes strains of mycobacteria by fragmenting target DNA from *M. tuberculosis* with restriction enzymes (endonucleases) that recognize specific sequences and cut DNA into fragments of varying length. Cloned mycobacterial DNA (IS6110) probes are used to hybridize the fragments, which produce specific electrophoretic patterns and can be compared from strain to strain.

Luciferase Reporter Phages

A functional assay for the rapid assessment of drug-resistant mycobacteria using luciferase reporter phages has been recently developed but has not yet been tested clinically. This system can provide susceptibility results within 18 to 24 hours after a culture containing ³1 million mycobacteria has been obtained.

The assay involves placing the firefly gene for the production of luciferase into mycobacteriophages that then infect *M. tuberculosis,* introducing the firefly luciferase gene into the tubercle bacillus. Luciferin is added to the system and the activity of luciferase is monitored. Luciferase in the presence of adenosine triphosphate oxidizes luciferin to oxyluciferin, resulting in the production of light that can be measured in a luminometer. If an antituberculosis drug is added to the system, drug-resistant strains continue to produce light, whereas drug-susceptible strains do not.

Adenosine Deaminase

Adenosine deaminase is an enzyme produced by macrophages and activated T lymphocytes. Levels of adenosine deaminase have been reported in various studies to be present in increased amounts in several different body fluids infected with *M. tuberculosis.* Clinical value is still not clear.

SCREENING

In the United States, screening is a valuable method for controlling and ultimately eliminating tuberculosis. Screening should be performed only in selected, high-risk populations to identify infected persons who would benefit from therapy to prevent the development of tuberculosis, and to identify persons with active tuberculosis who should be treated to prevent transmission. Table 3 lists high-risk groups of people for whom screening is indicated. Groups not at high risk for tuberculosis should not be routinely screened because of cost and low yield; false-positive reactions may lead to inappropriate preventive treatment.

Persons with or at risk for HIV infection
Close contacts of persons with infectious tuberculosis
Persons with certain medical conditions
Persons who inject drugs
Foreign-born persons from areas where tuberculosis is common
Medically underserved, low-income populations, including high-risk racial and ethnic groups
Residents of long-term care facilities
Locally identified high-prevalence groups (e.g., migrant farm workers or homeless persons)

TABLE 3. *Groups that should be screened with the tuberculosis skin test*

Screening in most instances is carried out by health departments or health care providers affiliated with drug treatment centers, long-term care facilities, correctional institutions, and hospitals. However, all primary health care providers should be aware of the high-risk persons in their practices and should administer skin tests to these patients as part of their routine medical evaluations.

The Mantoux tuberculin skin test is the preferred method of screening for tuberculosis infection. However, to identify tuberculosis in specific settings where the risk of transmission is very high and/or the stay is short (conjugate settings such as homeless shelters, hospitals, and jails), intake screening with chest roentgenograms or sputum smears may be more appropriate. Tuberculin screening in institutional settings provides baseline information on the tuberculin skin test status of clients and staff, identifies candidates for preventive therapy, and detects whether transmission of tuberculosis is occurring within the facility.

Tuberculosis screening is recommended for residents of long-term care facilities. It is also recommended for staff members, who may be exposed to patients with tuberculosis on the job, or who would pose a significant risk to large numbers of susceptible persons if they became infectious with tuberculosis disease (e.g., staff of AIDS wards or child care centers). These people should be screened on entry or beginning of employment and at least yearly thereafter, depending on the risk for transmission in a particular facility. For persons who are screened periodically (e.g., staff of tuberculosis clinics), a two-step Mantoux skin test procedure should be used for initial skin testing.

Two-Step Mantoux Skin Testing

DTH to tuberculin tends to wane with aging. Persons who are given a tuberculin skin test many years after their initial infection with *M. tuberculosis* may have a negative reaction. However, that skin test may boost or recall their DTH response to tuberculin, causing a positive reaction to a subsequent test that may be misinterpreted as a skin test conversion.

A two-step Mantoux skin test should be used for the initial testing of elderly patients and adults who will be retested periodically as follows:

1. If the first test result is negative, give a second test 1 to 3 weeks later.
2. If the second test result is positive, consider that the person is infected with the tubercle bacillus but is not a skin test converter. If the second result is negative, consider the person uninfected with the tubercle bacillus.
3. Any positive reaction to a subsequent test is considered a conversion.

TREATMENT

More than a quarter of a century ago, Dr. Wallace Fox stated that effective chemotherapy and patient cooperation in taking prescribed medications were important factors influencing the success of a tuberculosis treatment program. The passage of time has borne out the accuracy of his observations.

Current principles on which recommendations for treatment are based include (1) the use of multiple drugs to which the tubercle bacilli are sensitive, (2) continuation of treatment for a period of time that is sufficient to control and usually eradicate the disease, and (3) regular ingestion of medications by the patient.

Two-Phase Chemotherapy

Multiple drugs are used to treat primary resistance present at the inception of therapy, or to prevent the emergence of acquired drug resistance. The concept of initiating treatment with multiple drugs is based on the fact that tuberculosis may occur from infection with initially resistant strains of *M. tuberculosis.* In addition, at the initiation of treatment of cavitary pulmonary tuberculosis, a large population ($>10^8$ bacilli) of mycobacteria is present, with the potential for spontaneous emergence of resistant strains. These mutants can be resistant to any of the antituberculosis drugs, but resistance occurs more frequently with some drugs than with others.

It is estimated that the frequency of mutations resistant to INH and streptomycin (SM) in populations of *M. tuberculosis* is approximately 1 in 1 million (1 in 10^6), and for mutations resistant to RIF it is 1 in 100 million bacilli (1 in 10^8). Therefore, mutants resistant to both INH and RIF given at the same time would occur approximately once in a population of 10^{14} organisms. By giving initial chemotherapy with two or more drugs, the likelihood of drug resistant bacilli surviving in the bacterial population

is extremely small.

Drug Treatment

After multiple drug therapy has been started, the second principle of treatment is to ensure that therapy is continued for a sufficient period of time. Prolonged therapy is necessary to eliminate persistent bacilli and prevent relapse of tuberculosis.

Before the introduction of RIF or currently when RIF is not used in a treatment regimen, 18 to 24 months of treatment are required to ensure a cure of tuberculosis. However, using multidrug regimens currently available that contain INH, RIF, and PZA, treatment can be completed in as short a period as 6 months, and trials for even shorter courses of chemotherapy are under way.

Chemotherapy is divided into an initial bactericidal phase, in which INH is the most effective drug, followed by a sterilizing phase, during which RIF and PZA are the most effective drugs. INH has its greatest effect against actively dividing tubercle bacilli, and PZA exhibits its greatest effect on organisms in an acid environment (tubercle bacilli ingested by macrophages). RIF is noted for the speed with which its bactericidal action starts, resulting in the selective killing of organisms that are largely dormant but have occasional short spurts of growth. Completely dormant mycobacteria are not killed by any drugs but may be eliminated by the host immune response.

Studies initiated by the British Medical Research Council and expanded by the U.S. Public Health Service, using 6 months of therapy with INH and RIF supplemented by PZA for the first 2 months, clearly established that short-course treatment regimens are both safe and effective.

Drugs available for the treatment of tuberculosis have been separated into “first-line” (Table 4) and “second-line” (Table 5) agents. The initial regimen for the treatment of tuberculosis consists of four drugs, including INH, RIF, PZA, and either ethambutol (EMB) or SM in communities where INH resistance is >4%. The treatment regimen can be adjusted as soon as drug susceptibility results are known.

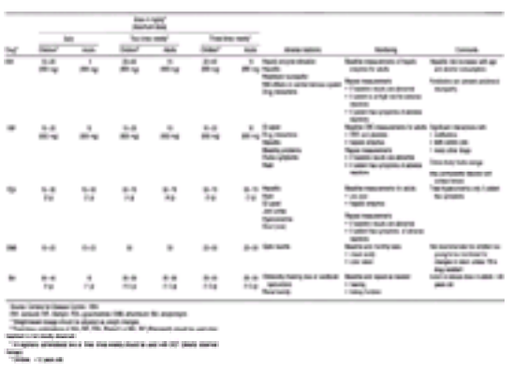

TABLE 4. *First-line drugs for tuberculosis*

TABLE 5. *Second-line drugs for tuberculosis*

In areas where INH resistance is <4%, an initial regimen of INH, RIF, and PZA may be used; alternatively, in very rare instances, a 9-month regimen containing INH and RIF may be used for those who cannot be treated with PZA. EMB or SM should be included in the treatment regimen until the results of drug susceptibility studies are known.

Patient adherence to a prescribed drug regimen is a major determinant of treatment success. The use of bus passes, vouchers, fixed drug combinations of demonstrated bioavailability, and other treatment incentives and enablers enhance patient adherence to a given drug regimen. Recent publications have emphasized the importance of directly observed therapy (DOT) in reducing tuberculosis case rates. DOT is the standard of care in the United States. Whenever possible, all patients should receive DOT. All intermittent regimens should be administered only under direct observation.

CASE 1: TUBERCULOSIS IN AN HIV-NEGATIVE PATIENT WITH SENSITIVE ORGANISMS

A 43-year-old African-American male bookbinder was admitted to the hospital with a productive cough of 3 months' duration, chest pain, fever, night sweats, easy fatigability, and weight loss of 10 lb. He denied having a known tuberculosis contact, had never had a tuberculin skin test, and stated that a findings on a chest roentgenogram taken 2 years previously were normal.

The patient was febrile (102°F), and crackles were heard over the posterior left lung base.

The admission chest x-ray films (Fig. 4) revealed volume loss with associated tracheal deviation and elevation of the left diaphragm, bilateral upper lobe infiltrates, and a large left upper lobe cavity. Laboratory findings included a negative HIV serology, a hemoglobin of 11.3 g/dL, and an erythrocyte sedimentation rate of 59 mm/h; three separate sputum specimens were reported positive on smear for AFB.

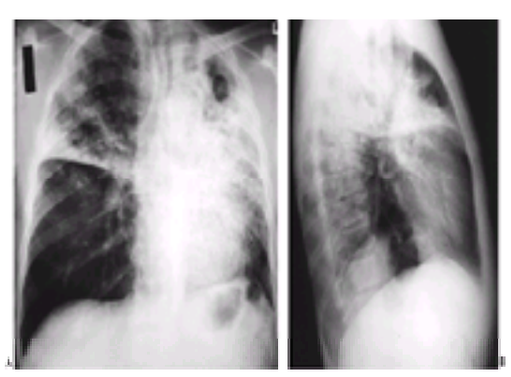

FIG. 4. Admission posteroanterior (**A**) and lateral (**B**) x-ray films of case 1. Note the volume loss and bilateral upper lobe infiltrates with a cavity in the left upper lobe.

The patient was started on daily DOT with a four-drug regimen of 300 mg of INH, 600 mg of RIF, 1500 mg of PZA, and 1200 mg of EMB. He tolerated the regimen well and after 1 week was continued on DOT five times weekly under the supervision of a trained field worker. On weekends he took a fixed-dose combination of INH, RIF, and PZA (Rifater) with EMB. All members of his immediate household (five people) were receiving preventive treatment with INH or therapy for active tuberculosis.

After 8 weeks, *M. tuberculosis* isolated from the patient was reported sensitive to all first-line antituberculosis drugs (INH, RIF, PZA, EMB, and SM). At this point, PZA and EMB were discontinued and he was maintained on twice-weekly oral DOT with 900 mg of INH and 600 mg of RIF for an additional 16 weeks, after which all medications were discontinued. His compliance taking antituberculosis medications approached 100%. On discharge, he noted marked improvement in his symptoms and had regained approximately 25 lb; despite improvement, residual changes persist on his chest roentgenogram (Fig. 5).

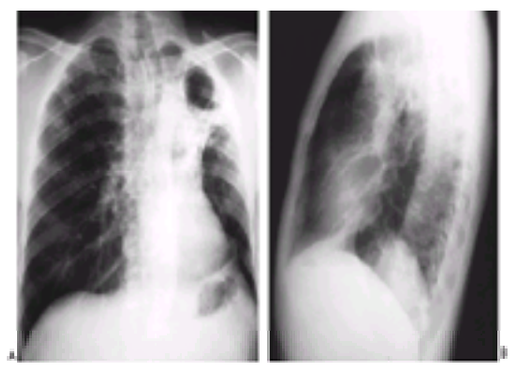

FIG. 5. Posteroanterior (**A**) and lateral (**B**) chest x-ray films of case 1 after the completion of treatment for tuberculosis. Note the clearing of disease in the right lung with residual cavitation and scarring in the left lung with volume loss.

COMMENT: This is a case of recrudescent, drug-sensitive tuberculosis in an HIV-seronegative patient that responded well to treatment. Unfortunately, the tubercle bacilli of this patient were transmitted to two of his children and his spouse, documenting the infectiousness of symptomatic cavitary tuberculosis. Despite appropriate treatment, he has significant residual lung damage.

TREATMENT OF SMEAR-NEGATIVE, CULTURE-NEGATIVE TUBERCULOSIS

Patients with smear- and culture-negative tuberculosis who are from areas where INH resistance is <4% and drug resistance is unlikely should be treated with a 4-month regimen of INH and RIF that is supplemented with PZA for the first 2 months. Patients with smear- and culture-negative tuberculosis who are from areas where INH resistance is ³4% or who have personal risk factors for drug resistance should be treated with a 4-month regimen of 4 drugs including INH, RIF, PZA, and EMB or SM.

TREATMENT OF HIV-SEROPOSITIVE PERSONS

Current recommendations for treatment of tuberculosis in HIV-seropositive patients are the same as those for HIV-seronegative patients, with the caveat that treatment should be prolonged if the response is suboptimal. There have been isolated cases of relapse of tuberculosis in AIDS patients, and when this occurs in AIDS patients with drug-sensitive tuberculosis, malabsorption of medications, new infection with tubercle bacilli, or some other reason for apparent treatment failure should be suspected. We recommend longer treatment and follow-up until clinical studies determine the optimal duration.

TREATMENT OF EXTRAPULMONARY DISEASE

The basic principles that guide the selection and duration of treatment for pulmonary tuberculosis are generally the same as for extrapulmonary tuberculosis, in which 6- to 9-month short-course regimens have proved effective. Some exceptions are miliary tuberculosis, bone and joint tuberculosis, and tuberculous meningitis in infants and children, in whom treatment should be extended for at least 12 months. For diagnostic as well as therapeutic reasons, surgery may be more commonly required in extrapulmonary tuberculosis than in pulmonary tuberculosis. Corticosteroid therapy has also been of benefit in treating some forms of extrapulmonary tuberculosis, and in preventing neurologic problems associated with tuberculous meningitis and cardiac constriction in tuberculous pericarditis.

TREATMENT FAILURE AND RELAPSE

Patients whose sputum remains positive on culture after 4 to 6 months of treatment should be considered treatment failures. Unlike patients undergoing initial treatment, patients requiring retreatment frequently are nonadherent, and their infecting organisms are drug-resistant. Patient motivation to adhere to treatment and selection of effective therapeutic regimens are more difficult to control but extremely important in such a setting. A detailed history, including the duration and frequency of previous treatment and the drugs used, should be obtained, and prior tuberculosis treatment records and chest x-ray films should be reviewed whenever possible.

Most patients who relapse following treatment with short-course chemotherapy have fully sensitive organisms and can be retreated with INH and RIF. However, drug susceptibility testing is of paramount importance when a retreatment program is undertaken. While waiting for results, which are frequently delayed, the original drug regimen may be continued, or new treatment should be started with at least two, but preferably three, drugs to which the patient's organisms have known sensitivity or that the patient has not previously received. *A potentially effective new or previously used single drug should never be added to a failing or failed regimen!* If the susceptibility pattern is known and the addition is highly unlikely to cause resistance, adding a single drug may be considered.

INTERMITTENT TREATMENT

Intermittent therapy is effective and more readily supervised than daily therapy. Several methods of delivering intermittent regimens have been identified and are listed in Table 6. In general, with the exception of the RIF dose, which remains the same, the dose of all the first-line drugs is increased when they are given intermittently.

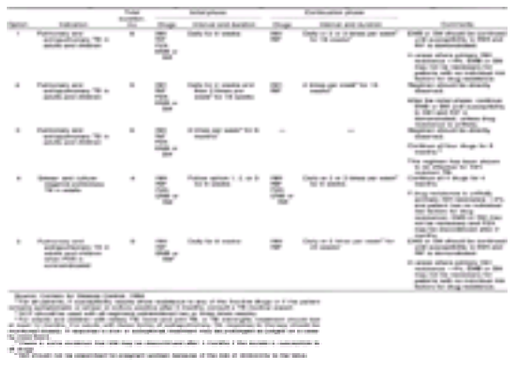

TABLE 6. *Regimen options for treatment*[a]

TREATMENT OF DRUG-RESISTANT TUBERCULOSIS

A 6-month regimen of RIF, PZA, and EMB or SM is adequate for treatment of tuberculosis that is known to be only INH-resistant. An acceptable alternative would be to treat with RIF and EMB for a minimum of 12 months. If for any reason RIF cannot be included in a treatment regimen, treatment should be continued for a minimum of 18 months. If resistance to PZA is demonstrated, treatment should be continued for a minimum of 9 months if INH and RIF are included in the regimen. Tuberculosis treatment in the face of resistance to EMB or SM only may not need to be prolonged but may require replacement of these two agents with second-line drugs.

MDRTB (i.e., tuberculosis resistant to at least INH and RIF) may be primary or secondary. Primary resistance is noted particularly in patients who are HIV-positive and have never had antimycobacterial treatment. Secondary resistance occurs in patients who have previously received treatment and whose infecting mycobacteria have acquired resistance to the antituberculosis medications previously given. MDRTB significantly complicates patient management and treatment, and treatment should be individualized based on the results of drug susceptibility tests and the patient's prior medication history.

When treating MDRTB, at least two and preferably three antituberculosis medications to which the organisms are susceptible should be used. Unfortunately, studies are not available that unequivocally establish the effectiveness and duration of various treatment regimens for MDRTB. In general, treatment should be continued with at least two drugs for a minimum of 18 to 24 months following culture conversion. Physicians unfamiliar with treatment of these patients should always seek expert consultation, as these are complicated, perhaps life-threatening situations, often with major significance to public health.

CASE 2: MULTIDRUG-RESISTANT TUBERCULOSIS

A 34-year-old African-American woman came to the hospital with fever and a persistent cough. Four years earlier, she had converted her tuberculin skin test but declined INH preventive treatment. Her chest roentgenogram revealed a left upper lobe pulmonary infiltrate (Fig. 6), and sputum smears were positive for AFB.

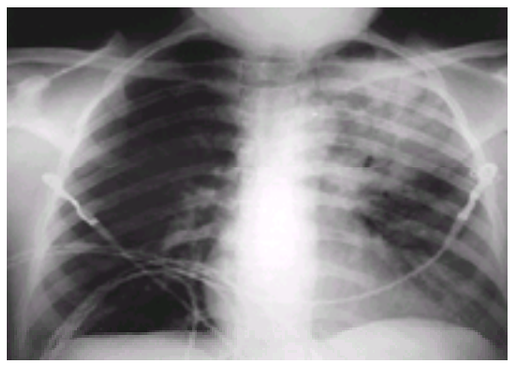

FIG. 6. Posteroanterior chest x-ray film of case 2 reveals a left upper lobe infiltrate.

Treatment with INH, RIF, PZA, and SM was begun while awaiting identification of the AFB and the results of drug susceptibility tests. The patient's symptoms worsened and sputum cultures obtained monthly remained positive at 12 weeks, when the initial sputum studies identified *M. tuberculosis* resistant to INH, RIF, SM, and ethionamide (ETA). Her chest x-ray film taken at that time is seen in Fig. 7.

FIG. 7. Posteroanterior chest x-ray film of case 2 shows bilateral infiltrates with worsening of the infiltrate in the left lung.

Directly supervised therapy during the next 9 months with various drug regimens comprising second-line drugs not previously used was not successful. Treatment failure may have been related to side effects of her medications, particularly gastrointestinal intolerance, that often led to discontinuation of one or another of the drugs, thus raising the possibility of monotherapy. Approximately 1 year after starting treatment, the patient remained stable but unimproved, with positive sputum cultures for *M. tuberculosis* on a drug regimen including PZA, EMB, rifabutin (RBT), cycloserine (CS), and capreomycin (CM).

At this point, the patient came to our center, where drug susceptibility tests were repeated and chest roentgenograms were taken. A decision was made to discontinue her treatment regimen and substitute a treatment regimen containing at least three drugs that the patient had not previously received and potentially effective drugs that she had previously taken. This was the approach used pending the results of drug susceptibility studies.

Under direct supervision, the patient was started on the following regimen: kanamycin (KM) (new), para-aminosalicylic acid (PAS) (new), clofazimine (new), RBT (previously received), EMB (previously received), ciprofloxacin (previously received). She tolerated the regimen well after slight modifications were made for gastrointestinal intolerance.

After 12 weeks of therapy with the new regimen, her symptoms improved, sputum smears were negative for AFB, and cultures were negative for *M. tuberculosis.* Drug susceptibility studies revealed resistance to KM, ciprofloxacin, INH, RIF, SM, ETA, and CS. The organism was sensitive to PZA, amikacin, PAS, clofazimine, EMB, and CM.

At this point (12 weeks after starting the new regimen), her treatment regimen was modified. KM and ciprofloxacin were discontinued and replaced with CM and PZA; PAS, RBT, EMB, and clofazimine were continued. Six months after starting this treatment, the patient remained culture-negative for *M. tuberculosis* and CM was discontinued. Eighteen months after initiation of treatment, sputum remained culture-negative and RBT and PZA were discontinued, and 24 months after initiation of treatment and sputum conversion, PAS and EMB were stopped. The patient remains clinically well, her chest x-ray findings are improved (Fig. 8), and she has returned to work full-time.

FIG. 8. Posteroanterior chest x-ray film of case 2 reveals residual scarring in the left lung after completion of treatment.

COMMENT: This case illustrates the importance of drug susceptibility tests in the treatment of tuberculosis. The delay in obtaining drug sensitivity information adversely influenced drug selection. It is probable that the drug resistance of the infecting organism was both primary and secondary.

TREATMENT DURING PREGNANCY

Certain precautions must be considered when treating tuberculosis during pregnancy. There is no doubt, however, that untreated tuberculosis represents a far greater hazard to a pregnant woman and her fetus than does any specific treatment.

In general, INH, RIF, EMB, and PAS are drugs that have been used during pregnancy in the United States because they have not been found to have teratogenic effects (Table 7). Although PAS is not associated with teratogenic effects, the frequent associated gastrointestinal side effects preclude its use as a first-line drug either with or without pregnancy.

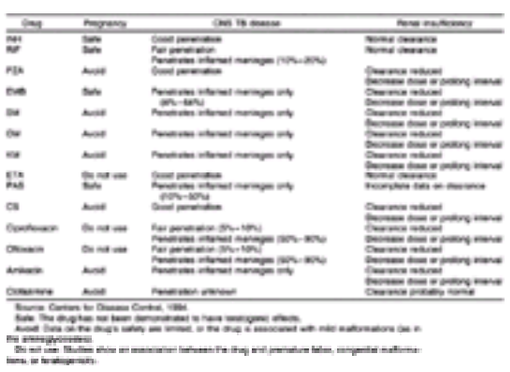

TABLE 7. *Drugs for tuberculosis in special situations*

PZA is approved by international guidelines for routine use during pregnancy; however, in the United States it is not recommended because of insufficient data concerning its teratogenic effects. Therefore, in the United States INH and RIF are the recommended initial treatment regimen. EMB should be included when primary INH resistance in the patient's locale is >4%. If PZA is not included in the initial treatment regimen, a minimum of 9 months of therapy must be given. SM has been demonstrated to have adverse effects on fetal development of the eighth cranial nerve in the third trimester, causing congenital deafness. KM and CM are also aminoglycosides, and all three are not recommended. Because data on the safety of the other second-line drugs and newer antimycobacterial agents, such as the quinolones and macrolides, are limited or suggest toxicity, their use should be avoided if possible during pregnancy.

Breast-feeding should not be discouraged, because the concentrations of drugs in breast milk are not sufficient to cause toxic effects in nursing infants. To prevent peripheral neuropathy, pyridoxine (10 to 50 mg/d) is recommended for pregnant women receiving INH.

TREATMENT OF TUBERCULOSIS IN CHILDREN

Treatment of tuberculosis in infants and children is generally guided by the same basic principles that apply to adults. However, because tuberculosis is more likely to disseminate in infants and younger children (<4 years old), the rapid institution of effective therapy is of the utmost importance. The initial treatment regimens prescribed for the treatment of tuberculosis in adults are also recommended for children (Table 4, Table 5 and Table 6). EMB is less useful in young children because the ocular toxicity that the drug may cause is difficult to monitor. SM or PZA is an acceptable alternative. Because there is less cavitary disease in children, confirmation of the diagnosis on culture is less likely than in adults. When hilar adenopathy or parenchymal infiltrates are present on chest roentgenograms in a child with a positive tuberculin test, the child should be treated as a case of active pulmonary tuberculosis.

Because the results of sputum culture are often negative in children, the results of culture and drug sensitivity studies from the contact case are very helpful in guiding the selection of treatment regimens. When knowledge of drug susceptibility patterns is critical, as in suspected MDRTB, it may be necessary to obtaining early morning gastric aspirates or BAL fluid. Assessing improvement in children depends more on clinical and x-ray findings than on results of sputum cultures, as noted above. Extrapulmonary tuberculosis in children is treated the same as pulmonary tuberculosis, except for tuberculous meningitis, bone and joint tuberculosis, and disseminated tuberculosis, for which a minimum of 12 months of treatment is recommended.

MONITORING TREATMENT

Adults who are treated with INH and RIF should have baseline measurements of hepatic enzyme, bilirubin, and serum creatinine levels, and a complete blood count and platelet count should be obtained. Serum uric acid should be measured if PZA is included in the regimen, and a baseline test of visual acuity and color vision should be obtained in those receiving EMB. Audiometry should be performed in patients receiving SM or other aminoglycosides. The purpose of these tests is to detect abnormalities that may cause complications or require modification of treatment regimens, and to provide a baseline for comparison if abnormalities develop during therapy. Table 4 and Table 5 present guidelines for monitoring during treatment with both first-line and second-line drugs.

All patients should be educated regarding adverse reactions to the medications they are receiving and instructed to stop medications and seek help immediately if these symptoms develop. Patients should be followed by a physician monthly while on treatment and specifically queried regarding symptoms at each visit. Monthly laboratory monitoring for toxicity in adults with normal baseline values is not required. If symptoms develop, laboratory testing should be performed immediately.

PREVENTIVE TREATMENT

INH preventive therapy has been shown to reduce substantially the risk for progression of tuberculous infection to disease. Infected persons at high risk for development of tuberculosis, listed below, should be given INH preventive therapy regardless of their age:

1. Tuberculin-positive reactors (³5 mm) who are HIV-seropositive; included are positive reactors who have risk factors for HIV infection but whose HIV serologic status is unknown. Tuberculin-negative reactors (<5 mm) who are HIV-seropositive and who live in areas with a prevalence of tuberculosis infection of 10% or greater should be given INH preventive therapy regardless of their age.
2. Tuberculin-positive reactors (³5 mm) who are close contacts of infectious tuberculosis cases. Tuberculin-negative (<5 mm) children and adolescents in this category should also be started on INH preventive therapy. The tuberculin skin test should be repeated 12 weeks later; if the result is still negative and contact with the infectious case was interrupted when preventive therapy was started, INH can be discontinued.
3. Tuberculin-positive reactors (³5 mm) who have chest roentgenograms suggestive of old healed tuberculosis and who were inadequately treated or untreated (these individuals can be given INH and RIF for 4 months).
4. Tuberculin-positive persons who have within the past 2 years converted their tuberculin skin test from negative to positive (³10 mm increase if <35 years of age; ³15 mm increase if ³35 years of age).
5. Tuberculin-positive (³10 mm) persons with certain medical conditions that have been reported to increase the risk for tuberculosis, including silicosis, diabetes mellitus, prolonged corticosteroid therapy (>15 mg of prednisone daily for 2 to 3 weeks), other immunosuppressive therapy, some hematologic and reticuloendothelial diseases, injection drug use in a person known to be HIV-seronegative, end-stage renal disease, and conditions associated with weight loss to 10% or more below ideal body weight or chronic undernourishment (head and neck cancer, intestinal bypass surgery or gastrectomy, chronic malabsorption syndromes).

Tuberculin-positive reactors (³10 mm) <35 years of age who remain high-priority candidates for preventive therapy but are at somewhat lower risk for development of

tuberculosis than persons in the above groups should also receive INH preventive treatment; they include the following:

1. Foreign-born persons from regions of the world with a high incidence of tuberculosis, such as Asia, Africa, and Latin America
2. Medically underserved low-income domestic populations, including high-risk ethnic or racial minorities such as blacks, Hispanics, and Asian-Americans
3. Residents of long-term care facilities such as mental institutions, nursing homes, and correctional institutions
4. Other groups, such as migrant farm workers and the homeless that are locally identified as having an increased prevalence of tuberculosis

Tuberculin positive reactors (³15 mm) who are <35 years of age and have no risk factors for tuberculosis should also be considered for INH preventive therapy but should be given a lower priority for preventive treatment than the groups previously discussed.

Because the risk for INH-induced hepatitis outweighs the benefits of preventive therapy, INH is not recommended for tuberculin-positive reactors (³10 mm) who are ³35 years of age and are not at high risk for development of tuberculosis.

To prevent the progression of tuberculous infection to disease, INH is used alone as preventive therapy in a single dose of 5 mg/kg of body weight per day up to 300 mg/d in adults and 10 to 15 mg/kg of body weight per day in children, not to exceed 300 mg/d.

Clinical trials have demonstrated that the greatest reduction (90%) in the risk for development of tuberculosis occurs with daily administration of INH for 12 months. However, 6 months of daily INH preventive therapy also conveys a high degree of protection and reduces the risk for development of tuberculosis by approximately 70%. Administration of daily INH for <6 months has been shown to reduce the level of protection significantly. Administration of INH for >1 year has not been shown to convey additional protection. Therefore, current recommendations are that every effort should be made to ensure continuation of daily INH preventive therapy for at least 6 months. Children should receive therapy for 9 months and individuals with HIV infection for 12 months.

Data on the effectiveness of intermittent INH preventive therapy are limited; however, studies in which INH is given twice weekly during the sterilizing phase of tuberculosis treatment suggest that this would be an effective preventive treatment. For potentially nonadherent treated persons at high risk, supervised intermittent INH preventive therapy has been recommended twice weekly at a dose of 15 mg/kg. Tuberculin-positive adults who have silicosis or abnormalities on chest roentgenograms as noted above with no evidence of current disease should receive 4 months of therapy with INH and RIF, as they are considered to have sputum-negative, active pulmonary tuberculosis. An acceptable alternative is 12 months of INH therapy, provided that infection with INH-resistant organisms is unlikely.

Pregnant women with positive tuberculin skin test results generally should not be started on INH preventive treatment until after delivery. Exceptions are made when recent skin test conversion has occurred or when high-risk medical conditions such as HIV infection exist. Under these circumstances, INH preventive therapy should be given.

No data are currently available that document the clinical efficacy of any drug other than INH for preventive therapy in any setting. Short-course preventive therapy regimens using RIF and PZA for 2 months and RIF alone for 4 months have shown promise in animal models and are being evaluated in humans.

When the source case has INH-resistant organisms or when treatment candidates cannot tolerate INH, preventive treatment with RIF should be considered. The RIF should be given daily in standard doses for at least 6 months in adults and 9 months in children. Guidelines for preventive treatment of individuals who may be infected with INH- and RIF-resistant organisms are based on the likelihood that the infection is recent and the probability that active tuberculosis will develop (i.e., HIV-seropositive patients). If these circumstances are unlikely, then observation of the patient or the administration of standard preventive therapy has been recommended. For patients with an especially high risk for tuberculosis, as in HIV infection or other immunosuppression, preventive therapy with EMB and PZA or PZA and one of the quinolones (ofloxacin or ciprofloxacin) in the usual standard doses should be considered.

Peripheral neuropathy may result from the use of INH but is extremely uncommon at a daily dose of 5 mg/kg of body weight. We give pyridoxine (10 to 50 mg/d) only in the presence of conditions commonly associated with neuropathies, such as diabetes, alcoholism, anemia, malnutrition, seizure disorders, and pregnancy.

Increasing age, chronic liver disease, and alcohol abuse have been associated with an increased incidence of INH-induced hepatitis in patients receiving preventive therapy. Young women, particularly blacks and Hispanics, have been reported to be at increased risk for fatal hepatitis associated with administration of INH. It is recommended that all patients ³35 years of age and younger patients at risk for hepatoxicity have liver function tests (measurements of hepatic transaminase, bilirubin, and alkaline phosphatase) before starting INH preventive therapy. If patients report symptoms of adverse reactions after therapy is begun and hepatic transaminase measurements exceed five times the upper limits of normal, INH should be discontinued. Baseline measurements of liver function parameters are not necessary for persons <35 years of age. Patients should be told what the symptoms of hepatitis are and advised to discontinue INH and report immediately if they occur. Patients should be clinically evaluated monthly while receiving INH preventive therapy.

BCG Vaccination

The bacille Calmette-Guérin (BCG) was developed from an attenuated strain of *M. bovis* in 1919 and serially cultured into several different, variable strains. It is used in many countries as a vaccine to protect against tuberculosis and is the most widely used vaccine in the world. Because the potency of the various strains varies, the protection obtained from the vaccine has been reported from none to 80%. A recently conducted meta-analysis by the Harvard School of Public Health attributes an overall 50% protective effect to the vaccine and a 64% protective effect against tuberculous meningitis. A large number of studies have suggested that it protects infants and young children from the more serious forms of tuberculosis, although its ability to prevent disease in adults is much less clear. Thus, its contribution is epidemiologic control of tuberculosis is not great. (Most cases of tuberculosis in children are sputum-negative and thus not infectious.)

BCG is not generally recommended for use in the United States, where most cases of tuberculosis occur in persons who are already infected with *M. tuberculosis* and would not benefit from BCG. Additionally, the use of BCG vaccination causes tuberculin skin test conversion, thus rendering the tuberculin test, the major indicator of new infection, useless. BCG vaccination of tuberculin-negative infants and children may be warranted when they are at high risk for intense, prolonged exposure to untreated or ineffectively treated cases of infectious tuberculosis, contact with the infectious case cannot be broken, and long-term effective preventive therapy is not possible. BCG is contraindicated in patients who are immunosuppressed.

In the United States, all persons who have a positive tuberculin skin test and who have a history of BCG vaccination should be considered infected with *M. tuberculosis* and evaluated for INH preventive therapy.

INFECTION CONTROL

This section briefly discusses selected public health aspects of tuberculosis control and the importance of coordinating the activities of public health departments and facilities that provide health care for tuberculosis patients. Effective tuberculosis control programs are based on the early detection, isolation, and treatment of infectious tuberculosis patients to reduce the risk for exposure to others. Infection control programs utilize various measures to achieve these goals, including administrative, engineering, and personal respiratory protective measures to prevent the transmission of *M. tuberculosis.*

Administrative Controls

The essential components of administrative infection control consist of detecting infectious tuberculosis cases early, isolating them, and providing rapid, effective therapy to reduce the risk for transmitting the organism to others. This requires a high index of suspicion by health care providers, particularly regarding HIV-infected patients with tuberculosis whose presentation may be unusual. Following diagnosis, all infectious tuberculosis patients should be isolated and started on DOT with an appropriate drug regimen (see above).

All facilities that provide health care to tuberculosis patients should have procedures for reporting cases and for coordinating activities between public health departments and other facilities that are involved in patient care.

Administrative controls should focus principally on reducing the risk of exposing susceptible persons to patients with infectious tuberculosis. Such administrative controls include the following:

1. Developing and implementing effective written policies and protocols to ensure rapid identification, diagnosis, isolation, and treatment of individuals who are likely to have tuberculosis
2. Implementing effective work practices among health care workers within health care facilities
3. Educating, training, and counseling health care workers regarding basic concepts of tuberculosis transmission, pathogenesis, diagnosis, treatment, and infection

control
4. Screening health care workers for tuberculosis infection and disease

The transmission of the tubercle bacillus has long been a recognized risk in health care facilities, and as a result infection control guidelines were developed by the CDC. Unfortunately, a relaxation of infection control practices occurred with time, which led to several outbreaks of tuberculosis.

In the early 1990s, numerous accounts of institutional outbreaks of MDRTB were reported. These outbreaks occurred primarily in HIV-infected persons and were associated with high mortality rates and a rapid progression from diagnosis to death. The outbreaks occurred most often in clinics or wards where HIV-infected patients received care. Not only was patient-to-patient transmission identified, but the spread of infection from patients to health care workers was reported to be common.

Major factors that contributed to these outbreaks included the comingling of highly susceptible immunocompromised patients with infectious tuberculosis patients, delayed recognition and treatment of both drug-sensitive and drug-resistant tuberculosis, delayed initiation and premature discontinuation of isolation, and delayed implementation of existing infection control measures (adequate respiratory protection during cough-induction procedures).

Recently collected data from several of the health care facilities involved in the outbreaks indicates that once implemented, infection control measures significantly limited or entirely stopped the continued transmission of *M. tuberculosis.*

Engineering Controls

Engineering and personal respiratory protective measures used during outbreaks of MDRTB were proved to be important infection control measures for stopping further spread of MDRTB in institutional settings.

In health care facilities, as part of a tuberculosis infection control plan, rooms for isolation and treatment of infectious tuberculosis patients, in addition to facilities for sputum induction and aerosol-generating procedures, should be available.

Ventilation reduces the concentration of droplet nuclei in room air by diluting and removing contaminated air and directing air flow patterns within a room. Two types of general ventilation systems (single-pass and recirculating) are used for dilution and removal of contaminated air. The preferred choice is the single-pass system, in which the air supply (either outside air or clean air from a central reservoir) is passed through a room or area and completely exhausted to the outside.

For optimal air mixing, the air supply source and exhaust should be located at opposite sides of the room, so that clean air flows from areas where health care workers are located across the infectious source (patients) and out through the room exhaust. It is currently recommended that a minimum of six air changes per hour be required for tuberculosis isolation and treatment rooms.

Air normally flows from an area of higher pressure to one of lower (negative) pressure. Negative pressure can be achieved by exhausting air from a room faster than it is being supplied to the room. Thus, the direction of air flow can be controlled. Preferably, the direction of air flow should be from a less contaminated area to a more contaminated area. A minimum pressure difference of 0.001 inch of H_2O is required to create and maintain adequate air flow.

Ideally, potentially infectious tuberculosis patients should be isolated and treated in a negative-pressure room ventilated by a single-pass ventilation system having at least six air changes per hour and exhausted directly to the outside.

As an interim measure, a small exhaust fan placed in a window or an outside wall will exhaust air to the outside and create a negative room pressure, but it will not provide clean air and thus offers suboptimal dilution. Negative room pressure can be checked visually with smoke tubes or by measuring the pressure difference between a room and its surrounding area.

Booths, hoods, and tents (local exhaust ventilation devices) are useful for preventing the introduction of airborne tubercle bacilli into room air by trapping them near their source; this prevents exposure of health care workers in the area. The use of these devices is especially important during sputum induction procedures.

Of the two types of local exhaust ventilation devices (enclosing and exterior) that are available for use, enclosing devices are preferable because they completely enclose the infectious source. Enclosing-type devices should provide adequate air flow to remove at least 99% of airborne tubercle bacilli. All air from booths, hoods, and tents should be exhausted to the outside; however, if it is recirculated, air should be exhausted through a high-efficiency particulate air (HEPA) filter.

HEPA filtration is a method of removing tubercle bacilli from room air that supplements the previously discussed ventilation control measures. HEPA filters have a minimum efficiency of 99.97% for removing particles ³0.3 µm in size from room air. Although their ability to filter tubercle bacilli from room air has not been studied, the droplet nuclei that contain tubercle bacilli are approximately 1 to 5 µm in size. HEPA filtration can be used to remove droplet nuclei from room air before it is exhausted to the outside or recirculated to other areas, in fixed or portable room air filtration units for recirculating air within a room, or, as previously discussed, in the exhaust of ventilation equipment such as booths and hoods.

Ultraviolet germicidal irradiation (UVGI) kills tubercle bacilli under experimental conditions; it has been shown to reduce transmission of other microbes in hospitals and classrooms and has been recommended as an engineering control measure to supplement other infection controls. UVGI probably kills or inactivates airborne tubercle bacilli, but before its role can be unequivocally defined in preventing tuberculosis transmission, further study is required. Germicidal ultraviolet lamps are low-pressure mercury vapor lamps that emit radiant energy at a wavelength of 253.7 nm.

UVGI can be used to inactivate tubercle bacilli from contaminated room air by placing ultraviolet lamps within ventilation ducts that exhaust air before it is recirculated from tuberculosis isolation or treatment rooms or other areas of general use, including waiting rooms, emergency rooms, or patient rooms where air could be contaminated by undiagnosed cases of tuberculosis. The advantage of using UVGI within ventilation ducts is that patients and other persons are protected from its harmful effects.

UVGI is also used to inactivate tubercle bacilli in contaminated upper room air by placing ultraviolet lamps on an upper wall or suspending them from the ceiling. The lamps are constructed to direct the flow of irradiation upward, which minimizes exposure to individuals in the lower part of the room. UVGI of upper room air is used in tuberculosis isolation and treatment rooms, hallways, and patient, waiting, and emergency rooms.

Short-term exposure to UVGI can cause erythema and keratoconjunctivitis, and long-term exposure is associated with an increased risk for squamous and basal cell carcinomas of the skin. Recent studies have reported an increase in HIV replication caused by ultraviolet radiation. However, in places where UVGI has been used properly, there have been no reports of untoward effects.

Personal Respiratory Protection Controls: Particulate Respirators

From a public health perspective, the use of personal respiratory protective equipment is the least efficient and least effective of all infection control methods, because it protects only the user and must fit well to work well. Such equipment is used primarily when it is likely that high concentrations of tubercle bacilli are contaminating room air, as in tuberculosis isolation and treatment rooms during sputum induction and aerosol-generating procedures, or when administrative and engineering controls are inadequate to remove droplet nuclei from room air.

The Occupational Safety and Health Administration (OSHA) standard for respiratory protection requires certification by the National Institute for Occupational Safety and Health (NIOSH) of all respiratory protective devices used in the workplace.

Until recently, the only particulate respirators used for protection against transmission of *M. tuberculosis* that met NIOSH certification criteria were HEPA filter particulate respirators. Recently, NIOSH developed new regulations that are more stringent, under which nine types of particulate respirators are certified. Three different levels of filter efficiency of 95%, 99%, and 99.97% were classified, and three different categories based on the resistance to filter efficiency degradation, labeled *N, R,* and *P,* were outlined. In health care settings, either N, R, or P respirators may be selected.

All nine classes of particulate respirators certified by NIOSH meet or exceed CDC filtration efficiency performance standards. Several of the newer classes of particulate respirators will be less expensive and easier to wear than the HEPA filter respirators previously certified.

The policy of OSHA with respect to particulate respirators currently allows the use of an HEPA filter particulate respirator or any of the nine classes of particulate respirators for protection against *M. tuberculosis.* OSHA requires that all respirators be properly fit-tested. Manufacturers recommend that users of the respirators follow

fit-checking procedures each time the respirator is worn.

Role of the Public Health Department

Tuberculosis is a prime example of the impact that public health policy may have on the diagnosis and treatment of disease. The best trained, most informed clinicians cannot ever hope to have any impact on tuberculosis care and control without dedicated and sustained cooperation from the local public health agency.

Because many tuberculosis patients are beset with a myriad of social problems, a practicing physician cannot treat tuberculosis in isolation. DOT, follow-up of contacts, and investigation of outbreaks are at least three areas in which major interactions are required between the clinician and the public health agency.

In an era of reform of health care delivery strategies, it behooves all treating clinicians not only to forge and sustain relationships with health departments to facilitate a beneficial clinical and public health outcome, but to advocate the proper appreciation and funding of these specialized services.

CHAPTER

29 Nontuberculous Mycobacterial Pulmonary Disease (NTM)

Bonita T. Mangura · Lee B. Reichman

B. T. Mangura and L. B. Reichman: New Jersey Medical School National Tuberculosis Center, University of Medicine and Dentistry of New Jersey, Newark, New Jersey 07107.

BACTERIOLOGY

After the tubercle bacillus (*Mycobacterium tuberculosis*) was identified as a cause of human disease, identification of other mycobacteria affecting various animals, such as livestock, fowl, and marine creatures, followed. Better and more specific bacteriologic techniques allowed microbiologists to separate and identify various mycobacteria pathogenic for humans.

Early on, *Mycobacterium avium,* pathogenic to fowl, was found not to be pathogenic for humans, but subsequently *M. avium* complex (MAC) was described as pathogenic for humans. Seroagglutination has allowed the identification of 28 types of MAC. It is difficult to distinguish *M. avium* from *M. intracellulare* without seroagglutination; Infection/disease by either one is generally referred to as MAC or *Mycobacterium avium-intracellulare* (MAI) disease. *M. avium* includes serotypes 1 through 11 (except 7) and 21; *M. intracellulare* includes serotypes 7, 12 through 20, and 25.

A wider spectrum of mycobacterial lung disease was recognized following the descriptions of *M. fortuitum* in individuals with chronic obstructive lung disease secondary to aspiration, and of *M. kansasii* in individuals without prior lung diseases.

Timpe and Runyon's classification of nontuberculous mycobacteria (NTM) in the 1950s provided a working algorithm; groups were based on pigment production, colony morphology, and growth rates. The schema in Fig. 1 shows temperature growth preferences; the cutaneous mycobacteria grow best at 30°C to 32°C. At 37°C and above, two growth rates are noted: rapidly growing mycobacteria and slowly growing mycobacteria. *M. chelonei* and *M. fortuitum* are rapidly growing organisms, also classified as Runyon group IV. Runyon groups I through III are slowly growing mycobacteria. The organisms included in Runyon group I are photochromogenic mycobacteria; cream-colored colonies grown in the dark turn yellow on exposure to light. Runyon group II organisms are scotochromogens; yellow-colored colonies change to orange in the dark. Runyon group III mycobacteria produce cream-colored colonies that do not change pigment color on exposure to either light or dark. Pigmentation was eventually found to be related to soluble beta carotene found in mycobacteria and controlled by an oxygen-dependent light-activated enzyme. *M. tuberculosis,* MAC, and *Mycobacterium xenopi* belong to Runyon group III and are differentiated by their reaction to niacin (*M. tuberculosis* is niacin-reactive, whereas MAC does not react to niacin). Arylsulfatase activity differentiates MAC from *M. xenopi.*

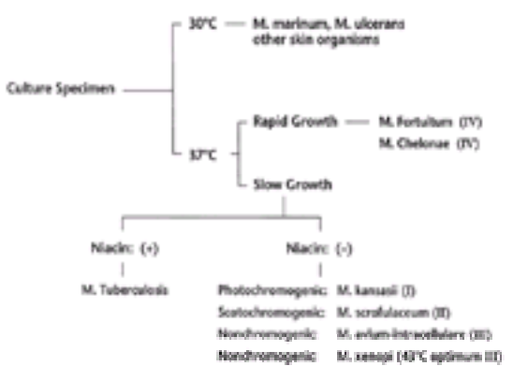

FIG. 1. Temperature growth preferences of NTM (nontubercular myocobacteria).

The tree in Fig. 1 includes some of the important pathogens and highlights the biochemical reaction (niacin) that differentiates *M. tuberculosis* from the rest of the NTM organisms. The laboratory characteristics of pigment production and growth rate have not contributed to clinical diagnostic or therapeutic decision making. The only clinical correlates were that the organisms were easy to treat or difficult to treat (Bailey classification). Standard antimycobacterial drugs had to be juggled to find an appropriate combination.

More modern techniques are currently available to identify specific mycobacteria rapidly. These include thin-layer chromatography, gas-liquid chromatography, high-pressure chromatography, species-specific DNA probes, and the Bactec NAP (*p*-nitro-L-acetylamino-b-hydroxypropiophenone) test. These are sensitive and specific tests that may provide identification of species within 4 hours using isolates from broth or agar.

The geographic distribution of the NTM is wide and variable. Species-specific skin-testing antigens have not been standardized and are not highly specific. Clinically, some patients with NTM disease may have a positive skin test using purified protein derivative-tuberculin (PPD-T), with reactions of <10 mm. The only utility of the tuberculin skin test in the clinical setting in which NTM are suspected is to determine the presence of intact delayed hypersensitivity.

Because many mycobacterial species have similar bacterial wall antigens, cross-reactions are expected and common. However, among a group of patients with cystic fibrosis and documented NTM infection, none responded to PPD-T. All were from the southeastern United States (an endemic area for NTM). The few who reacted to PPD were known to have been exposed to *M. tuberculosis.*

Data from restriction fragment length polymorphic (RFLP) typing, plasmid typing, and serotyping show two populations of *M. avium,* one infecting humans and the other infecting animals. Until more specific skin-testing antigens are available, however, skin-test antigens developed from different geographic locations and strains must be utilized with caution.

The most important NTM pulmonary pathogens are MAC, *M. kansasii, M. fortuitum-M. chelonei,* and *M. xenopi.* Occasional pulmonary pathogens are *M. scrofulaceum, M. szulgai, M. simiae,* and *M. malmoense.* Because NTM disease is not reportable, information regarding its incidence and prevalence is based largely on estimates. In 1979–1980, these diseases were estimated to occur in one third of 32,000 mycobacterial isolates. Of these, 60% were MAC, 19% were *M. fortuitum-M. chelonei,* and 10% *M. kansasii.* The estimated incidence of NTM disease is 1.8 cases per 100,000 in the U.S. population.

SPECIFIC NONTUBERCULOUS MYCOBACTERIAL DISEASES

Mycobacterium avium-intracellulare Complex Disease

MAC occurs in the environment, notably soil, bodies of water, and water systems, and in animals, such as poultry. The epidemiology of disease, however, has no correlation with the distribution of MAC in the environment, as MAC is found throughout the United States, including the western states. Migration of native residents from primary endemic regions to nonedemic areas after primary infection (not unlike what occurs with *M. tuberculosis*) may contribute to the wide distribution. The clinically predominant serovar types are 1, 4, and 8. Serovar 4 is dominant in northern California and the eastern United States, while serovar 8 is dominant in southern California.

MAC is found in geographically warmer environments and in highly acidic brown swamps of the southeastern coastal plains of the United States. MAC isolates from patients differ from environmental isolates. In addition, MAC isolates from patients with acquired immunodeficiency syndrome (AIDS) differ from environmental isolates and those found in patients without AIDS. In San Francisco, for example, environmental contamination does not account for the high prevalence of MAC cultured from AIDS patients.

Next to *M. tuberculosis,* MAC organisms are the most common mycobacteria in human disease. It traditionally occurs in patients with underlying pulmonary conditions, such as chronic obstructive pulmonary disease (COPD), bronchiectasis, old healed tuberculosis, or currently active tuberculosis. Individuals in occupations associated with heavy exposure to dust are also more likely to be infected.

During the last two decades, attention has been directed to other groups of patients infected with pulmonary MAC or other NTM. Infections have been reported in patients with cystic fibrosis and in women without underlying lung diseases. MAC has also been associated with human immunodeficiency virus (HIV) disease, especially in full-blown AIDS; it is a case-defining pathogen in HIV-infected persons. Pulmonary disease and extrapulmonary involvement occur frequently in the latter group when the CD4-cell count falls to <100/µL. MAC infection occurs in from 15%–40% of HIV-infected patients.

Pulmonary MAC disease develops in three major groups of patients (Table 1). There may be overlap of the groups (i.e., patients with AIDS may have underlying COPD).

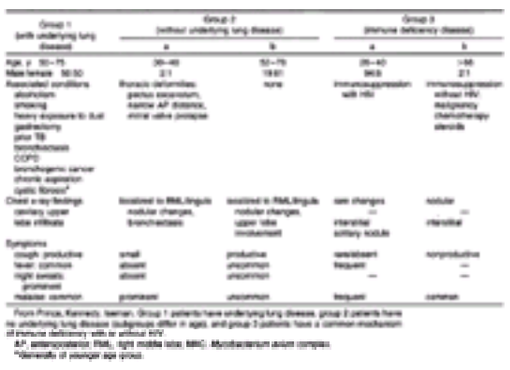

TABLE 1. *Clinical description of groups with pulmonary MAC infection*

In group 1 (patients with underlying lung disease), the most important underlying disease is COPD. It is fairly evenly distributed among men and women, and generally, the patients are older (>50 years). Chronic alcoholism and cigarette smoking are associated conditions in most patients. Eighty-five percent of patients with MAC disease are white. Upper lobe cavitary changes are a common radiologic feature. Symptoms are usually progressive and include productive cough accompanied by fever and night sweats. Malaise is common. When disease is unilateral initially, clinical progression results in bilateral radiologic involvement.

Because of improvements in the care and treatment of patients with cystic fibrosis, they are living longer but are increasingly vulnerable to a multitude of bacterial organisms, including NTM. MAC appears to be the most important NTM pathogen in adult patients with cystic fibrosis. Patients range in age from 18 to 35 years. As with the other chronic lung diseases, diagnosis and treatment may be confounded by the underlying disease. Although some patients with cystic fibrosis have diabetes mellitus resulting from pancreatic insufficiency, they generally do not have immune dysfunction. Their underlying lung disease is obstructive and their nutritional status is often poor. Clinical deterioration resulting from pulmonary bacterial infection is frequent. It is difficult to distinguish colonization from disease, as bacterial infections (*Pseudomonas* and *Staphylococcus aureus*) are particularly common causes of radiologic changes and clinical deterioration. Bacterial contamination (i.e., overgrowth of *Pseudomonas*) has been described, often adding to the clinical dilemma of assessing true disease from colonization.

Patients in group 2 have no underlying lung disease. The majority in this group are women, both young and old. In the younger patients (group 2a), associated thoracic deformities, such as narrowing of the anteroposterior diameter of the chest, pectus excavatum, and scoliosis with mitral valve prolapse, have been observed. These abnormalities may occur singly or in combination. Male patients are less frequently affected. Chest x-ray abnormalities are fairly localized, involving predominantly the right middle lobe or lingula. Nodules and bronchiectasis are usually prominently displayed by computed tomogram (CT) of the chest.

The patients in group 2b are elderly women without underlying lung disease. Radiologic changes in the chest are similarly localized to the right middle lobe and/or lingula. Nodular changes as well as bronchiectasis have been observed. Some patients have upper lobe involvement, most commonly of the anterior segment. Symptoms are similar for both subgroups, including productive cough, malaise, fever, and night sweats. Although the disease course is indolent, it can accelerate and become fatal without treatment.

Group 3 comprises patients with immunosuppression. Group 3a has been fairly recently described as a major part of the AIDS epidemic. The main feature is the presence of infection with HIV. MAC infection has occurred together with *M. tuberculosis* disease; the HIV transmission categories are usually homosexual and bisexual men. Extrapulmonary involvement is a prominent feature in these cases. Disseminated MAC infection is associated with pulmonary involvement in 80% of cases. Patients generally present with gastrointestinal symptoms, fever, weight loss, and fatigue. There are usually no pulmonary symptoms or radiologic evidence of pulmonary disease unless another pulmonary disease is present.

Described radiologic abnormalities have included hilar masses, solitary pulmonary nodules, upper lobe changes, diffuse infiltrates, and cysts, with diffuse infiltrates accounting for 85%. Most of the infiltrates are caused by concomitant *Pneumocystis carinii* pneumonia, tuberculosis, cytomegalovirus infection, and other opportunistic infections.

The patients in group 3b have secondary or acquired immunosuppression resulting from malignancy or blood disorders (leukemia and lymphoma) or from therapeutic interventions, such as chemotherapy and steroid therapy. Immunosuppression is not HIV-related. Pulmonary disease is associated with cavitary infiltrates, as in group 1, and often accompanied by constitutional symptoms, such as productive cough, fever, night sweats, and malaise. The course of the disease is dictated by the underlying malignancy or blood disorder.

Diagnosis of pulmonary MAC infection is made by acid-fast smear of sputum and culture. Diagnostic procedures have included sputum induction, bronchoscopy with lavage, aspiration, and tissue biopsy. Rarely, open lung biopsy is performed. MAC has been identified as a cause of solitary nodules after resection, tissue biopsy, and culture performed as part of the nodule workup. Adenopathy may also require a surgical biopsy (open excision or via mediastinoscopy). CT of the chest has been widely used to detect bronchiectasis and nodules, whereas ventilation-perfusion scan is utilized to determine residual function of a nonresectable lung or the remaining lung.

Treatment

Few clinical trials of the treatment of pulmonary MAC disease were undertaken until 1988, when rifabutin was introduced. Promising responses of combination therapy for MAC infection in AIDS began to be reported. Clearly, monotherapy had no role in MAC disease, because it was associated with rapid relapse, recurrence, and development of bacterial resistance. Treatment results were limited by persistence of MAC and inability to eradicate the infection. The application of this experience using four-drug therapy to treat pulmonary MAC disease has been derived from seemingly successful trials for disseminated MAC infection in AIDS.

Recommendations for the treatment of MAC infection are based on evolving and accumulating experience. Isoniazid and pyrazinamide have no role in the treatment of

MAC disease. Susceptibility testing based on *M. tuberculosis* standards is not applicable in MAC infection. In addition, MAC isolates have a broad range of drug susceptibility, so that a standardized regimen may not be useful. For example, MAC isolates from AIDS patients have shown genetic diversity—that is, individuals may be concurrently infected with more than one strain of MAC. Thus, the choice of antimycobacterial agents should be based on quantitative tests for drug susceptibility.

In the treatment of MAC lung disease, regimens are separated into two treatment phases. During the initial phase, at least four drugs are used: clarithromycin (500 mg orally twice daily), ethambutol (25 mg/kg orally once daily), rifabutin (300 mg orally once daily) or clofazimine (200 mg orally once daily), and streptomycin (10 to 12 mg/kg intramuscularly once daily) or amikacin (12 to 15 mg/kg intravenously three times a week). This regimen is given for 2 months and is followed by a continuation phase. The regimen during the continuation phase is clarithromycin (750 mg orally once daily), ethambutol 15 mg/kg orally once daily), and rifabutin (300 mg orally once daily). Treatment should continue for 24 months or at least 12 to 18 months past the last positive sputum culture. There will likely be instances of relapse. For unresponsive localized disease, surgical resection is often indicated. Commonly used antimycobacterial agents for MAC infection are listed in Table 2, along with some of their adverse effects.

Agents	Dose (adults)	Side effects/toxicity[a]
Azithromycin	250–500 mg PO od	diarrhea, nausea, abdominal pain, elevated liver enzymes
Clarithromycin	500 mg PO bid; 750 mg PO bid	same as above
Ethambutol	25 mg/kg PO od	optic neuritis, soreness, nausea, vomiting
Rifabutin	450 mg PO od	similar to those of rifampin
Ciprofloxacin	500 mg PO bid; 750 mg PO od	GI complaints: nausea, diarrhea
Amikacin	12–15 mg/kg three times a week	cranial nerve (auditory/vestibular)
Rifampin	600 mg PO od; 450 mg for <45 kg	orange discoloration of body secretions, flulike illness, hepatitis, low platelet count
Clofazimine	50–200 mg PO od	skin discoloration, GI complaints
Streptomycin	10–15 mg/kg od	cranial nerve VIII and renal toxicity, low potassium and magnesium levels

Adapted from Masur H, and the Public Health Service Task Force on Prophylaxis and Therapy for MAC. Special report: recommendations on prophylaxis and therapy for disseminated Mycobacterium avium complex disease in patients infected with the human immunodeficiency virus. *N Engl J Med* 329:898–904.

[a] Patients should be monitored for side effects and toxicity.

TABLE 2. *Antimycobacterial agents commonly used in pulmonary MAC infection*

Therapeutic goals may include a reduction in symptoms (fever, night sweats, cough), stabilization or diminution of chest radiologic abnormalities, and improvement in pulmonary function. Adverse reactions should be monitored. An incremental dosing strategy or dose staggering has been recommended for non-HIV patients to reduce discontinuation of treatment because of toxicity and intolerance.

Prophylaxis for MAC Disease in HIV-Infected Persons

Rifabutin was approved by the U.S. Food and Drug Administration for prophylaxis of MAC disease based on two cohort studies. The studies reported significant reduction in bacteremia, clinical symptoms, and laboratory abnormalities when rifabutin was used as a prophylactic agent. The drug was found to be safe, effective, and well tolerated, and adverse effects were infrequent. It improved the quality of life, but there was no overall survival benefit from its use. The current recommendation is 300 mg of rifabutin orally once a day for HIV-infected persons having a CD4-cell count of <100/mm^3, with the treatment to continue for life. In areas with a high prevalence of tuberculosis, the use of rifabutin may preclude the use of rifampin as part of the standard antimycobacterial treatment for tuberculosis because of high levels of cross-resistance. Rifampin-resistant cases of tuberculosis have been documented as a result of rifabutin use for MAC infection. Rifabutin is not recommended as MAC prophylaxis for non-HIV patients.

Drug Interactions

Absorption and efficacy of the drugs may be affected by drug interactions. Clarithromycin interferes with compounds metabolized by the hepatic P_{450} cytochrome system; azithromycin does not interfere with the P_{450} system. Fluoroquinolones are chelated by aluminum compounds, such as antacids. Iron and multivitamin compounds may also reduce their bioavailability. Rifabutin may interact with zidovudine.

M. kansasii Disease

Most isolates of *M. kansasii* have been recovered from tap water in cities known to be endemic for *M. kansasii.* In Texas, where both *M. kansasii* and MAC occur, *M. kansasii* infection and disease were noted to be more frequent in urban dwellers with pulmonary disease, whereas MAC infections were noted in rural dwellers. Almost all strains of *M. kansasii* are susceptible to rifampin and only slightly resistant to isoniazid, ethambutol, and streptomycin. However, rifampin-resistant strains of *M. kansasii* have been reported among patients with and without AIDS. Patients with rifampin-resistant isolates have clinical profiles showing prior use of one or two antimycobacterial drugs and noncompliance. One third of the resistant isolates were from HIV-seropositive patients.

Clinical features of pulmonary *M. kansasii* disease are similar to the features of pulmonary MAC infection. Cavitary lung disease is common; *M. kansasii* disease predominantly occurs in white, middle-aged men; the ratio of men to women affected is 2:1. A greater number of cases are noted among the 30- to 39-year age group in both sexes; upper gastrointestinal disorders, such as prior gastrectomy and peptic ulcer disease, are frequently observed. The majority have previous or existing lung diseases, especially COPD. The presence of underlying lung disease adversely affects the course of treatment and prognosis. Conversely, the absence of prior lung disease portends a more favorable outcome with treatment.

M. kansasii disease in HIV-infected persons has been extensively described. Clinical features include fever, cough, dyspnea, and rarely hemoptysis. Most diagnoses have been made from spontaneously produced sputum specimens, whereas a third have been based on bronchoscopy specimens. Sputum positive for acid-fast bacilli (AFB) is more likely in patients with pulmonary infiltrates, which range from predominantly upper lobe infiltrates to pulmonary cavitary and reticulonodular types. Concomitant organisms such as *P. carinii, S. aureus,* and cytomegalovirus are more frequent when infiltrates are bilateral, diffuse, and interstitial.

Treatment

A better response to treatment with chemotherapy alone has been reported among patients without prior or existing underlying lung disease. Treatment failures are associated with persistence of cavities in association with isoniazid-resistant organisms. Sputum conversion is generally achieved by 92% of drug-treated patients in the first 6 months of treatment. Consideration of surgical resection of cavities was previously suggested if improvement was not observed after 6 months of treatment. The use of rifampin at a higher dose (600 mg to 900 mg) in the initial therapeutic regimen along with ethambutol and isoniazid has changed this situation, with almost a 100% response rate to chemotherapy.

Treatment for *M. kansasii* disease has been suggested using a triple regimen (isoniazid-rifampin-ethambutol). However, in most instances only smears positive for AFB are available at the onset, and the patient is started on four drugs (including pyrazinamide) to treat conventional tuberculosis empirically. When cultures for *M. kansasii* become available, pyrazinamide can be dropped, as it does not have any activity against *M. kansasii.* At the very least, *M. kansasii* is intermediately susceptible to isoniazid; thus, the raised dose of 600 mg is indicated.

A combination regimen of rifampin and ethambutol for 9 months has been used successfully in Great Britain. Relapse rates (8%) were similar to rates in groups who initially started with combinations of four drugs in the first 2 months. A quadruple regimen is recommended for rifampin-resistant cases. Susceptibility testing using the proportion method may not be reliable in predicting resistance, and minimal inhibitory concentrations (MICs) may differ, especially with isoniazid and streptomycin. Clarithromycin is a promising alternative drug.

M. fortuitum-M. chelonei Complex Disease

M. fortuitum complex includes *M. fortuitum* and *M. chelonei* strains. This is the third most prevalent NTM infection in the United States. Men are likely affected by *M. fortuitum,* whereas women are affected by *M. chelonei.* These mycobacteria are generally cutaneous and pulmonary pathogens.

A rapidly growing organism, *M. chelonei* causes a significant number of pulmonary cases. It is not readily isolated from the environment. As is typical in most NTM disease, bronchiectasis, prior mycobacterial disease, and chronic lung disease from aspiration are found in *M. fortuitum-M. chelonei* complex lung disease.

M. fortuitum was first described in cases of chronic aspiration pneumonia and esophageal achalasia. Bilateral patchy infiltrates are frequent; cavitary disease is not common. A slow, progressive course is characteristic, and response to therapy may be observed with amikacin and cefoxitin. Both isolates (*M. fortuitum, M. chelonei*) are often susceptible to amikacin, cefoxitin, and imipenem, and are partially susceptible to doxycycline. Separately, *M. fortuitum* is also susceptible to ciprofloxacin and sulfonamides, whereas *M. chelonei* is susceptible to tobramycin. Some *M. fortuitum-M. chelonei* isolates have been shown to be susceptible to erythromycin. Both *M. fortuitum* and *M. chelonei* are generally resistant to first-line antituberculosis agents.

M. xenopi Disease

Water is a favorite habitat for *M. xenopi;* it is thermophilic, known to grow at 42°C. It has been reported in outbreaks as a pseudoinfection, mostly in nosocomial settings (contaminated bronchoscopy). Pulmonary disease in AIDS has also been reported. The organism is common in Europe, Asia, and Canada. An outbreak of *M. xenopi* pulmonary disease was described in a Veterans Administration hospital in Connecticut. The nosocomial infection was ascribed to the hospital's hot water system. Predisposing factors were pre-existing lung disease and prior hospitalizations in the same environment. Radiographic findings included nodular/mass lesions, thick-walled cavities, and associated apical pleural changes, singly or in combination. Nosocomially acquired infections were indolent and often asymptomatic. In patients not infected with HIV, sporadic cases have been reported to be asymptomatic, with abnormal chest x-ray findings on routine examination. On the other hand, other *M. xenopi* pulmonary disease has been described accompanied by cough, fever, weight loss, and hemoptysis. It has rarely been reported in the United States among AIDS patients presenting with positive findings on sputum smear and negative radiographic findings. It has also been associated with pre-existing conditions such as alcoholism, gastrectomy, cigarette smoking, and lung cancer. Diagnosis has been made from spontaneous sputum, bronchial washing, and resected lung tissue in a workup to exclude neoplasm. The organism is fairly responsive to antituberculosis agents, especially streptomycin, isoniazid, and para-aminosalicylic acid. The initial recommended regimen is isoniazid, rifampin, ethambutol, and pyrazinamide pending cultures for specific mycobacteria.

DIAGNOSIS OF NONTUBERCULOUS MYCOBACTERIAL PULMONARY DISEASE

A general approach to diagnosis in NTM pulmonary disease was recommended in 1990. Some controversies and disagreements still exist, however. A sputum culture positive for NTM must be assessed by determining and defining transient contamination versus true pulmonary disease versus prolonged colonization, usually in the presence of chronic lung disease. Contamination of specimen culture is defined by a single positive culture among several specimen collections and by absence of clinical features or evidence of NTM disease. True pulmonary infection/disease is more difficult to distinguish from NTM colonization. For colonization, bronchial hygiene has been recommended as the first therapeutic step, with or without antimycobacterial drugs. This has been successfully employed with *M. kansasii* and MAC. It has not been studied in other NTM colonization but would be presumed to work as well. In the evaluation of such situations, fungal, neoplastic, and *M. tuberculosis* disease must be considered in the differential diagnosis.

For patients with a radiologic cavitary infiltrate, contamination must be ruled out. Thus, the presence of mycobacteria must be confirmed in two or more sputum or other respiratory specimens on smear and/or by a moderate or heavy growth on culture. Other reasonable diagnoses must have been excluded.

For patients with radiologic noncavitary infiltrate, the criteria are as follows: (1) Two or more sputum or other respiratory specimens (bronchial washings, endotracheal aspirates) must show a positive stain for AFB and/or moderate to heavy growth on culture; (2) after bronchial hygiene has been attempted with or without 2 weeks of antimycobacterial therapy and the NTM does not clear on smear, disease may be presumed when (3) other causes for the infiltrate have been ruled out.

If a sputum evaluation is nondiagnostic in the presence of either a cavitary or noncavitary infiltrate and other diagnoses cannot be excluded, an invasive procedure such as lung biopsy is recommended. True disease is confirmed by the presence of changes consistent with mycobacterial histopathology (i.e., granulomatous inflammation and/or a positive tissue stain for AFB). When two or more sputum specimens are positive for NTM in low numbers and accompanied by the histologic changes described, the diagnosis is presumptive. Clinically, a symptomatic patient with a single culture positive for NTM and a noncavitary infiltrate may require empiric therapy.

Solitary Nodules in Nontuberculous Mycobacterial Infection

Sixty percent of asymptomatic solitary pulmonary nodules are caused by MAC. This entity is generally discovered during routine chest examination. Excellent outcome is observed following resectional surgery in cases treated preoperatively with a standard antituberculosis regimen (two drugs) for positive AFB smears and compatible histology before culture reports become available. There are generally no postoperative complications or dissemination of infection.

Endobronchial Nontuberculous Mycobacterial Infection

Endobronchial mycobacterial disease is infrequently reported, because the ready availability of sputum for diagnosis in most cases of NTM disease precludes bronchoscopy. A few reports have noted that patients having mycobacterial disease may present with normal lungs and a mediastinal mass mimicking malignancy, seen with MAC, *M. kansasii,* and rarely *M. fortuitum.* In the reports, bronchoscopic findings have included ulcerating mass lesion and submucosal masses obstructing bronchial orifices, with resulting segment collapse.

SURGICAL CONSIDERATIONS

The outcome of surgical resection for NTM pulmonary disease is poorer than that of similar resection for multidrug-resistant *M. tuberculosis* pulmonary disease. Complication rates are high, especially in patients with previous chest irradiation or pulmonary resection, perioperative positive sputum cultures, and multimicrobial lung infection. Bronchopleural fistulas, prolonged air leak, and space problems may be frequent, although the use of muscle flaps has reduced these complications. Consideration of early resection for localized disease is still recommended in NTM. Preoperative treatment for at least 3 months and continuation of drug therapy postoperatively are also recommended.

CHAPTER

30 Embolic Infections of the Lungs and Lipoid Pneumonia

Richard J. Blinkhorn Jr.

R. J. Blinkhorn Jr.: MetroHealth Medical Center, Cleveland Ohio 44109.

EMBOLIC INFECTIONS

Embolic infections may result from secondarily infected bland infarcts or from septic emboli. Pulmonary infarction usually arises from thrombotic emboli situated in the deep venous system of the lower extremities (Chapter 66). Secondary infection of the infarcted lung occurs most often as a result of invasion by way of the airway but occasionally via the bloodstream. Autopsy studies indicate that the incidence of secondary infection is between 4.0% and 5.0%, but actual incidence is probably lower, because infection results in a higher case fatality rate. Predisposing factors are cardiac decompensation and oropharyngeal sepsis. Empyema may be the presenting feature.

The diagnosis may be suspected by persistent fever and leukocytosis and the production of purulent or fetid sputum. Chest radiography confirms the presence of an abscess in the previously infarcted area, with or without pleural fluid. Bacteriologic diagnosis is made by the examination of sputum, occasionally from positive blood cultures, and from examination of pleural fluid if it is present. Oropharyngeal anaerobic bacteria are commonly involved, as are *Staphylococcus aureus* and gram-negative bacilli. In the differential diagnosis, cavity formation caused by ischemic necrosis in the center of large infarcts resulting from inadequate bronchial arterial collateral circulation should be considered.

Septic emboli of the lungs most commonly arise in the right side of the heart (endocarditis) or in the peripheral veins, where the underlying process is septic thrombophlebitis. Other, less common sites of origin include the head and neck (postanginal sepsis, mastoiditis, dental infections), the pelvic veins of women post partum (septic pelvic thrombophlebitis), and the central veins when catheters are placed therein for prolonged administration of therapeutic biologic products. The latter site has become more important as the numbers of patients with acquired immunodeficiency syndrome (AIDS) or advanced cancer who require total parenteral nutrition has increased. Similar embolization may accompany suppurative thrombophlebitis of the internal jugular vein from deep infections of the pharynx and tonsils, known as *postanginal sepsis* or *Lemierre's syndrome.*

The presenting clinical picture usually is that of the underlying disease, although occasionally the primary manifestations are related to the lungs. The pulmonary signs are pleuritic pain, cough, and eventually purulent sputum. The radiographic findings have been well characterized. There may be areas of consolidation with subsequent suppuration and necrosis, especially in *S. aureus* infection (Fig. 1). More often, small, localized infiltrates are scattered through both lungs that rapidly break down to form thin-walled cavities (Fig. 2). On occasion, necrosis causes a piece of lung tissue to be sequestered in the centers of such nodules, with the development of an intracavitary loose body simulating a “target.” Computed tomography (CT) is useful in diagnosis. Typical CT appearances include multiple peripheral nodules, a feeding vessel sign, cavitation, wedge-shaped lesions abutting the pleurae, and air bronchograms within the nodules.

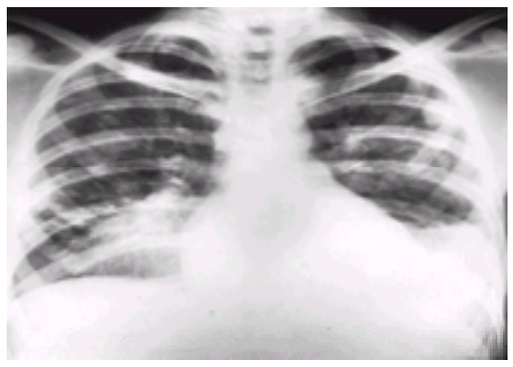

FIG. 1. Embolic lesions of lung associated with submandibular *S. aureus* infection in a 30-year-old man.

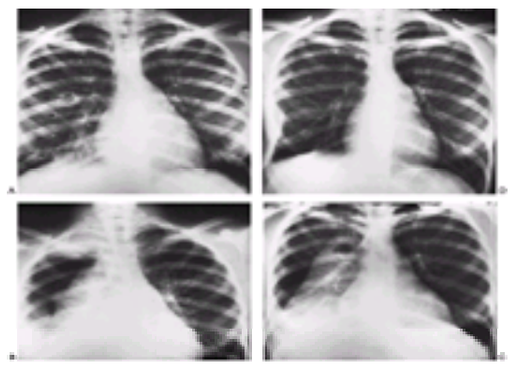

FIG. 2. Serial chest roentgenograms taken during a 6-month period in an 18-year-old girl with pelvic inflammatory disease demonstrate multiple metastatic lung abscesses caused by *Bacteroides* and microaerophilic streptococci (**A**) and paravertebral empyema (**B**) with gas formation (**C**), which eventually resolved following drainage (**D**). Note multiple abscesses (*arrows,* A.)

In Lemierre's syndrome, the common etiologic agent is an anaerobic organism, especially *Fusobacterium.* When pelvic veins are infected, the agent is generally an anaerobe of the *Bacteroides* group. *S. aureus* is the usual culprit from other sites. Treatment should be directed at the underlying condition and may include surgical drainage, removal of infected catheters, and administration of appropriate antibiotics. Progression of the lung disease to empyema requires repeated aspiration, tube drainage, or thoracotomy.

LIPOID PNEUMONIA

The inflammatory reaction associated with the presence of oil or fat in the alveoli is known as *lipoid pneumonia.* The lipid material may originate in the lung itself, or it may be aspirated or inhaled into the lung.

Endogenous Lipoid Pneumonia

In endogenous lipoid pneumonia, the lipid material consists of cholesterol and its esters, released during the breakdown of cell walls in atelectatic pulmonary tissue distal to an obstructed airway. Endogenous lipoid pneumonia may also be seen in association with long-standing tuberculosis, chronic pulmonary abscesses, or bronchiectasis. The usual cause of obstruction in the airway is tumor. In primary or idiopathic endogenous lipoid pneumonia, there is no underlying condition to explain the process. In children, coexisting endogenous lipoid pneumonia and pulmonary alveolar proteinosis have been reported as complicating otherwise benign pulmonary disorders.

The clinical presentation is that of the underlying bronchogenic tumor or chronic infection. Fever, chills, productive cough, and pleuritic chest pain are common. No predisposing conditions that favor aspiration are present, nor is there any history of ingestion of oily substances. The chest radiograph shows a segmental or lobar consolidation with many variations, depending on the underlying condition (Fig. 3). Neither expectorated sputum nor bronchial washings contain lipid-laden macrophages. Only after open lung biopsy or lobectomy is the diagnosis established. The lung is golden-yellow in appearance, and the bronchial lymph nodes often are enlarged. Under the microscope, a dense infiltrate of foamy macrophages containing homogeneously distributed vacuoles of fat can be seen (Fig. 4). The lipid material may form the cleft-like crystals of cholesterol after extrusion into the parenchyma.

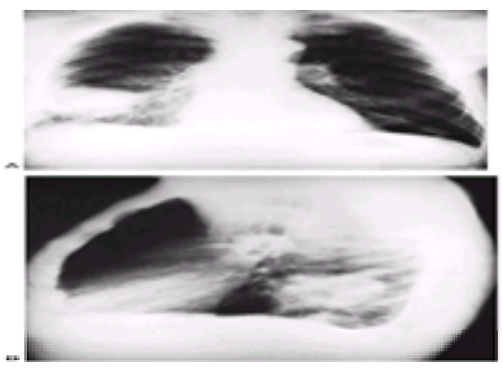

FIG. 3. Posteroanterior (**A**) and lateral (**B**) chest roentgenograms showing a well-circumscribed homogeneous infiltrate in a patient with endogenous lipoid pneumonia. (Courtesy of Dr. Robert Pugatch.)

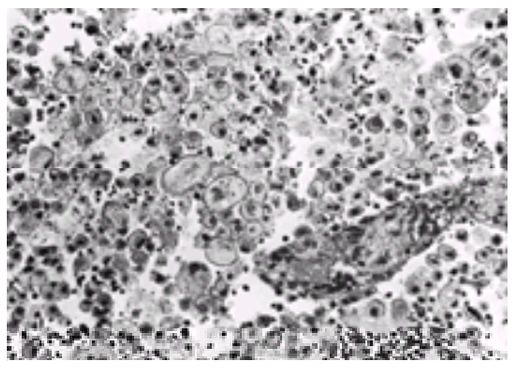

FIG. 4. Microscopic section of lobectomy specimen obtained from patient whose roentgenograms are shown in Fig. 3. Foamy macrophages are consistent with cholesterol pneumonia. (Courtesy of Dr. Y. Jung Legg.)

Exogenous Lipoid Pneumonia

Exogenous lipoid pneumonia is an inflammatory reaction to the aspiration or inhalation of oil or fat. The disease is seen mainly in children, elderly debilitated adults, or individuals with underlying conditions predisposing to aspiration (e.g., altered consciousness, difficulties in swallowing resulting from neurologic disease, or disorders of esophageal motility). There is usually a history of prolonged use of mineral oil in laxatives or nose drops. Undoubtedly, exogenous lipoid pneumonia now is less frequent than in the 1930s, when it was seen during almost 9% of autopsies in children and 1.2% in adults. Retrospective studies since the 1950s, nevertheless, indicate that the disease persists. A survey of 389 chronically ill patients showed that 58 (15%) had exogenous lipoid pneumonia, and 87% of them admitted to the ingestion of mineral oil or oil-containing medication or the use of oily nose drops.

It is reasonable to postulate that the oil reaches the lungs because of an incompetent lower esophageal sphincter and aspiration from the esophagus during the night. Radiopaque oily material instilled into the nose of healthy people during sleep often may be detected in chest radiographs the next morning. When instilled intratracheally, oil fails to provoke two important protective responses of the airway: glottic closure and coughing. In addition, it overcomes another defense mechanism, mucociliary transport. Although mineral oil does not affect ciliary beating, it markedly impairs the movement of the mucous blanket by altering the physical properties of the secretions.

The nature of the oil reaching the alveoli determines the pathologic response. Simple vegetable oils provoke little response and may be cleared from the lung largely by expectoration. Animal oils cause inflammation involving mononuclear and giant cells, proliferation of connective tissue, and variable necrosis. Mineral oil is rapidly emulsified and elicits a brisk outpouring of alveolar macrophages, which ingest oil globules. Later, a foreign-body granulomatous reaction is seen, and with time, a proliferative fibrotic reaction develops. Although most of the oil remains within alveoli, some droplets and lipid-laden macrophages may travel via lymphatic vessels to regional bronchial lymph nodes.

The clinical presentation may be one of chronic cough, wheezing, dyspnea, and low-grade fever. About half of the patients have no symptoms, their disease being evident only because of abnormal findings on a chest radiograph taken for other reasons (Fig. 5). In early disease, the acinar location of oil causes a homogeneous dense consolidation, often with air bronchograms and a “spun glass” appearance. A pattern of reticular markings can develop as emulsified oil enters the interstitium, and Kerley B lines may be visible. Fibrosis may result in nodules or masses. CT may be useful in detecting areas of consolidation with low attenuation values typical of fat. Although early reports of magnetic resonance imaging (MRI) in lipoid pneumonia indicated that the high signal intensity observed on T_1-weighted images (equal to subcutaneous fat) were indistinguishable from findings of hemorrhagic infiltrates, recent studies suggest that the use of chemical-shift MRI can differentiate these two conditions.

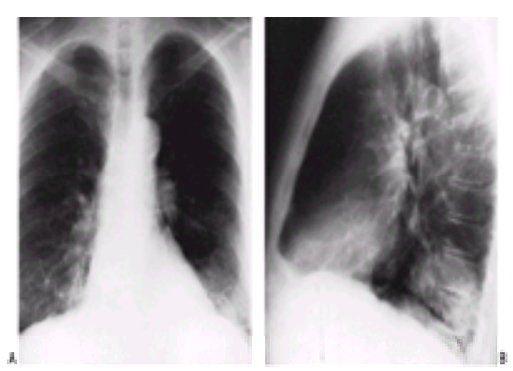

FIG. 5. Posteroanterior (**A**) and lateral (**B**) chest roentgenograms demonstrating a well-circumscribed homogeneous retrocardiac infiltrate in the left lower lobe. The patient was asymptomatic and initially denied taking any medicines. Repeated questioning revealed daily ingestion of mineral oil using a gulping technique. Results of cytology, stain for acid-fast bacilli, and Sudan stain for fat in specimens of expectorated sputum were negative.

The diagnosis may be confirmed by the finding of macrophages containing stainable fat in the sputum, bronchial washings, or bronchoalveolar lavage (BAL) fluid (Fig. 6). BAL fluid may be grossly oily. Transbronchial or open lung biopsy may be necessary for cases in which the diagnosis cannot otherwise be established. Stains for oil in tissue must be performed on frozen sections, because routine preparation for paraffin-embedded samples removes the oil.

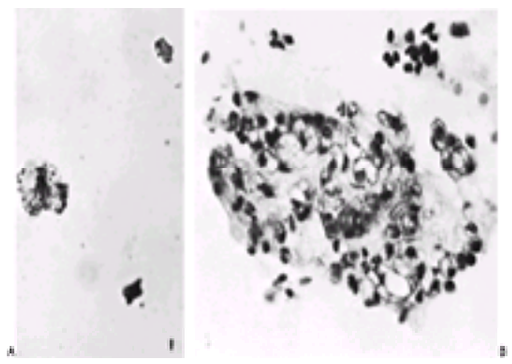

FIG. 6. Bronchial washings from patient whose roentgenograms are shown in Fig. 5. **A:** Hematoxylin and eosin stain shows typical clear areas of lipid-laden macrophages. **B:** Sudan black stain reveals oil. In this setting, such findings are considered diagnostic of exogenous lipoid pneumonia. (Courtesy of Dr. J. Merriam.)

A careful study of BAL fluid from seven patients with mineral oil pneumonia was recently reported. Increased numbers of polymorphonuclear leukocytes, eosinophils, and lymphocytes were indicative of a cell-mediated immune response; the authors postulated that this response accounted for the later appearance of interstitial fibrosis. The alveolar macrophages contained large vacuoles in which liquid paraffin could be identified by thin-layer chromatography and infrared spectroscopy.

Secondary infection may be demonstrable in and around areas of lipoid pneumonia. Especially important is infection with rapidly growing mycobacteria, as discussed in Chapter 29.

The most important aspect of treatment is immediate cessation of use of the oily material. Underlying conditions, such as swallowing dysfunction and disorders of esophageal motility, should be corrected whenever possible. Mycobacterial infection should be treated with appropriate drugs (Chapter 29). Repeated BAL with physical removal of oily material may be helpful in early cases, at least theoretically. Resection may be beneficial for selected patients who have circumscribed areas of disease.

ASPIRATION PNEUMONIA

Pathogenic organisms can invade and infect the lung through four pathways: aspiration, inhalation, hematogenous seeding, and contiguous spread. Aspiration of pathogens from a previously colonized oropharynx is the primary pathway by which organisms gain entrance to the lungs, and thus in a broad sense, most pneumonias are aspiration-related. However, when the term *aspiration pneumonia* is used, it is meant to refer to the development of a radiographic infiltrate in the setting of either a witnessed episode of gross aspiration or risk factors for aspiration.

Aspiration pneumonia, like other respiratory tract infections, usually occurs in patients with underlying disease. Although normal adults commonly aspirate while sleeping without any obvious health effects, pneumonia can develop after episodes of aspiration in patients with certain underlying diseases that predispose to host defense impairment. Other factors that modify the risk for pneumonia after aspiration, besides host factors, include certain characteristics of the aspirated material. The pH, tonicity, and volume of the aspirate in addition to the frequency of aspiration all contribute to the development of pneumonia.

Not all infiltrates that follow aspiration represent an infectious process. In some patients, depending on the type of material aspirated, a noninfectious inflammatory response develops that results in pulmonary leukocyte sequestration. Most of these noninfectious infiltrates resolve, but 25%–50% progress to infectious pneumonia or fulminant acute lung injury. In a study by Croghan and colleagues of patients in a nursing home who were evaluated for aspiration with videofluoroscopy, pneumonia developed in 50% of patients with documented aspiration during a 12-month period and in 12.5% of patients without aspiration. In that study, the volume of the aspirate was directly related to the risk for pneumonia; pneumonia developed in 43% of patients with mild aspiration (of thin liquids), and in 67% of patients with severe aspiration (of material of all consistencies at almost every swallow). In a study by Bynum and Pierce, 50 patients with significant aspiration were evaluated. Rapid clearing of infiltrates was noted in 62%, and adult respiratory distress syndrome (ARDS) developed in 12%. Infectious pneumonia developed in the remaining 26% of patients, often after initial improvement.

Risk Factors

Risk factors for aspiration pneumonia are numerous and complex. One general way of categorizing these risks is according to whether they are host factors or characteristics of the aspirated material. Host factors lead to impaired host defenses and/or increased exposure to bacteria because of an increased risk for aspiration. Usually, it is the combination of disease-related immune impairments and exposure to large numbers of aspirated bacteria that leads to pneumonia.

Host Factors

Host factors that predispose to aspiration pneumonia are numerous (Table 1); they either impair host defenses or enhance the risk for aspiration. A number of conditions, such as diabetes mellitus, congestive heart failure, malnutrition, chronic obstructive lung disease, renal failure, and malignancy, can impair host defenses. Diabetes is associated with neutrophil dysfunction, including diminished chemotaxis and impairment of phagocytosis. In patients with congestive heart failure, clearance of pneumococci and staphylococci from the respiratory tract can be impaired as a result of pulmonary edema. If liver disease is complicated by cirrhosis, atelectasis from pleural effusions and/or ascites can result in stagnation of secretions. Cirrhosis is also associated with diminished leukocyte chemotaxis in response to inflammation, depressed levels of complement, and defects in cellular immunity. Renal failure can increase the rate of colonization of the oropharyx by gram-negative bacteria and *Staphylococcus aureus* and can lead to complement deficiency, impaired cellular immunity, and, in animal models, decreased clearance of staphylococci and *Pseudomonas aeruginosa* along with an increase in the binding capacity of buccal cells for gram-negative bacteria. Neoplastic disease can affect host defenses either directly or as a consequence of therapy. For example, neutropenia, endobronchial obstruction, and impaired cough reflex are common in cancer patients and can all predispose to the development of pneumonia.

Host risk factors	Aspirate risk factors
Underlying serious illness	Fluid pH ≤ 2.5
Altered sensorium	Large particles
Stroke	Large volume (1 mL/kg)
Dysphagia	Hypertonic fluid
Gastroesophageal reflux	Bacterial contamination
Postgastrectomy	
Xerostomia	
Feeding tube	
Periodontal disease	

TABLE 1. *Aspiration pneumonia*

Host factors that predispose to aspiration as the result of neurologic, mechanical, and/or contractile dysfunction of the esophagus and upper airway are listed in Table 2. They include stroke, dysphagia, gastroesophageal reflux, altered sensorium, placement of a feeding tube, and the postgastrectomy state. Once material has gained access to the airways, the clinical response depends on the characteristics of the aspirate. If the aspirate is small in volume but highly contaminated with bacteria, then host defenses may be overwhelmed and pneumonia can result. If the aspirate is large in volume but relatively less contaminated, then pneumonia will result only if the aspirated organisms are highly virulent or the host defenses are severely abnormal. Most episodes of aspiration involve oropharyngeal flora, which can achieve extremely high concentrations in the presence of periodontal disease. Whereas normal saliva contains 10^8 organisms/mL, saliva from a patient with gingivitis may contain 10^{11} organisms/mL. In periodontal disease, anaerobes predominate among the oral flora.

Neurologic	Mechanical	Contractile
Unconsciousness	Obesity	Gastroesophageal reflux
Laryngeal nerve damage	Head and neck surgery	Diabetic gastropathy
Advanced age	Bowel obstruction	Critical illness
Acute stroke	Abdominal surgery	Trendelenburg position
Pseudobulbar palsy	Enteral feeding	Protracted vomiting
Seizures	Pregnancy	
Parkinson's disease	Endotracheal intubation	
General anesthesia	Tracheostomy	
Insulin-induced hypoglycemia		
Alcoholism		
Drug abuse		
Cardiac arrest		
Metabolic encephalopathy		

TABLE 2. *Conditions that increase the risk for aspiration*

Xerostomia has recently been shown to predispose to aspiration pneumonia, probably reflecting the fact that normal saliva flushes the oral cavity and maintains a bacterial level of $<7 \times 10^8$ organisms per milliliter. With xerostomia, the normal salivary flow rate is diminished and patients are at risk for gingivitis, and these two factors can result in bacterial counts that are higher than normal. When a patient with xerostomia aspirates, the lower respiratory tract is exposed to larger numbers of bacteria than normal, and aspiration pneumonia can result.

When aspiration develops in the hospitalized patient, many of the same host risk factors prevail. However, for patients in an intensive care unit, particular issues to consider in evaluating aspiration risk include patient position, site of enteral feeding (stomach or small bowel), volume of gastric contents, and size of any feeding tube that is used. Studies have suggested a reduced risk for aspirating gastric contents in patients who are maintained in a semi-erect position, in those whose feeding tubes are placed in the small bowel, and in those with small-bore feeding tubes.

Characteristics of the Aspirate

The characteristics of aspirated material play an important role in the pathogenesis of pneumonia. As only 25%–50% of all cases of aspiration progress to pneumonia, infection is particularly likely if the patient aspirates contaminated material. Pneumonia may also develop in patients who aspirate noninfectious material as a result of the lung injury caused by certain types of material.

Aspiration of very toxic, irritant material with high concentrations of hydrogen ion (pH ≤2.5) results in a chemical pneumonitis. This initial type of lung injury is typically noninfectious and characterized by a predominance of neutrophils. The magnitude of lung injury is directly related to the volume and hydrogen ion concentration of the aspirated material. In animal models of aspiration, acid pneumonitis does not occur unless the pH is <2.5. The resulting damage renders the mucosal barrier of the lower respiratory tract incompetent and places the patient at risk for infectious pneumonia as new sites for bacterial binding are created.

Large-volume and large-particle aspirates predispose to pneumonia by a different mechanism. A number of studies have shown that the majority of large-volume and large-particle aspirates are composed of vegetable matter, which can mechanically obstruct the lower airways and cause atelectasis, stagnation of secretions, and thus an increased risk for infection. In addition, aspirates containing particulate matter can be contaminated by bacteria, as oral secretions are often heavily colonized by potentially pathogenic organisms. In hospitalized patients, the stomach can harbor large numbers of enteric gram-negative bacteria if the gastric pH is >3.5 to 4.0. In patients in the intensive care unit, the risk for development of pneumonia is great when morning gastric pH is high (>3.5). Gastric pH may be elevated by enteral feeding, antacids, or H_2 antagonists. The role of prophylaxis for intestinal bleeding in the pathogenesis of pneumonia is uncertain, with continuing controversy about the role of the stomach in causing pneumonia. In addition, H_2 antagonists have not uniformly led to an increased risk for pneumonia in all studies, and their impact must be considered in relation to gastric volume, patient position, and site of enteral feeding.

Classification of Aspiration Syndromes

The aspiration of material into the tracheobronchial tree can result in a number of clinical consequences, ranging from no evident reaction to respiratory failure, ARDS, and/or death. Three different types of aspiration syndromes can result, depending on the type of material entering the tracheobronchial tree. These syndromes, which are not mutually exclusive and can occur in combination, include the irritant-toxic type, the inert-nontoxic type, and the infectious type.

The irritant-toxic syndrome is caused by aspiration of acidic liquids (pH ≤2.5) and/or fine particulate material; it results in acute pneumonitis or, if severe enough, ARDS. The inert-nontoxic syndrome is caused by aspiration of large particulate matter and/or large volumes of fluid; the clinical response ranges from chronic respiratory symptoms (e.g., cough and wheezing) to atelectasis or, if massive enough, sudden death. Infectious aspiration syndromes result from the entry of potentially pathogenic organisms into the lower airways. Although pneumonia is part of the infectious aspiration syndrome, other infectious syndromes can result, including lung abscess, necrotizing pneumonia, and empyema.

As community-acquired aspiration pneumonia usually involves anaerobic bacteria, aspiration pneumonia should be viewed as part of a continuum that can progress to cavitation (lung abscess) or even development of empyema. If aspiration pneumonia is not treated, necrotizing abscess formation follows in 8 to 14 days, usually in a peripheral location, and is characterized by the expectoration of putrid sputum. When anaerobic lung infection occurs, the pleura is commonly involved, being affected alone or in combination with parenchymal tissue in up to half of all patients.

Mendelson's syndrome (acid pneumonitis) is an example of irritant-toxic lung injury; it usually follows a witnessed episode of aspiration of acidic gastric fluid. Initially, an asthma-like reaction occurs, but within 2 hours a patient may exhibit dyspnea, cough with nonpurulent sputum, bronchospasm, bilateral lower lobe infiltrates, hypoxemia, and decreased lung compliance. In Mendelson's original description of this syndrome, no deaths were documented, although subsequent investigators have reported mortality rates as high as 70%, with some patients progressing to ARDS.

Pathogenesis

Aspiration-induced lung injury is believed to be biphasic, with the volume and pH of the material dictating the severity of the response. The first phase of injury is characterized by an acute localized response to the physical effects of the material aspirated, which, in the case of acid-induced lung injury, is a consequence of the chemical burn. This local response is immediate and limited to the areas of direct contact with the acid; the amount of resulting injury is directly related to the acidity and volume of the aspirated material.

The first-phase response results in local inflammation; this triggers a second phase characterized by a generalized neutrophilic infiltration, occurring within 2 to 6 hrs after aspiration. The initial response, although local in nature, causes cell injury and death secondary to the physical insult of the aspirated material. Pathologically, peribronchial hemorrhage, bronchial epithelial cell death, and pulmonary edema can be seen. This in turn can lead to the release of multiple inflammatory cytokines and proteases. Once released, these inflammatory substances set off a cascade of responses that result in microvascular permeability defects, pulmonary leukocyte sequestration, fibrinous alveolar exudation, tissue hypoxia, and hyaline membrane formation, all of which characterize the acute lung injury.

Neutrophils are thought to be the cells primarily responsible for the second-phase response to injury, and several inflammatory mediators have been identified as potential neutrophil chemoattractant agents. In one animal model, acid-induced lung injury was mediated by a mechanism dependent on interleukin-8 (IL-8). IL-8, a potent chemoattractant for neutrophils, also primes neutrophils for activation and upregulates neutrophil adhesion molecules on endothelial cells. Acid-induced abnormalities of oxygenation and enhanced amounts of extravascular lung water did not develop in animals given anti-IL-8 antibodies, either as pretreatment or 1 hr after acid aspiration.

Aspiration-induced neutrophil sequestration in the pulmonary vasculature can lead to lung injury in several ways. In one study, the complement system was shown to play a role; animals pretreated with a complement-receptor inhibitor had reduced lung edema, decreased alveolar protein accumulation, and improved tissue oxygenation after acid aspiration when compared with untreated animals. There was no effect of complement inhibition on pulmonary leukocyte sequestration, possibly indicating that neutrophils activate the complement system and cause lung injury via this mechanism. Another possible mechanism of lung injury in these patients is the release of high levels of neutrophil-derived serine proteases, which can overcome the normal antiprotease defense mechanisms of the lungs. In one study using a model of acid-induced lung injury, high levels of serine proteases were found in the bronchoalveolar fluid of injured animals. This pathophysiologic response can impair both local and systemic lung defense mechanisms and predispose to pneumonia, even if the aspirated material is sterile.

Bacteriology

The bacteriology of aspiration pneumonia is intimately tied to the flora of the oropharyngeal cavity. Under normal circumstances, the saliva of the oral cavity contains 10^8 organisms/mL, with a predominance of anaerobic organisms. Individuals with poor dental hygiene or gingivitis can have anaerobic bacterial levels of 10^{11}/mL of saliva, and patients with underlying illness who are hospitalized for prolonged periods can become colonized by enteric gram-negative bacilli. The majority of cases of aspiration pneumonia are caused by anaerobic organisms originating in the oropharynx and are usually polymicrobial, with at least two anaerobic organisms and sometimes a mixture of aerobic and anaerobic pathogens.

The bacteriology of aspiration pneumonia has not changed much during the last few decades, although the taxonomy of some of the involved pathogens has. For example, some organisms originally classified in the *Peptostreptococcus* genus have now been reclassified in the *Streptococcus* genus, e.g., *S. intermedius.* With this in mind, many studies in the 1970s and 1980s documented anaerobic streptococci, *Fusobacterium nucleatum,* and *Prevotella melaninogenicus* (formerly classified in the genus *Bacteroides*) as the three major pathogens in aspiration pneumonia. It was once thought that *B. fragilis* was a significant pathogen in anaerobic lung infections, although recent data make this seem less likely.

Aerobic bacteria are found as either primary pathogens (approximately 10% of the time) or as coinfectors (approximately 40%); they include *Streptococcus* species, *S. aureus, Klebsiella pneumoniae, Escherichia coli, E. cloacae,* and *P. aeruginosa.* A more recent study examining early aspiration pneumonia in intensive care unit patients has documented a more virulent profile of aerobic pathogens. In this series, no anaerobes were isolated, but in those patients who had community-acquired early aspiration pneumonia, *Streptococcus pneumoniae, S. aureus, E. coli, E. cloacae, Haemophilus influenzae, Streptococcus viridans,* and *P. aeruginosa* were isolated alone or in combination. In those patients who aspirated in the hospital, *S. aureus, H. influenzae, Serratia marcescens, Morganella morganii, Candida albicans, K. pneumoniae, P. aeruginosa,* and *Proteus mirabilis* were isolated alone or in combination by a protected specimen brush. These data suggest that the bacteriology in severely ill patients with underlying medical diseases may differ from that of patients with aspiration pneumonia that is not severe.

Treatment

The two major modes of therapy for aspiration pneumonia are administration of antibiotics and supportive care. In the setting of a witnessed or suspected aspiration, antibiotics should be started if an infiltrate is present. If the infiltrate clears in 24 to 48 hrs, the pneumonitis was likely noninfectious, and therapy can be discontinued. If no infiltrate is present, therapy can be withheld provided that the patient is followed with serial chest radiographs. Antibiotic therapy for patients with aspiration pneumonia should be based on an assessment of the severity of illness (Table 3), where the infection was acquired (community versus hospital), and the presence or absence of risk factors for gram-negative colonization (Table 4).

Respiratory rate >30 breaths per minute
Need for mechanical ventilation
Chest radiographic findings:
50% increase in the infiltrate in 48 hours
Bilateral multilobar involvement
Presence of shock
SIRS (systemic inflammatory response syndrome) or need for vasopressors to support blood pressure
Severe lung injury (PaO_2/FIO_2 ratio ≤ 250 mmHg)
Urine output <20 mL/h
Acute renal failure requiring dialysis

TABLE 3. *Severe aspiration pneumonia*

Malnutrition
Severe illness
Coma
Intubation
Diabetes
Prior surgery
Lung disease
Renal failure
Prior antibiotic use
Hypotension
Cigarette smoking
Prolonged hospitalization

TABLE 4. *Risk factors for gram-negative colonization*

If pneumonia is acquired in the community, then an anaerobic pathogen is more likely than if the infection was acquired in the hospital. In community-related aspiration pneumonia, the antibiotic regimen should be directed against the oral anaerobes (e.g., anaerobic streptococci, *F. nucleatum,* and *P. melaninogenicus*). Patients should be treated empirically without collection of sputum for culture by expectoration or invasive aspiration. The initial empiric antibiotic used in this case may be clindamycin, penicillin alone, or a combination of penicillin and metronidazole. Some data show a lower failure rate in patients treated with clindamycin compared with penicillin for anaerobic pleuropulmonary infection, suggesting a primary role for clindamycin in this infection. Recent data from patients with community-acquired lung abscess found resistance rates to penicillin, metronidazole, and clindamycin of 21%, 12%, and 5%, respectively, again supporting a primary role for clindamycin in anaerobic lung infections.

Clindamycin is a bacteriostatic antibiotic that binds to the 50S ribosomal subunit of bacteria and inhibits protein synthesis. Clindamycin potentiates opsonization and phagocytosis of bacteria, and has a prolonged effect that suppresses bacterial growth after concentrations fall below the minimal inhibitory concentration for the target organism. Clindamycin has antibacterial activity against most anaerobes, including *Bacteroides, Prevotella, Fusobacterium, Clostridium,* and *Porphyromas* species, and against aerobic gram-positive cocci, such as group A, B, C, and G streptococci, microaerophilic streptococci, *S. viridans,* most pneumococci, and methicillin-sensitive *S. aureus.*

The route of antibiotic administration is determined by the severity of the pneumonia and whether the patient is treated as an outpatient or inpatient. Treatment may be given orally on an outpatient or inpatient basis, depending on the severity of illness, but initial therapy in severely ill and hospitalized patients is usually by the intravenous route.

The above antibiotic regimen needs be modified if the patient has severe infection, hospital-acquired aspiration, or risk factors for gram-negative colonization (Table 4). In this situation, the likelihood of infection with a virulent gram-negative bacillus or an aerobic organism is greater, and therefore additional antibiotic coverage is required. Sputum or tracheal aspirate may be helpful in identifying high-risk pathogens, such as *P. aeruginosa,* in intubated patients. After empiric therapy has been started, culture results can be useful to determine the presence or absence of infection with *P. aeruginosa.* In this patient population, clindamycin plus an antibiotic with activity against gram-negative bacilli is recommended, or a single antibiotic with activity against anaerobes and gram-negative bacteria is adequate (e.g., ampicillin/sulbactam or ticarcillin/clavulonate) (Table 5). If risk factors for infection with *P. aeruginosa* are present, we recommend empiric antibiotic therapy with a dual anti-*Pseudomonas* combination until culture results are known.

Community-acquired infection that is not severe	Hospital-acquired infection or severe community infection
Oral route	**Intravenous route**
Penicillin	Clindamycin plus ciprofloxacin[a]
Penicillin plus metronidazole	Clindamycin plus aminoglycoside[a]
Clindamycin	Ampicillin/sulbactam
Amoxicillin/clavulanate	Cefoxitin
Intravenous route	Piperacillin[a]
Penicillin	Imipenem[a]
Penicillin plus metronidazole	
Clindamycin	
Ampicillin/sulbactam	
Ticarcillin/clavulanate	

[a] If any of the following are present, *P. aeruginosa* infection is possible: prior antibiotic use, prolonged hospital course, and/or severe pneumonia. If *P. aeruginosa* infection is suspected, dual anti-*Pseudomonas* therapy should be initiated with a β-lactam/aminoglycoside or a β-lactam/quinolone combination.

TABLE 5. *Initial antibiotic regimen for aspiration pneumonia*

LUNG ABSCESS

A lung abscess is defined as a localized (usually >2 cm in diameter), suppurative, necrotizing process occurring within the pulmonary parenchyma. Several processes, either respiratory or systemic, can lead to abscess formation. Most abscesses are primary and result from necrosis in an existing parenchymal process, usually an untreated aspiration pneumonia. Among the causes of necrotizing pneumonitis, infections and neoplasms are the most frequent. A secondary abscess is one that complicates either a septic vascular embolus (e.g., right-sided endocarditis) or a bronchial obstruction (e.g., aspirated foreign body).

Classically, anaerobes have been identified as the most common cause of lung abscess, although aerobic bacilli, fungi, parasites, and mycobacteria may also be responsible. Among neoplastic causes, primary squamous carcinoma of the lung is the most common malignancy associated with abscess formation. Between 8% and 18% of lung abscesses have been associated with neoplasms in all age groups, but in patients whose age is >45 years, the association approaches 30%.

The incidence of lung abscess has declined by as much as 10-fold during the last few decades, presumably as a result of improved treatment regimens for pneumonia. Accompanying this decrease in incidence is a decrease in mortality to between 5% and 10%, with a recent series reporting a mortality rate of 2.4% in community-acquired lung abscess and 66.7% in hospital-acquired abscess. Diagnosis and treatment have changed little through the years, as lung abscesses are uncommon and it is difficult to obtain enough patients to perform controlled clinical trials. As will be discussed, administration of antibiotics is the most important treatment, as in aspiration pneumonia. The role of the newer antimicrobial agents remains controversial, although they may represent an advance over traditional therapeutic agents (penicillin), especially as drug-resistant bacteria become more prevalent.

Pathogenesis

Most lung abscesses are caused by infectious agents, such as bacteria, fungi, parasites, and mycobacteria. In the majority of cases, a mixed bacterial flora can be found, with anaerobes being present in up to 90% of cases. Aerobic bacilli may be present in up to 50% of patients, but in most cases they coexist with anaerobes, and in only 10% of cases are they the sole responsible pathogens.

As in aspiration pneumonia, the basis of lung abscess formation is aspiration of infectious oropharygeal material in a host who cannot adequately clear the infectious challenge. Individuals predisposed to lung abscess formation are those with host defense defects in the setting of risk factors for aspiration (Table 1 and Table 2). Aspiration, as described above, is more likely in patients who have neurologic, mechanical, and muscular dysfunction associated with alcoholism, seizure disorders, drug overdose, general anesthesia, protracted vomiting, or neurologic disorders such as cerebrovascular accidents, myasthenia gravis, amyotrophic lateral sclerosis, and other bulbar processes.

In addition to having risk factors for aspiration, patients predisposed to the formation of lung abscess are exposed to large concentrations of potentially pathogenic bacteria, usually orogingival in origin. It appears that the size of the aspirated bacterial inoculum is important, as abscess formation is enhanced by the presence of poor dentition and gingival disease, two conditions that are associated with bacterial counts in saliva in excess of 10^{11}/mL. Approximately 73% of patients with lung abscess have at least one predisposing factor for aspiration, and many have clinically silent gingival disease.

The pathophysiology of lung abscess formation appears to be related to a combination of aspiration, host defense defects, and the size of the infectious inoculum. Experimental data suggest that lung abscess formation occurs 8 to 14 days after aspiration of infectious orogingival material. When aspirated in large amounts, a single species of anaerobic bacteria or a combination of organisms can cause a necrotizing pneumonitis that, if progressive or untreated initially, forms a lung abscess. As expected, the location of the abscess is determined by gravity and body position at the time of aspiration. Lung abscess is typically located in the basal segments of the lower lobes, the superior segment of the lower lobe, or the posterior segments of the upper lobes, analogous to the location of infiltrates found in patients with aspiration pneumonia.

With these pathogenetic principles in mind, it is clear that an abscess arising in an edentulous patient (without oral anaerobes) or in a location other than the ones mentioned should raise suspicion of another pathologic process, involving either a nonanaerobic infection (such as tuberculosis), an esophageal disorder, or an obstructing endobronchial lesion.

Microbiology

Approximately 90% of lung abscesses are associated with anaerobic bacteria, either as the primary pathogens or in combination with aerobic bacteria. This observation may be explained by the fact that anaerobic bacteria commonly cause necrotizing inflammation. Other bacteria associated with lung abscess include *S. aureus, E. coli, K. pneumoniae, P. aeruginosa,* other gram-negative bacilli, *Streptococcus pyogenes, Pseudomonas pseudomallei* (melioidosis), *H. influenzae* (especially type b), *Legionella pneumophila, Nocardia asteroides, Actinomyces* species, and rarely pneumococci. Parasites (*Paragonimus westermani, Entamoeba histolytica*), fungi, and mycobacteria also may cause lung abscess (Table 6).

INFECTIOUS		
Bacterial	**Fungal**	**Parastic**
Anaerobic abscess	Coccidioidomycosis	Echinococcosis
Aerobic abscess	Histoplasmosis	Amebiasis
Infected bulla	Blastomycosis	
Infected pulmonary infarct	Aspergillosis	
Empyema	Cryptococcosis	
Tuberculosis		
Actinomycosis		
NEOPLASTIC	**INFLAMMATORY**	
Bronchogenic carcinoma	Wegener's granulomatosis

TABLE 6. *Cavitary lung lesions*

Anaerobes are usually part of a polymicrobial flora, with the average number of organisms isolated being three, either strictly anaerobes or a combination of aerobic-anaerobic bacteria. The change in bacterial taxonomy has been referred to in the section on aspiration pneumonia.

Classification

Lung abscesses have been categorized using several methods, but the classification into acute versus chronic appears to have the most clinical utility. This distinction is not absolute but can aid the clinician by helping to formulate treatment regimens and identify patients who may need further diagnostic evaluation, such as

bronchoscopy.

A lung abscess is defined as acute if the patient presents with symptoms of <2 weeks' duration. Patients with an acute lung abscess are less likely to have an underlying neoplasm but are more likely to have an infection caused by a virulent aerobic bacterial agent, such as *S. aureus.* In a recent series of patients with acute community-acquired lung abscess, a mean of 2.3 bacterial species per patient was identified, with anaerobes isolated alone in 44% of cases, aerobes alone in 19%, mixed aerobes and anaerobes in 22%, and the remainder caused by an unidentified pathogen or *Mycobacterium tuberculosis.* The most common anaerobic pathogens identified were from the *Prevotella* species, and the most common aerobic pathogens were *S. viridans* and *Staphylococcus* species.

A chronic lung abscess is defined by symptoms lasting for >4 to 6 weeks; patients are more likely to have an underlying neoplasm or infection with a less virulent, anaerobic agent. There may be some overlap in this classification scheme, because it does not take into account host defense factors or serious comorbidity, but this scheme can be useful during initial patient evaluation.

Clinical Features

Most patients with lung abscess have an insidious presentation, with symptoms lasting at least 2 weeks before evaluation. Signs and symptoms include cough, foul-smelling sputum that forms layers on standing, hemoptysis (25% of patients), fever, chills, night sweats, anorexia, pleuritic chest pain (60% of patients), weight loss, and clubbing. Although most of these signs and symptoms are seen, their specificity for lung abscess is low. On the other hand, putrid sputum is a highly specific sign that is pathognomonic for anaerobic infection, although it is found in only 50%–60% of patients. A history of weight loss is also common, occurring in 60% of patients, with an average loss of between 15 and 20 lb. Historical data usually include risk factors for aspiration, such as alcoholism, drug overdose, seizures, head injury, or stroke, and the absence of such risk factors should prompt a search for a diagnosis other than primary lung abscess.

Laboratory data are also nonspecific. Erythrocyte sedimentation rate is elevated, and anemia of chronic inflammation and leukocytosis are present. Culture and microbiologic information from sputum are generally not helpful unless the abscess is caused by nonanaerobic agents, such as mycobacteria, fungi, or aerobic bacteria. Sputum is contaminated with anaerobes from the oral cavity, so that finding these organisms is not specific. If the abscess is associated with an empyema, as is the case 30% of the time, then culture of the empyema fluid may yield reliable bacteriologic data.

More invasive methods for microbiologic diagnosis (transtracheal aspiration and bronchoscopy) are rarely employed, as the majority of patients are treated empirically. This approach is supported by recent data showing that most lung abscess pathogens are sensitive to conventional antimicrobial therapy. If, on the other hand, the patient presents in an atypical fashion or is not responding to therapy, then invasive techniques are justified (Table 7).

Atypical presentation
Absence of fever
WBC count < 11,000
Absence of systemic symptoms
Fulminant course
Absence of predisposing factors for aspiration
Atypical abscess location
Abscess formation in an edentulous patient
Failure to respond to antibiotics
Presence of mediastinal adenopathy
Suspected underlying malignancy
Suspected foreign body

TABLE 7. *Criteria for fiberoptic bronchoscopy inpatients with lung abscess*

Chest radiography generally shows a solitary cavitary lesion of variable size. Some studies report that the size of the cavity is helpful in distinguishing neoplastic from non-neoplastic lung abscesses, but others have not found such a correlation. A dearth of inflammation seen radiographically surrounding the abscess suggests patients with underlying neoplasm.

Radiographically, empyema and infected bullae are sometimes difficult to distinguish from a lung abscess. Empyema is a purulent infection that in most cases is confined to the pleural space, although it can develop as a complication of, or be a cause of, a lung abscess. An infected bulla is pneumonia within a pre-existing bullous cavity and does not result from tissue necrosis. Both entities can demonstrate air-fluid levels, but one is parenchymal (infected bulla) and the other is extraparenchymal (empyema). If an empyema contains an air-fluid level, then a bronchopleural fistula is present. When the chest radiograph cannot distinguish these two entities from a lung abscess, computed tomography (CT) suggests a lung abscess if a thick, irregular, walled cavity with no associated lung compression is seen (Fig. 1). Empyema and an infected bulla usually have thin, smooth walls with compression of uninvolved lung and, in the case of the infected bulla, minimal surrounding inflammation (Fig. 2). The real difficulty arises when one tries to differentiate between a lung abscess and an empyema with a bronchopleural fistula. Prior pleural fluid on chest radiograph, extension of the air-fluid level toward the chest wall, extension of the air-fluid level across a fissure, and tapering of the air-fluid collection on the radiograph suggest empyema.

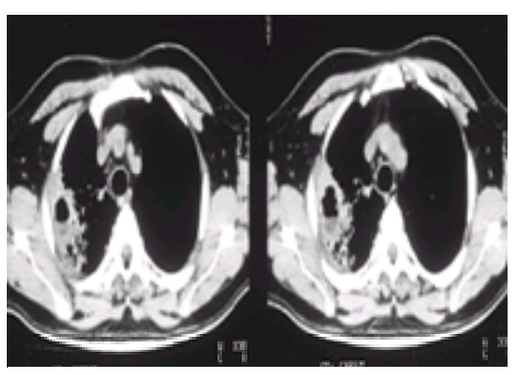

FIG. 1. CT of a patient in whom a lung abscess was diagnosed. Note the cavitary lesion with the characteristic air-fluid level and surrounding inflammation and tissue necrosis.

FIG. 2. CT of the chest showing typical findings in an infected bulla. The cavity is thin-walled without surrounding inflammation or necrosis.

If a lung abscess fails to communicate with a bronchus, the characteristic air-fluid level within a cavity will not be seen radiographically. In this case, the radiographic appearance is one of a focal, ground-glass infiltrate with indistinct borders. Given the history of illness and this radiographic picture, the differential diagnosis includes other chronic pulmonary infections, such as postobstructive bacterial pneumonia, nocardiosis, fungal pneumonia, tuberculosis, and actinomycosis. In addition, a variety of noninfectious pulmonary processes can also be confused with a noncavitary lung abscess. These include BOOP (bronchiolitis obliterans organizing pneumonia), radiation pneumonitis, chronic eosinophilic pneumonia, and allergic bronchopulmonary aspergillosis. When a lung abscess presents in this manner, it is usually necessary to perform a further diagnostic workup, such as bronchoscopy and or lung biopsy. This is also the case if multiple cavities are seen on the radiograph, a rare finding in an anaerobic process not complicated by immunosuppression, recurrent aspiration, or virulent anaerobe(s) causing a necrotizing pneumonitis.

Treatment

In the pre-antibiotic era, three treatment modalities were available for lung abscess. These included supportive care, postural drainage with or without bronchoscopy, and surgery. All three modalities led to the same mortality rate of 30%–35%. Currently, the mainstay of therapy for lung abscess is antimicrobial therapy with either intravenous penicillin alone, penicillin plus metronidazole, or clindamycin. Penicillin has historically been the therapy of choice since its first use in the 1950s, with a cure rate of 95%. With the growing concern over penicillin-resistant anaerobes, two trials compared clindamycin with penicillin in a prospective study design. Both studies found that clindamycin therapy was associated with fewer treatment failures and a shorter time to symptom resolution. When metronidazole was evaluated as a single treatment modality, it was found to have a 43% rate of treatment failure and hence is not recommended for single-agent therapy. Metronidazole in combination with penicillin is considered an appropriate treatment regimen for lung abscess, because penicillin has activity against the aerobic and microaerophilic streptococci that are often resistant to metronidazole. Many other antibiotics have *in vitro* activity against oral anaerobes but have never been evaluated in clinical trials to gain FDA approval for use in these infections. These antibiotics include chloramphenicol, imipenem, erythromycin, azithromycin, clarithromycin, and b-lactams with a b-lactamase inhibitor (e.g., ampicillin with sulbactam).

After the appropriate antimicrobial agent has been selected, the next issue is determining the length of therapy. Although there is considerable controversy in the literature, the approach taken by Bartlett seems the most conservative and appropriate. He recommends treating most patients until the pulmonary infiltrates have resolved or until the residual lesion is small and stable. Initially, antibiotics are given intravenously until the patient is afebrile and shows clinical improvement (4 to 8 days). Oral medications are then given, usually for a prolonged period, although the length of time needed varies from patient to patient. Many patients require a total of 6 to 8 weeks of antimicrobial therapy.

In the past, bronchoscopy was part of the standard care of patients with lung abscess. Its uses included helping to promote drainage and ruling out underlying malignancy. Currently, bronchoscopy is reserved for those patients with atypical presentations who are suspected of having an underlying malignancy or foreign body (Table 7). Bronchoscopy is no longer routinely used for abscess drainage, as the majority spontaneously communicate with the airways and drain. There is also a possibility of rupturing an abscess during bronchoscopy and causing contamination of previously uninvolved lung segments.

As for using bronchoscopy to rule out underlying malignancy, several patient characteristics appear to be correlated with underlying carcinoma. Criteria for bronchoscopy in patients with lung cavities are (1) mean oral temperature ≤100°F, (2) absence of systemic symptoms, (3) absence of predisposing factors for aspiration, and (4) mean leukocyte count ≤11,000/mm^3. When more than three of these factors are present in a patient with lung abscess, an underlying carcinoma is likely. Other factors that should prompt bronchoscopic evaluation include an atypical clinical presentation (noncavitary lesion or lesions and fulminant time course), atypical abscess location (especially in the anterior half of the lung), abscess formation in an edentulous patient, failure to respond to antibiotics, and lung abscess associated with mediastinal adenopathy, a finding not commonly found in anaerobic lung infection.

Complications of lung abscess include empyema formation resulting from a bronchopleural fistula, massive hemoptysis, spontaneous rupture into uninvolved lung segments, and failure of the abscess cavity to resolve. Although uncommon, these complications often require prolonged medical therapy as well as surgical intervention, either with tube thoracostomy in the case of empyema or lung resection in the case of massive hemoptysis.

Surgical treatment of lung abscess is usually reserved for cases with complications such as massive hemoptysis, bronchopleural fistula, and empyema. It is also used in the setting of fulminant infection and in those patients who fail medical therapy. Approximately 10% of lung abscesses require surgical intervention. Prognostic factors associated with failure of medical treatment include recurrent aspiration, large cavity size (>6 cm), prolonged symptom complex before presentation, abscess associated with an obstructing lesion, abscess with a thick-walled cavity, advanced age, neoplasm, and other chronic medical conditions (Table 8). An alternative to surgical drainage is percutaneous catheter placement. At this time, percutaneous drainage should be reserved for patients who are unresponsive to medical therapy and have lung abscesses located peripherally. Placement of a percutaneous catheter can obviate the need for surgery in a significant percentage of patients who have failed medical treatment, with a mean time to abscess resolution of 10 to 15 days and improvement in clinical parameters within 48 hours. These patients should also receive intravenous antibiotics during and after percutaneous drainage of a lung abscess.

Recurrent aspiration
Large cavity size (>6 cm)
Prolonged symptom complex before presentation
Abscess associated with an obstructing lesion
Presence of thick-walled cavities
Underlying serious co-morbidity
Development of empyema

TABLE 8. *Factors associated with failure of medical therapy in patients with lung abscess*

LIPOID PNEUMONIA

Lipoid pneumonia is a chronic illness of the lower respiratory tract resulting from the accumulation of lipoid material in the alveoli and/or the interstitium; it is not strictly an infectious syndrome. The clinical characteristics of this disease depend on whether the syndrome is exogenous or endogenous in origin. A noninfectious alveolar filling process causes chronic, nonresolving pneumonia, but lipoid pneumonia can be complicated by secondary infection. An example of this can be seen in patients with postobstructive pneumonia secondary to an endobronchial lesion.

Exogenous lipoid pneumonia, now an uncommon occurrence, was first described by Laughlen in 1925, when he identified lipid deposits in four autopsy specimens from the lungs of patients who had received either oil nose drops or oily laxatives. Experimental studies later confirmed similar findings in animals who had mineral oil artificially instilled in the trachea. Exogenous lipoid pneumonia is the result of aspiration of lipid material such as mineral oil, vegetable oil, and animal fats, with the type of aspirate predicting the underlying pathologic response. As a result of fatty acid production, aspiration of animal fat usually causes a severe inflammatory reaction resulting in hemorrhagic pneumonia. On the other hand, aspiration of vegetable oil results in little to no pathologic response, whereas mineral oils usually cause a foreign body reaction resulting in pulmonary fibrosis. This pathologic response to mineral oil is actually used, in animals, as a model of pulmonary fibrosis.

In exogenous mineral oil lipoid pneumonia (the most common syndrome), the clinical features include cough, dyspnea, sputum production, occasional hemoptysis, and chest radiographic abnormalities consisting of nonspecific infiltrates in the lower lobes, although any pattern can be seen, including cavitary lung lesions. Ordinarily, patients have minimal or no clinical symptoms and seek medical assistance because of abnormal findings on a chest radiograph. Intratracheal aspiration of mineral oil usually occurs subclinically, and patients are usually without cough, other signs associated with liquid aspiration, or acute inflammation.

The typical patient who recurrently aspirates mineral oil-based medicinal aids is an elderly individual who has used oil-based nose drops or an oil-based laxative for several years. The diagnosis can be made by a history of use of mineral oil or other oil in a patient with respiratory symptoms and a chronic nonresolving pneumonia. Not uncommonly, the diagnosis is made on biopsy, as lipoid pneumonia can mimic infectious diseases and lung malignancy. Once the diagnosis of exogenous lipoid pneumonia is made, treatment consists of removal of the cause (e.g., oil-based laxatives) and supportive therapy. Other therapeutic modalities, such as repeated bronchoalveolar lavage and corticosteroids, are available, but their overall clinical usefulness is uncertain.

Endogenous lipoid pneumonia is caused by the accumulation of lipids derived from the breakdown of endogenous products (e.g., cell membranes and surfactant). The

material most often associated with this type of lipoid pneumonia is cholesterol, and thus *cholesterol pneumonia* is another name for this entity. The pathologic process is usually localized and limited to an abnormal region of the lung, in contrast to what occurs in exogenous lipoid pneumonia. The most common underlying abnormality resulting in endogenous lipoid pneumonia is an obstructing endobronchial lesion, either lung cancer or a foreign body.

The clinical presentation of patients with endogenous lipoid pneumonia is typically that of the underlying cause. In the case of an obstructing lesion, it is characterized by cough, fever, chills, and a chest radiograph revealing an underlying mass or segmental lesion with a concomitant postobstructive pneumonia. In sharp contrast to exogenous lipoid pneumonia, there is no predisposition to recurrent aspiration or history of use of an oil-based substance. Like the exogenous type, endogenous lipoid pneumonia is not infectious in origin, but secondary infection from the underlying obstructive process can occur.

CHAPTER

32 Occupational Lung Diseases Caused by Asbestos, Silica, and Other Silicates

Jason Kelley

J. Kelley: Department of Medicine, University of Vermont College of Medicine, Burlington, Vermont 05405.

INTRODUCTION

Lung diseases caused by asbestos, silica, and the other silicates are the most prevalent pneumoconioses. They have produced very significant morbidity and mortality, particularly during the early part of the twentieth century. In the industrialized regions of the world, conditions of exposure increased rapidly during the nineteenth century. Like all major health problems, the pneumoconioses have been easier to recognize in the field at times when exposures of large cohorts of workers have been intense. As the twentieth century draws to an end, the epidemiology of the life-threatening pneumoconioses is undergoing global shifts. Dust-induced diseases are becoming more problematic in emerging nations with rapidly expanding industrial sectors. This has occurred while disease in advanced nations has gradually been reduced through enforcement of strict regulations to control dusts in the workplace.

Typically, cases of pneumoconiosis that continue to accumulate in the advanced nations represent incidental radiographic findings not associated with disability or premature mortality. Under these conditions, the challenge to the diagnostician to recognize subtle but typical radiographic features is more daunting. Characteristic presentations of pneumoconiosis at the end of the twentieth century in nations with effective dust controls in place are complicated by (1) the minimal extent of disease (often apparent only radiographically), (2) a history of multiple dust exposures leading to aberrant radiographic patterns, and (3) the preponderance of cigarette smoke-induced lung disease in the exposed population. Ever increasingly, pneumoconioses are detected as a perplexing radiographic pattern in an elderly patient undergoing evaluation for an unrelated medical problem. When cases of severe pneumoconiosis do occur, they tend to be limited to small groups of employees receiving intense but often brief exposures not appropriately monitored by regulatory agencies.

OCCUPATIONAL HISTORY

The most important step in the diagnosis of unsuspected pneumoconiosis is to question the subject regarding specifics of the actual job and of the minerals or materials involved. Without an adequate occupational history, scientific principles of risk management cannot be implemented. Often, the subject's past or present occupation may not immediately suggest mineral dust exposure. In an era of a mobile work force, it is always important to seek a detailed account of the subject's past employment. Because some pneumoconioses develop after only brief but intense dust exposures, it is important to inquire about part-time employment. Sometimes, the subject's story must be corroborated by reviewing samples of suspected dusts or materials brought from the workplace. Mixed exposure to silica, talc, or other mineral dusts occurs when multiple minerals are mined in a single region or used in a single factory setting. The type of work done may give clues to the severity of exposure. When the interviewer is unfamiliar with the work-related terms (e.g., bagger, miller, weaver, pipe fitter, fettler, tunneler), it may be easier to seek a description of the actual working habits. Many pneumoconioses are now related to exposures outside the workplace; hence, it is of key importance to ask about hobbies and unusual activities in the home. Subjects should be questioned about whether they worked with a respirator or other protective equipment and whether they were alerted to potential hazards. Given the gender composition of the blue collar work force, almost all workers exposed to asbestos have been men. Moreover, because increased regulation of exposure has been a relatively recent development, chronic asbestosis is generally found in the older segment of the work force.

Cigarette smoking can have a particularly devastating impact on workers exposed to mineral dusts. For the clinician/epidemiologist, the coexistence of smoking-related diseases invariably confounds all epidemiologic studies of the pneumoconioses. In those mineral dust diseases causing minimal impairment, the deleterious effects of smoking far overshadow any effects attributable to dust. Rates of smoking as high as 80% have often been recorded among miners and hard rock workers.

ASBESTOS-RELATED DISEASE

Asbestos (from the Greek asbestos, “unquenchable”) is the collective term for a group of fibrous mineral silicates of the serpentine and amphibole groups that break into fibers when crushed rather than into dust. They share the properties of being nearly indestructible, heat- and acid-resistant minerals. Perhaps no mineral has presented more social and political controversy during the past century than asbestos. During the middle of the twentieth century, an epidemic of asbestos-related disease afflicted many heavily exposed workers.

There is no doubt that asbestos continues to be an important health concern. However, as the disorder has abated in prevalence and severity, concern for other than occupational exposures, particularly among groups such as schoolchildren and office workers, has grown, often without sound basis. Many observers feel that this heightened level of concern with asbestos has inappropriately drawn public attention from other, potentially more hazardous features of the environment.

Asbestos exists in multiple forms, all of them fibrous silicate minerals. They are variably resistant to heat and to destruction by acids and other chemicals. All asbestos forms have a fibrous structure, which makes them suitable for use in woven fabric. The main elements present in addition to silicon are magnesium, calcium, iron, and sodium in differing proportions. All forms of asbestos can be divided into one of two mineralogic types, the serpentines and the amphiboles. Commercially, chrysotile is the most important serpentine. Long chrysotile fibers have a curled appearance; the amphiboles have more needle-shaped fibers (Fig. 1). Common amphiboles include crocidolite, amosite, anthophyllite, tremolite, and actinolite (Table 1).

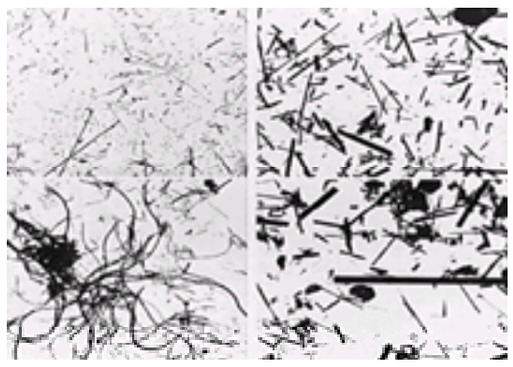

FIG. 1. Various types of asbestos. Anthophyllite (*top left*). Chrysotile (*top right*). Amosite (*bottom left*). Crocidolite (*bottom right*).

Amphiboles	Serpentines
Crocidolite (blue asbestos)	Chrysotile
Amosite (brown asbestos)	
Tremolite	
Actinolite	
Anthophyllite	

TABLE 1. *Mineral forms of asbestos*

Commercial Uses of Asbestos

Chrysotile accounts for the preponderance (>95%) of asbestos mined and used in the world. It has been mined primarily in eastern Canada and New England as well as in Russia. Crocidolite comes primarily from South Africa and was previously mined in western Australia. However, with recognition of its toxicity, demand for crocidolite has greatly decreased.

Asbestos has been widely mined since the end of the nineteenth century. Regulatory efforts by government agencies, such as the Environmental Protection Agency (EPA) in the United States, has greatly cut down on its use. World production of asbestos rose steadily from <0.2 million tons in 1920, peaked at 5 million tons in the late 1970s, and has shown a slight decline since that time. For many years, sheathing and insulation used in the construction of office buildings and houses consisted largely of agents that had been reinforced and rendered heat-resistant with asbestos fibers. Asbestos was used to line furnaces and lag pipes; it was also used as friction material in brakes, as a fire retardant in spray paints, and as a binder and strengthener for cement pipes. It was extensively used in warships as insulation and to prevent fire. In the 1950s, asbestos was even a component of cigarette filters.

Historical Aspects and Effects of Exposure to Asbestos

Asbestos exposure can lead to three serious pulmonary conditions: asbestosis (a diffuse fibrosing disease of the lungs), lung cancer, and mesothelioma. Whereas asbestosis can vary from mild to lethal, the latter two disorders are almost invariably fatal.

Asbestosis was first recognized as a distinct disease entity in 1907 by Murray in the United Kingdom. The magnitude of the hazard and the exposure-response relationship were worked out in the subsequent decades. Recommendations for improved industrial hygiene practices grew out of those seminal studies. The risk to users of the finished asbestos products became more generally apparent by the early 1960s. Before that, sporadic case reports of asbestosis occurring in pipe fitters, welders, and others had been reported. Most such instances suggested that the victim had acquired the condition as a result of an exceptional and unusual exposure. Studies in the 1960s made it clear that a significant risk existed in all users of asbestos. Furthermore, it was clear from those studies that the prevailing regulatory statutes were not protecting the work force from asbestosis.

The role of asbestos as a carcinogen was debated during the 1930s and 1940s. However, the issue remained controversial until 1955, when Doll published a classic article presenting the statistical evidence needed to confirm the association with certainty. Doll's study described the increased risk for lung cancer only in subjects with coexisting asbestosis, and did not consider asbestos exposure in the absence of fibrosis as a potential cause of lung cancer.

In the late 1950s, the association between malignant pleural mesothelioma and prior asbestos exposure was made by clinicians in South Africa. The risk for development of mesothelioma, like that for asbestosis and lung cancer, is concentration-related and depends significantly on the type of asbestos fibers inhaled. The prolonged inhalation of asbestos fibers has been said to be associated with an increased risk for laryngeal, ovarian, gastrointestinal, and renal carcinomas. This association is not clear, however, as some cases of mesothelioma may have been incorrectly diagnosed as primary cancers of other organs.

Standards for Asbestos Exposure

Exposure limits for asbestos have been developed and applied throughout the twentieth century in response to epidemic disease and disability. Precise standards vary somewhat between industrialized nations. In the United States, the regulated standard has progressively been reduced to 0.2 fibers per cubic centimeter. To allow for frequent changes in ambient dust levels in the workplace, this standard refers to an 8-hr time-weighted average (TWA). Asbestos fibers 5 µm and larger are responsible for most of the toxicity and are therefore the focus of regulatory standards. To account for the different toxicities of different fiber types, some jurisdictions apply more rigorous standards for the amphiboles.

For many years, asbestos levels were measured as the number of particles present per cubic centimeter of the ambient air. Asbestos content is usually determined by trapping airborne particles on filters. Fiber size and number are then determined by phase-contrast microscopy. Only fibers >5 µm in length are measured, as smaller fibers are cleared from the lungs and are not likely to lead to pulmonary disease or malignancy. When particles and fibers are counted, asbestos is not distinguished from other substances. Although this does not matter much in asbestos textile factories, where most of the airborne fibers are asbestos, in other occupational settings the percentage of asbestos fibers is much smaller and may be as low as 5%–10%. Under such circumstances, optical counts using a microscope can be misleading, and when it is imperative to separate asbestos fibers from other types of fibers, more definitive techniques, such as transmission or scanning electron microscopy, must be used.

As a result of regulatory efforts in the industrialized nations of the world, the incidence of asbestos-related lung disease has become less common during the past several decades. Subjects with established asbestosis are thus becoming an increasingly elderly population. Moreover, as the ambient levels have fallen in the workplace, the latency time between exposure and appearance of asbestos-related disease has lengthened. For example, a report from 1938 showed that asbestosis was present with exposures as short as 5 years. At that time, dust levels could be as high as 400 particles per cubic centimeter. During and after World War II, the average duration of exposure before the development of asbestosis rose from 10 to 12 years to >20 years. Nonetheless, asbestosis still occurred in certain industries. Since then, the regulations have become considerably more stringent; it is highly likely that no new cases of asbestos-related lung diseases will develop under current standards. The reduction in the use of amphiboles makes this prospect even more likely.

Specific Occupational Risks

It has been estimated that as many as 27 million workers in the United States received a significant exposure to asbestos during the middle four decades of the twentieth century. Environmental exposure to asbestos and other minerals can occur at each stage of production and use: extraction (miners), purification and

production (weavers), and use of the finished product (plumbers, laggers, insulation layers). Workers involved in removal of the used product from buildings, ships, and other sites may be exposed. This statement applies only to those involved in removal efforts in older buildings and equipment in which the risk of asbestos is not apparent. Somewhat surprisingly, miners of asbestos have generally been found to be at lower risk for disease than millers and weavers. Regardless of the context, exposure to chrysotile carries significantly less risk than exposure to crocidolite and the other amphiboles.

Very close contact is a critical determinant of risk. Examples abound of work forces in which certain jobs carried much higher risks than others. Thus, welders working in the same factory with pipe fitters had little or no increase in asbestos-related lung disease, whereas the latter group was at high risk.

Asbestos-related disease as a result of exposure outside the workplace occurs but is infrequent and requires very substantial exposure. Stories of wives washing their husbands' asbestos-laden clothing may be true but are less frequently documented as regulations have been enforced. Low levels of asbestos fibers are found in ambient air in the urban environment. Sources include demolition of equipment and buildings. These levels continue to drop as regulatory measures have been implemented. People who work or live in older buildings containing asbestos are not at significant risk, as the asbestos is largely immobilized in building materials. One recent study has indicated that public buildings contain as few as 0.002 fibers per cubic centimeter, far below the regulated standard. Finally, asbestos occurs as an air and water pollutant in certain regions of the world where surface deposits are a part of the landscape.

Pathogenesis of Asbestos-Related Disease: Inhalation and Deposition

Inhaled asbestos fibers deposit on airway bifurcations of terminal and respiratory bronchioles. Lesser degrees of deposition occur in the alveoli. Somewhat paradoxically, it is the longer fibers that have the potential to reach the distal lung and exert toxicity. Fibers as long as 60 µm, a size not normally considered to be in the respirable range, evade impaction in the large airways. Their exaggerated length-to-width ratio allows them to penetrate into the small airways, from which they migrate into the lung interstitium. Small fibers (<5 µm in length) are removed by the mucociliary escalator mechanisms of the lungs and therefore represent less of a lasting risk.

On ingestion by macrophages, asbestos fibers undergo a process of chemical leaching and partial dissolution. This phenomenon occurs chiefly with chrysotile asbestos; the amphiboles are more resistant to macrophage ingestion and leaching, and once deposited, they have a much longer half-life. As a result of their different half-lives, the longer-lasting amphiboles tend to become predominant with time in subjects exposed to mixed dusts. Clearance cannot be effected if the length of the fiber is >20 µm. Fibers that cannot be cleared via the mucociliary escalator up the airway lumen move into the interstitium, from which they migrate to the regional lymph nodes.

How might asbestos prove toxic to lung cells? Heintz and colleagues have shown that asbestos increases the expression of certain proto-oncogenes (c-*fos,* c-*jun*) in mesothelial cells and tracheal epithelial cells. Asbestos induces increases in protein factors that bind specifically to the DNA sites that mediate gene expression by the AP-1 family of transcription factors. The persistent induction of transcription factors by asbestos suggests a model of asbestos-induced carcinogenesis involving chronic stimulation of cell proliferation through activation of the early-response gene pathway, which includes c-*jun* or c-*fos.* The inflammatory nature of the evolving asbestos lesions can be seen graphically in workers and in experimental animals using gallium scanning. In workers with positive findings on gallium scanning, the intensity of gallium uptake correlates with the activity of the inflammatory process.

Nuclear factor kappa B (NF-kB), a transcription factor regulating expression of genes intrinsic to inflammation and cell proliferation, may be an important intracellular intermediary in initiating asbestos-associated diseases. Crocidolite asbestos causes protracted and dose-responsive increases in proteins binding to nuclear NF-kB-binding DNA elements in airway epithelial cells. NF-kB induction by asbestos may prove to be a key event in the regulation of multiple genes involved in the pathogenesis of asbestos-related fibrosis and lung cancers.

The issue of variability of susceptibility to asbestosis and other pneumoconioses between workers with comparable exposures has long interested investigators. The best available evidence suggests that the retention and accumulation of dust in the lungs is a more important determinant than absolute exposure levels. Lung and airway size correlate with the presence or absence of disease in workers exposed to asbestos, silica, and other dusts. Airway caliber in particular seems to be a major determinant of person-to-person variation.

The weight of evidence suggests that smokers are at greater risk for the development of asbestos-related disease through similar mechanisms. Smoking has the potential to delay the clearance of particles such as asbestos from the lungs by incapacitating the mucociliary escalator. In line with the hypothesis presented above, cigarette smoking enhances fiber retention in the lungs; the longer residence time and greater burden of fibers in the lungs of smokers allows uptake of fibers by epithelial cells and other structural cells.

Asbestosis

Asbestosis is a diffuse interstitial fibrosis of the lungs caused by inhalation of asbestos. It results from heavy exposure to respirable forms of asbestos. The common presenting symptoms of asbestosis are dyspnea and dry cough, which may initially be ascribed by both subject and physician to heavy cigarette use. As with other pulmonary disorders, the victim often does not seek medical advice until the condition is fairly disabling. Weight loss is an early feature. If the original asbestos exposure was intense, disabling symptoms may continue to progress despite removal from further exposure.

Early in the disease process, the clinician can hear middle- to late-inspiratory crackles, which are most prominent in the bases of the lungs. As the disease progresses, these extend from the bases to the middle zones and become more widespread. Tachypnea is almost always present by the time the disease has reached the symptomatic stage. Cyanosis may be visible. Clubbing of the fingers, when present, usually signals advanced disease and a poor prognosis. Signs consistent with failure of the right side of the heart also become apparent later in the course.

Radiographic Features

Asbestosis is characterized by the development of irregular small shadows on chest x-ray films. To assist in standardization of interpretation of chest radiographs, the International Labor Office (ILO) developed a classification based on plain chest radiography. In the ILO system, small irregular shadows are described as *s, t,* and *u* in increasing size. Rounded shadows (such as are seen typically in silicosis) are termed *p, q,* or *r* shadows. The amount or profusion of small round or irregular shadows is graded as either 0, 1, 2, or 3. When the reader is somewhat uncertain about the grading, intermediate grades can be indicated with a slash mark. For example, a reading between grades 1 and 2 would be 1/2, with the first number given being the one the reader believes to be correct and the second one being also possible. In asbestosis, the smaller *s* and *t* shadows predominate over the larger *u* shadows. Scanty irregular shadows are present on chest radiographs in a significant percentage of smokers who have had no asbestos exposure, making their presence less specific. As in other interstitial lung disorders, these small irregular shadows tend to blur the margins of normal anatomic structures such as the diaphragm and the cardiomediastinal and bronchovascular markings (Fig. 2). Initially, the small irregular shadows appear in the lower zones, the site of most intense asbestos inhalation. With progression of disease, the upper lung zones become more obviously involved. Use of computed tomography (CT) to detect disease in exposed workers with normal chest x-ray findings is controversial. In asbestos-exposed subjects who have normal chest x-ray films, high-resolution CT can identify a group with significantly reduced lung function, indicative of restrictive lung disease, in comparison with a group having normal or near-normal CT scans. Pathologic correlation to indicate what early shadows signify are limited. Because the ILO classification system was set up to categorize disease according to plain chest x-ray features, the chest x-ray remains the widely used diagnostic standard.

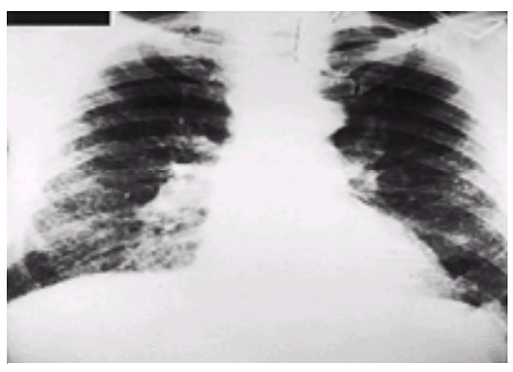

FIG. 2. Radiograph of a worker with category 2/3 asbestosis. He had worked for 30 years as an insulator.

Often, the parenchymal shadows are accompanied by pleural thickening with or without calcification (Fig. 3). In this circumstance, the evaluation of the character and profusion of the irregular parenchymal shadows can be confounded; the pleural changes when viewed *en face* can be mistaken for parenchymal disease. CT is particularly helpful in clarifying this issue. Another clue on the posteroanterior chest x-ray film is that the pleural thickening is most prominent in the middle third of the chest.

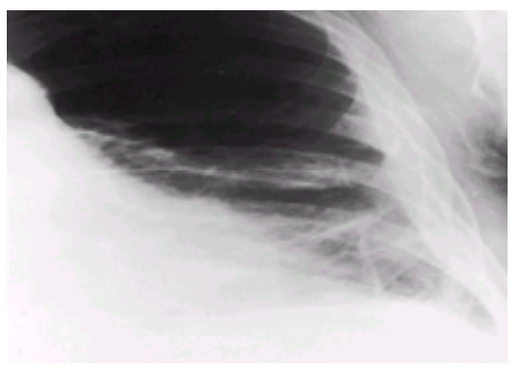

FIG. 3. Lateral wall pleural thickening and pleural plaques. Also evident are calcified pleural plaques viewed *en face.*

With late disease, other radiographic features emerge. As in other forms of interstitial fibrosis, a pattern of honeycombing—radiographically apparent cystic spaces in the lung—develops. In all the interstitial disorders in which it is seen, honeycombing provides incontrovertible evidence of advanced and irreversible lung remodeling and fibrosis. Its appearance, therefore, confirms that the asbestosis is severely disabling. In advanced disease, CT reveals features similar to those of other forms of late interstitial pulmonary fibrosis. Enlargement of the right ventricle and the central pulmonary arteries occurs late in the disease process, when pulmonary hypertension and cor pulmonale develop. Exceptionally large conglomerate masses in upper lung zones, such as are seen in coal workers' pneumoconiosis and silicosis, are rarely seen in asbestosis. These generally occur in subjects with concomitant silica exposure or in conjunction with rheumatoid arthritis (Caplan's syndrome, discussed below).

The presence of irregular shadows in low profusion in the lower zones cannot be considered unique or specific for asbestosis. Exposure to fibrous dusts other than asbestos may cause the appearance of small irregular shadows in the lung bases, particularly in smokers and elderly patients. Irregular shadows are seen in all forms of interstitial fibrosis, after exposure to non-asbestiform fibers, and in cigarette smokers. However, in these circumstances the irregular shadows are usually not profuse. Finally, the ILO classification can be used in predicting life expectancy.

Rounded atelectasis is a distinctive radiographic pattern nearly unique to asbestosis. It probably develops as an exuberant focal pleural reaction that entraps subjacent lung tissue in a swirl of pleural inflammation. It is important to recognize this lesion, as it may be mistaken on the plain chest x-ray film for a peripheral lung mass, an error that often leads to an unnecessary search for a lung tumor (Fig. 4). Rounded atelectasis, when suspected, can easily be confirmed by CT, which shows the characteristic atelectatic lung tissue and distorted bronchovascular markings.

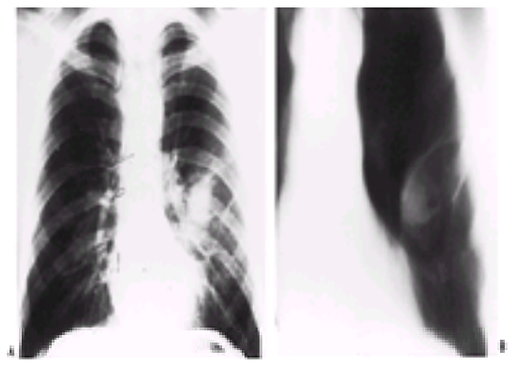

FIG. 4. Rounded atelectasis in a worker who had been an insulator for 15 years. The subject had no chest symptoms and normal lung function. **Panel A:** Posteroanterior film. **Panel B:** Tomographic view.

Pulmonary Function Studies

Symptomatic asbestosis is associated with changes in mechanical properties of the lungs resembling those seen in other forms of interstitial fibrosis. As remodeling progresses and extracellular matrix proteins are deposited in excess amounts, the lungs become regionally less compliant and all lung volumes are reduced. In consequence, there is a marked increase in the respiratory rate, a decrease in the tidal volume, and an absolute increase in the minute volume as the ventilation-perfusion relationship becomes less evenly matched. The diffusing capacity may be reduced before lung volumes are overtly lowered. Tests of regional lung function have shown impaired ventilation of the lower zones. As a result of the altered ventilation-perfusion relationship, hypoxemia and hypercapnia may be severe in advanced disease, particularly during exercise.

A number of attempts have been made to detect the disease at a presymptomatic stage and in the absence of overt chest radiographic abnormalities. Most such efforts have focused on measurements of lung mechanics. It has been possible to show a lower maximal expiratory flow for a given transpulmonary pressure in subjects with normal chest x-ray findings but with significant dust exposure. However, because these approaches require invasive studies with particular attention to calibration and are relatively cumbersome, measurements of lung mechanics are not feasible in field studies of exposed populations.

The potential importance of small-airways disease in asbestos exposure remains unclear. Certainly, the early lesions in asbestos exposure are localized to the terminal and respiratory bronchioles, and tests of small-airways function detect flow limitation in small airways before results of other pulmonary function tests become abnormal. However, asbestos-induced small-airways disease may occur independent of the other abnormalities of asbestosis.

Diagnosis of Asbestosis

The diagnosis of asbestosis is based on four criteria: (1) an appropriate history of exposure, (2) compatible radiographic changes (ILO category >1/1), and (3) diffusing capacity and forced vital capacity below the lower limits of normal. These criteria and the evidence supporting their applicability have been published by the American Thoracic Society. It is particularly difficult to diagnose asbestosis in the absence of changes on the chest x-ray film. Lung biopsy via bronchoscopy, thoracotomy, or video-assisted thoracoscopy are only rarely required or justified in making the diagnosis. Biopsy can be occasionally justified to exclude other causes of interstitial fibrosis but should never be carried out merely to provide evidence for litigation.

Pathology of Asbestosis

Visual inspection of lungs from victims of asbestosis usually demonstrates thickened visceral pleural membranes. The cut surfaces of the shrunken lungs display honeycombing and fibrosis identical to those seen in other forms of diffuse interstitial fibrosis.

The microscopic hallmark of asbestosis is the asbestos is body. Asbestos bodies are elongated, golden-brown structures beaded with proteinaceous material; their lengths correspond to the individual asbestos fibers that form their cores (Fig. 5). Because of their high iron content, they stain particularly well with iron stains. Early in the disease process, asbestos fibers are found intracellularly within macrophages recruited to the area of deposition. Within the macrophage, the fiber may become leached and fragmented to a smaller size. The beading represents biologic modification of the fiber and is composed of proteinaceous material rich in ferritin. After the

death of the macrophage, the acellular coated fiber can be recognized under the microscope as a mature asbestos body.

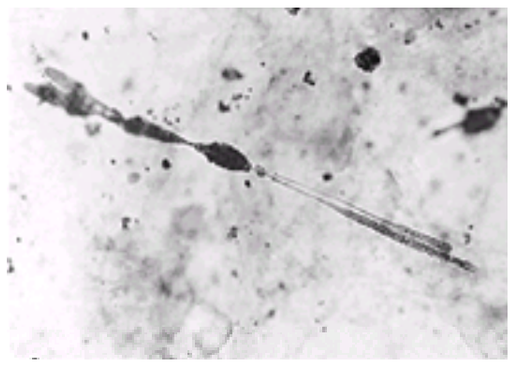

FIG. 5. High-power photomicrograph of asbestos body.

The minimal number of asbestos bodies in lung samples needed for a certain diagnosis of asbestosis remains unclear despite considerable research. One study has shown that lungs of urban dwellers with no occupational exposure to asbestos should contain only one asbestos body for every hundred sections of lung tissue examined. To make the diagnosis of asbestosis, there should be evidence of interstitial inflammation (early) and fibrosis (later) in the presence of asbestos bodies.

With a few notable exceptions, asbestos bodies are found regularly in patients with asbestosis; conversely, the absence of asbestos bodies is a reliable sign that the disease is not present. In any case, large tissue samples are required for certain diagnosis; biopsy material obtained by bronchoscopic biopsy is not adequate to identify the occasional asbestos body.

Inhalation of certain other fibrous minerals, such as glass wool, fibrous alumina, or silicon carbide, may induce formation of similar bodies. Because the core of these structures is composed of fibers other than asbestos, they are more accurately referred to as *ferruginous bodies.* Specific mineralogic identification of the fibers using electron microscopy and x-ray energy spectroscopy may be required to distinguish between asbestos and the other fibrous minerals.

The expectorated sputum of workers exposed to asbestos often contain asbestos and asbestos bodies many years after exposure has ceased. Asbestos bodies can also be found in samples of alveolar lavage fluid recovered by bronchoscopy. These findings confirm the exposure to asbestos but do not indicate the diagnosis of asbestosis. Most residents of industrialized areas have some asbestos bodies in their lungs. However, their presence is not diagnostic of asbestosis in the absence of clinical manifestations of disease.

When ferruginous bodies are detected in lungs or respiratory secretions of subjects who report no occupational exposure, the types of asbestos most often found are chrysotile and tremolite. Tremolite may be inhaled during the use of facial powder composed of talc contaminated with small amounts of the nonasbestiform mineral tremolite.

Chrysotile is particularly susceptible to the leaching process; with time the number and size of chrysotile fibers decline notably. In contrast, amphiboles are more resistant to chemical leaching and tend to persist in the lungs. The intracellular production of asbestos bodies may inacti-vate the fiber and prevent further toxicity. In chrysotile-induced asbestosis, numerous asbestos bodies and uncoated fibers may be found for prolonged periods despite the leaching process.

From the above discussion, it is apparent that the numbers of fibers and ferruginous bodies found in respiratory secretions and lung tissue at postmortem examination can vary considerably, depending on exposure history and other factors. Urban dwellers without specific occupational exposure have relatively few fibers; much greater numbers of fibers are seen in subjects with clear occupational exposure and clinical manifestations of asbestosis.

The hazards of asbestos exposure—namely, asbestosis, pleural thickening and plaques, bronchogenic carcinoma, and mesothelioma—can be related to the extent of exposure. The density of fibers found in the dried lung samples of various population groups depends on the intensity of exposure and shows an enormous range. Although subjects with no occupational exposure have detectable fiber counts, it is important to keep in mind that the numbers of coated and uncoated fibers are hundreds of times lower than in exposed healthy workers and thousands of times lower than in workers with apparent lung disease. Urban dwellers without occupational exposures have <1000 fibers per gram of dry lung tissue. Fiber counts in lung samples from established cases of asbestosis and mesothelioma usually exceed 80 million per gram of dried tissue. In subjects with lung cancer, fiber counts are more difficult to relate to disease risk because of the dominant carcinogenic effect of cigarette smoke.

Measuring Asbestos Fibers in Tissues

Most of the asbestos present in the lungs of exposed workers is in the form of short (<5 µm) translucent fibers that do not take up histologic stains. Hence, most of the asbestos burden in lung tissue is invisible by standard light microscopy but can be seen by phase-contrast or electron microscopy techniques. Only a very small minority of the longer fibers evolve into more conspicuous asbestos bodies. To overcome this problem, standardized scientific approaches for evaluating the asbestos burden have been developed.

The Pneumoconiosis Committee of the American College of Pathologists has specified that the minimal criteria for the histologic diagnosis include the identification of peribronchiolar fibrosis and at least two asbestos bodies in tissue sections. Fiber counting can be done on a digest of tissue. However, enumerating asbestos bodies in tissue sections is the usual approach for general pathologists. Because the segmented coating of asbestos bodies is rich in iron, the use of iron staining is a particularly sensitive method for detecting asbestos bodies. It turns out that agreement is excellent between the numbers of asbestos bodies seen in tissue sections and those present in digests of tissue. An average of two asbestos bodies on 2 × 2-cm sections of lung tissue is equivalent to approximately 200 asbestos bodies per gram of wet fixed tissue.

Pathogenesis of Asbestosis

Little is known about the earliest tissue responses to inhaled asbestos in humans. Experimental studies in animals exposed to asbestos in relatively high concentrations show that the first lesions are inflammatory in nature and are localized to bifurcations of small airways, the sites of most intense deposition of inhaled fibers. With further exposure, a macrophage-dominant inflammatory process involves the lumina of small airways and extends into alveoli. Because the macrophage is central to dust phagocytosis, it can be assumed to modulate many of the subsequent pathologic events. It is important to note that activated macrophages release a number of inflammatory mediators and proinflammatory cytokines. These include chemotactic cytokines and peptides, growth modulators such as insulin-like growth factor-1, platelet-derived growth factor, interleukin-1a, and tumor necrosis factor-a. Also produced are enzymes allowing rapid generation and release of active oxygen species, such as peroxides, hydroxyl radicals, and superoxide anions. These in turn directly oxidize lipids of cellular membranes and damage DNA and proteins. The proteolytic enzymes such as elastases and cathepsins induce injury and death of adjacent structural lung cells, such as epithelial cells, endothelial cells, and interstitial fibroblasts.

A second step in the pathogenesis of asbestos lesions involves fibers interacting directly with epithelial cells and fibroblasts. Undegraded asbestos fibers enter epithelial cells by endocytosis and are transported along the intracellular microtubular network. From the basolateral surfaces of the cells, the fibers migrate into the interstitium and can directly interact with interstitial fibroblasts.

With time, pathologic amounts of extracellular matrix proteins such as collagen, elastin, and proteoglycans are deposited. The lungs lose air space volume and elasticity. The lesions are found more in the lower lung zones, reflecting the proportionally greater ventilation (and hence particle burden).

Clinical Course of Asbestosis

Severe asbestosis advances to physiologic deterioration, disability, and death. Death is the result of respiratory failure, failure of the right side of the heart, and respiratory malignancies. The major reductions in deaths caused by asbestos during recent years can be traced to the relatively milder disease present in the population of aging workers. Efficacious therapy for asbestosis does not exist. Treatment of the symptoms—bronchodilators if obstruction is present, cardiac medications if right-sided heart failure is present—probably have little effect. Whether continuous low-flow oxygen therapy is helpful in hypoxemic patients has not been

proved.

Pleural Effusion and Diffuse Pleural Thickening

Benign pleural effusions often appear during or after asbestos exposure. Effusions usually occur within the first decade of exposure. The chief symptoms are dyspnea and pleuritic pain. The radiographic appearance is no different from that of other effusions. Because the majority of such effusions are not associated with signs of established asbestosis, diagnostic thoracocentesis is often required. Systemic signs of inflammation, including an elevated white blood cell count and elevated sedimentation rate, may be present. The pleural fluid is an exudate and may contain both polymorphonuclear leukocytes and mononuclear cells. Only infrequently is the fluid overtly bloody. Asbestos fibers are hard to find, and usually biopsy of the pleura shows only a chronic, nonspecific reaction. The effusion tends to linger for several months and frequently leads to diffuse pleural thickening and a fibrothorax. In some instances, the fibrothorax leads to appreciable restrictive impairment. When a substantial fibrothorax develops, there is a tendency to consider surgical decortication; however, asbestos-induced pleural thickening and fibrothorax generally improve during the course of several years and should be observed without intervention. Pleural effusions and thickening do not portend the development of mesothelioma.

Pleural Plaques

Pleural plaques are a characteristic feature of prolonged asbestos exposure. Plaques, often calcified, are usually located on the lower lateral chest wall and on the central portion of the diaphragm; radiographically discernible plaques usually do not develop until after more than a decade of exposure. Their pathogenesis is distinct from the development of effusion and fibrothorax. They represent markers of asbestos exposure but do not by themselves constitute a disease process, nor do they portend later pulmonary impairment. In many instances, such plaques may extend around the lateral curvature of the chest. Sometimes they are seen on the anterior or posterior chest wall only. Pleural plaques, usually on the diaphragm, can be found at autopsy in most subjects who have worked for >5 years with asbestos. Although diffuse pleural thickening is often associated with fibrothorax and restrictive ventilatory impairment, pleural plaques probably have no adverse effect on lung function. Plaque formation and calcification may also involve the pericardium (Fig. 6).

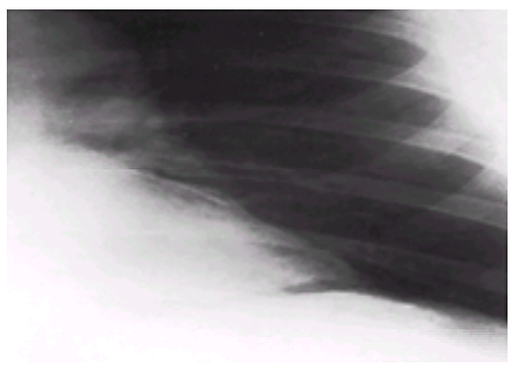

FIG. 6. Calcified plaques of pericardium and left diaphragm.

When viewed *en face* on the posteroanterior chest film, plaques can be mistaken for parenchymal shadows and disease (Fig. 3). In such cases, absence of parenchymal disease on the lateral chest film should alert the interpreter that pleural disease has obscured the interpretation of the posteroanterior film. Also, CT has proved to be a sensitive and definitive method for defining plaques and distinguishing them from parenchymal disease, but it is not required except in complex cases.

It is a mistake to assume that the presence of plaques portends the development of mesothelioma or lung cancer. Pleural plaques are seen more frequently after exposure to the amphiboles than to the serpentine chrysotile. Calcification usually appears in the plaque that has been present for more than a decade. However, calcification is seldom noted on the plain film until two decades after first exposure to asbestos.

Asbestos as a Carcinogen

No aspect of asbestos is more controversial than the issues surrounding its association with malignancy. That there is an association between exposure to asbestos and risk for malignancy has been clear for the past 40 years. Moreover, at intense exposure levels there is an approximately linear dose-response relationship. What remains difficult to pin down is the precise risk of asbestos exposure relative to other carcinogens, and the precise mechanisms of tumor induction. One analysis suggested that lung cancer may account for as many as 26% of deaths in some groups of asbestos workers, a risk three to five times higher than that expected in other workers. The excess mortality is detectable after at least a decade of exposure and climbs progressively thereafter. The risk depends somewhat on the type of industrial exposure, as asbestos textile workers exhibit a higher incidence of lung cancer than cement workers, who in turn have more malignancies than asbestos miners. In most of these studies, the populations were exposed to chrysotile fibers only; the amphiboles are considered more carcinogenic than chrysotile.

With control of asbestos exposure in the workplace, cigarette smoking may be a more important determinant of lung cancer risk in exposed workers than asbestos itself. In this regard, lung cancer has developed in relatively few nonsmoking workers with significant asbestos exposures. Moreover, the very high incidence of smoking among industrial workers increases the risk for lung cancer in nonsmoking co-workers through secondhand exposure to smoke. Certainly, the risk of smoking in the induction of lung cancer was considerably underestimated in early population studies.

The minimal level of asbestos exposure or disease that puts an individual at risk for malignancy remains uncertain. Back extrapolation of the concentration response that applies for workers with heavy exposures cannot be scientifically justified; there are too few reliable data among subjects with lower levels of exposure. One analysis suggested a threshold level of exposure rather than a finite but decreasing risk at low exposure levels. This threshold is close to the threshold for development of asbestosis. Studies in asbestos cement workers in the United States and miners exposed to amosite in South Africa both provide support for the notion of a threshold value for asbestos-induced lung cancer.

Malignant Mesothelioma

Pleural mesotheliomas can occur as either benign or malignant tumors. The benign form, which is not associated with asbestos exposure, is frequently accompanied by hypertrophic pulmonary osteoarthropathy. In contrast, malignant mesothelioma is an aggressive, uniformly fatal, diffuse cancer arising from the pleura and sometimes the peritoneum (Fig. 7, Fig. 8 and Fig. 9). Most malignant mesotheliomas can be traced to previous exposure to asbestos or the non-asbestiform fibrous mineral erionite. As mentioned previously, asbestos-induced mesotheliomas develop only after intense exposure; they do not occur following the minimal exposures experienced by urban dwellers.

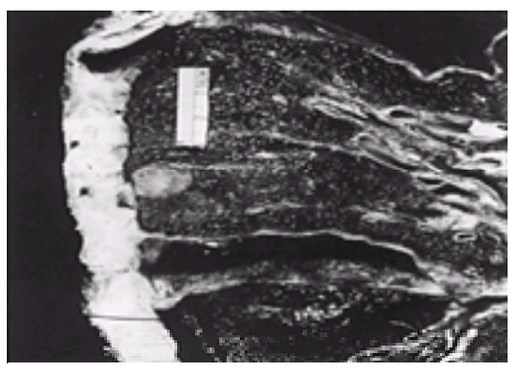

FIG. 7. Whole-lung section of a subject dying of malignant mesothelioma. The lung is encased in white tumor tissue, and a secondary deposit is apparent in the lung parenchyma.

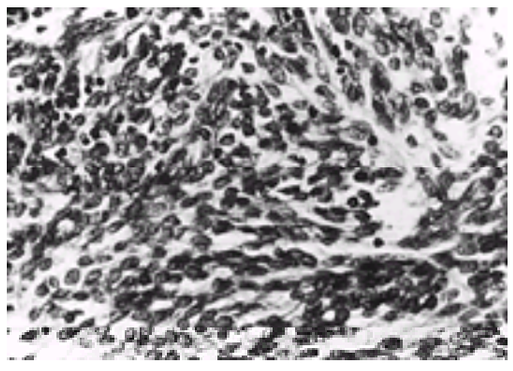

FIG. 8. Photomicrograph showing the histologic features of a sarcomatous type of mesothelioma.

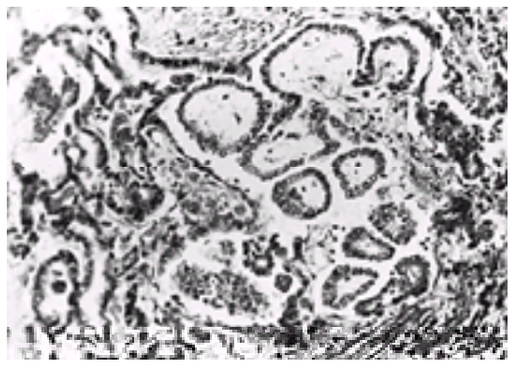

FIG. 9. Photomicrograph of a section of a tubopapillary mesothelioma. This histologic variant bears a close resemblance to a papillary carcinoma of the thyroid.

Malignant mesothelioma remains a rare cancer. It typically appears several decades after the first exposure to asbestos, although shorter incubation periods have been recorded following particularly intense exposures. In certain instances, however, the intense exposure may have ceased several decades before the mesothelioma becomes clinically apparent. Treatment options for this resistant neoplasm, which remain limited, are discussed in Chapter 70.

DISEASES ASSOCIATED WITH EXPOSURE TO SILICA

Silicosis is the disease induced by the inhalation of free crystalline silica (silicon dioxide). Silicon is the second most abundant element and forms the greater part of the earth's crust. It is therefore ubiquitous in the human environment, and some exposure to silicon dioxide and the salts of silicic acid is a fact of life. Silicosis probably occurred in paleolithic times, as soon as humans began to make stone tools. Indeed, the term *silicosis* derives from the Latin word *silex,* meaning “flint.” Intense exposure leading to disease occurs in mining and in those industries in which the mineral is used, such as the manufacture of ceramics, pottery, and bricks. However, as with asbestos, public health regulations have significantly reduced the numbers of silicosis cases in the industrialized world.

Silicon can exist free, that is, not chemically combined with other elements, or it may form silicates by combining with various elements. Silicon dioxide exists in crystalline and amorphous forms, as well as mixed forms. The crystalline forms include cristobalite, tridymite, and quartz. All can produce fibrotic pulmonary disease, with quartz being somewhat less potent in this respect than the others. The amorphous silicas include diatomite, derived from the skeletons of oceanic diatoms, and vitreous silica, a manufactured product of heated silica. The amorphous forms are generally not fibrogenic. Mixed forms, deposits containing crystalline and amorphous features, include chert and flint.

Many of the silicates, salts of silicic acid, are also variably fibrogenic. With the obvious exception of asbestos, the silicates tend to be less toxic than the free crystalline forms of silica. Sandstone and flint are composed of almost pure quartz; granite contains from 15%–70% of free silica by weight, slate 30%–45%, and shales around 10%.

Sources of Exposure

The harmful effects of hard rock mining have been known for millennia. Pliny the Elder wrote about them but may not have associated them with the respirable dusts. In the sixteenth century, Agricola correctly associated most of the lung disease of metal miners with the continued inhalation of mine dust in *De Re Metallica.* Later, Ramazzini pointed out that many diseases originated from workers' occupations and that mining was particularly dangerous. He noted that stone cutters were particularly at risk for the development of lung disease. In the nineteenth century, grinding, the manufacture of pottery, and trades using flint and slate emerged as particularly hazardous.

Definitive regulatory efforts in the industrialized nations have resulted in a major decrease in silicosis during the past half-century. New cases of silicosis tend to be sporadic rather than epidemic. In contrast, the pneumoconioses present a growing problem in the emerging industrial nations. Silicosis persists as a public health menace in coal and metal mines, sandblasting, ceramics refractories, and foundries. Silica flour, finely ground silica used as filler for cosmetics, abrasives, and paint extenders, represents a particularly hazardous form of silica.

Sandblasting is a particularly high-risk occupation, generating large amounts of airborne silica. The use of silica for this purpose has ceased under regulatory pressure in many advanced nations. In nations such as the United States, where its use persists, it remains the most frequent cause of acute silicosis.

Exposure-Response Relationships

As many as a million Americans may be exposed to silica in the workplace. Precise figures of the prevalence and incidence of silicosis are not available. It is certain, however, that the prevalence of silicosis has fallen very significantly in recent decades. This drop has been best documented in the small but well-studied Vermont granite industry.

Although large groups of workers exposed to free silica have undergone surveillance for many years, few attempts have been made to derive an exposure-response relationship. Currently, studies are under way in the United States, South Africa, and Canada to establish the relationship between the development of silicosis and cumulative dust levels. The current evidence suggests that an air quality standard for free silica of 0.1 mg/m^3 should protect the vast majority of the work force. Chronic forms of clinically important silicosis are seldom seen before a decade of moderately intense exposure.

Silicosis

Clinical Features

For clinical purposes, silicosis has traditionally been divided into chronic, subacute, and acute forms (Table 2). Classic or chronic silicosis, the usual type, can be further divided into simple and complicated forms based on the radiographic appearance. Simple silicosis is characterized by the presence of small rounded shadows that usually appear in the upper lobes and later are noted throughout all lung zones (Fig. 10). Complicated silicosis is said to be present when shadows on the chest x-ray film expand to >1 cm in diameter (conglomerate masses).

Chronic silicosis
Simple silicosis
Complicated silicosis
Conglomerate shadows ("progressive massive fibrosis")
Caplan's syndrome (rheumatoid pneumoconiosis)
Acute silicosis (silicoproteinosis)
Other syndromes
Irritant bronchitis
Small-airways disease
Emphysema

TABLE 2. *Clinical classification ofsilica-induced syndromes*

FIG. 10. Chest radiograph of a worker with simple silicosis. Note the evidence of a resolved pleural effusion in the right hemithorax.

Simple silicosis is not associated with respiratory symptoms. Typically, simple silicosis is discovered during radiographic screening. The chest x-ray film shows a striking profusion of small rounded shadows, not associated with symptoms. If any respiratory symptoms, such as cough or dyspnea, are present at this stage, they are more likely the results of an associated respiratory illness other than silicosis. Given the high prevalence of cigarette smoking among workers exposed to mineral dusts, smoking-related lung disorders must also be considered as a cause of symptoms at this stage.

In general, simple silicosis does not progress after cessation of exposure, and the patient can be assured that disability will not occur. In complicated silicosis, however, the large shadows on the chest x-ray film slowly enlarge during a period of years. This can occur even without further exposure. Subjects with massive fibrosis, high relative levels of exposure to dust, or tuberculosis are most likely to progress to complicated silicosis. The earlier the onset of complicated silicosis, the greater the likelihood that the disease will progress and become disabling. When complicated disease reaches more advanced stages, symptoms of breathlessness, cough, and sputum production appear. As the size of the conglomerate masses increases, the symptoms worsen, and pulmonary function tests demonstrate a worsening restrictive pattern. When cor pulmonale develops, it is not related as much to hypoxia as to a generalized decrease in the vascular bed. Thus, pulmonary hypertension and overt cor pulmonale occur late in the disease course.

Irritant Bronchitis and Emphysema in Silicosis

Productive cough in victims of silicosis is usually a consequence of smoking; less frequently, cough may be a result of silica exposure. Silica-induced bronchitis would appear to be limited to severe cases of silicosis. The possibility that it is caused by other substances in the workplace (industrial bronchitis) cannot be ruled out. Pulmonary function tests show somewhat reduced flow rates. Correlation between these abnormalities and the radiographic evidence of advanced silicosis is poor.

The airways obstruction appears to be a result of torsion and distortion of the large airways and is usually associated with some bullous emphysema and marked overdistension. Questions have been raised as to whether silicosis might be associated with an increased incidence of emphysema. This issue has been difficult to study, given the very high incidence of smoking among workers exposed to silica. A recent Canadian study based on CT analysis suggests a significant excess of emphysema in both smokers and nonsmokers working with silica. Radiographically evident emphysema was associated with abnormal pulmonary function both in those with established pneumoconioses and in smokers with silica exposure but no radiographic changes of silicosis. In nonsmokers, radiographic evidence of emphysema was detected by CT only when there was evidence of established pneumoconiosis. Not surprisingly, smokers in this study had emphysema even without evidence of overt pneumoconiosis.

Acute Silicosis

Intense exposure to very high ambient concentrations of silica within a short period leads to the characteristic syndrome of acute silicosis. Because acute silicosis shares pathologic features with alveolar proteinosis, it has also been referred to as *silicolipoproteinosis.* Certain exposed workers, including sandblasters, ceramic workers, and surface coal miners who drill holes to place explosives, are at particular risk for acute silicosis. The production of silica flour may be associated with intense exposure and lead to the development of acute silicosis. The duration of exposure to silica is usually a matter of only months. In the United States, the most notorious epidemic of acute silicosis involved miners constructing a hydroelectric tunnel through a sandstone mountain, the Hawk's Nest Tunnel at Gauley Bridge, West Virginia, in 1933. In what was the United States' worst industrial disaster, nearly 500 miners died of acute silicosis within several years, and many more were severely disabled.

The clinical features of acute silicosis include severe dry cough, fever, intense dyspnea, and weight loss. Hypoxemia may be profound. Pulmonary hypertension and cor pulmonale rapidly develop. The chest x-ray findings may resemble those of classic silicosis; alternately, it may show coalescent shadows in the lower lung zones (Fig. 11). Once acute silicosis becomes established, hypoxic respiratory failure develops inexorably. Patients who survive for more than a few months with acute silicosis have been thought to be particularly susceptible to infection with various intracellular respiratory pathogens, such as mycobacteria and *Histoplasma capsulatum.* Use of antifibrotic and anti-inflammatory drugs such as corticosteroids has proved ineffective; lung transplantation or heart-lung transplantation may prove to be the only effective therapy.

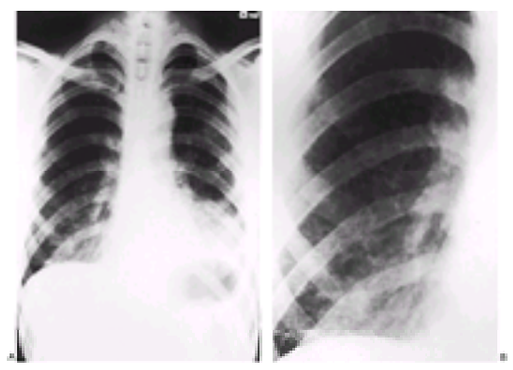

FIG. 11. Chest radiograph of a subject with acute silicosis. **Panel A:** Acinar filling pattern in both lower zones and in the left lateral chest. The extensive soft shadowing seen in acute silicosis is more often seen in the upper zones. **Panel B:** Detail of a right lower lung zone containing an acinar filling pattern with scanty irregular opacities.

Pulmonary Function in Silicosis

Altered pulmonary function accounts for much of the disability and death in severe cases of silicosis. However, in the early stages of simple silicosis, pulmonary function is usually not impaired. Spirometric values, gas exchange, and lung volumes and mechanics are normal or minimally altered. Perhaps because of their focal nature, the silicotic nodules present throughout the lung parenchyma have surprisingly little effect on lung function. The pathways of removal of silica particles into the pulmonary interstitium and regional nodes bypass the distal airways and alveoli, minimizing any deleterious effects on gas flow or mechanics. In this regard, silicosis differs importantly from asbestosis, in which extensive bronchiolar and alveolar inflammation and scarring of the gas exchange surface takes place.

In simple silicosis, a small but statistically significant decrement in the forced vital capacity can be detected when exposed population groups are studied and compared with control subjects without exposure. These changes have no clinical significance and are not associated with symptoms. Because these changes are small, they cannot routinely be detected in individual subjects. The lung volumes in simple silicosis are nearly always normal. Indices of gas exchange, such as the diffusing capacity and arterial oxygen concentration, are generally normal. Pulmonary compliance may be reduced even though spirometric values are normal. The extent of the mechanical changes, although somewhat more sensitive than the spirometric measurements, can only roughly be related to radiographic score.

Studies defining the rate of decrement of pulmonary function among exposed workers have been used to justify current standards for ambient dust levels. Cross-sectional studies of workers in the Vermont granite industry have provided the most comprehensive picture of the impact of any respirable dust on pulmonary function and indicate that granite dust exposure leads to a loss of vital capacity of 2 mL/y. This compares with a decline of 30 mL/y attributable to aging and of 9 mL/y to smoking. This study served as the basis for the National Institute of Safety and Health criteria document recommending that the permissible exposure limit be halved from 0.10 to 0.05 mg/m^3. An additional longitudinal study in the same workers found no difference in the rates of decline in function and no difference in the changes between granite workers and unexposed blue collar workers from the same region. At this time, there is no compelling evidence that exposures to quartz at levels at or below the current standard of 0.1 mg/m^3 result in loss of pulmonary function.

Without a doubt, declines in pulmonary mechanics and volumes occur more rapidly in workers with complicated silicosis. In subjects with simple silicosis in an Asian study, most of whom continued to smoke, the FVC (forced vital capacity) and FEV_1 (forced expiratory volume in 1 second) declined by 59 and 64 mL/y, respectively.

The presentation of the patient with acute silicosis is that of rapidly progressing respiratory insufficiency. Both the lung volumes and the diffusing capacity are markedly reduced. The reduction is generally proportional to the extent of the conglomerate shadows. Lung compliance is markedly reduced, and marked hypoxemia results from ventilation-perfusion mismatch.

Radiographic Features

In uncomplicated early silicosis, the chest x-ray film shows multiple small round shadows, usually developing in the upper zones first. These represent the summation of multiple small silicotic nodules superimposed on one another. High-resolution CT demonstrates the individual nodules.

In complicated silicosis, larger rounded nodules (type *r*) become more profuse than the *p* and *q* shadows. However, these radiographic changes resemble those of many other advanced nodular pneumoconioses, including coal workers' pneumoconiosis (Chapter 33). Eggshell calcification in the hilar nodes occurs fairly frequently, and peripheral shadows themselves may also become calcified. Volume loss in the upper lobes results in overdistension of the lower lobes and retraction upward, with migration of the hila. The conglomerate shadows that form in complicated silicosis are not specific to silicosis and resemble those seen in coal workers' pneumoconiosis. They typically appear in the periphery of the upper lobes first, later appearing to migrate toward the hilum. High-resolution CT allows their detection before they are apparent on the chest x-ray film. However, the prognostic significance of such findings is unknown. Hence, it is rarely necessary to perform CT in the initial evaluation or follow-up of silicosis.

Cavitation of conglomerate shadows may occur and in some cases indicates superinfection with tuberculosis. Pleural plaques can develop in silicosis but are infrequent. Single conglomerate shadows often represent a diagnostic dilemma, as malignancy and tuberculosis must be ruled out. Acute silicosis, as already mentioned, presents as a bilateral alveolar filling process, often in the absence of small rounded shadows.

Pathology

The lungs of silicotic subjects are adherent to the chest wall, and the pleural surfaces are thickened. There may be calcified pleural plaques on the visceral pleural surfaces. The cut surfaces of the lungs are studded with rounded grayish nodules, usually more numerous in the upper lobes; calcification may be present. In some instances, individual nodules may have aggregated into conglomerate masses. These masses may form cavities as a result of ischemic necrosis or superinfection with tuberculosis.

Under the microscope, the hallmark of simple pulmonary silicosis is the silicotic nodule, a pathognomonic feature. The nodule begins as an aggregation of dust-laden macrophages within the interstitium, particularly near respiratory bronchioles, pulmonary vessels, and pleura. The mature nodule has a central area that gradually becomes acellular and is composed of connective tissue arranged in a concentric onion skin pattern. The central area may eventually become necrotic. The periphery is populated with inflammatory cells, particularly lymphocytes and dust-laden macrophages. The nodules may actually assume a granulomatous appearance. Accompanying these changes may be some interstitial thickening in the alveolar wall and a proliferative response of type II pneumocytes in areas of epithelial denudation.

As simple disease progresses to complicated silicosis, the small nodules enlarge and coalesce into large masses of hyalinized tissue. One sees a whorled nodule consisting of an acellular center, through which course fibers of hyalinized collagen. More peripherally, there is granulation tissue and some palisading of epithelioid cells (Fig. 12). The nodules are most prominent around pulmonary arterioles and respiratory bronchioles. The pulmonary vascular bed is slowly obliterated as the nodule increases in size. Smaller vessels become incorporated into the evolving nodule. Expanding conglomerate masses eventually envelop larger segmental and lobar arteries, which then undergo thrombosis and gradually become engulfed by the fibrotic tissue mass. The center of the silicotic nodules, when viewed microscopically under polarized light, contains birefringent silica particles. These tend to be located at the periphery of the nodule, away from the acellular center.

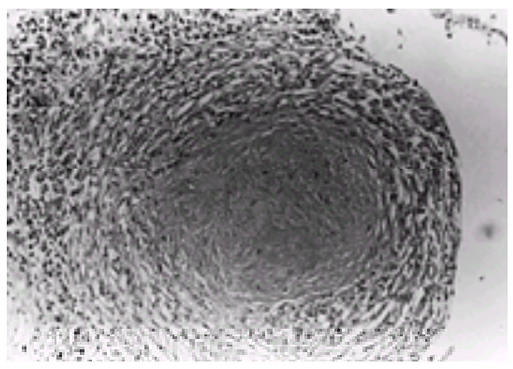

FIG. 12. Photomicrograph of silicotic nodule. Note the typical whorled appearance.

Complicated silicosis usually develops in the upper lobes, which become fibrotic and atelectatic. The lower lobes in turn become overdistended (Fig. 13 and Fig. 14), and the hila shift upward. A variant of the classic conglomerate mass is the even larger rheumatoid silicotic nodule. As its name implies, it is seen in subjects with obvious rheumatoid arthritis or those with high circulating levels of rheumatoid factor.

FIG. 13. Chest radiograph of a worker with complicated silicosis. There is a conglomerate shadow in left middle-upper lung zone.

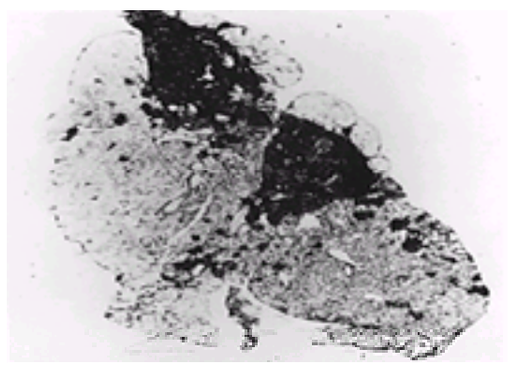

FIG. 14. Whole-lung section of complicated silicosis.

In acute silicosis, the alveoli are diffusely filled with a homogeneous pinkish exudate; the interstitium is infiltrated with mononuclear cells (Fig. 15). The alveoli are lined with degenerating pneumocytes and abundant quantities of birefringent material. The interstitium is thickened and fibrosis is apparent. Mixed pathologic patterns containing features of both acute and chronic silicosis are occasionally seen and have been dubbed *subacute silicosis.*

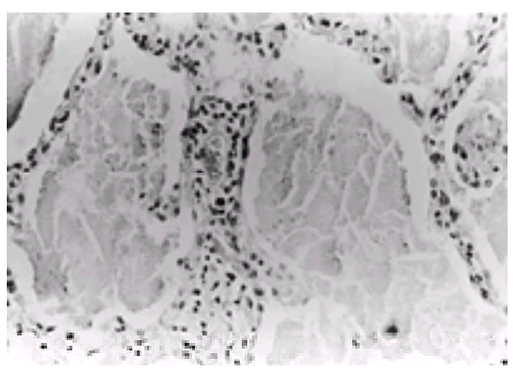

FIG. 15. Photomicrograph showing acute silicosis (silicolipoproteinosis) in the lungs in a sandblaster dying of acute respiratory insufficiency. Proteinaceous (pink) exudate fills all the alveoli. Interstitium is thickened by round-cell infiltration.

Cellular Pathogenesis of Silicosis

Free silica is not biodegradable and presents a toxic burden to a wide variety of lung cells; it is not surprising then that all cellular constituents of the lung may be involved in silicosis. However, the precise mechanisms by which silica exerts its toxic effects are poorly understood. Because ingestion of silica particles by macrophages is such a prominent feature of the disease, their possible role in pathogenesis has been well studied. Ingested silica particles appear in the phagosomes of macrophages; the phagosomes fuse with and damage lysosomal membranes, which then rupture. When this occurs, the macrophage dies and disgorges the silica particles. Along with the released silica particle (which is available to be ingested by another phagocyte), the macrophage releases cytokines, oxidant species, proteolytic enzymes, and other mediators of cellular toxicity.

Alveolar lining cells (type I pneumocytes) are also major targets of silica toxicity. Death of type I cells denudes the alveolar wall, exposing interstitial cells, such as fibroblasts, to contact with fibrogenic mediators, such as growth-promoting cytokines. Proliferation of these cells and their migration into the damaged alveolar space may result in effacement of the distal air spaces by extracellular matrix components.

Plausible and comprehensive hypotheses regarding the exact mechanisms of toxicity of inhaled silica have been put forward by Ghio and colleagues. Biophysical and biochemical interactions between the negatively charged surfaces of silica particles may be a central event. It has been proposed that deposited silicates result in the local generation of oxidants in the lung. The surface of all silicates contains silanol (SiOH) groups. These dissociate, resulting in a net negative charge on the particle surface and allowing adsorption of organic and inorganic cations. In particular, ferric ions react and form complexes with silanol groups. Silanol groups found on silicates have the ability to attract ferric ions, forming silicate-iron complexes.

Reduction of iron in the complex results in the generation of hydroxyl radicals. These in turn oxidize cellular proteins and lipids, presumably resulting in the observed cytotoxicity. Thus, the surface of the ingested silicate particle brings together chelated iron, hydrogen peroxide, and a reductant such as superoxide to allow cytotoxicity to proceed. Experimentally, the toxicity of silica has been mitigated by coating the particles before exposing susceptible cells. In support of this theory, agents such as aluminum or polyvinyl pyridine N oxide, by changing the charge properties of the silica surface, block or markedly reduce the cellular toxicity. This theory also appears to account for the observation that different forms of silica exhibit differing toxicities.

Various inflammatory mediators have been implicated in the development of silicosis. The cytokine tumor necrosis factor (TNF-a) is produced by macrophages in response to exposure to silica in animal models, and antibodies to this particularly toxic cytokine block progression of disease. Some of the effects of silica may represent reparative responses to the ongoing cellular injury. For example, hyperplasia of type II pneumocytes helps to repopulate the alveolar surfaces. This process has been shown to be driven by transforming growth factor-a, a mitogenic cytokine released by macrophages.

The effects of inhaled silica are not limited to the lungs. They affect the immune system, with both cellular and humoral immune responses being markedly altered. Patients with silica exposure and silicosis frequently have elevated levels of circulating autoantibodies, such as antinuclear antibodies. Rheumatoid factor is usually not elevated. This response is thought to represent a systemic response to continued tissue damage and release of nuclear components from dying lung cells. Further studies have shown that there is no reduction in the number or function of circulating T or B lymphocytes. Delayed hypersensitivity remains intact. A postulated decrement in suppressor T-cell function has been invoked to explain the prevalence of autoantibodies in silicosis. To understand genetic factors involved in the development of silicosis, human leukocyte antigen (HLA) phenotyping has been carried out in silica-exposed workers, mostly with inconclusive results. Experimental studies of the immunologic effects of silica delivered as an aerosol or a slurry instilled through the trachea of experimental animals have shown profound changes in immune function.

Diagnosis

The occupational history and radiographic findings almost always suffice to make the correct diagnosis of simple or complex silicosis. The occupational exposure to silica should be appropriately intense and prolonged, and the radiographic and/or CT features should be characteristic. Only in cases of mixed dust exposure might lung biopsy or other invasive studies be required. Isolated cases of acute silicosis may be an exception to this rule, as the disease progresses to respiratory failure so rapidly that lung biopsy may be required to rule out other or coexisting pulmonary disorders. If coexisting infection with *Mycobacterium tuberculosis* is suspected, bronchoscopy may be employed to collect cultures of organisms not found in sputum samples.

Treatment and Prevention

There is no effective treatment for silicosis. Palliative measures are nonspecific and similar to those offered to any patient with other severe restrictive pulmonary disorders and failure of the right side of the heart. Low-flow oxygen is recommended; however, there is no evidence that this prolongs life in patients with silicosis. Steroid therapy is probably of no benefit. Long-term steroid therapy may help patients with silicosis and a second pulmonary disorder that is steroid-responsive. Lung transplantation is offered to patients with end-stage pneumoconioses, including silicosis, and represents approximately 1% of lung transplants done in the United States.

Preventive measures are based on dust control through minimizing generation of respirable dust and providing adequate ventilation at the work site. Respirator masks may be used, but it is far preferable to provide adequate ventilation to remove airborne dust. Sandblasting remains particularly hazardous and has been outlawed in a number of advanced countries. Where allowed, sandblasting should be undertaken only when a positive pressure respirator with its own air supply is used.

Silicotuberculosis

Among the pneumoconioses, silicosis is unique in predisposing to tuberculosis and atypical mycobacterial disease. Miners and other workers with significant exposure to silica have long been known to have a high incidence of tuberculosis. Those parts of the world in which tuberculosis infection and disease rates have declined to low levels have seen a commensurate decline in silicotuberculosis. In contrast, in the emerging industrialized nations, silicotuberculosis remains a significant problem among miners and other exposed workers.

The presenting manifestations of silicotuberculosis are identical to those of tuberculosis and include anorexia and weight loss, fever, and cough. Radiographic features of the infection may be difficult to detect during its early stages, superimposed as they are on the features of silicosis. Later, the appearance is quite similar to that of classic tuberculosis. Silicotuberculosis may progress to cavitation quite rapidly (Fig. 16).

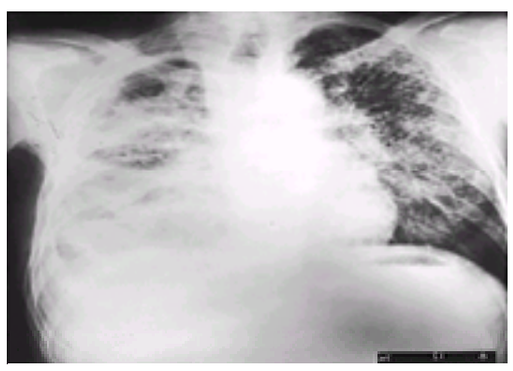

FIG. 16. Simple silicosis (ILO category 3/2) with tuberculous cavities in right middle and lower zones along with pleural effusion. This worker had been a borer and shot firer in a company that sank portals for deep coal mines.

The inhalation of silica has long been recognized to impair the phagocytic functions of macrophages specifically. Because monocytes and macrophages are key effector cells in host defense against *M. tuberculosis* and other intracellular organisms, tuberculous infection tends to progress rapidly in the silicotic lung. Enhanced susceptibility to tuberculosis can be demonstrated in several ways in experimental animals: Initial infection can be established with relatively smaller numbers of organisms than are required to produce disease in control animals; counts of recovered organisms are higher, and there is a greater propensity for spread from subcutaneous inoculation sites to the lungs.

Under conditions of laboratory culture, there is no evidence that silica alters the growth properties or infectivity of the tubercle bacillus itself. Nor does the inhalation and deposition of silica appear to interfere with other components of the immune response. Indeed, greater humoral and cell-mediated immune responses develop in animals exposed to silica than in control animals. Recently, it has been suggested that the increased incidence of tuberculosis in silica workers results from the accumulation of iron that forms complexes with silica dust particles in the lung. According to this hypothesis, silica particles may act as a local reserve of iron, which can be used by dormant mycobacteria as a virulence factor.

Mycobacteria other than *M. tuberculosis* have also been associated with silicosis. *M. avium-intracellulare* and *M. kansasii* have been isolated in subjects with silica exposure, even before overt disease is apparent on the chest x-ray film. When these atypical mycobacteria are detected in sputum samples, efforts must be made to determine whether they represent true pathogens or are simply opportunistic colonizing organisms.

The basic precepts of treatment of silicotuberculosis are the same as for treatment of tuberculosis in the absence of pneumoconiosis (Chapter 28). However, several important distinctions should be made. First, in severe cases of pneumoconiosis, the chest radiographic appearance may be dominated by the silicosis rather than by the tuberculosis. As a result, radiographic improvement during the course of chemotherapy may be minimal. Second, because macrophage phagocytic and killing functions are permanently impaired in silicosis, bacteriologic relapse is common despite the use of appropriate drugs and an adequate duration of therapy. Hence, more vigilance for relapse is in order after a full course of chemotherapy. Finally, disappearance of organisms from the sputum may be somewhat slower than in tuberculosis without accompanying silicosis.

All subjects with silicosis should be monitored with tuberculin skin tests. Those with a positive tuberculin skin test result but no mycobacteria in their sputum should receive routine isoniazid chemoprophylaxis (Chapter 28). Unfortunately, this is probably not as effective a preventive measure as in the general population. Some public health experts have therefore recommended that isoniazid be continued indefinitely in this disease; often, however, side effects preclude this approach.

A recent double-blinded, placebo-controlled trial of antituberculosis chemoprophylaxis was undertaken in 679 silicotic subjects in Hong Kong, where there is a high prevalence of both silicosis and tuberculosis. During the 5-year study, active tuberculosis developed in 27% of the placebo-treated workers and in 13% of those who received any of three chemoprophylaxis regimens. There were no significant differences between the several chemoprophylaxis regimens tested. There was no evidence that chemoprophylaxis led to the development of drug-resistant strains of bacilli. These data support the concept of decreased resistance of silicotic workers to tuberculosis and reaffirm the need for more effective antituberculosis chemoprophylaxis in this population.

Silica as a Potential Carcinogen

In recent years, the long-recognized possibility that silica might be a carcinogen has received renewed attention. Theoretical considerations consistent with this notion are derived from our understanding of the molecular biology of the silica-cell surface interaction. Reactions between silanol groups on the surface of silica particles, ferric iron, and cell surface components might be expected to activate intracellular signaling pathways involved in oncogene expression. However, there is little evidence that even advanced silicosis is associated with lung cancer. Indeed, during the early part of the twentieth century, when complex silicosis was much more prevalent, no association with carcinoma was apparent. Many studies have been unable to separate effects attributable to silica alone from those of other carcinogenic agents in the workplace, such as organic compounds, radon, and cigarette smoke. Animal studies are of limited value in answering these questions, given the relatively short term and high intensity of exposure necessary to elicit malignant responses in target species.

In summary, the evidence for an association between lung cancer and either silicosis or silica exposure remains quite controversial. If such an association exists, it is likely that silica has only a weak carcinogenic potential compared with such notorious carcinogens as cigarette smoke. The public policy consequences of any

abatement projects would be prohibitively expensive. Moreover, the cost of diverting resources away from other more clearly hazardous dusts would be a societal tragedy.

Inflammatory and Immune Disorders Associated with Pneumoconioses

Progressive massive fibrosis seen in conjunction with rheumatoid arthritis is a syndrome described by A. Caplan in 1953 in Welsh coal miners with pneumoconiosis. Caplan's syndrome has occasionally been reported in association with silicosis and rarely with asbestosis. However, in the latter case the association may simply be the result of mixed exposure to silica or coal dust. The majority of reports of Caplan's syndrome come from the United Kingdom; the disorder appears rare in North America. Caplan's syndrome may occur in workers with elevated serum rheumatoid factor who do not have manifestations of arthritis.

Some investigators have suggested that rheumatoid arthritis and other connective tissue disorders are associated with silicosis. This is not surprising, given the regional and systemic alterations of the immune system associated with silicosis. Patients with silicosis often have elevated serum antinuclear activity. However, this activity may simply represent a marker of ongoing tissue damage rather than a sign of rheumatologic disease. It has been suggested that systemic sclerosis develops more frequently following silica exposure, although statistical support is lacking. Despite the possible associations between silica exposure and rheumatologic disorders, the majority of disabled workers have osteoarthritis, not rheumatoid arthritis, as a consequence of the heavy mechanical labor they perform during their careers.

DISEASES CAUSED BY NON-ASBESTOS SILICATES: THE SILICATOSES

In this section, the silicatoses other than asbestosis are discussed. Like silica, the various silicates are ubiquitous on the surface of the earth. As a result of mining and a wide variety of industrial processes, they become airborne and have the potential to be inhaled. The fibrous silicates are relatively long and narrow (i.e., their aspect, or length-to-width, ratio is >3). Both fibrous and nonfibrous silicates induce pneumoconioses but are generally far less fibrogenic than silica. Perhaps as a result of their lesser degrees of toxicity, descriptions of the clinical syndromes induced by the silicates are less clear-cut than those of asbestosis or silicosis. Furthermore, the silicates are often contaminated with more toxic minerals, such as tremolite, that produce effects that tend to dominate radiographic patterns and the course of disease.

Most silicates are nonfibrous (called *phyllosilicates,* based on their leaflike structure). This group includes mica, kaolin, and vermiculite. Wollastonite, zeolite, and fibrous erionite are examples of the fibrous silicates. A number of silicates, such as talc, occur in both fibrous and nonfibrous forms. There is no substantial evidence that the nonfibrous silicates are in any way carcinogenic except when contaminated by asbestos.

Talc Pneumoconiosis (Talcosis)

Talc is a hydrated magnesium silicate having the chemical formula $Mg_6Si_8O_{22}(OH)_4$. It occurs in both fibrous and nonfibrous forms. Talc is mined in a number of parts of the United States, including Vermont, New York, Texas, and Montana. Talc deposits in the United States are contaminated with fibrous silicates such as tremolite, actinolite, and anthophyllite, but these are non-asbestiform variants of these minerals. As much as 40%–50% of some talc deposits may be contaminating minerals. In the United Kingdom, similarly impure talc ore was mined in the Shetland Islands. Talc has also been produced in Canada, Norway, Italy, France, and China.

Talc and mica have a platelike morphology that permits them to slide easily. This property makes them of value as lubricants and as a base for cosmetic powders. Talc is generally mined as soapstone, then milled and calcined. The latter process involves reduction of the milled material to a powder through heating at high temperatures (1200–1400°C). The finished product is used in the production of paints and ceramics, and as a lubricant in the roof-felting industry. It is also important in the production of pharmaceuticals and in the cosmetic industry, where it is used in face powder and talcum powder. High-grade talc from Italy, Vermont, and China is preferred for these uses.

Industrial exposure has been prominent in the rubber industry, where talc is frequently dusted into tire molds so that the finished tire can be more easily removed. Finely ground talc is used in the production of glossy paper. Low-grade talc is important in the fertilizer industry, where it is used for its anticaking properties and as a refractory filler.

Clinical Features of Talc Pneumoconiosis

Talcosis was described at the end of the nineteenth century. Like silicosis, simple talcosis causes few or no symptoms. Dyspnea and productive cough, when present, are usually a consequence of cigarette smoking, industrial bronchitis, or lung disorders other than the talcosis. However, when conglomerate shadows develop, the subject becomes increasingly dyspneic. Although it is clear that the talc itself (rather than its contaminants) is responsible for the pneumoconiosis seen in talc miners, it is far less fibrogenic than silica. Complicated talcosis with conglomerate shadows and disability is now a rare entity in North America, but it is still seen in Europe.

The chest radiographic appearance of chronic talc pneumoconiosis depends on the nature of the talc deposits to which the worker was exposed. When pure talc is involved, there is usually a mixture of rounded *q* and *r* shadows and irregular (*t* and *u*) shadows located in the middle zones, usually in a perihilar distribution. As the disease progresses with time, the shadows extend peripherally from the hila to involve the upper and lower zones. Small irregular shadows in the lower lobes are seen, particularly in cigarette smokers.

When talc deposits contain high concentrations of silica, the radiograph takes on a nodular pattern of shadows involving the middle and upper zones, more reminiscent of silicosis. The shadows are usually of the rounded *q* or *r* types and are located in the upper lobes.

Like asbestos, talc has the capacity to induce pleural plaques, and this can occur in the absence of contamination by asbestos. Pleural thickening is also seen in workers exposed to other silicates, such as sepiolite, wollastonite, kaolin, and zeolite. Such plaques often undergo calcification and are otherwise indistinguishable from those induced by asbestos.

Workers with talc pneumoconiosis who have not smoked have little or no impairment of pulmonary function. With advanced categories of simple talcosis, mild restrictive ventilatory impairment may be found. Only with the appearance of large conglomerate shadows is dyspnea likely to develop in the affected worker. The well-delineated plaques that occur in chronic cases are not associated with significant respiratory impairment. Diffuse pleural fibrosis is occasionally reported, but this is usually a consequence of a prior pleural effusion and so no calcified plaques are noted.

Pathology of Talcosis

Chronic inhalation of talc initially produces a mild alveolar inflammatory process. However, this process seldom progresses to alveolar fibrosis; talc particles are constantly being removed by alveolar macrophages and cleared from the parenchyma by the pulmonary defense mechanisms. With time, dust macules form. These are aggregations of dust-laden macrophages, foreign body giant cells, and epithelioid cells within the walls of the respiratory bronchioles. They resemble foreign body granulomas rather than the typical whorled nodule of silicosis. When these enlarge, small nodules may appear in the interstitial tissue in the same anatomic pattern of distribution as noted with silicotic nodules. Polarizing microscopy easily identifies an abundance of birefringent particles in the nodules. An unusual form of talc granulomatous lung disease occurring in intravenous drug users is associated with a typical vasculitis. Diffuse interstitial fibrosis and massive fibrosis have also been reported in talc pneumoconiosis but are exceedingly uncommon. The potential of talc as a carcinogen is minimal or nonexistent.

Silicatoses Other Than Talcosis

Kaolinosis

Kaolin pneumoconiosis was first reported in 1936 in the United Kingdom. Kaolinite, a complex hydrated aluminum silicate, is used for the manufacture of ceramics (china clay), glossy paper, soap, toothpaste, and medicine. As with silicosis, both simple and complicated pneumoconioses exist. The simple form is characterized by the development of rounded shadows in the lung (Fig. 17). Complicated kaolinosis evolves slowly and mimics silicosis on the chest radiograph (Fig. 18). Although kaolin is usually contaminated with silica, it is clear that the kaolin is responsible for the pneumoconiosis. Deposits of china clay are often heavily contaminated with silica. In the United States, kaolin is mined in the southeastern regions of the country. Intense exposure to kaolin is most likely to occur during the processing stages (drying and bagging). The simple and complicated pneumoconioses noted in shale miners may in part be a consequence of the kaolin content of shale.

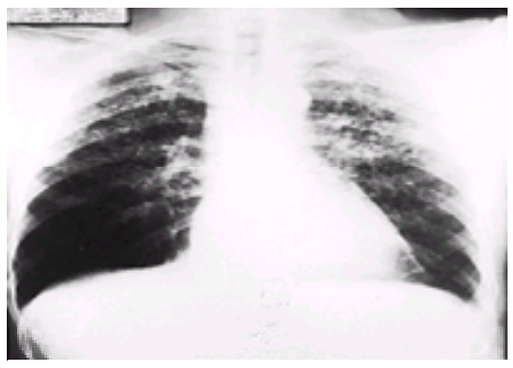

FIG. 17. Chest radiograph of simple kaolinosis. Pneumoconiosis is apparent in upper and middle zones.

FIG. 18. Complicated kaolinosis in a kaolin worker. Conglomerate shadow appears adjacent to the heart.

The pathologic picture in the lungs varies somewhat from that of silicosis and includes both interstitial and nodular fibrosis as well as mild fibrosis of the alveolar wall. In simple kaolin pneumoconiosis, the lungs show grayish nodular lesions that are less prominent than those seen in silicosis. Simple kaolinosis is usually not associated with symptoms or alterations in pulmonary function parameters. However, as simple kaolinosis progresses to the complicated form, the patient notes the development of dyspnea. In complicated kaolinosis, a restrictive ventilatory pattern is present. Even more so than in silicosis, the profusion of shadowing on chest radiographs is more prominent than the degree of functional impairment.

Fuller's Earth Pneumoconiosis

Fuller's earth is a fine-grained absorbent clay originally used to remove grease and oil from wool (fulling). The highly adsorbent property of Fuller's earth makes it an ideal product to remove unwanted oil and grease. It has found use in oil refining and as a binder in foundry molding sands. It is also occasionally used as a filter and in cosmetic preparations. The various Fuller's earths are fine-grained calcium montmorillonite clays, attapulgite (palygorskite), and bentonite. Contaminating silica may be responsible for the development of disease, as Fuller's earth itself is innocuous. Fuller's earth is obtained by open-cast and underground mining. It is then dried, crushed, and milled. It is produced in the United Kingdom, Germany, and in the United States in the Midwest and Georgia (attapulgite).

Fuller's earth pneumoconiosis is a rare and little-studied clinical entity. It appears to occur in both simple and complicated forms. As with talcosis, only complicated cases appear to lead to impairment and disability. In the few autopsy-based studies available, the lungs contain large, peribronchial, black nodules, usually in the upper zones. Microscopically, there is a relative paucity of cellular reaction around the birefringent particles. The very few reports of Fuller's earth pneumoconioses that have been published suggest a benign course with little risk for symptomatic disease. Secondary users of materials containing Fuller's earths are not at risk for disease.

Bentonite Pneumoconiosis

Bentonite is a fine clay consisting mostly of calcium montmorillonite. It can swell inordinately when hydrated, giving it a high capacity for water absorption. It is this property that makes it so useful as a muddy slurry in oil well drilling and also in the refining of petroleum products. Much of the world mining of bentonite is done in Wyoming, with open-cast methods used, and in the nations of the northern rim of the Mediterranean. Bentonite is variably contaminated with quartz, shale, and sandstone.

Crushing and drying bentonite in ovens is dusty work and presents a hazard to workers. Bentonite pneumoconiosis can develop rapidly, be disabling, and result in fatal respiratory failure. Although bentonite is nonfibrogenic, it induces an abnormal pathologic change: the formation of foamy macrophages containing a periodic-acid-positive material. This pneumoconiosis is in large part a response to the cristobalite content of the product.

Anhydrous Aluminum Silicates

The anhydrous aluminum silicates include sillimanite, kyanite, and andalusite. They find important uses in the manufacture of refractory materials and in porcelain-containing materials such as spark plugs. Dust released during the preparation of these natural minerals can contain contaminating amounts of cristobalite. In general, radiographic changes have been minimal, but interstitial fibrosis appears to have developed in a few subjects. It is generally agreed that contaminating quartz is the underlying cause of the very few cases of mild pneumoconioses reported in sillimanite workers.

Miscellaneous Silicates

Mullite is a rare aluminum silicate that can cause pneumoconiosis. It occurs naturally but is also artificially produced for refractory construction. It also finds use in mortars, kilns, and furnaces. Prolonged exposure to mullite may cause mild pulmonary fibrosis, but probably only when dust exposure has been mixed.

Zeolites

The zeolites, which include fibrous erionite, are a group of hydrated aluminum silicates quarried from deposits of volcanic lava (tuffs). As a result of their marked adsorptive properties, they are used as molecular sieves, in gas chromatography, in the separation of radioactive gases, and as fillers in paper products.

Zeolites do not cause pneumoconiosis. However, during recent decades they have been implicated in the high rates of pleural fibrosis, pleural plaques, calcification, and premature malignant mesotheliomas seen in two villages in Turkey. Approximately half the deaths in this region have been caused by mesothelioma and lung cancer. In addition, pleural plaques, calcification, and fibrosis have been noted but have not resulted in deaths. Although these cases were initially thought to be the result of exposure to asbestos, more recent investigations have shown that ambient levels of fibrous zeolite are responsible for the epidemic. Erionite (a zeolite substance) is composed of long, thin mineral fibers and is extensively used in local building materials and stucco. Fibers of erionite have been found in the lungs of patients from the two villages concerned. Erionite has proved to be a particularly potent inducer of pleural disease in animal exposure studies. Of interest is the observation that many houses in the western United States and southern Mexico contain measurable amounts of locally mined erionite.

OTHER NATURAL FIBROUS MINERALS

Attapulgite

Naturally occurring clays such as attapulgite are composed of small, elongated, fiberlike particles and have not been shown to be harmful. Attapulgite is used as cat litter, in paints, and in fertilizers, and it is also pumped into oil wells to remove moisture during the drilling process. Palygorskite is a chemically related mineral

consisting of longer, thinner fibers. It is quarried mainly in eastern Europe. Animal experiments have shown that palygorskite is capable of inducing mesothelioma in animals, as well as producing other effects induced by the amphiboles or asbestos.

Wollastonite

Wollastonite is a fibrous calcium silicate ($CaSiO_3$) sometimes contaminated with quartz. It is used in ceramics and paints. In recent decades, it has found an expanding market as a substitute for asbestos in insulation, wallboard, and brake linings. It is mined in the United States, Mexico, and Finland. An extensive survey of the wollastonite mines of the Adirondack Mountain region of New York State, one of the major production areas of the world, found no concentration relationship between respiratory symptoms and exposure. There was no evidence of fibrotic pulmonary disease or pleural disease. A follow-up study showed no change of chest radiographic patterns with time.

Vermiculite

Vermiculite is the name of a group of hydrated laminar magnesium aluminum silicates containing iron. More than twenty varieties occur in deposits that are quarried from open-cast mines.

Deposits of vermiculites are often contaminated by silica, talc, tremolite, or actinolite. These, rather than vermiculite itself, account for the pleural effusions and plaques found in vermiculite workers. Several studies have assessed the deleterious respiratory effects of exposure in vermiculite mining. Both positive and negative study results have been reported. Studies suggesting increased morbidity and mortality may reflect the contamination of vermiculite deposits by asbestiform minerals.

Artificial Fibers

During the past several decades, an effort has been made to replace asbestos with fiberglass and other artificial mineral fibers. Fiberglass is a continuous filament and therefore not respirable unless modified. Insulation wool is made from metal slag, igneous rocks, and glass, which are mixed and then melted down and spun into a fibrous mat. Many of the fibers produced in this process are in the respirable range. These ceramic fibers are produced from molten kaolin or from a combination of alumina and silica. Most of these artificial mineral fibers exhibit little or no toxicity.

Although these fibers may induce mesothelioma when implanted directly in the pleural or peritoneal cavity of experimental animals, they do not induce pulmonary fibrosis or tumors when given by inhalation. Moreover, fiberglass has been shown to undergo leaching and fragmentation and can therefore be removed from the lungs. Although a preponderance of evidence speaks against any increased risk from the use of artificial fibers, caution is wise. The mineralogic structure of these agents is fairly similar to that of other fibers known to be pathogenic or carcinogenic. Several factors limit the potential of these fibers to induce pneumoconioses. First, the factories producing these artificial fibers generate relatively few respirable fibers in the workplace environment; second, inhaled and deposited fibers are susceptible to fragmentation and leaching by pulmonary cells.

CHAPTER

33 Occupational Lung Diseases: Coal Workers', Beryllium, and Other Pneumoconioses

W. Keith C. Morgan

W. K. C. Morgan: Chest Disease Unit, London Health Sciences Centre University Campus, London, Ontario N6A 5A5 Canada.

COAL WORKERS' PNEUMOCONIOSIS AND RELATED CONDITIONS

Coal has been used as a source of fuel for hundreds of years. Initially, it was dug from outcroppings or augered from seams that came to the surface on the slopes of hills. It was the invention of pumps by Savery (1698) and Newcomen (1708) that made it possible to mine coal underground. Until the advent of the pump, there had been no means of controlling underground flooding or of providing adequate ventilation. Coal mining remains a major industry in the United States, Germany, France, Australia, the former U.S.S.R., China, India, and South Africa. Demand, however, has decreased, particularly in the United States and Britain, where the number of miners has been drastically reduced.

Work Force

Coal is mined extensively from both open-cast or surface mines and underground mines. In the United States, open-cast mines are mostly located in the Far West. With this method of mining, dust exposure is relatively limited. A few borers or shot firers who drill their way through rock before placing the explosive charges are exposed to high concentrations of silica, and the rapid development of silicosis has been noted in these workers.

The underground work force is usually subdivided into face workers, persons employed in transportation, workers concerned with the maintenance of machinery, and finally surface workers. Face workers include those who operate continuous miners and the cutting machines (Fig. 1), as well as roof bolters. Face workers have the dustiest jobs. Workers employed in transportation are responsible for moving coal from the face to the portal. They spend a considerable portion of time near the face, and their job is fairly dusty. Silicosis may develop in transportation workers, as they apply sand to the rails to provide traction for the diesel trains frequently used to carry the coal from the face to the portal. Behind and well back from the transportation workers are the miners whose responsibility it is to maintain equipment and carry out other miscellaneous jobs. This group includes electricians, welders, and mechanics. Finally, a few workers are employed in the lamp house and on the coal tipple. The latter is the site where the coal is washed before being transported for use. Surface coal miners, with the exception of drillers, have only very minor exposures to dust, and coal workers' pneumoconiosis is a rare finding in this group of people unless they have previously been employed underground. Drillers bore through rock strata and are subject to development of silicosis unless proper precautions are taken.

FIG. 1. Coal cutter in a U.S. coal mine.

Respiratory Disease in Coal Miners

The hazards of mining were known to Agricola and Paracelsus in the sixteenth century. These early observers noted that Carpathian miners died of what was then known as *miners' phthisis.* It is also now abundantly clear that this term had a generic connotation and included a large number of diseases, ranging from silicosis on the one hand to tuberculosis, bronchitis, bronchiectasis, and probably lung cancer on the other.

Long-term exposure to coal dust leads to three chest diseases: (1) coal workers' pneumoconiosis (CWP), (2) silicosis, and (3) industrial bronchitis. Silicosis is seen uncommonly except in roof bolters, who bore through adjacent rock strata containing silica to place the roof bolts, and in transportation workers, who apply sand to the rails to provide traction.

Earlier in this century, it was noted that radiographic opacities, similar to those seen in silicosis, developed in the lung fields of Welsh coal miners. It was initially presumed that these radiographic features represented silicosis, as it was known that coal mine dust often contains a fair amount of free silica. However, it was observed that radiographic changes identical to those seen in the coal miner also developed in the coal trimmer, a type of stevedore who was responsible for the even distribution of the coal once it had been loaded into the holds of ships. The trimmers handled only coal that had been washed and, as such, contained virtually no free silica. Subsequent analysis of the lungs of some of these coal trimmers showed that they had no more silica in their lungs than did the inhabitants of Cardiff and Swansea. Confirmation that inhalation of pure carbon could induce similar changes was subsequently noted. There is now compelling evidence to indicate that CWP is distinct from silicosis not only epidemiologically but also pathologically and in regard to prognosis.

CWP is best defined as the deposition of coal mine dust in the lung parenchyma and the reaction of tissue to its presence. It is customarily divided into simple and complicated pneumoconiosis, according to the radiographic features.

Simple Coal Workers' Pneumoconiosis

Simple CWP is recognized from its radiographic features plus a suitable history of exposure—that is, >10 years underground. The lung fields show the presence of multiple, small, rounded (regular) opacities. These usually appear first in the upper lobes and gradually spread all over the lung fields. Simple CWP is graded according to the profusion of small opacities on the chest x-ray film. Categories 1, 2, and 3 are recognized. The classification most commonly used was devised by a group of experts from the International Labor Office (ILO) and has received general acceptance. For epidemiologic purposes, a 12-point elaboration of the standard ILO classification was devised. Use of this 12-point elaboration is essential in the assessment of radiographic progression. Small opacities can be subdivided into *p, q,* and *r* types according to size, with *p* (punctate) being <1.5 mm in diameter, *q* (micronodular) being between 1.5 and 3 mm, and *r* being between 3 mm and 1 cm. Although there are occasions when all three types of opacity are present in a single radiograph, in general, a specific type predominates. In the vast majority of radiographs, the appearances tend to be fairly uniform, and one can detect only one type of opacity (Fig. 2 and Fig. 3). Larger nodules (*r*) are more commonly seen in silicosis than in CWP.

FIG. 2. Radiograph of a subject with category 2/2, *q*/*q* simple CWP.

FIG. 3. Radiograph of a subject with category 3/2, *q*/*r* simple CWP.

Symptoms

Simple CWP is not associated with symptoms, although many of those showing the characteristic radiologic features of the condition will admit to bronchitic symptoms—namely, cough and production of sputum. These symptoms are a consequence of either cigarette smoking or industrial bronchitis, should they happen to be present in nonsmokers.

Pathology

Simple CWP is a reaction to dust alone and does not progress in the absence of further exposure. By the same token, it probably never regresses, despite sporadic case reports purporting to demonstrate radiographic improvement. Most such reports are best explained by erroneous diagnoses, such as sarcoidosis or welder's siderosis, which are known to regress, or by changes in technique in taking serial films. The value of the chest radiograph is that it provides an indication of the coal dust present in the lungs. Many investigations have shown that each successively higher category of simple CWP is associated with a comparable increment in the coal dust content of the lung. The mineral content of the lungs also influences the radiographic appearance, and it is of paramount importance to note that radiographic category is a direct reflection of the dust deposited and retained in the lung and an indirect reflection of cumulative dust exposure (Fig. 4). When coal dust particles are deposited in the alveoli, they are taken up by the macrophages, which in turn convey the dust toward the respiratory bronchioles. The exact means whereby the macrophages migrate from the alveoli to the terminal bronchioles and to the interstitial tissue and the source of energy for their translocation are unknown. Provided dust exposure is not intense and prolonged, the clearing mechanisms usually remain effective, but in the face of high and prolonged exposure to coal dust particles, the dust-laden macrophages begin to accumulate at the portion of the respiratory bronchiole that lies adjacent to the pulmonary arteriole. Many subsequently die and liberate dust around the second-order respiratory bronchioles. This engenders a reticulin response and the development of limited fibrosis. Occasionally, with time, a few collagenous fibers are also formed. If the dust contains a high concentration of silica, then the fibrotic response is greater and more collagen is formed. The aggregates of coal pigment appear as small, black spots in large sections of the lungs and are known as *coal macules.*

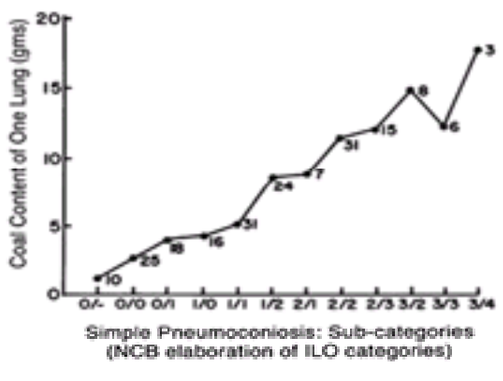

FIG. 4. Relationship between the coal content of one lung and the radiologic category of CWP. The numbers over the points on the graph denote the number of lungs examined within each category of simple CWP.

Initially, the coal macule is small, but with prolonged exposure it slowly increases in size. This increase in size is accompanied by a concomitant increase in the amount of fibrous tissue present. Once this occurs, the smooth muscle in the bronchiolar wall atrophies and, as a result, the bronchiole dilates. It is uncertain what causes the dilatation, but it is probably a consequence of the application of extraluminal forces to the bronchiolar wall. The dilatation eventually becomes large enough to be seen by the naked eye and is then known as *focal emphysema* (Fig. 5). The location of the focal emphysema—namely, in the center of the secondary lobule—is similar to that seen in cigarette smoke-induced centrilobular emphysema. Whereas Gough and Heppleston distinguished focal from centrilobular emphysema and maintained that centrilobular emphysema induced by cigarette smoking is invariably accompanied by bronchiolitis, which is absent in focal emphysema, others maintain that the two pathologic conditions cannot be distinguished.

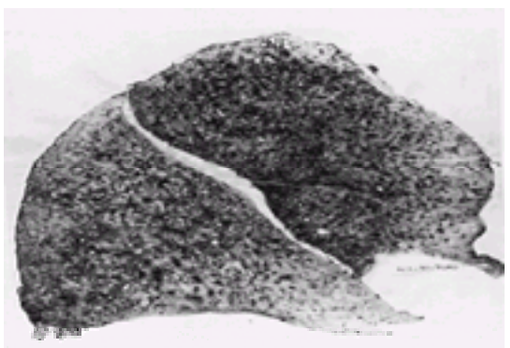

FIG. 5. Large lung section of a subject with CWP showing macules and focal emphysema.

Recent investigations have suggested that the histologic appearance of the macules is affected by the composition and contents of the coal mine dust to which the miner has been exposed.

Lung Function

Although the ventilatory capacity of miners as a whole is decreased in comparison with that of persons of comparable socioeconomic status who are not miners, a higher category of simple CWP is not associated with a larger decrement in ventilatory capacity. If one studies nonsmoking miners with simple CWP, it becomes evident that a variety of pulmonary impairments are present. These impairments include a disturbance in the distribution of inspired gas, which is manifested by a slight increase in the alveolar-arterial pressure gradient, $P(A\text{-}a)O_2$; a minor reduction in the diffusing capacity, especially in subjects with type *p* opacity; and minimal hypoxemia caused by physiologic shunting in categories 2 and 3. With exercise, the $P(A\text{-}a)O_2$ may increase slightly, but in many instances it improves. The focal emphysema that accompanies categories 2 and 3 simple CWP is often associated with a minor loss of elastic recoil and a slight increase in the compliance of the lungs. In addition, an increase in the residual volume often occurs, which is probably related to the same factors mentioned earlier—namely, a change in the elastic properties of the lung (Fig. 6,Fig. 7 and Fig. 8). The increase in residual volume occurs in subjects with and without airways obstruction and cannot be attributed to increased airways resistance.

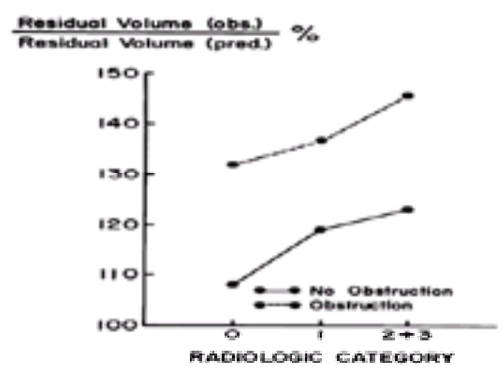

FIG. 6. The relationship of residual volume to radiographic category in coal miners with and without airways obstruction. (Reproduced from Morgan WKC, et al. *Thorax* 1971; 26:585.)

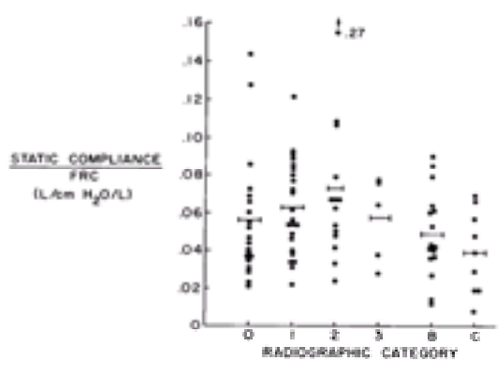

FIG. 7. Static compliance of lungs of coal miners according to radiographic category. *Bars* represent mean values with standard deviation. *FRC,* functional residual capacity.

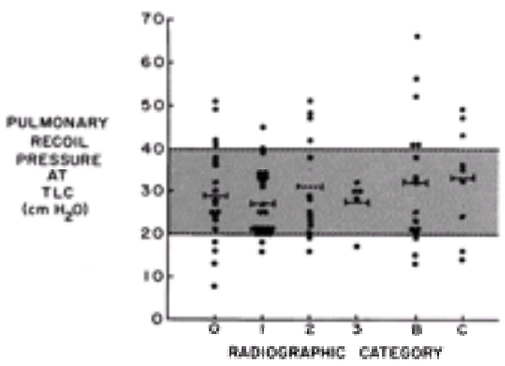

FIG. 8. Pulmonary recoil pressure of coal miners according to radiographic category. *Bars* represent mean values with standard deviation.

In subjects with categories 2 and 3 simple CWP, as mentioned earlier, the diffusing capacity may be mildly reduced (Fig. 9). This is a consequence of ventilation-perfusion mismatching and is mainly present in type *p* opacities. Frans and associates have carried out more detailed studies in which the components of the diffusing capacity have been measured in subjects with simple CWP. They partitioned the diffusing capacity into the capillary blood volume (Vc) and the membrane component (Dm) and found that both were slightly reduced. Although pneumoconiosis had a slight effect on both these components, cigarette smoking had a far greater effect. An extensive study of the effect of CWP on the diffusing capacity was carried out by Kibelstis. He measured the steady-state diffusing capacity (D_LCO_{SS}) at rest and during exercise. The vast majority of nonsmoking miners had a normal D_LCO_{SS}. The effects of cigarette smoking far outweighed those of years spent working underground and the presence of pneumoconiosis.

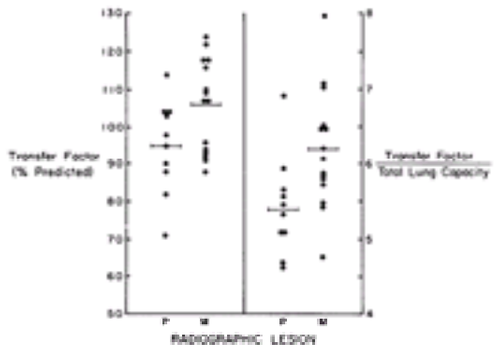

FIG. 9. The diffusing capacity (transfer factor) of a group of nonsmoking coal miners with simple CWP. *P,* punctate or *p*-type opacity. *M,* micronodular or *q*-type opacity. (Reproduced from Seaton A, Lapp NL, Morgan WKC. The relationship of pulmonary impairment in simple coal workers' pneumoconiosis to type of radiographic opacity. *Br J Ind Med* 1972;29:50.)

Evidence of abnormal small-airways function is frequently observed in coal miners and appears to be unrelated to the presence of simple CWP. Abnormalities of closing volume and frequency dependence of dynamic compliance have been noted. It is likely that there is no one simple explanation for these abnormalities, and that small-airways obstruction, regional changes in compliance, and the mechanical properties of the lung all play a role. The presence of these small-airways abnormalities, however, cannot be regarded as disabling or of any clinical significance.

Complicated Pneumoconiosis or Progressive Massive Fibrosis

Unlike simple CWP, complicated pneumoconiosis is associated with symptoms, significant impairment, and decreased longevity. The condition is recognized by a large opacity or opacities 1 cm in diameter occurring on a background of simple CWP (Fig. 10). Although a number of investigators claim that progressive massive fibrosis (PMF) can occur on a background of category 0, the basis for this statement is somewhat suspect, in that other causes of large opacities cannot be excluded. Stage A (i.e., an opacity between 1 and 5 cm in diameter) is seldom if ever associated with either symptoms or a significant decrease in lung function. Stages B and C, however, may be associated with both symptoms and a decrement in lung function. Stage B is defined as an opacity or opacities 5 cm in diameter but not extending over a third of the lung field. Stage C is defined as a large opacity or opacities occupying more than a third of one lung field (Fig. 11).

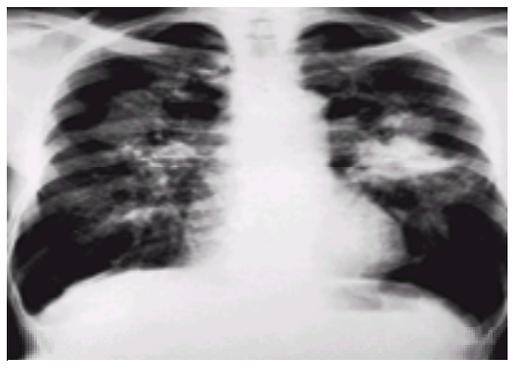

FIG. 10. Radiograph of a subject with stage C complicated CWP.

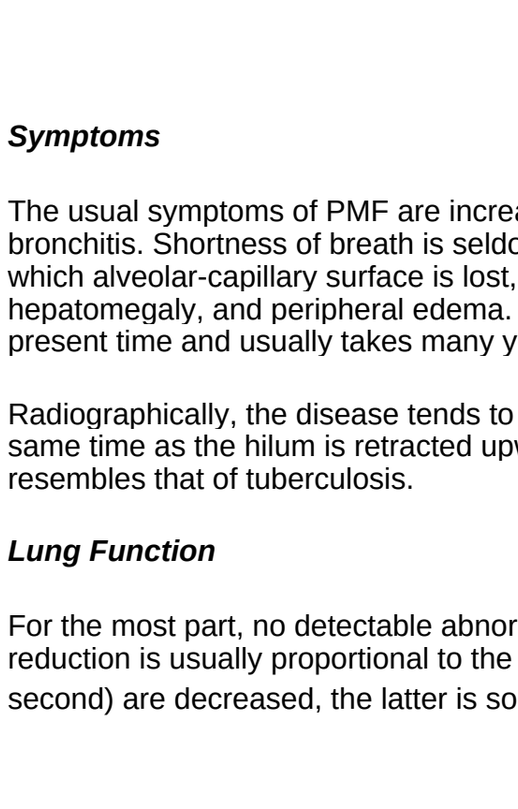

FIG. 11. Stage C complicated CWP with ischemic necrosis in the cavity in the left upper lobe. This subject had worked as a “slave laborer” for 4 years in the Belgian coal mines during the war.

Symptoms

The usual symptoms of PMF are increasing shortness of breath, cough, and production of sputum, but again, the latter is probably a consequence of coincident bronchitis. Shortness of breath is seldom seen until stage B is fairly well advanced, but it becomes more evident as the disease progresses. In far-advanced disease, in which alveolar-capillary surface is lost, non-hypoxemic cor pulmonale often develops. This is associated with a right ventricular heave, the presence of large “a” waves, hepatomegaly, and peripheral edema. It must be stressed that cor pulmonale arising as a result of complicated CWP is an unusual finding in the United States at the present time and usually takes many years to develop.

Radiographically, the disease tends to appear in the axillary region of the posterior segment of either upper lobe. It then often slowly migrates toward the hilum at the same time as the hilum is retracted upward. It also is seen in the superior segment of the lower lobe, and the distribution of the massive fibrosis in this regard closely resembles that of tuberculosis.

Lung Function

For the most part, no detectable abnormalities are present in stage A complicated pneumoconiosis. In stages B and C, the ventilatory capacity is reduced, and the reduction is usually proportional to the size of the conglomerate masses. Although both the FVC (forced vital capacity) and the FEV_1 (forced expiratory volume in one second) are decreased, the latter is sometimes reduced disproportionately. The ratio of FEV_1 to FVC ratio is generally reduced, especially in advanced stage C

disease. The diffusing capacity is likewise affected, and the decrement observed is proportional to the size of the masses. The precise pathophysiologic explanation for the obstruction remains unclear, but it appears to resemble that occurring in far-advanced tuberculosis or widespread end-stage sarcoidosis. Large masses destroy both the vascular bed and many of the airways, and their effects on the former are responsible for non-hypoxemic pulmonary hypertension. Eventually, hypoxemia develops, but it is observed earlier and more frequently in those subjects who happen also to be cigarette smokers.

Pathology

As already mentioned, conglomerate shadows usually develop in the posterior segment of the upper lobes or the superior segment of the lower lobes. Macroscopically, they consist of large, black, amorphous masses that on section tend to liberate a jet-black grumous fluid. They are rubbery in consistency, and occasionally an irregular, thick-walled cavity may be present. The latter represents either ischemic necrosis or tuberculous infection.

Microscopically, the periphery of the masses seems to be composed of dense aggregates of fibrous tissue. Although formerly it was believed to be almost pure collagen, this is now known to be incorrect; the collagen bundles tend to be peripherally situated in the wall of the cavity. Even there, they are often separated by deposits of coal dust. The lung masses gradually encroach on and destroy adjacent airways and blood vessels. Remnants of former internal elastic laminae can be observed on microscopy. The pulmonary arteries, veins, and capillaries are all obliterated.

A rigid separation of simple from complicated pneumoconiosis is probably fallacious, and it is clear that the opacities of <1 cm in size gradually increase in diameter and form a large opacity. It has been shown that the hydroxyproline content of the large masses is only about 3%–4%, implying that the collagen content is about 25%–30%. In an analysis of fresh tissue from the center of conglomerate lesions, there was demonstrated a significant increase in calcium phosphate content and the presence of glycosaminoglycans such as hyaluronic acid and chondroitin sulfate in the mass lesion. These findings are supported by the normal urinary hydroxyproline content in both simple and complicated CWP. It also has been shown that fibronectin is an important component of the masses that characterize PMF.

Necessary for the development of PMF is a suitable dust burden and some factor or factors as yet unknown. Unlike simple CWP, PMF may develop after exposure has ceased, provided category 2 or 3 disease is present at the time the subject stops working. In addition, the disease may progress in the absence of further exposure.

Immunologic Aspects of Coal Workers' Pneumoconiosis

In 1953, Caplan described a syndrome in coal miners characterized by the presence of multiple rounded opacities in the lungs and associated with rheumatoid arthritis. Since then, the condition has been known as *Caplan's syndrome* or *rheumatoid pneumoconiosis.* The opacities differ from those in the usual form of PMF in that they tend to be peripherally situated and often appear in crops during a relatively short period. Moreover, they frequently occur on a background of category 0 or 1 pneumoconiosis. Although most of the patients who were originally observed had rheumatoid arthritis, subsequent studies showed that the condition may appear to antedate the development of rheumatoid arthritis. Typical nodules of Caplan's syndrome and the large opacities of PMF may be present in the same subject. The nodules are often accompanied by the typical rheumatoid nodules found on the Achilles tendon and elbows. Histologically, although the nodules bear some resemblance to the rheumatoid nodules found on the elbows, there are distinct differences. It has been noted that there are concentric layers of dust and granulation tissue with a necrotic area in the center. Beside the necrotic area, there is often a cellular zone infiltrated with mononuclear cells and, in particular, lymphocytes and plasma cells (Fig. 12). Endarteritis is often present. This zone of active inflammation was named the *rheumatoid zone* by Gough and co-workers.

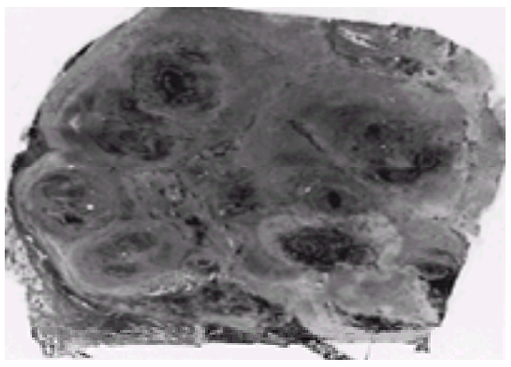

FIG. 12. Cluster of Caplan nodules from a large section of the lung of a deceased coal miner. Note the concentric layers of dust deposition in the nodules. The subject had severe rheumatoid arthritis, but only category 1/0 simple CWP.

Through the years, a number of studies have compared the prevalence of rheumatoid factor in coal miners with that of a comparable referent population. Rheumatoid factor was present in about 70% with typical Caplan's syndrome. This far exceeded the prevalence in subjects with simple CWP. Furthermore, a significant proportion of those subjects with a radiographic appearance of Caplan's syndrome in whom rheumatoid factor was lacking when they were first seen subsequently tested positive for rheumatoid factor. Because of the fact that some subjects with Caplan's syndrome continued to test negative for rheumatoid factor, it was suggested that PMF existed in two forms: one form, much less common, associated with vasculitis, cellular infiltration, and rheumatoid factor in the serum, and a second form, nonspecific and associated with mild inflammation and obliteration of the vascular bed. The evidence in favor of this hypothesis is tenuous. Antinuclear antibody (ANA) is also frequently present in miners who have PMF.

Studies of immunoglobulin levels in miners with and without CWP have shown that the sera of anthracite miners with PMF contain relatively higher levels of complement (C3), a_1-antitrypsin, and immunoglobulins A and G (IgA and IgA) than do comparable sera from bituminous coal miners with PMF. Immunoglobulin levels, however, are normal in miners with simple CWP. Lung reactive antibodies have also been demonstrated in miners with CWP, but their role in the etiology of the condition is not apparent.

Emphysema and Coal Workers' Pneumoconiosis

Although there is no doubt that a form of emphysema usually referred to as *focal emphysema* occurs in coal miners with pneumoconiosis, the effects of this type of emphysema are presently a source of argument. Focal emphysema occurs in the center of the secondary lobule and, in this regard, resembles centrilobular emphysema. Gough and Heppleston maintained that focal emphysema is distinct from centrilobular emphysema as seen in cigarette smokers and does not lead to pulmonary hypertension. They also maintained that centrilobular emphysema of cigarette smokers is always accompanied by a bronchiolitis and in this respect differs from focal dust emphysema.

During the past few years, in a series of articles from South Wales, investigators have proposed that it is the emphysema in the lungs of coal miners that causes airways obstruction. The coal miners chosen for these studies were all disability claimants who had been reviewed by pneumoconiosis panels. As such, they can hardly be regarded as representative of coal miners as a whole. The investigators attempted to show a relationship between lung function in life and the extent of emphysema diagnosed at postmortem examination. They were, however, unable to demonstrate that obstruction increases with higher categories of simple CWP.

There are a number of compelling arguments to refute this hypothesis. It is well accepted that an increasing amount of dust deposited in the lungs is associated with a higher radiographic category. Similarly, it has been shown that the extent of focal emphysema increases in higher categories of simple CWP. If the focal emphysema is responsible for the obstruction, then a decrease in the ventilatory capacity should be noted with a higher category of simple CWP, but it is not. Second, extensive studies in which the hearts and lungs of deceased miners were examined have considered the relationship of antemortem smoking habits and simple and complicated pneumoconiosis. Right ventricular hypertrophy and cor pulmonale do not occur in coal miners if they have not been cigarette smokers or have not had PMF. Similarly, if the emphysema noted in the lungs of miners with simple CWP is truly disabling and leads to a reduction of the alveolar-capillary surface, then a significant reduction in the diffusing capacity should occur, but it does not. The argument has been further developed in the Surgeon General's Report of 1985.

More recently, other investigators have endorsed the concept that the excess emphysema in the lungs of coal miners is responsible for the observed increase in airways obstruction. The proponents of this theory rely on a report of the findings in an autopsy study of the lungs of 1400 coal miners. The prevalence of emphysema was examined in 503 men, and a differentiation was made between panacinar and centriacinar (centrilobular) emphysema. Ninety-five nonsmokers were included, of whom 42 had some emphysema. The presence and type of emphysema were related to dust exposure, age, cigarette smoking, and bronchitis. Thirty-five percent (33 subjects) of the nonsmokers had centriacinar emphysema and 23% had panacinar emphysema. No relationship was found between the presence of panacinar emphysema and coal dust. Only 2 of the 21 nonsmokers who had no coal-induced fibrosis (i.e., no CWP) had centriacinar emphysema. Moreover, emphysema was

regarded as being present when as little as 1/30 of the lung was involved. From this it might be inferred that many of those with emphysema had negligible involvement and were asymptomatic. Elsewhere, it has been shown that at least 20%–25% of the lung must be involved before the subject has symptoms of breathlessness.

The study defined three pathologic groups according to the presence of particular dust lesions. Group M included lungs showing circumscribed dust accumulations with minimal evidence of fibrosis. Most of these did not show radiographic evidence of CWP. Group F showed one or more fibrotic lesions between 1 and 9 mm in diameter. The third group comprised lungs from subjects with PMF having fibrotic lesions ³1 cm in diameter. In a group of 257 miners who had undergone spirometry during life, only two nonsmokers had emphysema in the absence of PMF. Moreover, an exposure-response relationship was lacking between dust and extent of emphysema. Finally, the nonsmokers in the M and F groups, of whom there were almost none, showed no difference in lung function between those with and without emphysema. Thus, the report seems to provide little support for the hypothesis that centriacinar emphysema of nonsmoking coal miners produces airways obstruction, and in smoking coal miners it is clear that cigarettes are the main cause of obstruction.

Bronchitis and Coal Mining

There is no doubt that coal mine dust induces an increase in the size of the mucous glands and an increase in the number of goblet cells. These changes are associated with cough and production of sputum and a small reduction in ventilatory capacity. For the most part, only the large airways are affected. The reduction in ventilatory capacity is unrelated to radiographic category and is present in miners with no radiographic abnormality.

Relative Contributions of Dust Versus Cigarette Smoking and Airways Obstruction in Coal Miners

A number of cross-sectional and longitudinal studies have been carried out in coal miners comparing the effects of dust versus cigarette smoking. Most studies have shown that dust does have an effect, even in the absence of cigarette smoking. Two long-term studies, one carried out in Britain and the other in the United States, have reported that cigarette smoking has about three times the effect of coal dust on the development of airways obstruction. This conclusion is based on a comparison of the mean decrements induced by dust, cigarette smoking, age, and other factors. Unfortunately, such comparisons are misleading. It is well established that significant airways obstruction develops in only about 13%–15% of cigarette smokers. The vast majority of smokers are unaffected. In contrast, most miners who have spent 25 years in the coal mine (and this applies also to nonsmokers) have cough and sputum. Many of them have a small decrement in ventilatory capacity. Thus, when the effects of smoking are compared with those of dust, a significant and occasionally disabling decrement in a small percentage of subjects (13%–15%) is being compared with a much smaller decrement in a far greater proportion of subjects (40%–60%). There seems to be little doubt that coal dust in itself does not lead to disabling obstruction unless PMF is present. Moreover, as mentioned earlier, right ventricular hypertrophy and respiratory failure do not appear to occur in coal miners in the absence of cigarette smoking or PMF.

Lung cancer occurs less frequently in coal miners than it does in the general population. This is probably related to the fact that coal miners are not allowed to smoke in the mines, so that 8 hours of the day are spent in a smoke-free atmosphere. This observation has been made in numerous studies. Similarly, other studies have shown that heart disease occurs less frequently in coal miners than it does in the general population.

Effects of Coal Workers' Pneumoconiosis on Life Expectancy

A number of studies have been carried out showing that simple CWP has no effect on life expectancy, but that PMF is associated with decreased longevity. This has been observed in both Britain and the United States. It also has been noted that coal miners as a group have a normal life expectancy at the present time. Although the death rate from accidents and complicated pneumoconiosis is increased, this is counterbalanced by the decreased death rate from heart disease and lung cancer.

Radiographic Progression

Repeated observations have shown that increasing exposure, as measured by years underground or by cumulative dust exposure, leads to radiographic progression. Originally, this was measured using the standard ILO 3-point scale (categories 1, 2, and 3), but it became apparent that the scale was not sensitive enough. As a result, Liddell and May elaborated their 12-point scale. The adoption of the more accurate gravimetric method of estimating coal mine dust, plus the use of the elaboration of Liddell and May, have made it possible to relate long-term dust exposure to the attack rate of pneumoconiosis and the likelihood that a person with pneumoconiosis will progress from a particular subcategory to another. Using such an approach, a dose-response relationship has been derived, both in Britain, by the National Coal Board, and in Germany. The results obtained in both countries were very similar despite completely different methods of measuring coal dust. Jacobsen has derived a series of curves suggesting that, provided the time-weighted average is kept below 2 mg/m^3, category 2 disease or higher will develop in about 2% of miners who work 8 hours a day, 5 days a week, for a period of 35 years (Fig. 13). Hence, if one can prevent simple CWP, then there is every likelihood that PMF will not develop. The fact that the U.S. coal mines have a standard of 2 mg/m^3 should mean the virtual elimination of CWP by 2005.

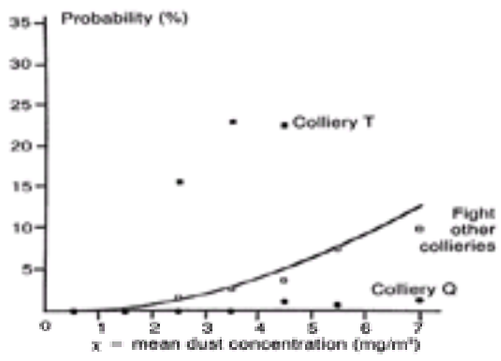

FIG. 13. The percentage of miners with disease evolving to category 2 or higher. This is based on 35 years of exposure for 8 hours a day, 5 days a week. (Reproduced from Jacobsen M. New data on the relationship between simple pneumoconiosis and exposure to coal mine dust. *Chest* 1980;78(Suppl):408.)

Bronchoalveolar Lavage Studies

A number of bronchoalveolar lavage studies of coal miners have recently been performed. Most have been poorly conducted, and the information yielded so far has not been particularly helpful in diagnosing or unraveling the mechanisms involved in the pathogenesis of CWP. There have also been a number of studies of tumor necrosis factor (TNF) in CWP, and it has been shown that in subjects with CWP the level of TNF is increased. Once again, the significance of increased levels of TNF is not understood. Although investigators have related the progression of CWP to increased levels of TNF, the authors of these studies have never been sure what constitutes progression—worsening of the radiograph or a decline in lung function.

OTHER PNEUMOCONIOSES

Several other pneumoconioses have been recognized. Most are relatively uncommon and the existence of some is questionable, but many of those that are well recognized result from the inhalation of metals.

Respiratory Conditions Associated with Exposure to Aluminum

Aluminum is mined as bauxite. Bauxite contains about 40%–50% alumina and other oxides, in particular iron. Deposits of bauxite are found in Jamaica, Australia, Guyana, and France. Metallic aluminum does not occur in a natural state but is found in combination with oxygen, silicon, and fluorine. It is frequently found as combined complex salts of silicic acid. Many minerals, including all types of asbestos, contain aluminum. Cryolite is aluminum fluoride and is found mainly in Greenland.

The production of aluminum involves two steps, the first of which is to convert the bauxite to aluminum oxide. This involves the digestion of bauxite with caustic soda at a high temperature and pressure. The resulting hydrate is then dried and calcined to the oxide. Subsequently, the alumina (Al_2O_3) is reduced by the Hall-Heroult electrolytic process. This takes place in the pot room, where the alumina is mixed with cryolite flux and the mixture placed in large steel pots into which carbon electrodes dip. With the passage of an electric current, the metal accumulates at the bottom of the pot while a crust of alumina and other impurities forms on top. The

metal is subsequently removed from the pot.

A number of respiratory conditions have been attributed to exposure to alumina or metallic aluminum.

Shaver's Disease

This condition was first described in the Niagara Peninsula by Shaver. It was recognized in workers manufacturing the abrasive corundum. The process involves the mixing of bauxite with iron and coke and fusion in large iron pots at a temperature of 2000°C. During the process, dense white fumes are given off containing Al_2O_3 and amorphous silica. Subsequently, it was realized that during fusion some of the free silica had been converted to cristobalite and tridymite.

In a survey of four plants that were manufacturing alumina abrasives, Shaver and Riddell found 23 subjects with radiographic abnormalities. Those affected had shortness of breath and recurrent chest pain. Many also had a cough that was productive of some mucoid sputum. Subsequently, it became evident that the recurrent chest pain was often related to the development of spontaneous pneumothorax. On examination, the subjects were noted to have tachypnea, and cyanosis was present in those with advanced disease. Crackles were present in most, and occasionally signs of consolidation were noted.

The radiologic findings varied considerably. In most cases, both lungs were affected by a diffuse reticulonodular process. The upper lobes were most often involved, and with the passage of time, blebs began to appear and regional honeycombing became evident. In those in whom the condition developed rapidly, the first changes noted were those of an acinous filling pattern. This later resolved, but often only partially, and in doing so left a diffuse interstitial pattern.

Pathology

Macroscopically, the lungs appeared solid and were of a gray-black color, with much pleural thickening and frequent emphysematous bullae at the apex and elsewhere on the pleural surface. In the acute stage, alveolar edema and thickened septa were often present. Interstitial fibrosis developed later, but the classic whorled nodules of silicosis were absent.

Subsequent analysis of the fumes emitted showed that they contained about 70% aluminum and 4%–7% free silica. Initially, it was thought that the free silica occurred as amorphous silica and was probably harmless. However, it became evident later that at the high temperatures, some of the silica had been converted to cristobalite. The latter is one of the more fibrogenic forms of crystalline silica.

Shortly after Shaver described this outbreak, ventilation was improved, and since that time no further outbreaks have occurred. Moreover, numerous surveys of persons exposed to alumina, including those who work in aluminum plants that convert bauxite to alumina, have not revealed any additional cases of Shaver's disease or indeed pulmonary fibrosis. Furthermore, although the intratracheal injection of alumina has successfully induced fibrotic conditions in the lungs of animals, inhalation techniques using high concentrations of aluminum oxide have failed to induce fibrosis.

Aluminum Lung

Molecules of aluminum metal cannot exist in the air for any length of time because they are almost instantaneously oxidized to aluminum oxide. By the same token, larger particles of aluminum metal are invariably coated with aluminum oxide. It is this thin, self-generating coating that gives aluminum its corrosion-resistant properties. Every particle of aluminum is surrounded by a hard coating of alumina that is around 20 ³ thick. When the coating is scratched off the surface of the particle so as to expose the metallic aluminum, it almost instantaneously regenerates.

For commercial use, aluminum particles are prepared in two forms. When fine metallic particles are necessary, aluminum is atomized. This process involves spraying a fine stream of molten metal into a high-velocity air jet, leading to the formation of granular particles with a smooth surface and a shape that is either ovoid or spherical. Granular aluminum particles have a number of uses, especially in the manufacture of pigments. A particular form of aluminum known as *flake* is used in the manufacture of paints and fireworks. This is also known as *stamped aluminum,* and it is processed into fine flakes by ball milling. Whereas granular aluminum particles have a limited surface area, the leaflike flake powder has a much larger surface area. A special type of flake powder known as *pyro* finds a particular use in the manufacture of fireworks and explosives. This is produced by ball milling flake aluminum into exceedingly fine particles that have a large surface area. During the ball milling of pyro, a lubricant is added to prevent impact welding, maintaining separation of the particles during stamping. The lubricant also increases and maintains the large surface area, a prerequisite for the manufacture of aluminum paints, and lessens oxidation. The lubricant that has been used predominantly for this purpose is stearin, a vegetable oil. Its addition during the stamping process causes the pyro flakes to be coated with aluminum stearate. The latter acts as a barrier between the flake surface and the atmospheric oxygen, thereby preventing further oxidation.

In wartime Germany and later in Britain, Sweden, and elsewhere, mineral oil (spindle oil) was substituted for stearin in the manufacture of pyro. The much-quoted reason for the substitution was a shortage of animal fats in Germany during wartime, but it seems that the real reason for the change was that mineral oil allowed more pyro powder to be packed into a cartridge so that the explosive effects were far greater. The latter property was desirable in the manufacture of fireworks.

Just before and during the war, Goralewski noted that pulmonary fibrosis developed in a number of German workers involved in the manufacture of pyro aluminum powder. As a result of Goralewski's experience in Germany, epidemiologic studies were subsequently carried out in Britain. No comparable condition was detected, and no explanation for the difference between the British and German findings was evident. Subsequently, however, a pulmonary fibrosis similar to that described by Goralewski developed in several British subjects who were working with metallic aluminum powder. The various effects of aluminum on the lung and the history of aluminum-induced fibrosis of the lung have been well described.

Clinical Features

These are essentially the same as seen in Shaver's disease, namely, the onset of cough, production of sputum, and anorexia. Basal crackles are noted. As in Shaver's disease, the upper lobes tend to be predominantly involved. In the case of one subject who had pulmonary fibrosis, a diffuse toxic encephalopathy also was present. Radiographs show nodular and flocculent shadows in the upper lobes with an occasional pneumothorax.

Pathology

Macroscopically and microscopically, the changes are similar to those seen in Shaver's disease and most other forms of interstitial fibrosis. There does tend to be somewhat more involvement of the upper lobes than in most other types of interstitial fibrosis. Analysis of the lungs usually reveals a grossly increased aluminum content.

Pathogenesis

Corrin, in a series of in vitro and animal experiments, demonstrated that stamped aluminum powder reacts vigorously with water, whereas granular aluminum is almost entirely inert. The latter form of aluminum, as already mentioned, is coated with aluminum oxide, and this explains its relative inertness. Stamped aluminum, whether in the metallic form or treated with mineral oil, reacts vigorously with water, but the addition of stearin reduces this propensity. As mentioned earlier, during wartime in Germany mineral oil was substituted for stearin, and shortly thereafter Goralewski noticed pulmonary fibrosis developing in pyro workers. He correctly attributed the development of the pulmonary fibrosis to the substitution of mineral oil for stearin. Corrin also noted that it was only after stearin had been replaced by mineral oil that aluminosis began to occur in Britain.

This observation prompted Corrin to conduct a series of experiments in animals, in which he administered intratracheal injections of both granular aluminum and several forms of stamped aluminum, including stamped aluminum with stearin, stamped aluminum coated with mineral oil, and stamped aluminum with both lubricants removed. All three forms of stamped aluminum induced marked pulmonary fibrosis; however, granular aluminum was much less fibrogenic. He therefore concluded that all forms of aluminum powder were fibrogenic, although to differing extents. He still was of the opinion that stamped aluminum, when lubricated with mineral oil, was much more hazardous, but he could not completely exonerate stearin-treated pyro. He likewise realized that intratracheal injection did not necessarily reflect worker exposures, and in this regard he was remarkably prescient. Subsequently, in an attempt to prevent silicosis, metallic aluminum powder was administered by inhalation to many thousands of metal miners in Ontario and elsewhere, with no ill effects.

The patient described by McLaughlin and associates was believed to provide further confirmatory evidence that both stamped and granular aluminum powder could induce aluminosis. At the time this subject was given a diagnosis, he was working with pyro that had been treated with stearin, but it subsequently came to light that he had worked previously in the same factory at the time spindle oil was being used. Thus, it seems that aluminosis has been described only in subjects who have been heavily exposed to pyro treated with mineral oil. Similarly, granular aluminum is fibrogenic only when given by intratracheal injection, and this method of administration

is not physiologic and should not be regarded as a suitable model for human disease.

Other Effects of Aluminum

Development of a granulomatous condition of the lung, attributed to the inhalation of alumina, has been described in two subjects. Once again, there was a lack of evidence to indicate that the disease was related to aluminum, although an increased aluminum content was noted in the lungs of both. As the aluminum content of the lungs is increased in virtually every subject who works with alumina or is involved in the reduction of alumina to metallic aluminum, this finding is of little significance.

A more recent study describes nine workers exposed to Al_2O_3 during the production of abrasives from alundum ore. Most had long-term exposure and all had abnormal chest radiographs (category 1/0 or higher). In three, the respiratory symptoms, prevalence of pulmonary impairment, and radiographic appearances were more significant than in the others, and as a result open lung biopsy was performed. In all three, interstitial fibrosis with honeycombing was seen. The lungs were found to contain a variety of metals, and in one case a significant amount of silica and an increased number of asbestos fibers. All three subjects who underwent biopsy had an increased aluminum burden in the lungs; however, the burden as measured by the number of aluminum particulates varied greatly. Five of the remaining six subjects had radiographs that showed changes of either category 1/0 or 1/1. All five were smokers. The finding of a high concentration of aluminum in the lungs is to be expected with long exposure and cannot be construed as indicating that the aluminum caused the fibrosis. Moreover, in most cross-sectional studies there has been no evidence whatsoever of restrictive impairment, decreased lung compliance, or other changes that indicate pneumoconiosis. All three subjects who underwent biopsy may well have had other forms of interstitial fibrosis, such as fibrosing alveolitis. It should also be borne in mind that radiographic changes have previously been demonstrated in workers exposed to aluminum oxide. The changes noted by these investigators were scanty, irregular opacities ranging from category 0/1 to 1/1 at the most, and predominantly, but not entirely, related to cigarette smoking. The circumstances in which aluminum may cause pulmonary fibrosis have been previously described by Morgan and Dinman and by Abrahamson and associates. The evidence that aluminum oxide produces pulmonary fibrosis is tenuous and unconvincing.

A subject with pulmonary alveolar proteinosis attributed to the inhalation of aluminum dust has also been described. The affected subject was a 44-year-old man seen with shortness of breath, radiographic infiltrates, and restrictive disease. A biopsy showed pulmonary alveolar proteinosis. The affected worker had been employed as an aluminum rail grinder for the prior 6 years. It was suggested that grinding rails generated a large quantity of aluminum particles, many of which were deposited in the lungs. The illustrations left little doubt that the subject had pulmonary alveolar proteinosis; however, the electron micrograph of the aluminum particles showed them to be completely spherical. It seems inconceivable that the particles generated by grinding would be spherical, and indeed the only way in which the aluminum particles could have been spherical is if they were generated as droplets of vapor at a very high temperature. It is well established that pulmonary alveolar proteinosis may develop after high exposure to a number of dusts, but there is no compelling reason to incriminate aluminum in this case report.

Potroom Asthma

An ill-defined and nonspecific form of airways obstruction has been reported in certain groups of potroom workers. This occurs relatively rarely and is completely absent in some aluminum plants. Whether it is a true form of asthma or industrial bronchitis is not definitely known. It has been suggested that the asthmatic symptoms may be a consequence of exposure to fluorides. Nevertheless, there is little doubt of increased evidence of chronic air flow limitation in potroom workers, which tends to worsen with continued exposure, so that by the end of the week a small decrement in lung function is often noted.

Antimony Pneumoconiosis

Antimony is a metal closely related to arsenic that has been used in the manufacture and plating of vases since the time of the Pharaohs. Antimony ore, before it can be used, has to be pulverized into a fine dust. A pneumoconiosis may develop in those workers, particularly at the furnace, who are exposed to the pulverized oxide. Although radiographic changes are present in the lung, pulmonary function does not seem to be affected, and similarly the lungs do not show any fibrosis.

Baritosis

The inhalation of barytes may induce a condition known as *baritosis.* Baritosis also has been described in the manufacture of lithopone, in which barytes is used. Some deposits of barytes are contaminated by significant concentrations of silica, and silicosis may be observed in such workers.

Baritosis is not associated with respiratory symptoms, but the radiographic appearances are quite striking. The deposits of barium appear as multiple, extremely dense, small, rounded opacities. Some radiographic clearing occurs with the passage of time.

Berylliosis

Beryllium is a rare metal. It is found in a number of naturally occurring minerals, of which beryl or beryllium aluminum silicate is the most important. Deposits of beryl are found in Argentina, Brazil, Zimbabwe, and South Africa. Beryllium is in demand as a metal that is often added to other metals to increase their tensile strength. It is nonmagnetic and transmits x-rays. It is frequently used in the manufacture of x-ray tubes as well as in the space program.

Two processes are used to extract beryllium from beryl. These are known as *sulfate* and *fluoride extractions.* The sulfate process involves melting beryl in an arc furnace at about 1700°C and pouring it through a high-velocity water jet to form frit. This is then treated with concentrated sulfuric acid and subsequently ammonia. Later, sodium hydroxide is added to form sodium beryllate, which is hydrolyzed so that beryllium hydroxide is precipitated. Beryllium hydroxide can be easily converted to metallic beryllium.

The fluoride process involves sintering in a rotating furnace a mixture of beryl sodium, silicofluoride, and soda ash. The sintered residue is pulverized, melted, and separated by leaching. Once again, sodium hydroxide is added and beryllium hydroxide is precipitated.

Exposure to beryllium can cause three conditions: dermatitis, acute pneumonitis, and chronic berylliosis.

Acute Berylliosis

The acute syndrome leads to the development of rhinitis, tracheitis, and pulmonary edema. The mucous membranes of the nose are swollen, ulceration may be present in the nasal mucosa, and septal perforation occasionally occurs. Tracheitis and bronchitis associated with a dry, irritative cough are common. When the exposure is severe, a chemical pneumonia develops and the subject becomes acutely short of breath; death is a frequent occurrence. Although many such cases were reported in the 1930s and 1940s, acute berylliosis has not been seen in North America for many years.

The subject with acute berylliosis is noted to be acutely short of breath, often with cyanosis and tachypnea, and in great distress. Crackles may be present all over the lungs. The chest x-ray film shows a bilateral acinous filling process with the appearance of noncardiogenic pulmonary edema. If the subject is capable of carrying out spirometry and other lung function tests, it will be observed that the lungs are stiff and that the patient has severe restrictive disease and a low diffusing capacity.

Treatment consists of giving supplementary oxygen and antibiotics to prevent secondary infection. In many instances, mechanical ventilation becomes necessary. Although steroids are given, usually in high doses, there is no conclusive evidence that they are of any use.

Subacute or Reversible Berylliosis

This entity has been described by Sprince and colleagues, who suggested that interstitial disease may develop in subjects exposed to high concentrations of beryllium that improves after the introduction of better ventilation and adequate industrial hygiene measures. Subacute berylliosis is a nebulous entity, and it remains somewhat unconvincing as a specific form of berylliosis.

Chronic Pulmonary Berylliosis

This condition was first described by Hardy and Tabershaw in 1946. It is a systemic disease associated with the development of granulomas throughout most of the body, but with a particular predilection for the lungs. Those initially affected were mainly involved in the manufacture of fluorescent bulbs for strip lighting; however, beryllium refineries now present the major hazard. Chronic berylliosis mainly develops in those working directly with beryllium, but there have been a few sporadic reports of berylliosis developing in wives of workers, presumably from beryllium dust brought home on their husbands' clothes. There also have been a number of so-called neighborhood cases, but most of these are not convincing. A latent period from first exposure to the development of the condition ranges from 2 or 3 to 15 to

20 years. Berylliosis is now a rare condition, but sporadic cases still occur, mainly resulting from exposure many years ago.

Clinical Features

Although most persons in whom the condition develops are currently working with beryllium, in a few cases it appears many years after exposure has ceased. This emphasizes the need for a detailed occupational history. The presenting symptoms are usually shortness of breath and a dry cough. Both are progressive and unremitting. Occasionally, skin lesions are also present. Physical examination usually reveals tachypnea and a small tidal volume. In the initial stages, few if any crackles are heard. With the passage of time, usually several years, and the development of fibrosis, crackles become evident. Initially, weight loss and fatigue are frequently present.

Berylliosis closely resembles sarcoidosis, and most of the features seen in the latter condition are common to both. Thus, lymphadenopathy occurs in both conditions, although generalized lymphadenopathy is much less frequent in berylliosis. Berylliosis, however, seldom presents without both parenchymal changes and hilar adenopathy. Hilar adenopathy by itself is rare. Granulomatous skin lesions are seen in both berylliosis and sarcoidosis, but the deforming facial rash leading to scarring that occasionally appears in sarcoidosis does not occur in berylliosis. Hepatosplenomegaly is present in both diseases, but parotid enlargement and cystlike bone changes are not seen in berylliosis. Renal involvement, including both nephrocalcinosis and hypocalcemia, occurs in both conditions. In contrast, the development of meningeal symptoms, peripheral neuropathy, and myocarditis indicates that the condition is likely to be sarcoidosis, and this is also true for uveitis and uveoparotid fever. Berylliosis does not seem to affect tuberculin reactivity. Similarly, spontaneous remission, although common in sarcoidosis, is extremely rare in berylliosis. Abnormalities of the plasma proteins occur in both sarcoidosis and berylliosis and do not help to distinguish them. Gamma globulin production is predominantly affected, and the IgG fraction is often elevated. It is also elevated in beryllium workers who have no evidence of berylliosis. As the disease progresses, the patient becomes more and more short of breath, the lungs become increasingly stiff, and the classic signs of cor pulmonale are noted. Pneumothorax may occur from bleb formation, and right ventricular hypertrophy is evident. The disease tends to progress slowly, and survival times of 15 to 20 years are frequent.

Radiographic Features

The most common radiographic presentation is one of miliary mottling, similar to that seen in miliary tuberculosis. Hilar adenopathy is distinctly uncommon. Large, blotchy, coalescent infiltrates resembling those seen in sarcoidosis also occur, and uncommonly, nodular infiltrates similar to those seen in nodular sarcoidosis may be observed. Gradually, the lungs become small, and the typical features of reticulonodulation and interstitial fibrosis develop along with honeycombing.

Pulmonary Function

Abnormalities typical of diffuse fibrosis are found—that is, stiff lungs and restrictive impairment. These abnormalities are entirely nonspecific. Obstruction does not occur except terminally, when minor degrees may be present. It has also been suggested that long-term exposure to beryllium is associated with the gradual reduction in pulmonary function. Such reductions are said to occur in workers who have no radiographic abnormalities. Moreover, it has been suggested that the alveolar-arterial oxygen difference gradually increases with cumulative exposure after controlling for age and smoking. The evidence for this, however, is tenuous and unconvincing.

Other Diagnostic Tests

In 1951, Curtis described a beryllium patch test. Results are usually positive in chronic berylliosis, but there is good evidence that its use may lead to a flare-up of the chronic pulmonary berylliosis. Metallic beryllium cannot be used for skin testing, and the patch test is best carried out by applying to the skin a piece of filter paper soaked in beryllium fluoride, sulfate, or nitrate. The Kveim test result is negative in berylliosis.

Tissue biopsy and spectrographic analysis of specimens for beryllium are not helpful. Increased levels are found in the tissues of most healthy workers in a beryllium refinery. This is true for the lungs only if exposure has been relatively recent, as beryllium is rapidly removed from the lungs and deposited in the bones and liver. It may be present in increased amounts in the urine, but usually only if the subject is currently exposed. Thus, analysis of tissue specimens cannot confirm the presence of disease. On the other hand, a lung biopsy specimen may have a normal beryllium content despite the presence of chronic berylliosis.

Pathology

Chronic berylliosis is characterized by the presence of noncaseating granulomas indistinguishable from those found in sarcoidosis. Eventually, as time goes by, the granulomas become organized and fibrotic. Blebs may develop late in the course of the disease, and these are frequently associated with some pleural thickening.

A number of cellular responses have been described following experimental exposure to beryllium. The alveolar macrophages take up beryllium particles by phagocytosis and in doing so are damaged and release lysosomal enzymes. Any beryllium deposited in the alveoli is cleared relatively slowly. Initially, macrophage activity is decreased, but subsequently activity rebounds and increases. There is also evidence that macrophages sequester beryllium in the lung and in doing so become more active, with resultant damage to the lung.

Treatment

In general, steroids are administered when the condition is diagnosed, but there is no convincing evidence that they have ever produced a cure. Usually, the subject is started on a high dose of prednisone (e.g., 75 mg/d), and this is gradually tapered to a maintenance dose of about 10 to 20 mg. The patient is best followed by serial tests of pulmonary function.

Pathogenesis

All the evidence presently available suggests that berylliosis is a hypersensitivity disease characterized by a cell-mediated immune response to beryllium. Differentiation between sarcoidosis and berylliosis is difficult. Marx and Burrell have suggested that lymphocytotoxins can be demonstrated in the cells of sensitized but not of unsensitized subjects. Production of migration inhibitory factor (MIF) has likewise been noted. The cellular and immune mechanisms of berylliosis were later studied by Deodhar and co-workers. They investigated blast transformation of lymphocytes in subjects with berylliosis. About 60% of their subjects showed this phenomenon, to which severity of disease appeared to be related. They found that the serum IgA level was elevated in about half their subjects, but in this their findings differed from those of Resnick and associates, who noted that the IgG fraction was increased.

A beryllium lymphocyte transformation test has been developed and has been used with some success in the diagnosis of berylliosis. Bronchoalveolar lavage also has been carried out in subjects with berylliosis, and the proportion of bronchoalveolar T cells has been noted to be increased.

The evidence currently available suggests a cell-mediated response to the inhalation of beryllium takes place that includes the following:

1. Microscopic features in the lungs and lymph nodes similar to those seen in other cell-mediated reactions
2. Skin sensitivity reactions
3. Blast transformation and MIF production from lymphocytes
4. Selective stimulation of T lymphocytes
5. Transfer in animal models of cutaneous sensitivity by lymphocytes but not by serum

Prevention

Dust control is of the utmost importance in preventing berylliosis. The present standard recommends that exposure should not exceed 2 g/m^3 of air during an 8-hour period. Whether this is entirely effective in the prevention of chronic berylliosis is unknown, as most of the evidence suggests that the condition is related to hypersensitivity. Although pre-employment and periodic medical examinations, including serial radiography and lung function tests, are recommended, there is no evidence to suggest that they are of any benefit in this disease, as the condition tends to come on rapidly and progress despite separation from exposure. Educating workers about the symptoms of chronic berylliosis and how to avoid exposure would seem to be much more effective methods of prevention.

Graphite and Carbon Pneumoconiosis

Graphite is a form of carbon and is also known as *plumbago* or *black lead.* It is mined or extracted in Austria, the former U.S.S.R., Sri Lanka, Norway, and Korea. Usually, it is found in veins that traverse igneous rocks. It occurs naturally in three forms: lump, amorphous, and flake. The latter is usually extracted by strip mining.

Many deposits of graphite are contaminated by free silica, usually in low concentrations.

Graphite is used in the manufacture of steel and in lubricants, lead pencils, nuclear reactors, and electrodes. Because it also conducts electricity, it is often used in generator brushes. It was at one time used in the printing industry for duplicating plates.

It is now clear that inhalation of pure carbon may induce radiographic and pathologic changes indistinguishable from those associated with inhalation of coal. In some instances, the lung bases have been described as showing a fine reticulation, but more generally this disease appears as the typical nodulation seen in simple CWP. PMF likewise can occur. The pulmonary function abnormalities are similar to those seen in CWP.

Hematite Pneumoconiosis (Silicosiderosis) and Other Mixed-Dust Fibroses

Although iron oxide has been known for many years to produce a condition known as *siderosis,* it is also evident that a lung condition associated with radiographic changes may develop in iron miners. However, iron miners are not exposed to pure iron oxide, but to a mixture of dusts, often with a fair amount of free silica present. The condition that occurs in iron miners is usually known as *silicosiderosis* and has been described in Cumbria in Britain, Germany, Bergamo in Italy, and Alsace-Lorraine. It seldom develops without at least 10 years of exposure.

The best pathologic description of the condition was given by Stewart and Faulds, who noted a diffuse rather than nodular fibrosis, although if the proportion of silica was high, then the latter type of fibrosis often occurred. The whole lung was noted to be brick red in color, with associated areas of focal emphysema. Radiographically, diffuse fibrosis appeared to predominate. Massive fibrotic lesions also were seen and were usually situated in the same regions of the lung in which conglomerate silicosis and PMF occur. As in the other two conditions, these fibrotic masses encroach on the blood and bronchial supply of the affected area. They also may undergo cavitation, either from ischemic necrosis or secondary tuberculous infection. Microscopically, aggregated particles of hematite and silica are seen lying in the alveolar walls. The lesions are situated in the same areas of the acinus that are primarily affected by silicosis, and peribronchiolar and periarteriolar fibrosis are common. Whorled nodules may be seen, especially along the lymphatic vessels. A fair amount of dense collagenous fibrosis is present, usually in association with the typical nodules of silicosis.

There is good evidence that cancer of the lung occurs more frequently in Cumbrian iron miners. Most of the evidence, however, suggests that the increase is related to radon daughters rather than to any inherent carcinogenic property of iron oxide. The symptoms of the condition are very similar to those of silicosis. The presence of iron in the inhaled dust leads to a situation in which, for a given cumulative dust exposure, radiographic abnormalities appear somewhat more rapidly than they would in workers exposed to other dusts containing free silica. A relatively similar condition can also develop in ochre miners.

A mixed-dust fibrosis is commonly seen in foundry welders and burners as well as in boiler scalers. These workers likewise are exposed to a mixture of iron, silica, and other dusts. Iron, with its high atomic number, tends to produce radiographic changes, and such changes are frequent in foundry workers. There is, however, an absence of significant fibrosis. Boiler scalers, on the other hand, are often exposed to dust containing a high content of free silica, and there is a tendency for a condition more closely resembling silicosis to develop.

Labrador Lung

An unusual form of mixed-dust pneumoconiosis known as *Labrador lung* has been described in the iron miners of West Labrador. These miners are exposed to iron, silica, and some anthophyllite. Lung biopsies have demonstrated increased amounts of iron and silica in the lungs and, in addition, a number of ferruginous bodies. The histologic appearances are frequently modified by the presence of anthophyllite.

Polyvinyl Chloride Pneumoconiosis

The manufacture of polyvinyl chloride (PVC) leads to the production of a varying number of respirable dust particles. When administered to animals, PVC may lead to bronchiolitis, some alveolitis, and the formation of granulomas. During the past 10 to 15 years, radiographic changes have developed in a number of subjects working with PVC. Many of these individual case reports have been far from convincing, but a number of epidemiologic surveys have demonstrated that PVC pneumoconiosis indeed exists.

PVC pneumoconiosis was first described in 1970 by Szende and associates. A number of studies have been carried out since Szende's description suggesting that radiographic changes take place. Other studies have indicated that respiratory symptoms and pulmonary impairment may occur. A well-designed study of a large group of workers exposed to PVC was published in 1980, showing a minimal increase in respiratory symptoms in those most heavily exposed and a similar minimal effect on the FVC and FEV_1. The radiographic changes, however, were subtle and consisted of small, scanty, rounded opacities. Pathologic changes in this condition indicated that there may be infiltration of the lung parenchyma with histiocytes and a few multinucleated giant cells, and, rarely, a little collagenous fibrosis may be seen. Macrophages migrate into the tissue and many contain PVC particles.

Shale Pneumoconiosis

Shale deposits are found in many parts of the world, in particular in the Midwest of the United States, Alberta in Canada, and to a lesser extent Scotland. Such deposits are a known source of oil. Shale consists largely of silicates, including a fair proportion of kaolin and mica. Either simple or complicated pneumoconiosis may develop in shale miners. The pathology resembles either CWP or kaolin pneumoconiosis. The simple form of the disease has little effect on lung function, but the complicated pneumoconiosis of shale workers leads to both restrictive and obstructive impairment, as is seen in CWP.

Siderosis (Arc Welders' Lung)

Siderosis was first described by Zenker in the late nineteenth century. Both his subjects had tuberculosis, and the fibrosis he noted was probably related to the infection rather than to the inhaled iron. Siderosis is caused by the deposition of iron in the lungs, usually in the form of iron oxide. It occurs in arc welders, oxyacetylene cutters, silver finishers, and magnetite pulverizers. During oxyacetylene cutting and arc welding, the iron that is being cut or welded melts and then boils from the heat of the arc or torch. This leads to the emission of fine particles of ferrous oxide, which on contact with the air are immediately oxidized to ferric oxide. They appear as bluish-gray fumes. Most of the particles present in these fumes are respirable, with many being submicronic in size. Prolonged inhalation and deposition of welding fumes leads to the development of siderosis, a condition characterized by radiographic changes somewhat similar to those seen in silicosis.

Silver finishers use a preparation (“jeweler's rouge”) to polish their products. Jeweler's rouge consists of iron oxide and is applied to the finished product with a buffer; this creates an aerosol of small iron and silver particles. Prolonged inhalation of such particles leads to a condition known as *argyrosiderosis.*

Welders' Siderosis

Welders' siderosis was first described in 1936 by Doig and McLaughlin. The weight of the evidence suggests that provided only iron oxide is inhaled, the condition is not associated with symptoms and does not lead to fibrosis. Morbidity and mortality statistics from the United States and Britain do not indicate any increased morbidity or mortality among welders other than from lung cancer. However, they do indicate that welders may be more prone to pneumonia and, in addition, frequently have metal fume fever. Nevertheless, sporadic case reports through the years have suggested that welding induces fibrosis and other problems. In certain instances, the welding has been reported to be associated with the development of restrictive impairment and pulmonary fibrosis, whereas in others it has been claimed that it leads to airways obstruction and emphysema. In none of these subjects was there any smoking history or were there any data regarding other exposures. The case reports of Charr described symptomatic welders at the Philadelphia shipyards, and the somewhat inadequate description of the pathology and the few photomicrographs available suggest that these men almost certainly had asbestosis. In fact, in one photomicrograph there appears to be an asbestos body. It must be recalled, however, that at that time it was not known that persons other than miners and millers were at risk for asbestosis. The subject described by Meyer and colleagues, although a nonsmoker, had been a sandblaster, and despite the presence of vast quantities of silica in his lungs, along with massive fibrosis, his disease was attributed to welding. This is not to say that all constituents of welding rods are harmless in all circumstances. The rods and other materials with which welders work contain carbon, manganese, aluminum, silicates, and free silica. Arc welders also may be exposed to ozone, especially if they weld aluminum. Oxyacetylene cutters similarly may cut through cadmium-containing metal and thus be exposed to cadmium fumes.

In regard to the general health of welders, as already mentioned, they seem more prone to pneumonia and metal fume fever. The latter is a well-recognized cause of temporary morbidity. There also seems to be an excess risk for lung cancer that cannot entirely be accounted for by social class and smoking habits. However, many welders, including those studied by Beaumont and Weiss, have worked exclusively or for a long time in shipyards and thereby have had significant exposure to asbestos. Asbestosis is a well-recognized complication of shipyard welding.

Pathology

The pathologic effects of iron on the lung were first described by Harding and colleagues from autopsy findings of four arc welders and an oxyacetylene cutter. One of their subjects had coincident exposure to silica, and there was evidence of a mixed-dust fibrosis. The oxyacetylene cutter, however, showed no fibrosis. When fibrosis was found in the other subjects, it was not related to the deposition of iron oxide but to the other constituents of welding fumes or to other occupational exposures. Similar studies of silver polishers have shown an absence of fibrosis. Experiments in which animals have been exposed to the inhalation of iron have likewise failed to reveal any fibrosis.

The results of lung biopsies in seven welders described by Morgan and Kerr showed that although some of the iron lay free in the alveoli and respiratory bronchioles, most had been taken up by the macrophages and some could be seen in the lymphatic vessels. Fibrosis was entirely absent, except in the one subject who had had a mixed-dust exposure. An analysis of a portion of one subject's lung revealed an iron content 15 times greater than the normal level. Despite this, absolutely no fibrosis was present in the sections (Fig. 14 and Fig. 15).

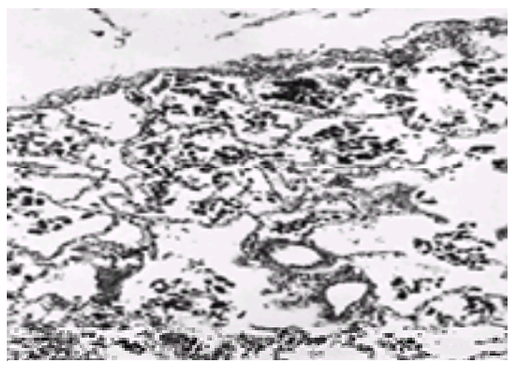

FIG. 14. Photomicrograph of a lung biopsy section taken from a welder. Note the absence of septal thickening and the pigment in the alveoli. Most of the latter is present in alveolar macrophages.

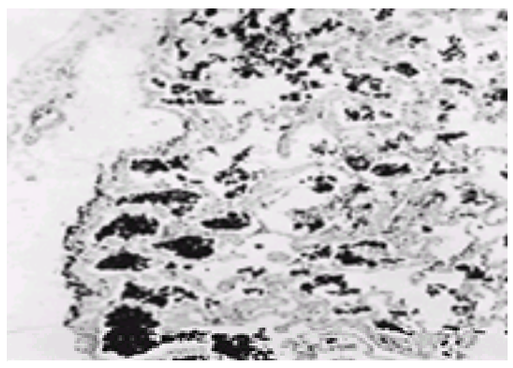

FIG. 15. Photomicrograph of a different section of the same lung as in Fig. 14, but on this occasion stained with Prussian blue. Note again the absence of fibrosis and the heavily stained deposits of iron, which appear intensely blue when viewed under the microscope.

A number of retrospective studies have been published purporting to show that welding fumes cause fibrosis. Of the 3600 cases referred to Liebow, nearly all of which were subjects with pulmonary fibrosis, it was possible to select 29 who were welders and who had fibrosis. No fewer than 14 were reported by Liebow as showing fibrosing alveolitis. Unfortunately, some have assumed that these cases are representative of welders as a whole, and this is clearly not the case. Others have assumed that low concentrations of the oxides of nitrogen induce pulmonary fibrosis, again with no scientific basis.

Radiographic Features

Radiographically, the lungs are characterized by small, rounded opacities widely distributed throughout both lung fields. The preponderance in the upper zones that occurs in silicosis is not usually evident. Moreover, the shadows tend to be somewhat smaller and of the *q* type rather than of the *r* type commonly observed in silicosis. Conglomeration can occur, but when it does, it is usually because of coincident exposure to silica (Fig. 16). Postmortem studies of the contaminants of the lung add little useful information other than giving an idea of the agents to which the welder was exposed during life. Serial observations of welders who have ceased exposure have shown that in certain instances the radiographic appearances tend to improve.

FIG. 16. Chest radiograph of a welder showing welders' siderosis. A large shadow is present in the left middle zone. The subject had a prior exposure to a number of mixed dusts, including some silica.

Pulmonary Function

Siderosis when not associated with the inhalation of other harmful agents is not related to significant pulmonary impairment. This is evident from the studies of Morgan and Kerr, who measured all aspects of pulmonary function except the diffusing capacity. Values obtained during subsequent measurements of the diffusing capacity were within normal limits. Stanescu and co-workers studied the pulmonary mechanics of a group of 16 welders who had abnormal radiographic findings. They were compared with a group of 13 unexposed healthy men. When certain of the more sophisticated parameters of lung mechanics were measured, including static and dynamic compliance of the lungs, values were slightly reduced. The minor abnormalities noted, however, do not cause symptoms.

A number of well-controlled epidemiologic studies of the respiratory status of welders have been carried out. These, for the most part, have shown that welding may be associated with a slight increase in airways obstruction, but this is present only in those welders who are smokers. There is also evidence that welders tend to smoke more often than does the general population.

General Health Effects of Welding

The biologic effects of exposure to welding fumes have generated considerable discussion during the past three to four decades. A fair number of articles have been published purporting to show that welding is a dangerous occupation associated with a number of conditions, ranging from lung cancer to dementia and motor neuron disease. The real and imaginary hazards of welding have been reviewed in detail.

The recognized and accepted hazards of welding can be grouped under (1) acute effects, (2) chronic toxic effects, (3) chronic respiratory effects, and (4) carcinogenic effects.

Acute Effects

A number of agents to which welders are exposed may produce acute effects. These include ozone, the oxides of nitrogen, cadmium fumes, phosgene, and metal fumes. There is little doubt that in exceptional circumstances all can be a respiratory hazard, and the effects of each are described elsewhere. Suffice it to say that exposure to the oxides of nitrogen does occur occasionally in welders working in confined spaces and has been noted in coal mines and elsewhere. Acute exposure to cadmium leading to the development of pulmonary edema and subsequently to emphysema also has been described. Metal fume fever is a recognized complication of welding and oxyacetylene cutting. It is entirely benign.

Chronic Toxic Effects

These occur as a result of exceptional circumstances. Manganese poisoning associated with central nervous system involvement has been described in the former East Germany and eastern Europe, but never in the West. Exposure to fluorides, lead, and various trace elements likewise may occur, but no reports of toxic effects from exposures to these agents have appeared in the last 10 to 15 years.

Chronic Respiratory Effects

A number of chronic respiratory effects may occur as a result of welding. First and of most importance is welders' siderosis. This has already been described in detail.

There is a suggestion that cough and production of sputum are greater in welders than in a comparable general population. Although part of this may be explained by the fact that welders smoke more, little doubt exists that exposure to welding fumes leads to mild chronic bronchitis that is not associated with any significant pulmonary impairment.

Carcinogenic Effects

Evidence is fairly good that welders as a whole have a slightly greater risk for lung cancer than does the general population. Part of this can be explained by the fact that welders smoke more than does the general population; however, a significant proportion of welders have worked or still work in shipyards and have done so for many years. As such, these workers have been exposed to asbestos, and overt asbestosis has developed in many of them. The combination of excess smoking and exposure to asbestos almost certainly accounts for the increased incidence of malignant respiratory disease.

Silver Polishers' Lung

Silver polishers' lung differs from siderosis in that although silver polishers use iron oxide while buffing silver, the buffing tends to aerosolize both silver and iron oxide particles. As a result, inhaled iron and silver are both deposited in the lungs, and the lungs appear black at autopsy because of staining with silver. No physiologic abnormalities occur in this condition.

Magnetite and Limonite Pneumoconiosis

Radiologic changes similar to those seen in siderosis have been described in workers exposed to magnetite and limonite. The appearances radiographically resemble siderosis, and respiratory impairment has not been observed.

Stannosis

Tin is an important metal that is used frequently to form alloys. Both the Phoenicians and the Carthaginians traded with the inhabitants of Cornwall for the tin that was mined there. In the Middle Ages, most of the tin that was mined came from Cornwall, Saxony, and Bohemia, but at the present time, Malaysia, Bolivia, Zaire, and Australia are the main sources. Although some tin is extracted by underground mining, in Malaysia the deposits are on the surface. Most Cornish tin mines are now closed down. Cornish miners, however, were not afflicted with stannosis, but rather with silicosis. The seams were usually located about 1000 ft below the surface, and the adjacent rock that had to be removed before reaching the seam frequently contained large amounts of free silica. Hookworm infection also was a problem. In Malaysia, tin is usually removed by open-cast mining.

The inhalation of tin oxide leads to a benign pneumoconiosis not associated with symptoms or respiratory impairment. Most of the subjects in whom the condition develops are involved in the bagging of concentrated oxide or in the smelting operation. During smelting, hot fumes are emitted that contain submicronic particles of tin. These are inhaled and lead to the development of stannosis.

The radiographic appearances of stannosis are so distinctive that it is difficult to confuse it with other conditions. The high atomic number of tin makes the opacities very dense, even denser than those noted in welders' siderosis and almost as dense as those noted in baritosis (Fig. 17 and Fig. 18).

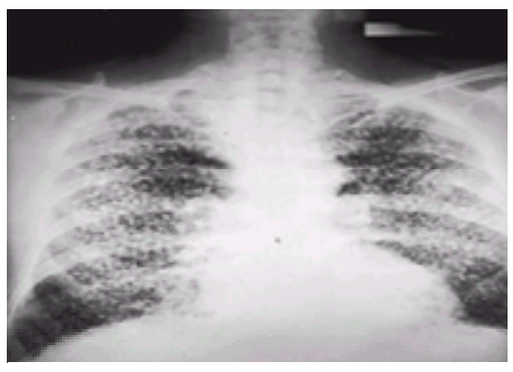

FIG. 17. Chest radiograph of a subject with stannosis. Tin oxide, having a high atomic number, shows up as intensely radiopaque deposits.

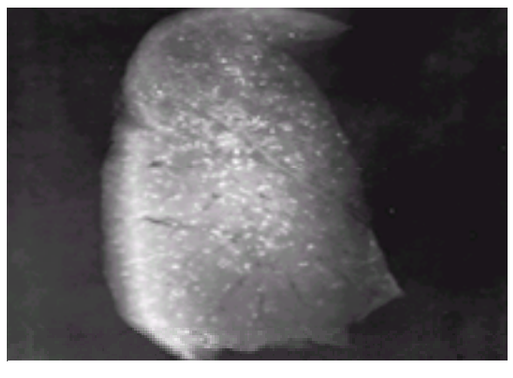

FIG. 18. Radiograph of a large lung section from a subject with stannosis. Death was caused by carcinoma of the prostate, not by stannosis.

Pathologically, blackish or grayish macules are widely distributed throughout the lungs. Gross pigmentation of the interlobular septa is frequent. The foci of dust are composed of dust-laden macrophages containing tin oxide and other agents. Focal emphysema occurs but is not as prominent as in CWP. Fibrosis does not occur.

Thesaurosis

Bergmann and colleagues in 1958 described several subjects with a chronic pulmonary disease that they termed *thesaurosis* or *storage disease.* They were generally young women exposed to hair spray, and Bergmann and associates attributed the condition to the inhalation of polyvinylpyrrolidone (PVP), a major constituent of hair sprays. Following their description, a series of subjects with so-called thesaurosis was described. Unfortunately, those who described thesaurosis seemed unfamiliar with Koch's postulates and certainly did not apply them when they weighed the evidence regarding the existence of this entity. In reality, the subjects described appeared to have sarcoidosis. Subsequent epidemiologic studies have provided absolutely no evidence that cosmetologists are at increased risk for the development of any lung condition other than chronic bronchitis and emphysema. The latter is related to the fact that the prevalence of smoking is exceedingly high in this trade.

Tungsten Carbide Pneumoconiosis (Hard Metal Disease) and Related Syndromes

Although the term *hard metal disease* is in common use, the available evidence at the present time suggests that it is not the tungsten carbide that leads to the respiratory problems seen in hard metal workers, but rather the cobalt that is almost invariably present. Cobalt is frequently added to various alloys to increase their tensile strength. Hard metal is produced by metallurgic compounding of tungsten and carbon, with cobalt being added as a binder. Tungsten carbide, or hard metal, is extremely hard, second only to diamonds, and is used for cutting metals. It is particularly useful in the manufacture of dental drills.

Tungsten carbide is prepared by compounding extremely fine particles of tungsten and carbon. These particles are at the smaller range of the respirable fraction and are about 1 to 2 m in size. The tungsten carbide mixture is then milled with the addition of between 3% and 25% cobalt. The tiny, hard metal crystals are deposited in the cobalt. Paraffin is added to provide body before the metal is pressed into ingots. The ingots are then sintered into hard metal, and the resultant tool is subsequently shaped as desired. Three respiratory diseases are produced by the inhalation of cobalt. These are (1) allergic alveolitis; (2) pulmonary fibrosis, or what is commonly called *hard metal disease;* and (3) a form of asthma.

In 1940, Jobs and Ballhausen noted that in a group of 27 German workers, abnormal chest radiographs developed in eight. A fine reticulonodulation was present. Subsequently, in an examination of 696 hard metal workers, Moschinski and colleagues found a high prevalence of bronchitis. Radiographic evidence of pneumoconiosis was found in a smaller percentage. Fairhall and associates surveyed 2000 tungsten carbide workers shortly after World War II and found that conjunctivitis, rhinitis, tracheitis, and bronchitis were frequent. In addition, pruritus and cobalt sensitivity occurred.

Cobalt-Allergic Alveolitis or Interstitial Pneumonitis

A description by Sjögren and colleagues of a syndrome similar to extrinsic allergic alveolitis in four subjects made it clear that an acute and reversible disease is induced by exposure to cobalt. All of Sjögren's subjects were grinders of hard metal, and symptoms and signs compatible with transient hypersensitivity pneumonitis developed in all. After an absence from work, the symptoms improved, the radiographic changes resolved, and the respiratory impairment decreased or in some instances resolved entirely.

The premonitory symptoms were cough, low-grade fever, muscle aches and pains, and generalized constitutional symptoms. These symptoms would often lead the subject to take several days off from work, during which time the symptoms would improve, only to recur on return to work. Medical examination during the acute phase would reveal basal crackles, low-grade fever, and in some subjects contact dermatitis. Of the four subjects described by Sjögren and colleagues, all had positive patch test results. Of particular interest, it was shown that during the grinding, small particles of cobalt were disseminated in the air and dissolved in the coolants used to cool the metal being ground. Subsequently, when the coolant was applied during the grinding process, it became aerosolized, and the worker would inhale the aerosolized coolant containing large quantities of cobalt. It appears that the cobalt was very soluble in the particular coolants used. The pathology of this condition shows an alveolitis with marked response of type II pneumocytes. Frequently, there is a granulomatous reaction with giant cells present. With repeated exposures, the granulomatous pneumonitis slowly evolves into interstitial fibrosis.

Interstitial Fibrosis (Hard Metal Disease)

An excellent description of the clinical features of hard metal disease is that of Coates and Watson. These workers described 12 subjects with diffuse interstitial lung disease, of whom no fewer than eight died. The symptoms included cough, which was usually dry but occasionally productive of some scanty mucoid symptoms. Later, breathlessness developed that became progressively worse. On examination, the subjects had tachypnea and frequently clubbing of the digits. Basal crackles developed late in the condition. Lung function tests showed restrictive impairment, arterial desaturation, and a low diffusing capacity. With the passage of time, pulmonary hypertension developed, usually on the basis of hypoxemia, and eventually overt cor pulmonale appeared.

The disease was seldom seen without at least 10 years of exposure, but in retrospect, some subjects were found to have had repeated flare-ups of minor constitutional symptoms, suggesting recurrent attacks of interstitial pneumonitis.

Radiographically, the disease presents initially as a fine reticulonodular pattern in the middle and lower zones, with the nodules sometimes being quite large. As the disease progresses, the characteristic features of interstitial fibrosis are noted, and honeycombing may eventually result.

Although the radiograph usually suggests diffuse involvement, on biopsy or at autopsy the fibrosis may be seen to be distributed in a patchy fashion. The interstitial tissue is often infiltrated with histiocytes and plasma cells. The alveolar septa may be thickened. In a few instances, fibrosis may be associated with a granulomatous reaction and the presence of giant cells. The latter are found particularly frequently in this condition, and some believe they are almost pathognomonic. The alveoli contain what are assumed to be desquamated type II alveolar pneumocytes. Electron microscopy reveals the deposition of collagen and elastic tissue in the septa and the presence of multifaceted crystals thought to be tungsten carbide. In one series of subjects with interstitial pneumonitis and hard metal disease, a nongranulomatous process was described characterized by intra-alveolar exudate and some interstitial reaction. Bronchoalveolar lavage showed bizarre giant forms of the alveolar macrophage (Fig. 19).

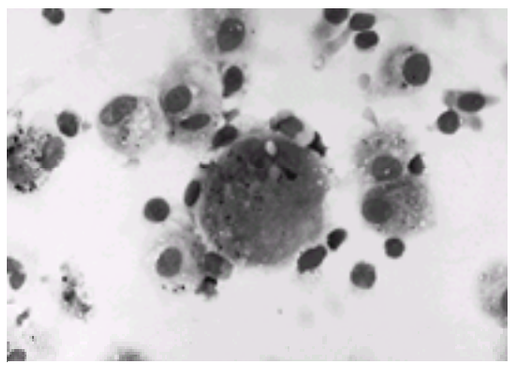

FIG. 19. Photomicrograph of bronchoalveolar lavage fluid showing a characteristic multinucleated giant cell with cytoplasmic vacuoles. Particulate matter is also present along with alveolar macrophages. Patient had hard metal disease.

Airways Obstruction or Asthma

Some subjects with interstitial pneumonitis may also have wheezing, cough, and shortness of breath. Such symptoms also occur in the absence of interstitial pneumonia. The symptoms tend to occur while at work. In most instances, they disappear on the weekends. When subjects return to work on Monday, they remain relatively free of symptoms until late in the afternoon, when symptoms recur. Once the symptoms have appeared, they usually slowly become more severe through the week, only to improve at the weekends. Most subjects with this type of response leave their jobs voluntarily. Those affected also may have itching and skin manifestations resulting from exposure to cobalt. Results of challenge studies with cobalt, but not tungsten, usually are positive, but not invariably so.

Treatment

There is no treatment for established hard metal disease characterized by extensive fibrosis. In contrast, the interstitial pneumonitis usually responds well to steroids and to separation from further exposure to cobalt. It will, however, recur should the subject return to work. Protective devices such as masks are seldom effective.

Etiology

Although a few persons still believe that tungsten carbide rather than cobalt may be responsible, the vast weight of evidence incriminates cobalt. Harding showed that powdered cobalt is toxic in animals, and it did not matter whether it was administered intratracheally or by inhalation. He also demonstrated that the metal was much more soluble in plasma than in saline solution. In contrast, tungsten carbide, when given to animals, is inert. Likewise, Harding was able to induce both an alveolitis and subsequently pulmonary fibrosis. Delahant was able to induce chronic bronchiolitis and metaplastic changes in alveoli with pulverized cobalt, but he failed to do so when he used tungsten carbide, titanium, and tantalum. Single exposures to cobalt during a short period induced granulomatous pneumonitis and bronchiolitis, but if exposures were continued for longer, interstitial fibrosis developed. The fact that cobalt is soluble explains why it may be completely absent in many biopsy specimens obtained from humans. There is little doubt that it is deposited in the lungs, but it is rapidly removed, and lung biopsy 1 month to 6 weeks later may show a normal cobalt content.

Miscellaneous Pneumoconioses

A number of miscellaneous pneumoconioses have been described. Most are of little clinical import. Nonetheless, when faced with a subject who has radiographic abnormalities, it is imperative to take a complete occupational history. Rare earths may induce pneumoconiosis, and cerium oxide is a recognized cause of radiographic abnormalities. Titanium likewise produces radiographic abnormalities, but no associated pulmonary impairment. The same is true of zirconium. Finally, it is important to remember that the esoteric habits of the “lunatic fringe” occasionally lead to the development of radiographic abnormalities and pulmonary impairment. Thus, the development of pulmonary fibrosis in a drug-snorting fire eater who played in a punk rock band serves to emphasize the importance of studying both avocation and vocation.

CHAPTER

34 Occupational Asthma and Industrial Bronchitis

R. John Looney · Mark J. Utell

R. J. Looney and M. J. Utell: Divisions of Immunology, Pulmonary/Critical Care, and Occupational/Environmental Medicine, Departments of Medicine and Environmental Medicine, University of Rochester Medical Center, Rochester, New York 14642.

OCCUPATIONAL ASTHMA

Occupational asthma may be defined as reversible airways obstruction caused by specific agents in the workplace. It should be distinguished from pre-existing asthma that may be worsened by workplace exposures. The focus of this chapter is primarily on new-onset asthma induced by workplace exposures.

Occupational asthma may be immunologic or nonimmunologic in origin and may be caused by a wide spectrum of low- and high-molecular-weight substances delivered as fumes, gases, or particles. Different classifications are useful when various aspects of occupational asthma are considered (Table 1). One classification divides immunologically mediated occupational asthma into subsets based on type of antigen (high- versus low-molecular-weight agents; Table 2). A second classification divides occupational asthma into subsets based on pathophysiologic mechanisms. Typically, immunologically mediated asthma is associated with a latency period; in contrast, irritant-induced asthma (e.g., reactive airways dysfunction syndrome) occurs without any latency.

Antigens
High-molecular-weight antigens
Protein derived from domestic animals, insets, fungi, or vegetable matter
Dextrans
Low-molecular-weight antigens
Haptens such as platinum and other metal salts
Penicillin and other drugs
Toluene diisocyanate and other reactive chemicals
Pathophysiology
Immunologic—characterized by a latency
IgE-mediated (seen with both high- and low-molecular-weight antigens)
Non-IgE-mediated (seen only with low-molecular-weight antigens)
Nonimmunologic—no latency
Pharmacologic—mast cells, sensory neurons, or smooth muscle as targets
Irritants and toxins (reactive airways dysfunction syndrome)

TABLE 1. *Classification of occupational asthma*

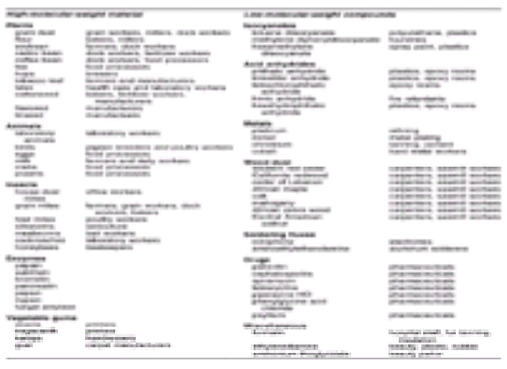

TABLE 2. *Causes of occupational asthma*

Epidemiology and Prevalence

Occupational asthma is now the most common form of occupational lung disease in many industrialized countries. In the United Kingdom and France, the number of claims for occupational asthma exceeds that of pneumoconioses. In the United States, asthma prevalence is increasing, involving approximately 5% of the population; recent studies indicate that 5%–10% of adult asthma is attributable to workplace exposures. However, disease prevalence varies greatly, as does the risk inherent to specific occupational exposures. For example, the prevalence of asthma can be as high as 50% for workers exposed to platinum salts and only 5% among workers exposed to either isocyanates or wood dust from western red cedar. Among 2500 asthmatic subjects ages 20 to 44 years studied in a large young adult Spanish population, the highest risk for occupational asthma was observed among laboratory technicians, spray painters, bakers, plastics and rubber workers, and welders; the risk for asthma attributed to occupational exposures after adjusting for age, sex, residence, and smoking status ranged from 5%–7%, depending on the definition of asthma.

It is difficult to estimate the true incidence or prevalence of occupational asthma. Many surveys have used questionnaire responses only, which may not accurately reflect airways hyperreactivity or its etiology. Cross-sectional studies of workers may underestimate asthma prevalence because of pre-employment screening to exclude sensitive workers and because of dropout of workers who become sensitized at work. Individuals who remain may reflect a healthy worker effect. Other workers may refuse to participate in epidemiologic studies for fear of losing their jobs.

Several risk factors that influence the development of disease have been identified. Genetic factors such as atopy predispose to the development of occupational asthma in industries using high-molecular-weight antigens; the significance of atopy with low-molecular-weight compounds is less clear. In some studies, cigarette smoking has been linked to an increased risk for occupational asthma. The relationship between pre-existing airways hyperreactivity and development of occupational asthma is unclear but is under investigation.

Mechanisms

Asthma is a common disease affecting as many as 20 million individuals in the United States. Workplace exposures may exacerbate symptoms in persons with pre-existing asthma (work-aggravated asthma) or trigger new disease. The mechanisms by which occupational agents induce asthma are similar to those that are operative in non-occupational asthma. Important mechanisms include reflex bronchoconstriction, acute inflammation, and immunologic sensitization. For some agents,

responses may be triggered through several pathways, whereas for others the mechanism by which the material causes asthma is undefined.

Work-Aggravated Asthma: Nonimmunologic Mechanisms

Work-aggravated asthma is defined as concurrent asthma worsened by gaseous or particulate irritants or physical stimuli in the workplace. Exposure to numerous industrial agents can cause reflex bronchoconstriction in asthmatic workers with hyperreactive airways. Sulfur dioxide, acidic aerosols, environmental tobacco smoke, chemicals, and automobile exhaust can precipitate cough or wheezing by stimulating irritant receptors. A striking example of an acute exposure occurs with the gas sulfur dioxide (SO_2), which induces bronchoconstriction in asthmatic individuals at concentrations £1.0 ppm after exposures lasting only 5 min. In contrast, inhalation of SO_2 at concentrations 5 ppm causes only small decrements in airways function in normal subjects. Lung function responses to SO_2 in asthmatic persons are greater when SO_2 exposure is accompanied by increased ventilation, usually stimulated by physical labor or exercise. SO_2-induced bronchoconstriction can be further intensified by breathing cold air and/or dry air. Thus, the irritant response can be enhanced by conditions in the workplace.

At times, it may be difficult to draw a clear distinction between work-aggravated and *de novo* occupational asthma. This is particularly true in the case of atopic individuals who may become sensitized to allergens at work. The pathogenic mechanisms and perhaps even the genetic predisposition are similar for the work-related and non-work-related allergen exposure. For example, the physician may encounter an atopic, asthmatic individual with baker's asthma who is sensitized to aeroallergens outside the workplace, such as house dust mites, and also to aeroallergens encountered at work, such as protein antigens in flour. The severity of disease is determined by a combination of immunologic sensitivity and level of exposure to both work-related and non-work-related aeroallergens. The management of such cases needs to address both exposures or risk the possibility of inappropriate attribution; that is, residual symptoms of house dust mite exposure or other non-occupational allergens may be blamed on responses induced by exposure to flour antigens at work. On the other hand, a specific material may act as both an irritant and immunologically specific antigen. For example, isocyanates can cause cough or irritation to the eyes at high concentrations, but immunologic sensitization can also result, causing asthma at extremely low levels.

A second type of nonimmunologic or irritant-induced asthma is the reactive airways dysfunction syndrome (RADS). In 1981, Brooks and Lockey first used the term in an abstract that described 13 workers in whom symptomatic and physiologic evidence of bronchoconstriction developed within hours after a single toxic inhalation exposure. The symptoms were persistent, lasting at least 3 months and averaging 3 years after the time of initial exposure. A case of RADS was defined in the American College of Chest Physicians Consensus Statement, *Assessment of Asthma in the Workplace,* as meeting the following criteria: (1) a documented absence of preceding respiratory complaints; (2) onset of symptoms after a single exposure incident or accident; (3) exposure to gas, smoke, fume, or vapor with irritant properties present in very high concentrations; (4) onset of symptoms within 24 hours after the exposure with persistence of symptoms of at least 3 months; (5) symptoms consistent with asthma, such as cough, wheeze, and dyspnea; (6) presence of air flow obstruction on pulmonary function tests; (7) presence of nonspecific bronchial hyperresponsiveness; and (8) other pulmonary diseases ruled out.

Histopathologic studies in RADS are limited but have shed light on the pathogenic mechanisms. In general, bronchial biopsy specimens have demonstrated only a mild inflammatory response, with sparse lymphocytes and polymorphonuclear cells and no eosinophils. However, biopsy results are variable depending presumably on type and severity of exposure, type of treatment, and time from injury to biopsy.

Although the acute symptoms following toxic inhalation are related to the resulting airways inflammation, the basis for the persistent bronchial hyperresponsiveness is not well explained. Hypotheses under investigation include altered receptor thresholds in the airways, increased airways permeability, smooth-muscle dysfunction as a result of massive mediator release, and persistent airways inflammation. The treatment of the patient with established RADS is no different from that of any other asthmatic patient.

Immunologically Mediated Occupational Asthma

Two observations suggest that immunologic mechanisms are involved in most cases of occupational asthma. First, there is clinical evidence of sensitization—that is, individuals do not experience respiratory symptoms when first exposed to an antigen, but repeated exposures begin to precipitate symptoms. Moreover, with repeated exposures, symptoms occur at extremely low concentrations. Second, there is immunologic evidence of sensitization. This is most easily seen with agents that induce an IgE response in which specific antibodies can be detected by immediate skin tests or radioallergosorbent test (RAST) and correlated with the development of allergic symptoms such as conjunctivitis and rhinitis in addition to asthma.

Antigens involved in occupational asthma fall into two categories. The first category consists of macromolecular antigens derived from animals, plants, microbes, and even recombinant DNA technology. These antigens resemble those responsible for atopic asthma and are mainly proteins. They are complete antigens containing both T- and B-cell epitopes, and they induce and elicit an immune response by themselves. Asthma secondary to these macromolecular agents is closely related to atopic/extrinsic asthma, as it is IgE-mediated. Indeed, atopy is a risk factor for the development of occupational asthma with at least some of these agents. Allergen-specific IgE is invariably found with occupational asthma caused by exposure to high-molecular-weight allergens. The second category consists of molecules of low molecular weight. These low-molecular-weight antigens are incomplete antigens—that is, they first haptenate macromolecules before they induce an immune response and therefore must themselves be chemically reactive molecules or metabolized to reactive intermediates. Asthma induced by some low-molecular-weight molecules is IgE-mediated. However, atopy is generally not a risk factor. Other risk factors have been sought and include, for example, cigarettes, which increase the risk for both immunologic sensitization to and occupational asthma with platinum salts. It is interesting that some low-molecular-weight molecules induce immunologically mediated asthma in which IgE antibodies appear to play no role. The mechanisms of non-IgE-mediated asthma are poorly understood.

Patterns of Cytokine Production

The importance of bronchial inflammation in asthma has become clear. Eosinophilic and lymphocytic infiltration is present in bronchial biopsy specimens of even mildly asthmatic subjects. A variety of proinflammatory substances are released into the airways tissues of asthmatic subjects, including lipids, proteases, bioamines, neurotransmitters, and cytokines. Of these mediators, cytokines are unique because they are primary effector mechanisms for T cells. The pattern of cytokine secretion appears to differ in the major categories of non-occupational asthma. Studies of cytokine production at the mRNA and protein levels indicate that in extrinsic asthma (allergic asthma) interleukin-4 (IL-4) is produced by mast cells and CD4 lymphocytes; IL-5 is produced by these cells and eosinophils. Intrinsic asthma (non-allergic asthma) has not been as extensively studied. Nonetheless, IL-5 and interferon-g are found, but not IL-4. These patterns of cytokines fit with the immunopathology. IL-5 is essential for eosinophil production in the marrow and additionally is able to attract, activate, and enhance the survival of mature eosinophils. In both intrinsic and extrinsic asthma, IL-5 is produced in the airways mucosa, and both conditions are associated with prominent bronchial tissue eosinophilia. In extrinsic asthma, IL-4 is produced in the airways; in intrinsic asthma, interferon-g is produced instead of IL-4. IL-4 is essential for IgE synthesis, whereas interferon-g inhibits IgE production. Thus, extrinsic or atopic asthma is associated with a pattern of cytokines promoting IgE production, whereas the pattern of cytokines in intrinsic, non-allergic asthma inhibits the production of IgE.

The results of studies of IgE-mediated and non-IgE-mediated occupational asthma are remarkably congruous with those of studies of extrinsic and intrinsic non-occupational asthma (Table 3). In both IgE-mediated and non-IgE-mediated occupational asthma, airways inflammation is a predominant feature, and as in non-occupational asthma, eosinophils and lymphocytes infiltrate the tissue. Analysis of cytokine production in occupational asthma has been limited. In one interesting study, lymphocytes were harvested from bronchoalveolar lavage (BAL) fluid and grown in vitro after exposure to toluene diisocyanate (TDI), an agent that induces non-IgE-mediated occupational asthma. These TDI-elicited T cells were 80% CD8-positive and produced large quantities of IL-5 and interferon-g but no IL-4. Challenge studies with non-occupational agents that induce IgE-mediated asthma elicit predominantly CD4 cells producing IL-5 and IL-4 but no interferon-g. BAL studies have not been done for IgE-mediated occupational asthma but presumably would be similar to those for IgE-mediated nonoccupational asthma. Thus, the two major differences between IgE-mediated and non-IgE-mediated asthma are the T-cell subset involved and the pattern of cytokine induced.

	IgE-mediated	non-IgE-mediated
Eosinophilic bronchitis	++	++
T-cell infiltration of airways	++	++
Predominant T-cell subset	CD4	CD8
MHC presentation	Class II	Class I
Interleukin-5	++	++
Interleukin-6	++	–
Interferon-γ	–	++

MHC, major histocompatibility complex.

TABLE 3. *IgE versus non-IgE immune-mediated occupational asthma*

The preponderance of CD8 cells in BAL fluid after challenge with TDI was surprising, because previous studies of BAL fluid in asthmatic patients reported a predominance of CD4 cells. However, these previous studies used protein antigens, such as house dust mite or pollens. Exogenous protein antigens do not enter the cytoplasm of antigen-presenting cells and are therefore not presented via class I molecules to CD8 T cells. Instead, exogenous protein antigens are taken up into cytoplasmic vesicles, where they become bound to class II molecules and are then returned to the cell surface for presentation to CD4 T cells. Because TDI is not a protein but a reactive chemical, it can form covalent bonds with a variety of macromolecules. These macromolecules include self-proteins in the cytoplasm of the cell and even the class I molecules themselves. TDI-modified self-peptides from cytoplasmic proteins or TDI-modified class I molecules would be presented to CD8 T cells. It is interesting to note that although many low-molecular-weight antigens, such as TDI, western cedar, or colophony, induce asthma by non-IgE-mediated mechanisms, another group of low-molecular-weight antigens, such as platinum salts and acid anhydrides, induce antigen-specific IgE. It is tempting to hypothesize that a crucial difference between the chemicals that induce non-IgE-mediated versus IgE-mediated asthma may be presentation of antigen via class I or class II antigens, respectively.

Pathophysiology of Airway Responses

Classically, inhaled protein allergens such as those from cats (Fel d I) or mites (Der p I) induce an immediate hypersensitivity response with an early- and/or late-phase pulmonary response in patients who have asthma caused by these agents (Fig. 1). Both the early and late phase depend on allergen-specific IgE on the surface of mast cells. The early phase begins within minutes of exposure and typically wanes in an hour. Bronchospasm in the early phase is mediated by soluble factors produced by mast cells. The late-phase response occurs after several hours and then wanes by 12 to 24 hours. It is accompanied by a cellular infiltrate: granulocytes, especially eosinophils, initially and mononuclear cells later. Bronchospasm in the late phase is mediated by soluble factors produced by the infiltrating cells. The vast majority of patients with atopic asthma have an early-phase response, and asthmatic patients with a severe early-phase reaction are more likely to have a late phase. An isolated late-phase response occurs in 10% of atopic persons with asthma. Protein allergens that induce occupational asthma are associated with the same airways changes as protein allergens that cause atopic asthma in the general population; typical IgE-mediated early- and late-phase responses are seen in challenge studies. The pattern of airways response is much more complicated in non-IgE-mediated occupational asthma. Although early- and late-phase responses occur, atypical patterns are also common. These can include isolated late responses, responses that peak early and then persist, responses that begin early and become progressively more severe, and responses that persist for several days (Fig. 1).

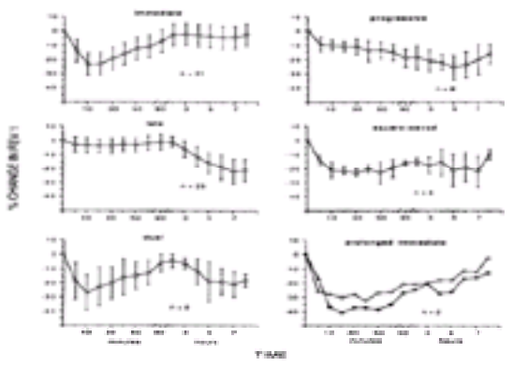

FIG. 1. Patterns of airway response to antigen challenge. (Adapted with permission from Perrin B, et al. Reassessment of the temporal patterns of bronchial obstruction after exposure to occupational sensitizing agents. *J Allergy Clin Immunol* 1991;87:630–639.)

The pathophysiology of acute bronchospasm induced by TDI and similar agents in the absence of antigen-specific IgE is not well understood. TDI has direct biochemical effects, including the induction of substance P secretion. Moreover, TDI can induce the release of histamine-releasing factor by peripheral blood mononuclear cells from sensitized patients. However, neither of these effects provides an adequate explanation for TDI-sensitized patients with immediate bronchospastic responses. The direct effects on substance P or other mediators should not differentiate TDI asthma from asthma of other causes. In addition, histamine-releasing factor is produced slowly and is associated with the late- rather than the early-phase response. Clearly, additional work is needed to clarify the pathophysiology of non-IgE-mediated occupational asthma.

Diagnosis of Occupational Asthma

The two general requirements for a diagnosis of occupational asthma are (1) a diagnosis of asthma, and (2) documentation that the asthma is work-related. Although fulfillment of these criteria is conceptually simple, in practice it is often not straightforward. Several important diagnostic considerations may confound the evaluation of occupational asthma. First, other diagnoses, some of which may also be occupationally related, need to be considered. Second, pulmonary function test results vary considerably depending on whether the patient is currently exposed. Third, many factors in the workplace may act as nonspecific triggers in patients who have hyperreactive airways. Such individuals have work-aggravated asthma, and their management and prognosis differ from those of individuals with true occupational asthma. Finally, the diagnosis has important consequences for both worker and employer. Indeed, patients may either underreport or overreport symptoms for other than medical reasons. Our approach to the workup of occupational asthma is detailed below and illustrated in Fig. 2.

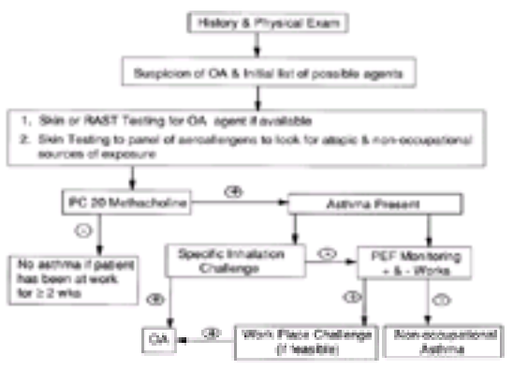

FIG. 2. Algorithm for the workup of occupational asthma. (OA = occupational asthma; PEF = peak expiratory flow)

Defining the Problem

A complete medical history and physical examination are essential in the workup of occupational asthma. The four primary goals are to (1) establish that occupational asthma is sufficiently likely to require further workup, (2) identify alternative diagnoses, (3) assess the severity of illness and the need to eliminate further workplace exposure, and (4) identify likely etiologic agents. In other clinical situations, interventions might be started with just the data provided by the history and physical examination, but in the setting of occupational asthma, additional objective documentation is usually required.

History of the Present Illness

The interview should be open-ended, allowing the patient to raise concerns, and then focus on identified problems. A chronologic history of symptoms should be elicited, including both work-related and unrelated episodes. Particular attention is given to whether symptoms existed before the current job was started. Preceding

asthma is rarely work-related except in the case of a common agent in the environment outside work or a previous work environment. Where and when in the workplace symptoms occur are important in tracking down an etiologic agent; for example, does the patient have problems only in certain areas, or are symptoms associated with a specific process or incidents, such as spills or other accidents? The temporal relationship between work and the occurrence or exacerbation of symptoms should be understood. Do symptoms begin immediately when the patient arrives at work, or do they appear only toward the end of the shift? Do they resolve after the patient has left work? Do they persist during the whole workweek but disappear during weekends or holidays? Are there eye or nasal symptoms, and how do these symptoms change in relationship to work? Are there known precipitants outside the work environment, such as a cat or other animal, damp basements, seasonal exacerbations? The severity and progression of symptoms determine the scope of the workup and whether continued exposure can be tolerated. Evidence of airways hyperreactivity, such as sensitivity to cold air or exercise, and the presence of symptoms that do not support a diagnosis of asthma, such as fever, weight loss, or peripheral edema and orthopnea, are important.

Past Medical History

The past history includes both the personal and occupational medical history. Previous medical records can be especially helpful in ascertaining whether symptoms developed before current workplace exposure. A history of smoking and atopy should be specifically elicited. Childhood respiratory problems such as bronchitis, asthma, frequent colds, hay fever, sinus problems, and allergies point to an atopic predisposition but do not rule out a diagnosis of occupational asthma. A listing of hospitalizations, medical emergencies, and medications should be obtained. Time lost from work and the course of recovery from prior illness may provide insight into how the patient copes with illness. A family history for atopy and other inherited respiratory diseases should be obtained.

Occupational History

Identification of potential etiologic agents for occupational asthma begins with characterization of present and past work-related exposures. This includes a general characterization of the types of potential allergens (chemicals, drugs, metals, animal- or plant-derived proteins, recombinant proteins, or organic dust) and respiratory irritants as well as a general description of the job and the type of job site exposure. Some jobs, such as spray painting or handling animals, necessarily involve exposure to potential allergens. Precautions taken at the workplace, including use of protective gear and ventilation, may mitigate such exposure but can be offset by noncompliance and accidents. The intensity and duration of exposure should be noted. The clinician should also determine if other workers at the same work site have had work-related respiratory illnesses. Problems with ventilation and humidification systems, including contamination with microbes, are common sources of respiratory complaints in the workplace and should be carefully queried. Dampness, particularly when cloth such as carpeting or decaying organic material is involved, may lead to overgrowth of molds or even allergenic mites. Infesting rodents or cockroaches are also potential sources of allergen.

Nonoccupational Environmental History

Environmental factors outside the workplace need to be investigated. The nature and type of housing, type of heating and floor covering, and the presence of any new construction or excessive dampness should be determined. In addition, household pets and rodents or roaches are potential sources of sensitization. Hobbies may involve exposure to chemicals that are sensitizers.

Physical Examination

Normal findings on physical examination are compatible with a diagnosis of occupational asthma. Wheezing and irritation of the conjunctiva or nasal mucosa are the more common positive findings. Nevertheless, determination of vital signs, including the rate and pattern of respiration, examination of the skin, head and neck, heart, extremities, and abdomen, and a screening neurologic examination should be performed in all cases. The primary purpose of this examination is not to make the diagnosis of asthma but instead to exclude other diagnoses.

Confirmation of Asthma

Pulmonary function tests are essential for documenting airways obstruction and reactivity (Table 4). In some cases, the patient will have substantial abnormalities in baseline spirometry, and the diagnosis of asthma can be confirmed by demonstrating a 15% improvement in FEV_1 (forced expiratory volume in 1 second) with inhaled bronchodilators. More commonly, the results of baseline flow studies are normal. In these cases, assessment of bronchial airways hyperreactivity to methacholine, carbachol, or histamine should be undertaken. These tests have not been completely standardized, so the results from different laboratories are difficult to compare. It is therefore important that the individual laboratory have its own database ensuring that normal and asthmatic persons can be discriminated and that results in the same individual are reproducible. In a commonly used protocol in North America, methacholine in doubled concentrations (0.03, 0.06, 0.125, 0.25, 0.5, 1, 2, 4, 8, 16, and 32 mg/mL) is administered as an aerosol via nebulizer for 2 minutes at each dose. A practical problem with this protocol is that the large number of doses requires substantial time in the asthmatic patient with mild or moderate reactivity; often, shorter protocols are used. A major variable in these studies is the nebulizer itself. Use of the same nebulizer in an individual for repeated measurements helps reduce variability.

	Ease	Availability	Sensitivity	Specificity	Comments
Skin prick tests and RAST	++	++	+++	+	Poor correlation with bronchial reactivity. Usefulness and availability depend on antigen.
Spirometry	++++	++++	+	++	Often normal unless illness is severe.
PEFR, serially	++	+++	+++	+++	Very useful with cooperative patient, but compliance is a problem.
Bronchial reactivity (nonspecific)	++	++	++++	+	Very sensitive, standardized. Not specific for etiology.
Bronchial challenge (specific)	+	+	+++	++++	Potentially hazardous. Dose poorly controlled, but reproduces actual exposures.

PEFR, peak expiratory flow rate; RAST, radioallergosorbent test.

TABLE 4. *Confirmation of occupational asthma*

The end point for testing is generally a 20% decrease in FEV_1, and the results are expressed as the PD_{20}. Use of bronchodilators and ingestion of compounds containing bronchodilator agents (e.g., beverages containing caffeine) are stopped before testing. Most inhaled bronchodilators can simply be withheld beginning the evening (12 hours) before, but salmeterol and oral theophyllines should be stopped 24 hours in advance. If the patient is still working (i.e., has been going to work regularly for at least 2 weeks) and is still having work-related symptoms, then an absence of airways hyperreactivity essentially excludes the diagnosis of occupational asthma, and other diagnoses should be entertained. If the worker has been away from the work site for some time or if symptoms have been intermittent (perhaps because of the intermittent presence of the etiologic agent in the workplace), then the absence of bronchial hyperresponsiveness does not exclude asthma, and additional studies are required. One caveat is that the presence of bronchial hyperresponsiveness does not unequivocally mean asthma, because there are asymptomatic individuals with hyperactive airways. In addition, normal individuals may have bronchial hyperreactivity lasting for several months after a respiratory viral infection, such as influenza.

Identification of Potential Agents

Exposure assessment and immunologic testing are the primary tools in identifying potential agents. Exposure assessment begins with a careful history (see above). Additional sources of information include data from an industrial hygiene program, health and safety personnel, material safety data sheets (MSDS), other workers, and in some cases a visit to the work site. When contamination with microbes or mites is suspected, air and/or dust may be sampled for culture, microscopic identification, assays for endotoxin, mycotoxins, and chemicals, or immunoassays for aeroallergens.

Identification of the causative agent occasionally involves an immunologic assessment, because immunologic tests are available for only a few common allergens (Table 4). Asthma with a latency period is immunologically mediated. In immunologically mediated asthma, the immune response induces inflammation in the airways, and this inflammation results in nonspecific airway hyperresponsiveness. In some instances, it has been impossible to demonstrate immune sensitization by skin testing or in vitro assays. This has been particularly difficult with low-molecular-weight antigens, especially those that induce asthma via nonIgE-mediated mechanisms. With both high-molecular-weight antigens and low-molecular-weight antigens that sensitize via IgE, skin testing is still the most sensitive assay for demonstration of immediate hypersensitivity. The problem in many cases is that the skin testing materials for these antigens are not standardized and frequently unavailable

commercially. The investigators may then be faced with the task of manufacturing skin test reagents and/or verifying that they are active.

With some low-molecular-weight sensitizers, manufacture of material for skin testing may involve conjugating haptens to human serum albumin (HSA) and measuring the extent of derivation. Allergen-specific IgE can be measured in vitro using RAST with some allergens. The ability of RAST to quantify results and determine the degree of sensitization may be helpful. False-negatives are more common with RAST, and false-positives may occur in patients with very high total IgE levels. As with airways challenge testing, a database for the individual testing facility can be instrumental in validating skin test or RAST results. Although these tests document immunologic sensitization, sensitization neither proves a diagnosis of occupational asthma nor confirms the test antigen as the cause of symptoms. Generally, more individuals have positive skin test results and no symptoms than have positive skin test results with symptoms. Nevertheless, demonstration of positive immediate skin test results and increased nonspecific bronchial hyperresponsiveness in a patient with both appropriate symptoms and exposure is highly predictive of a positive result on airways challenge with a specific antigen. Moreover, negative skin test results with a valid skin test reagent is strong evidence against involvement of that agent in asthma. For many low-molecular-weight antigens, no skin test reagent has been developed, either because the asthma is not IgE-mediated or because the appropriate carrier or metabolite has not been identified. Skin testing to a limited panel of common non-occupational aeroallergens (in the Northeast a routine panel includes cat, dog, *D. farinae, D. pyterinisinus,* cockroach, mouse, mixed grasses, mixed trees, ragweed, *Alternaria, Helminthosporium, Aspergillus, Penicillium,* and any other pet) can be quite useful in the evaluation of patients suspected to have occupational asthma. Results of this panel are used to define atopic status and determine if non-occupational aeroallergens may play a role. In vitro testing for IgG antibodies may also be done in selected cases, but the presence of IgG antibodies is more helpful in the diagnosis of hypersensitivity pneumonitis than of asthma.

Establishing a Relationship to Work

Monitoring pulmonary function over time and challenges in the laboratory or at the work site are important in relating the workplace exposure to symptoms and physiologic changes and may help to identify the specific agent. Although pulmonary function monitoring to document changes related to work site exposure seems straightforward, there are many potential pitfalls. Perhaps the most significant problem is patient cooperation and compliance. With a highly motivated and reliable individual, useful data can be obtained by measuring peak flows periodically (every 2 hours in most studies, four times a day in some) for 2 weeks. Two studies have evaluated monitoring of peak flows using airways challenge as the gold standard. Peak flow monitoring in these studies was 86% and 87% sensitive and 89% and 84% specific. These results are excellent, but other studies provide evidence that patients are often unreliable and results fabricated up to 25% of the time. The use of computerized meters that record time and results automatically may improve the reliability of peak flow monitoring. Other problems with peak flow monitoring include instances in which exposure may be highly erratic and unpredictable, such as with accidents or equipment failure. In addition, when exposure results in prolonged or delayed respiratory problems, it may be necessary for the worker to be away from the job or on the job for several weeks before a change in function can be seen. Criteria for defining a positive response have often been subjectively based on visual assessment of the record. Objective criteria that have been proposed include (1) diurnal variation in peak flow of 20% or more, (2) occurrence of changes more frequently on days at work than on days not at work, and (3) designation of indeterminate recording when a 20% diurnal change occurs only once or when changes occur over several days rather than daily. By these criteria, 26% of recordings were indeterminate and the specificity and sensitivity of the remaining recordings were 90% and 93%, respectively. However, “subjective” assessment of the record was essentially equivalent to the more “objective” reading.

Airways challenges with specific antigens remain the gold standard for the diagnosis of occupational asthma. Under most circumstances, challenges can be avoided because of good correlation between positive skin test results plus nonspecific airways responsiveness or peak flow monitoring and airways challenges. Nevertheless, challenges are still a necessary tool for some patients. For example, in the patient with a history highly suggestive of sensitivity to a specific agent but in whom monitoring has been indeterminate or unreliable, airways challenge may clarify the issue. Similarly, if the suspected agent has not previously been reported to cause asthma or if the worker has been away from work for a long time, then airways challenge will document sensitization in a physiologically meaningful sense.

The overwhelming consideration in these specific challenges is safety. Laboratory challenges should be performed in specialized centers with trained personnel, often in an investigative setting. An intravenous line should be in place to provide access for medications. Oxygen, inhaled bronchodilators, steroids, and equipment for intubation and resuscitation should be at hand. Laboratory challenge involves several days of observation (Table 5). On the first day, bronchodilator medications are stopped and clinical status, baseline pulmonary function, and fluctuation of FEV_1 during several hours are determined. If the variation in FEV_1 is >10%, then the patient should return when more stable. On the second day, the subject is exposed to aerosolized diluent. Finally, on the third day, exposure to test material is begun. With high-molecular-weight materials, the patient can be exposed to progressively greater amounts of material throughout the course of the day (every 15 to 30 minutes), as isolated late-phase responses are unusual with this type of allergen. During these repeated exposures, FEV_1 should be measured every 10 minutes. With low-molecular-weight materials, isolated late-phase responses and atypical patterns of response are common. Therefore, the patient should be exposed to progressively greater amounts of test material only on successive days. On each of these test days, FEV_1 should be measured every 10 minutes for the first hour after exposure, then every 30 minutes for 2 hours, and finally every hour for the rest of the 8-hour session. The starting dose of test material has to be individualized based on the material to be tested, the severity of the reaction by history, and the patient's nonspecific airways hyperresponsiveness. A 20% fall in FEV_1 is considered a positive response.

Day 1: No exposure
Baseline PFTs
FEV_1 fluctuation <10%
Day 2: Exposure to control material
Day 3: Exposure to specific antigen
For high-molecular-weight material:
Increase doses of antigen every 20 minutes.
Check FEV_1 every 10 minutes.
For low-molecular-weight material:
Increase doses of antigen on successive days.
Check FEV_1 every 10 minutes for 1 hour, then every 30 minutes for another 2 hours, then every 1 hour for the rest of the 8-hour session.

PFT, pulmonary function test; FEV_1, forced expiratory volume in 1 second.

TABLE 5. *Laboratory challenge*

If laboratory challenges are not feasible and peak flow monitoring is unreliable, it may be possible to have the patient return to the work site for progressively longer periods of time, with spirometry, and potential determination of airway responsiveness, performed before and after the exposures. If travel distance permits, these measurements may be made in the pulmonary laboratory, but more often a technician will have to visit the job site.

Although specific challenge tests may be considered the gold standard, false-negative and false-positive interpretations may result. Sources of false-negative results include testing with the wrong material or using an inadequate dose. In addition, nonspecific airways responsiveness decreases with time away from exposure, and a point may be reached at which several exposures are necessary before airway pathology is reinduced and a drop in FEV_1 occurs. Therefore, if there is no change in FEV_1 with exposure, nonspecific airways responsiveness can be measured at the end of the day and the next day to identify subtle changes. Such changes may be an indication for additional exposures. False-positive test results also occur; these may be caused by nonspecific irritation by the test substance or active asthma with a drop in FEV_1 that is independent of exposure. Suggestion may also play a role in airways responses. Indeed, there is some evidence that mast cell degranulation can be conditioned both in animals and humans. Thus, in some circumstances, blinding of both technicians and patient to the test substance may be an important consideration.

Management and Follow-up

The goals of medical treatment of occupational asthma are rapid control of symptoms, reversal of airways hyperresponsiveness, and prevention of irreversible changes to the airways leading to long-term persistence of symptoms.

In the management of occupational asthma, avoidance is the most important intervention. Once a person becomes immunologically sensitized, even infrequent low-level exposure may cause symptoms to persist. Therefore, patient and employer have to be advised that removal from the work site is essential. Interventions short of complete removal should be contemplated only if there is to be close follow-up and documentation of resolution of airways hyperresponsiveness. Such stringent environmental management may not be required in cases of work-aggravated asthma—that is, persons who do not have immunologic sensitization to workplace allergens. For these people, moderate improvements in workplace air quality may be sufficient to control work-related symptoms, especially if their non-occupational asthma is well managed.

Inhaled glucocorticoids are the cornerstone of the pharmacologic treatment of airways inflammation associated with chronic asthma. In a placebo-controlled trial, inhaled steroids have been shown to reverse the airways hyperresponsiveness that otherwise persists for many months after removal from exposure to TDI. It is too early to know whether the benefits of such treatment continue once the drug is stopped. However, if inflammation is the essential process in the development of irreversible changes in the airways, the sooner inflammation is eliminated, the lower the likelihood that permanent damage will result. At this point, it would seem prudent to treat occupational asthma aggressively with inhaled steroid for 6 months and then reassess; it may be reasonable to stop medication at that time and follow symptoms and airways reactivity.

Finally, it needs to be re-emphasized that a large number of diseases may mimic occupational asthma, and these need to be considered whenever the question of occupational asthma is raised. Such illnesses include asthma unrelated to occupational exposures, occupational or non-occupational rhinitis, occupational or nonoccupational bronchitis, RADS, bronchiolitis obliterans, hypersensitivity pneumonitis, sinus disease, adductor spasm of the glottis, and other causes of extrathoracic obstruction. These alternative diagnoses need to be carefully excluded.

Specific Agents of Occupational Asthma

Low-Molecular-Weight Materials

With asthma induced by low-molecular-weight compounds (Table 2), atopy is not a risk factor. In these cases, IgE-mediated sensitization is unpredictable and may or may not be found. Because the antigens are incomplete antigens and need to haptenate a protein carrier, reagents for immunologic testing are often difficult to find. Several examples of asthma resulting from exposure to low-molecular-weight materials are considered below.

Isocyanates

Diisocyanates (TDI, toluene diisocyanate; MDI, diphenylmethane diisocyanate; HDI, hexamethylene diisocyanate; NDI, naphthalene diisocyanate) are used in spray painting, plastic molding, foundry work, and in the manufacture of polyurethane foams. Asthma occurs in 5%–10% of exposed workers. Diisocyanate-induced asthma does not appear to be mediated by IgE. Although RAST or skin testing will detect specific IgE in some workers, these tests do not predict clinical sensitization. Airways hyperresponsiveness to histamine or methacholine and eosinophilic inflammation of the airways are consistently found in sensitized workers. Once airways hyperresponsiveness has been established, it may persist for many years. Early detection of sensitization and removal from exposure are essential to prevent this long-term sequela. In addition to removal from exposure, treatment of sensitized workers with inhaled glucocorticoids accelerates resolution of airways hyperresponsiveness and inflammation. Airways challenge with diisocyanates frequently results in an isolated late-phase response. Atypical delayed and persistent responses are also common. Thus, in contrast to challenges with allergens that induce IgE-mediated sensitization, airway challenges with diisocyanates cannot be immediately repeated with an increased dose when an early-phase response is not observed. Hypersensitivity pneumonitis with pulmonary infiltrates has also been reported with diisocyanates (TDI, HDI, and MDI). In these individuals, specific IgG precipitins can be demonstrated.

Acid Anhydrides

Acid anhydrides (PA, phthalic anhydride; TMA, trimellitic anhydride; HHPA, hexahydrophthalic anhydride; HA, himic anhydride; TCPA, tetrachlorophthalic anhydride) function as hardening agents in the manufacture of epoxy resins used in adhesives, encapsulating agents, surface coatings, and plastics. Workers are exposed to these reactive compounds as fumes from heated resins, dust generated during the grinding of resins, and powdered chemicals added to reaction chambers.

Acid anhydrides are potent irritants that may cause eye, respiratory tract, and skin symptoms; permissible exposure limits for PA have been developed on this basis (6 mg/m^3). IgE-mediated allergic sensitization also occurs, and the permissible exposure level does not account for this. Conjugates of acid anhydride and HSA are sensitive reagents for skin testing, and RAST can also be performed. Results of airways challenge with acid anhydrides are typical of IgE-mediated sensitization; both an early-phase and a late-phase reaction are frequently seen. Specific IgE can persist for years after exposure. Acid anhydrides (TMA) are also associated with a late-onset respiratory systemic syndrome (LRSS) or with a syndrome of pulmonary hemorrhage and hemolytic anemia. These non-asthmatic pulmonary syndromes are associated with elevated levels of specific IgG.

Metals

Platinum salts can induce the production of specific IgE in a high proportion of heavily exposed workers, and this sensitization may lead to the development of skin rashes, eye and nasal symptoms, or asthma. Skin testing with platinum salts can be used to document sensitization, but high concentrations of platinum salts can cause nonspecific mast cell degranulation in unexposed controls. A RAST using malic dehydrogenase as a protein carrier has been developed. Asthma caused by exposure to a number of other metals has also been reported, including nickel, chromium, vanadium, cobalt, and fumes from steel welding and smelting of aluminum. There is evidence for an IgE mechanism with cobalt, chromium, and nickel in some cases, but the mechanisms involving vanadium or fumes from steel or aluminum are unknown.

Wood Dust

A wide variety of woods have been associated with occupational asthma, but the best studied example is red cedar. In red cedar asthma, sensitization is to plicatic acid, a reactive compound found in red and white cedar. Although specific IgE can be found in many workers, asthma appears to be non-IgE-mediated, and bronchial challenge is the only reliable test for immunologic sensitization. Delay in removal from exposure following the development of symptoms, particularly in older workers, has been linked with persistent airways hyperresponsiveness and dyspnea.

Solder

Colophony is used as flux in soldering, and electrical workers can become sensitized to colophony, with development of asthma. Colophony is a derivative of pine tree resin in which several reactive chemicals are found, namely abietic, pimaric, and dihydroabietic acids. As with wood dust, sensitization is not IgE-mediated, and airways challenge is the only reliable test for sensitization. Prolonged symptoms after removal from exposure have also been reported for colophony. Another component of solder flux, aminoethanolamine, can cause isolated late or dual responses.

Drugs

Occupational asthma can develop in workers exposed in the manufacture or use of a number of drugs (e.g., penicillin). Typically, these reactions are IgE-mediated and can be demonstrated with skin testing or RAST.

High-Molecular-Weight Materials

Atopy *is* a risk factor for sensitization to high-molecular-weight materials (Table 2). Typically, the sensitization is IgE-mediated. Because these materials are complete antigens, reagents for skin testing or RAST are usually available.

Foods

Asthma is a frequent occupational disease among bakers. Grain allergens are the usual cause, but sensitization to contaminants such as mold spores or grain mites has also been reported. Other foods causing occupational asthma include coffee beans, tea, soybeans, eggs, snow crabs, and cocoa. Castor beans containing the toxin ricin appear to be a special problem, and epidemics of asthma in nearby residents as well as workers have occurred.

Latex

Latex allergy among health care workers is an emerging problem. Although contact sensitivity is frequently caused by chemicals used in manufacturing, occupational asthma and other IgE-mediated reactions result from sensitization to protein antigens in native latex. Occupational sensitization to latex may have severe consequences for the health care worker who becomes a patient. Sensitized individuals should wear a medical alert bracelet.

Animals

Asthma caused by animal proteins in dander, saliva, or urine frequently develops in laboratory workers, farmers, and other people who handle animals. Such sensitization can occur to any warm-blooded animal.

Insects

Sensitization to the insects used in their work can develop in bee workers and bait workers. Less obvious exposures include sensitization of farmers, grain handlers, or bakers to storage mites, and sensitization of poultry workers to fowl mites.

Vegetable Gums

Vegetable gums represent another, less obvious source of allergens that may cause occupational asthma in workers in a variety of occupations, including printing, carpet manufacturing, and hairdressing.

Enzymes

Proteolytic enzymes used in detergents, meat tenderizer, and various manufacturing processes are potent sensitizers.

Course of Occupational Asthma

Occupational asthma allows investigators to view the entire natural history of asthma in response to a single, clearly defined etiologic agent. This perspective provides insight into the pace and variability of asthma development and also an opportunity to look at the resolution of asthma as workers are removed from exposures. Thus, occupational asthma provides a unique opportunity to study the pathophysiology of asthma. There have been several surprising findings in terms of the natural history of occupational asthma.

The variability in latency—that is, the time from initial exposure to development of symptoms—is well demonstrated in studies of occupational asthma (Fig. 3). The onset of symptoms follows an exponential curve. For example, the latency period for 50% of cases of sensitization to high-molecular-weight antigens is 3 years, but it takes 9 years to get to 75% of cases. There are even cases of occupational asthma developing in some workers after 30 years of exposure.

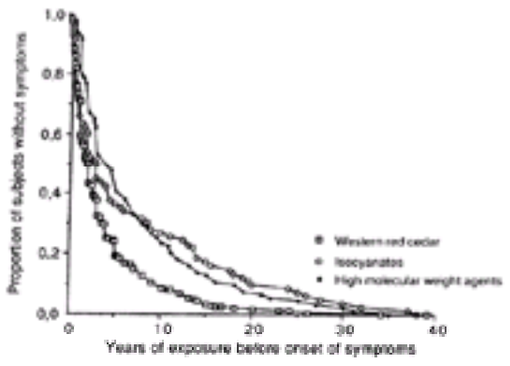

FIG. 3. Proportion of patients without symptoms as a function of exposure interval. (Modified with permission from Malo JL, et al. Natural history of occupation asthma: relevance of type of agent and other factors in the rate of development of symptoms in affected subjects. *J Allergy Clin Immunol* 1992;90:937–944.)

Another unexpected finding in occupational asthma is symptoms are often not reversible when the worker is removed from exposure (Table 6). Even years after removal, airways hyperresponsiveness and inflammation persist in the majority of patients with occupational asthma studied in large series. The prognosis is worse for workers who stay on the job after onset of asthma and better for those workers who leave as soon as symptoms develop. These findings suggest a window of opportunity to remove the worker before irreversible changes take place. Although these results have been criticized because pre-exposure airways responses were often not available, in several workers with normal baseline function before exposure, airways hyperresponsiveness persisted long after removal from exposure. The relationship of inflammation to the irreversible stage of asthma is still controversial. However, an essential component of these irreversible changes may be the development of inflammation in the absence of exogenous antigen. Treatment with inhaled steroids induces resolution of inflammation and the hyperresponsiveness that persists after removal from exposure to TDI. At this point, there is no compelling reason to believe that occupational and non-occupational asthma differ in regard to pathogenesis of chronic effects. The only real difference may be that it is easier to define the long-term effects in occupational asthma because symptoms persist despite removal from ongoing exposure.

Agent	No. of patients	Percentage with residual asthma	Follow-up
TDI	50	82%	>4 y
Red cedar	136	60%	4.3 y
Colophony	20	90%	29 mo
Snow crab	31	61%	1 y

TDI, toluene diisocyanate.

TABLE 6. *Irreversible asthma after occupational exposure*

INDUSTRIAL BRONCHITIS

Chronic bronchitis is defined as a productive cough lasting for >3 months per year for two consecutive years. Chronic bronchitis has been linked to cigarette smoke, which complicates the assessment of industrial bronchitis. Many workplace materials have been implicated as a cause of chronic bronchitis, including a variety of dusts (e.g., cotton dust), fumes, and vapors. The pathology of bronchitis is characterized by mucous gland hypertrophy and goblet cell hyperplasia in the large airways. There is an increase in mucus-secreting glands relative to serous acini, so that secretions tend to be more viscous and have less antibacterial activity. These changes in mucus may predispose to bacterial overgrowth. The role of inflammation in chronic bronchitis is not clear, although it may be important in the induction of mucous membrane metaplasia. In addition, one study indicates that sputum production correlates better with bronchial inflammation than with the structural changes in the mucous glands.

Many of the agents associated with industrial bronchitis have also been linked to an accelerated decline in FEV_1. The pathophysiology of this annual decline in FEV_1 is probably not bronchitis itself, which is a disease of the large airways. Instead, inflammation, mucous membrane metaplasia, and fibrosis in the small airways appear to be the pathologic features that lead to clinical airways obstruction. Thus, bronchitis and the development of small-airways disease with decreased FEV_1 are distinguished by their anatomic localization. They frequently occur together in the same person and often are both caused by exposure to the same agent. An agent inducing chronic bronchitis should alert the investigator to look for a decline in pulmonary function.

CHAPTER

35 Byssinosis and Respiratory Disease Caused by Vegetable Dusts

William S. Beckett · Mark J. Utell

W. S. Beckett and M. J. Utell: Divisions of Occupational/Environmental Medicine and Pulmonary/Critical Care, Departments Of Medicine and Environmental Medicine, University of Rochester Medical Center, Rochester, New York 14642.

INTRODUCTION

The term *byssinosis* is applied to acute and chronic diseases of the airways occurring in persons exposed to three vegetable textile fibers: cotton, flax (which is woven into linen), and soft hemp (which is used for making rope and net). It is applied both to the acute syndrome of chest tightness, dyspnea, and reversible air flow obstruction that occurs at work within a few hours of exposure to cotton dust, and more broadly to the other respiratory effects of cotton, flax, and hemp dust. Because many more people worldwide are exposed to cotton than to jute and hemp dust, much of the following discussion focuses on cotton dust disease but also applies to the effects of the other vegetable fiber dusts.

With sufficient exposure, dusts from these materials may produce eye and nasal irritation, bronchitis, occupational asthma (with a characteristic pattern of worsening symptoms and air flow obstruction on the first day of exposure after a break from work), fever, chronic air flow obstruction, or combinations of these. The delayed febrile response to these dusts is now known as the *organic dust toxic syndrome* (*ODTS*), which may occur after inhalation of a variety organic materials that have been kept in conditions permitting the profuse growth of contaminating micro-organisms (see below).

Long-term occupational exposure to a variety of vegetable dusts (including some grain and wood dusts) causes airways symptoms of cough, expectoration of mucus, and wheeze, and with sufficient exposure leads to chronic air flow obstruction.

COTTON DUST DISEASE

Cotton is a plant-derived cellulose fiber. The long, thin, flexible cotton fiber consists of glucose units connected by glycosidic linkages containing reactive hydrogen groups. However, it is in large part the dust of the bract (dry, friable materials at the base of the cotton flower), leaf, and stem of the cotton plant, and the micro-organisms that grow on them, that cause disease (Fig. 1). Cotton dust may contain ground-up plant matter, fibers, bacteria, fungi, soil, pesticides, plant matter other than cotton, and other contaminants in varying proportions according to the conditions of plant growth and stage in the processing of cotton.

FIG. 1. The cotton plant, with cotton fibers supported by bract, leaf, and stem. A boll in the process of opening is seen in the *upper right.* In the *center,* the white cotton fibers are surrounded at the base by the brittle cotton bract. Cotton dust is composed mainly of bract, leaf, and stem.

Although the relative importance of the different components of cotton dust in producing disease is controversial, the acute response of byssinosis correlates better with the measured exposure to endotoxin (from the cell walls of contaminating gram-negative bacteria), whereas chronic air flow obstruction correlates better with total cotton dust exposure.

Epidemiology

Cotton growing and production of cotton products are major industries worldwide. Hence, respiratory disease related to cotton dust will continue to be commonplace until dust control in these industries becomes more widespread. Among persons exposed to cotton dust are workers in cotton ginning, cottonseed oil mills, cotton thread and yarn manufacturing, cotton fabric manufacturing, and those working with textile waste used in padding, upholstery, and mattresses. Disease is not usually associated with the harvesting of cotton, flax, or hemp or with exposure only to cleaned cotton fibers once processed into their finished products (Fig. 2). In cotton textile production, where dust exposures are excessive, byssinosis may affect a large proportion of the exposed workers, reflecting a pharmacologic (rather than sensitizing) effect of inhaled materials in the airways. This pattern contrasts with that of typical sensitizing or latency occupational asthma, where fewer than 10% of exposed workers are usually affected.

FIG. 2. Cotton mill worker opening a bale of cotton that has been ginned and shipped to the mill for further processing. Opening bales is one of the dustiest jobs in the

cotton mill. (Photo copyright Earl Dotter, reproduced with permission.)

Cigarette smoking is believed to be associated with an increased susceptibility to the adverse effects of cotton dust.

Clinical Presentation

Airways symptoms of cough, mucous production, or the development of chronic bronchitis are a common response to cotton dust exposure and occur in workers exposed to cotton dust who do not have the chest tightness and reversible air flow limitation of the acute syndrome; they are found in both smokers and nonsmokers. These syndromes have been observed repeatedly in carefully controlled studies of cotton textile workers in the absence of other symptoms of byssinosis.

The cardinal symptoms of the acute byssinosis syndrome are chest tightness and shortness of breath that occur on re-exposure to cotton dust after a weekend or several days away from work. This very common temporal pattern, “Monday chest tightness,” may also occur in previously unexposed persons on first contact with the dust. The temporal relationship of the onset of chest tightness to first exposure at work differs from the latency typical of occupational asthma; it often occurs 2 to 3 hrs after exposure to dust has begun, whereas in occupational asthma the early asthmatic response usually begins within the first hour, and the less common late asthmatic response occurs usually after 6 or more hrs. The chest tightness may be associated with a productive cough. In more severe cases or in older workers, dyspnea on exertion also may occur. Tolerance to cotton dust with a reduction in symptoms on subsequent mornings of the workweek is often seen, with loss of tolerance after 1 day or more away from work. With progression to more severe disease, symptoms of chest tightness and dyspnea may be present each day at work, and eventually at all times. The severity of symptoms is enhanced if symptoms caused by chronic cigarette smoking are present, and both dust exposure and smoking contribute additively to chronic airways disease in cotton textile workers. Those with chronic air flow obstruction have the characteristic symptom of dyspnea on exertion, with reduction in exercise tolerance in proportion to the degree of air flow obstruction.

Thus, persons exposed to cotton dust may seek medical attention with a history of chest tightness occurring at work, intermittent or chronic bronchitis, acute fever occurring several hours after exposure to dust, or chronic dyspnea and exercise intolerance after years of exposure.

Pathogenesis

Byssinosis is a non-allergic airways disease. Bronchoconstriction and inflammation can be induced in previously unexposed persons with a first challenge to cotton dust extract. There are several theories regarding mechanisms, for which some experimental evidence exists. Local release of histamine from airways in contact with dust may result in the acute symptoms and air flow obstruction. A distinct inflammatory airways response to contaminating bacterial endotoxin, other bacteria-derived substances, or other components of cotton dust appears to be important in the chronic bronchitis associated with long-term exposure to cotton dust.

Physical Findings

Findings on chest examination are usually absent or minimal in patients with symptomatic dust disease, although wheezing may be heard. With chronic disease, the findings are chronic air flow limitation, weight loss, use of accessory muscles of respiration, prolonged expiration, and either a quiet chest or wheezing on expiration.

Laboratory Findings

No useful serologic markers have been found for byssinosis. Findings on chest radiographs in patients with byssinosis are usually unremarkable.

Pulmonary Function

In patients with the acute airways form of byssinosis, reversible air flow limitation may be demonstrated by comparing measurements made after a Monday work shift with those made before (Fig. 3). Lung function may be normal between episodes of byssinosis. If spirometry is performed before and after the work shift throughout a week, the FEV_1 (forced expiratory volume in 1 second) and the ratio of FEV_1 to FVC (forced vital capacity) are reduced during the day of exposure in symptomatic workers with byssinosis. The absolute value of the fall in FEV_1 may be greatest on the first day of exposure, and less through the workweek as a result of adaptation. However, the baseline level of FEV_1 at the beginning of the day may be reduced with serial daily exposure through the workweek, only to return to the previously normal baseline on the next Monday morning. The magnitude of the reversible decline in FEV_1 in symptomatic patients may be relatively small (10%–20% during the acute episode) in relation to the degree of chest tightness experienced.

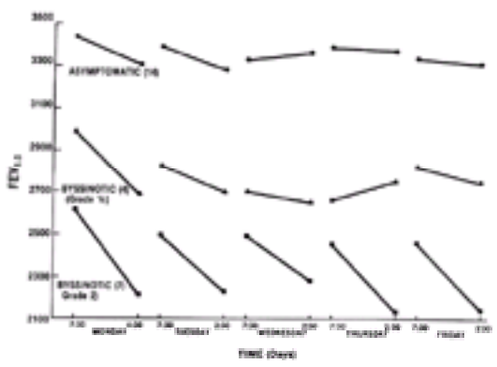

FIG. 3. Correlation of the grade (severity) of byssinosis with FEV_1 on spirometry during a work week in heavily exposed cotton mill carders. Grade 1/2 refers to those with occasional tightness or mild respiratory irritation on the first day of the work week. Grade 2 refers to those with usual chest tightness on the first day and other days of the week. Note that asymptomatic individuals also have work-related decrements in FEV_1. Carders with the higher grade of byssinosis have lower baseline lung function. *Numbers in parentheses* refer to the number of subjects in each group. (Reproduced with permission from Merchant JA, et al. Evaluation before and after exposure—the pattern of physiologic response to cotton dust. *Ann N Y Acad Sci* 1974;221:38–43.)

Patients with byssinosis have greater airways responsiveness to nonspecific challenge than do subjects without byssinosis from the same mill, and airways responsiveness has been demonstrated experimentally to increase across a Monday work shift in mill workers with byssinosis. The role or utility of nonspecific airways challenge in diagnosing byssinosis has not been defined.

Chronic air flow limitation with permanent impairment is seen as a result of long-term exposure to cotton dust through many years. The pattern cannot be distinguished on physiologic grounds from the chronic air flow limitation seen in cigarette smokers, and so the occupational history of exposure to cotton dust is important in establishing a diagnosis. Ascertaining the duration and levels of exposure to cotton dust, a history of acute respiratory symptoms, or a decline in FEV_1 across work shifts, as well as obtaining a complete smoking history, may be useful in determining the degree of chronic air flow limitation attributable to cotton dust versus that attributable to cigarette smoke in a cotton worker who has also smoked.

Treatment

Reduction in total exposure to cotton dust to prevent recurrence is the primary treatment of byssinosis. This can be achieved by control of airborne dust levels—for example, enhancing ventilation in areas with high dust levels. Prewashing of cotton has also been effective in reducing exposure to pathogenic dust.

When acute air flow obstruction is present, treatment with inhaled b-adrenergic agonist bronchodilators has been shown to reverse obstruction, and this treatment is advisable for the symptomatic patient in distress. The diagnosis of byssinosis is a sentinel health event indicating an excessive occupational exposure. Byssinosis is a reportable condition in many states and provinces, and the diagnosis is an indication for intervention in the workplace to reduce dust exposure for the symptomatic patient. Because of the high attack rate in areas of overexposure, the diagnosis of one case indicates that many others are likely to be similarly overexposed and

symptomatic. Occupational standards for dust in cotton-processing workplaces that do not produce acute symptomatic disease have been established and are enforced in many countries.

ORGANIC DUST TOXIC SYNDROME

The syndrome is characterized by prominent, delayed fever and systemic symptoms after an episode of inhalation of organic dust often described as moldy. The illness is self-limiting and without significant radiographic findings. It has been reported in a broad variety of circumstances, including in farmers unloading hay from silos and workers shoveling moldy wood chips. It is categorized among the inhalation fevers, which also include metal fume fever and (Teflon) polymer fume fever. ODTS is not an IgE-mediated allergic response, as it does not require previous sensitization and is characterized by tolerance to similar exposures on subsequent challenge. An acute febrile response to inhaled cotton dust after a period of 2 days or more away from work (“mill fever”) is well described in cotton textile workers with heavier exposure to dust, and cotton dust is now recognized as one cause of ODTS.

GRAIN DUST DISEASES

Epidemiologic studies of agricultural workers exposed to a variety of grain dusts, both in harvesting and in storing, unloading, and transporting grain, have discovered an important association of allergic manifestations, acute and chronic bronchitis, and chronic air flow obstruction related to the levels and duration of dust exposure. A similar pattern has also been observed with at least one kind of wood dust. The clinical picture is often one of an inflammatory bronchitis with mucous gland hyperplasia, chronic hypersecretion of mucus associated with cough and phlegm, and, in cases of prolonged and heavy exposure, accelerated decline in lung function during a period of years. Because of the absence of specific physical, laboratory, or radiographic findings, the occupational history of recurrent exposure to dust (usually at levels that are easily visible in the workplace) may be the most important clue to the underlying cause of the patient's respiratory symptoms. A short course of anti-inflammatory medication, such as an inhaled corticosteroid, may be tried to treat the acute response, and interventions to reduce dust exposure through control technology or the use of respiratory protective masks (still markedly underutilized in agriculture) are necessary to prevent recurrent or progressive disease.

CHAPTER

36 Occupational Pulmonary Neoplasms

David R. Graham · W. Keith C. Morgan

D. R. Graham: Whiston Hospital, Prescot, Merseyside L35, DR, United Kingdom.
W. K. C. Morgan: Chest Disease Unit, University Hospital, London, Ontario N6A 5A5 Canada.

INTRODUCTION

Although the incidence of lung cancer is increased in certain occupations, the most important cause of this disease remains cigarette smoking. Even if one considers those cancers associated with a particular trade, the occupational risk is small compared with that of smoking. However, in the belief that something can be done to reduce the occupational risk, whereas many smokers seem powerless or too ignorant to help themselves, occupational lung cancer requires further consideration.

HISTORY OF OCCUPATIONAL CANCER

The first neoplasm noted to be related to a particular occupation was cancer of the scrotum. In 1775, Percival Pott observed that the disease characteristically occurred in chimney sweeps and concluded that it seemed to derive from a lodgement of soot in the rugae of the scrotum. Tumors of the skin were later described in cotton workers, shale oil workers, and aniline dye workers.

Harting and Hesse were the first to recognize cancer of the lung as a frequent cause of death in miners of copper, iron, and silver in Schneeberg. It was only later that the cause was found to be radioactive air in the mines. This same problem was identified in uranium mines, where the presence of radon daughters was shown to be associated with bronchogenic carcinoma. In more recent years, the risks associated with several other materials used in industry have been recognized. Lung cancer has been shown to be associated with asbestos, arsenic, chromates, iron ores, coal gas, chloromethyl ethers, beryllium, nickel, and vinyl chloride. Several other substances are suspected, but as yet not proved, to be carcinogens.

EXTENT OF RISK: OCCUPATION VERSUS SMOKING

If the substances involved in producing human cancer can be identified and proved to be causally related, then those substances might be avoided. The portion of blame that can be attached to the various environmental factors thought to be carcinogens has been the topic of considerable debate during the last decade. Most of the work on this subject has been epidemiologic, relying on the incidence of cancers in various populations and countries. It has been suggested by some that environmental factors can account for up to 80% of human cancers. However, this figure is itself an exaggeration and includes not only the toxic materials of industry, but also factors such as diet, numbers of pregnancies, race, and so forth. Nevertheless, the figure of 80% has been used to suggest that exposure to chemicals and toxins such as asbestos is the major cause of cancer in Western society. This view is supported by Epstein, who goes further in stating that a cancer epidemic is in progress as a consequence of occupational and environmental exposures. Not surprisingly, these views have important political implications and have been supported by various governmental agencies. Bridbord and associates, under the auspices of the National Cancer Institute and the National Institute for Occupational Safety and Health (NIOSH), calculated the risk of exposure to six known carcinogens and concluded that occupational cancers comprise 23%–38% of the total number of cancers, with asbestos alone causing up to 18%. To this figure must be added the effects of ionizing radiation and other known carcinogens not included in their calculation.

When these facts, together with the preceding data, were re-examined, basic flaws in the epidemiologic method used by Bridbord and associates were noted. One of the main faults was a disregard for dose and duration of exposure to particular carcinogens, resulting in gross overestimation of the risk. It may well be that the Occupational Safety and Health Administration (OSHA) article was written for political rather than scientific purposes, and that the figure of 38% for cancer deaths caused by occupation should be dismissed. It appears that there is no current cancer epidemic apart from the epidemic of lung cancer, which is largely a consequence of cigarette smoking.

A more realistic view of the situation suggests that 15% of lung cancers in men and 5% in women are attributable to some extent to contact with occupational agents. Of this 15% in men, a third are caused by asbestos, a third by fossil fuels, and the remaining third by other recognized agents, such as chromium, nickel, chloromethyl ethers, and ionizing radiation. Similar estimates of a 10% and 14% excess risk for lung cancer have been suggested. In fact, the figure of 38% of cancers being attributable to industry, noted in the 1978 federal report, has since been acknowledged to be an overestimate.

It is important to note that the results of the above studies are based on exposure to carcinogens in excess of those encountered in industry today. Overall, industrial hygiene has improved, exposure to asbestos is now under strict control, and the introduction of natural gas has, at least in the United Kingdom, decreased the numbers of workers involved with coke ovens. Future studies should show that the excess risk for lung cancer attributable to industry will continue to fall.

A systematic approach was used to examine the proportion of lung and bladder cancers resulting from occupation. An analysis of several large studies of various occupational groups between 1977 and 1988 showed that the proportion of lung cancers attributable to occupation varied by as much as 1%–40%. The main reasons for this large variation are the differences in levels of exposures to carcinogens in the various studies and countries. The criteria used to assess exposure have been improved but are not always precisely defined and may be the origin of any miscalculations.

INTERACTION OF SMOKING AND OCCUPATIONAL CARCINOGENS

A further consideration is the effect of the combination of smoking and exposure to a known carcinogen. The result of such a combination is best documented in the case of asbestos. The risk from exposure to asbestos alone can be demonstrated by examination of asbestos-exposed persons who have never smoked. However, because lung cancer in nonsmokers (including those exposed to asbestos) is rare, large populations are required to produce reliable results. Authors of several studies conclude that the risk for development of carcinoma in a nonsmoker as a result of asbestos exposure is very small, but this risk is approximately five times greater than

that in an unexposed nonsmoker. The risk in a smoker exposed to asbestos is greatly increased, and not just additively; the level of risk can be calculated by multiplying the two separate risk factors. One view of this situation demonstrates that an unexposed nonsmoker has a mortality ratio of 1, a nonsmoking asbestos worker has a ratio of 5.17, and a smoking asbestos worker has a ratio of 53.3. The exposures also were quantified, and in smokers of more than one pack a day the mortality ratio rose to 87.4.

An interaction is also found between radon daughters and cigarette smoking, although it is not as clear as in the case of asbestos. It appears that there are two effects: first, an additive effect of the number of cancers induced by the two agents, and second, a hastening effect, so that the induction-latent period is shorter among smokers than among nonsmokers. Thus, cancers appear earlier in smokers.

Various explanations have been proposed for these interactions between cigarette smoke and carcinogens. Cigarette smoke is toxic to the ciliated epithelium, and the resultant loss of ciliary function with failure to clear sputum means that carcinogens can be in prolonged contact with the mucosa. Cigarette smoke can cause squamous metaplasia, and it also has been suggested that particles in cigarette smoke can absorb carcinogens and carry them farther down the bronchial tree. Conversely, the asbestos fibers may damage cells to allow entry of carcinogens present in cigarette smoke.

The overall conclusion is that no other known single measure would have as great an impact on the number of deaths attributable to cancer as a reduction in the use of tobacco. This view is supported by the Surgeon General of the United States, who stated that cigarette smoking is a greater cause of death and disability than the workplace environment. In occupations in which the worker is exposed to hazardous agents, control of both smoking and the agent itself provides the most effective means of reducing the risk.

INVESTIGATION OF OCCUPATIONAL LUNG CANCER

The investigation of a potential occupational carcinogen can be carried out in two ways: laboratory testing and epidemiologic survey. Under different circumstances, there is a place for both methods, although some agencies tend to give more weight to laboratory testing of animals than to epidemiology. This is a little surprising, as the majority of discoveries relating to occupational lung cancer have been made by astute observation backed up by epidemiologic confirmation. This approach not only led to the description of the first occupational neoplasm, but was also used by others to identify the associations between asbestos and lung cancer, asbestos and mesothelioma, nickel and lung and nasal cancer, and furniture work and nasal cancer.

Laboratory studies also have an important place, particularly when a carcinogen is suspected not because of an increased incidence in a certain trade but because a particular chemical has a structure similar to that of a known carcinogen. The experimental approach was used to identify the carcinogenicity of the chloromethyl ethers.

Laboratory Testing

If suspicion arises concerning a particular substance that physically or chemically resembles a known carcinogen, the approach should be in vitro testing, and if the suspicion is warranted, progression to animal exposure studies is appropriate. In vitro tests are the quickest and cheapest method of examining potential carcinogens. However, their use is limited, because their only function is to show whether or not a particular substance has any effect on DNA. They can be used as a screening test of new materials, or they can be used to show that one carcinogen is more dangerous than another. In *in vitro* testing, the ability of a substance to transform mammalian fibroblasts into particular colonies with malignant characteristics may be detected, or, as in the Ames test, a change in the rate of mutation of a nutritionally deficient strain of *Salmonella typhimurium* may be demonstrated. When such tests are used, known carcinogens will produce positive results nine times in 10. However, false-positive and false-negative results do occur, and no test is yet available that shows whether there is a threshold below which a suspected carcinogen is innocuous in humans.

Animal studies provide data that are more readily applied to humans. However, besides ethical considerations, there are important limitations; the production of tumors in animals remains uncertain and unpredictable and depends not only on variations between species but also on factors such as sex, diet, and age of the animals. Most animal experiments consist of a relatively short exposure of small rodents to substances at inordinately higher concentrations than those encountered in the workplace. Although valuable information can be obtained from animal experiments, as was the case with chloromethyl ethers, the results of carcinogenesis in animals cannot be blindly applied to humans.

The problem with laboratory studies as a determinant of carcinogenic properties lies in the process of carcinogenesis itself. There is evidence that certain compounds act as initiators and induce mutation in the DNA of target cells (irradiation, halo ethers, mustard gas). Others are responsible for the second phase of carcinogenesis and act as promoters, inducing increased cell multiplication (asbestos). Most compounds act directly on DNA. However, nickel interferes with replication, and benzpyrene requires activation by the host before carcinogenic properties develop. It is clear that the basic mechanisms of carcinogenesis are incompletely understood, and for this reason, laboratory testing is, at best, a rough estimate of the risks that might be involved. Laboratory tests should not be used to declare a compound safe or unsafe, but rather should be used as an indicator of whether protection, surveillance, and further research are required.

Epidemiology of Occupational Lung Cancer

The value of epidemiologic study has been emphasized already. Of the known occupational exposures (Table 1) related to cancer of the respiratory tract, 11 were first detected by observation in particular working groups. Only in the case of the halo ethers was carcinogenicity first demonstrated in animal experiments and subsequently confirmed in epidemiologic studies.

Agent	Occupation	Tumor
Asbestos	Mining, weaving, utilization	Lung cancer, mesothelioma
Radioactivity	Uranium metal mining	Lung cancer
Nickel	Refining	Lung, nasal cancer
Chromates	Electroplating, tanning pigments, chemical industry	Lung cancer
Chloromethy ethers	Fungicides, chemical industry	Lung cancer
Arsenic	Metal refining, sheep dip	Lung, skin cancer
Fossil fuels	Coal, coke, gas furnaces	Lung cancer
Mustard gas	Manufacture	Lung cancer
? Vinyl chloride	Manufacture, utilization	Lung cancer
? Beryllium	Utilization	Lung cancer
? Isopropanol	Manufacture	Nasal, ? lung cancer
? Printing ink	Utilization	Lung cancer
? Cadmium	Refining	Lung cancer
? Magnesium	Refining	Lung cancer
? Formaldehyde	Chemical industry	Lung cancer
? Diesel exhaust	Railroad, garage	Lung cancer
? Meat	Processing	Lung cancer

TABLE 1. *Occupational hazards causing respiratory tract cancer*

As shown in the discussion of the relative parts played by occupation and smoking, the epidemiologic method most often used is that of mortality studies of cohorts. A cohort with a particular contact or exposure is identified and examined. Mortality rates and the causes of death of this cohort are then compared with those of the community in general, groups of smokers, and persons of a particular social class, race, and so on. The cohort can be further subdivided with reference to levels of exposure, age, and tobacco consumption, and thus groups within groups can be compared. The main problems encountered with this type of study are that numbers must be large and data, particularly concerning smoking and exposure contact, must be accurate. An alternative epidemiologic method is the case-control approach. In this method, persons with a certain disease are identified and compared in terms of occupational exposure with matched control subjects who do not have the disease in question. Again, numbers must be very large; for example, a study to estimate the proportion of lung cancer caused by occupation would require 10,000 cases and 10,000 controls.

In the study of occupational lung cancer, despite the disadvantages of requiring large numbers and resources and using retrospective information, epidemiologic studies have provided the bulk of information presently available, alerting industry to hazards so that preventative measures can be undertaken to avoid risks.

PREVENTION OF OCCUPATIONAL LUNG CANCER

Prevention is the most effective method of treating lung cancer, and the prevention of occupational pulmonary neoplasia cannot be realistically separated from the prevention of lung cancer as a whole. The majority of cases of pulmonary cancer are avoidable. The way to reduce the incidence of carcinoma of the lung is to avoid exposure to the relevant carcinogens. The link between smoking and carcinoma is well established. The American Cancer Society records a prevalence of lung cancer

of 149,000 cases per year, and although approximately 10%–15% are associated with industry, the majority are caused by smoking. Within this 10%–15% attributable to industry, many cases will represent a combination of occupational exposure and smoking. In any discussion of prevention, these facts must be considered.

The responsibility for reducing the incidence of carcinoma rests with the medical profession, industry, the government, and the work force. The medical profession must make the facts available and educate industry, the government, and workers. It must continue both epidemiologic surveillance and research to identify new hazards. All this must be accomplished within the confines of available financial resources. Industry must accept advice from informed sources and do its utmost to protect the worker. The government must act responsibly, its first priority being the health of the work force.

The most important group, the workers, must be informed of the risks and must use all protective methods necessary. The most important fact, however, is that workers need to be aware of the risk of smoking, especially in the setting of an occupation with a known hazard.

SURVEILLANCE

Although prevention is the best approach to occupational cancer, another, albeit less effective, alternative exists—detection of early cases of disease in the hope that prognosis can be improved. There has been much debate concerning the value of screening for occupational cancer, and although the concept of medical monitoring has been received enthusiastically, it must be remembered that the value of screening programs is based on the assumption that early diagnosis is beneficial. Although this is true for most infections, it is not necessarily the case for occupational lung cancer. For example, is there any point in detecting mesothelioma earlier when no treatment or cure is available?

In 1968, the World Health Organization (WHO) produced guidelines for screening programs that still apply today. Although most of the criteria are relevant to occupational neoplasia, three require special mention. First, there should be an acceptable form of treatment for patients with recognizable disease. Second, the cost of case finding needs to be balanced economically in relation to possible expenditure for medical care as a whole. Finally, the benefits accruing to persons with true-positive findings should outweigh the harm done as a result of false-positive diagnoses. Added to the required standards of the screening program, the tests chosen must be accurate, sensitive, specific, and of predictive value.

The two tests available to screen for occupational lung cancer are the chest radiograph and sputum cytology. Although both these techniques are useful in detecting cancer, in practice many problems arise. Studies using serial radiography have not improved survival or at best have had only a minor effect. A particular problem is the case of patients with positive sputum cytology but no detectable tumor at fiberoptic bronchoscopy. Segmental bronchial lavage can be performed in an attempt to localize the tumor to a particular segment, but malignant cells can be obtained from several sites or even from both lungs, presumably as a result of spillover.

The results of an extensive three-center study on screening for lung cancer were published in 1984. There was little doubt that cancers could be detected earlier. The radiograph was the most sensitive method, with 40% of cancers identified as stage I (American Joint Committee on Cancer), whereas sputum cytology was effective at detecting early squamous cell carcinomas only. However, despite early detection, it was not clear that there was any subsequent decrease in mortality. A long-term study on chest x-ray screening in chromate workers demonstrated a modest improvement in 5-year survival of regular attenders; however, no significant improvement was seen in the 5-year survival when the total worker population was considered.

Finally, the cost of screening needs to be considered. In one reported experience, the cost per person per year was $135, and as the prevalence of detectable lung cancer is very low (1 in 2000 to 3000), the cost-to-benefit ratio becomes prohibitive. In an earlier series using the chest radiograph, the cost of detection of each cancer was $25,000, with no increase in life expectancy.

In view of all these facts, it may be that the money involved in such screening programs would be better used in preventing rather than detecting largely untreatable cancer.

MANAGEMENT

The treatment of occupational lung cancer is no different from that in the non-occupational setting. In general, the disease is incurable, but surgical resection is the treatment of choice and, if successful, affords a 20%–30% chance of surviving 5 years. The prognosis in occupational lung cancer is slightly worse for two reasons. First, there is a preponderance of small-cell and adenocarcinomas, both of which have a worse prognosis than the squamous cell type. Second, many workers have concurrent lung disease, such as fibrosis, which may make surgery less feasible. A relatively new concept is chemoprevention, and although no proven chemopreventative method exists, several substances, including vitamin A and selenium, have been under investigation. In any case, the improvements in prognosis with such methods are likely to be modest compared with the deleterious effect of smoking.

A problem peculiar to occupational cancer is that of medicolegal ramifications in the form of compensation to the worker or, as is sadly more often the case, to the family of the worker. However, such a discussion is beyond the scope of this chapter.

SPECIFIC CAUSES OF OCCUPATIONAL LUNG CANCER

Asbestos

It is quite clear that lung cancer and mesothelioma are associated with exposure to asbestos and that this association is dose-related.

Specific Occupational Risks

There is little doubt that weavers and certain users of the finished product, such as pipe fitters and laggers, are particularly at risk. In contrast, the risks associated with asbestos mining are significantly less, particularly for chrysotile miners in Quebec. This truism applies not only to mesothelioma, but also to asbestosis and lung cancer. One exception is the relatively higher risk in miners of crocidolite who were employed in the Wittenoom mine in West Australia. Shipyard welders and other workers, who may spend a good portion of their time in close proximity to pipe fitters and laggers, have either no increased risk or, at the worst, a slightly increased risk for asbestosis and lung cancer. Much the same can be said for railroad repair shed workers and, to a lesser extent, those who line furnaces. Garage mechanics working with brake linings do not appear to be at increased risk, and neither in general do persons who come in contact with asbestos merely through working in buildings that contain asbestos.

Asbestos as a Carcinogen

Asbestos is a cocarcinogen, and the presence of asbestosis, especially in smokers, is associated with a significantly increased incidence of lung cancer. The evidence suggests that asbestos is a promoter rather than an initiator of cancer. In regard to the excess of lung cancer that occurs in subjects with asbestosis, it is generally accepted that cigarette smoking is the usual initiator.

It has been estimated in the United States that about 430,000 construction workers and 648,000 workers involved in manufacturing have been significantly exposed to asbestos. Based on these estimates, it is calculated that asbestos plays a role in approximately 3% of all lung cancers that occur in the United States (i.e., 2501 deaths per year), but even then, asbestos acts synergistically with smoking, and the latter makes a greater contribution to the induction of the disease.

That lung cancer is a significant risk in asbestos workers is clear from Fig. 1. The relative risk in asbestos workers is said to be increased up to five to six times, irrespective of the smoking habit. It is now clear, however, that the risk of smoking in the induction of lung cancer was previously seriously underestimated. This is apparent from relating the calculated number of patients in whom cancer deaths were attributed to smoking to the number of cigarettes smoked per day. During the past decade, a number of studies have shown that provided the level of asbestos is kept below one fiber per cubic centimeter, the risk for development of asbestosis is negligible and the risk for development of lung cancer is not increased during a 35- to 40-year working life. In most of these studies, however, the population was exposed to chrysotile only. Smoking has now been shown to play the pre-eminent role. In this regard, it must be remembered that lung cancer has been diagnosed in only about 30 or so lifelong nonsmoking workers with asbestosis. If the smoking histories in these subjects were inaccurate, as is often the case when compensation is being claimed, the excess incidence in nonsmokers would completely disappear. Moreover, great differences exist between the calculated relative risks of lung cancer obtained by different investigators. Such differences are to be expected in the absence of uniform and consistent protocols. Thus, the selection of subjects for studies has differed greatly, with some studies including only asbestos workers with prolonged exposure (i.e., 20 years) and others including all exposures of 6 months. In addition, the smoking habits of the various populations studied have varied greatly. Clearly, these variables will greatly influence the incidence of lung cancer. In certain studies, additional clinical, surgical, and autopsy information was collected from the asbestos-exposed group in whom lung and gastrointestinal cancer developed, but not from the control group. Without applying this refinement to both the groups, the introduction of bias is inevitable. Nonetheless, it is clear that the risk for development of lung cancer is related to the cumulative dose of asbestos; the greater the dose, the greater the risk. It is also evident that increased risk for lung cancer

does not appear until the subject has had an exposure of at least 15 years plus asbestosis—that is, there has been a suitable incubation or latent period. The development of lung cancer in a subject who began to work with asbestos only 5 years before symptoms of the tumor appeared indicates that the cancer is unrelated to the asbestos exposure.

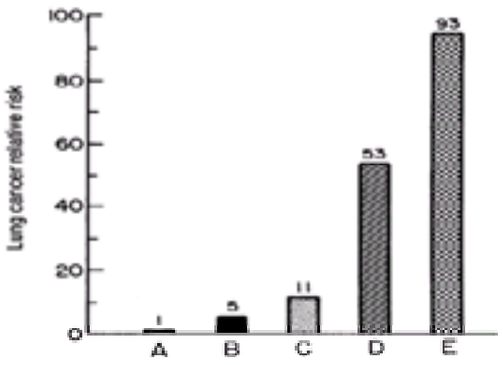

FIG. 1. The relative risk for lung cancer in persons exposed and not exposed to asbestos according to smoking habit. **A:** Unexposed nonsmokers. **B:** Nonsmoking asbestos workers. **C:** Unexposed workers. **D:** Exposed smokers, all. **E:** Exposed heavy smokers (20/d). (Based on data from Hammond EC, Selikoff IJ, Seidman H. Asbestos exposure, cigarette smoking, and death rates. *Ann NY Acad Sci* 1979;330:473.)

In regard to the development of lung cancer in asbestos-exposed workers, the assumption of a linear relationship has received wide but somewhat uncritical acceptance. Such a hypothesis is convenient and simple, but it is not necessarily valid. Deductions based on observations of the risk for lung cancer in subjects with high cumulative exposures cannot, of necessity, be used to predict the response at lower doses. Back extrapolation of the regression line to the intercept at zero is often forced and contrived, as there are usually either no excess deaths or very few deaths occurring at the lower exposures. In many instances, there is just as much mathematical justification for drawing the regression line so that it has either a negative or a positive intercept. Moreover, it is impossible in practice to devise a study that will provide the necessary data to confirm the straight-line, no-threshold hypothesis. Much the same problem exists when the death rate from lung cancer in nonsmoking asbestos workers is considered. In general, the excess death rate in most studies is limited to one or two subjects.

An excellent review of this subject appeared in a supplement to *Thorax* (1996), which examines the article by Williamson et al. (1995) suggesting that excess cancer morbidity occurs without lung fibrosis, and then reviews the subject as a whole. The current evidence indicates that asbestosis (radiographic or histologic) is a prerequisite for excess lung cancer morbidity.

It is true that mining tends to be far less hazardous than weaving. In contrast, users of the finished product are at greater risk. Nevertheless, the apparent safety of mining probably results from the fact that most reliable studies have been carried out on chrysotile miners from Quebec and that chrysotile is less hazardous. There is now fairly compelling evidence to indicate that crocidolite is more carcinogenic than chrysotile, with amosite carcinogenicity in between. This applies not only to mesothelioma, but also to lung cancer. Indeed, it appears that the amphiboles are not only significantly more carcinogenic than chrysotile for a given exposure, but are also more fibrogenic and thus more likely to induce asbestosis. Australian crocidolite miners had a standardized mortality rate (SMR) of 247 for lung cancer after 15 years of exposure, whereas Quebec chrysotile miners with 20 years of exposure had an SMR of only 127. The various dose-response relationships that have been calculated from American studies are shown in Fig. 2.

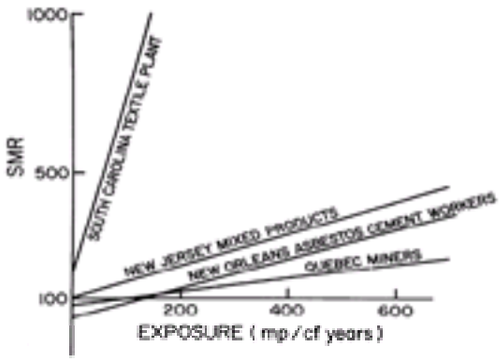

FIG. 2. The SMR for lung cancer in various exposed populations, showing a lesser risk in asbestos miners.

All types of lung cancer are reported to occur in asbestos-exposed populations. The original descriptions suggested that asbestos-associated lung cancer was more likely to be peripherally situated and to be an adenocarcinoma. However, all histologic types are found, and it is impossible to sort out which cancers result from smoking alone, smoking plus asbestos exposure, and asbestos exposure alone (if the latter by itself ever causes lung cancer). Thus, the evidence from pathologic and epidemiologic studies would suggest that fibrosis and epithelial hyperplasia are essential for the induction of cancer. The inability of short fibers to induce fibrosis would explain why such fibers are not associated with the development of lung cancer, and the same is true for fiberglass. From this it can be inferred that the prevention of asbestosis likewise prevents asbestos-induced lung cancer.

Mesothelioma

Mesothelioma occurs either as a benign pedunculated pleural tumor, usually associated with hypertrophic pulmonary osteoarthropathy, or as a diffuse malignant tumor of the pleura or peritoneum. Rarely, the pericardium and tunica vaginalis are affected. Only the diffuse malignant mesothelioma is related to asbestos exposure. Epidemiologic studies would suggest at the present time that about 75%–80% of malignant mesotheliomas are associated with prior asbestos exposure. The tumor also has been associated with exposure to fibrous erionite, a zeolite that is a non-asbestiform mineral. The relationship between asbestos exposure and the development of mesothelioma was established by Wagner and co-workers in 1960.

Malignant mesothelioma usually develops many years after a subject is first exposed to asbestos. The incubation period varies from about 15 to 40 years, with the vast majority of mesotheliomas developing between 25 and 40 years after exposure commenced. In many instances, there has been no exposure to the mineral for 20 to 30 years. There is good evidence that once the lung has been primed by a sufficient dose of asbestos, the development of the tumor is inevitable. However, contrary to previous teaching, mesothelioma does not develop as a sequel to minute or minimal exposures. Although it is true that it may develop after short exposures, in the range of 3 to 24 months, such exposures have usually been intense. Mesothelioma also has been reported in infants and in subjects with no history whatsoever of exposure to asbestos. Although mesothelioma is a rare tumor, it is estimated that it develops in about 1500 to 2000 subjects in the United States every year. In Canada, the figure is probably proportionally somewhat less, mainly because fewer Canadians were exposed to crocidolite in shipyards during World War II.

Mesothelioma and Fiber Type

Early experiments demonstrated that injection of asbestos fibers into the pleural space of animals induced development of mesothelioma. Abestiform fibers such as tremolite caused mesothelioma in the pleural space of rats, but equal doses of non-asbestiform fibers did not. Later, several non-asbestiform fibers, including fiberglass, were found to be capable of inducing mesothelioma provided the diameter of the fibers was 0.5 m, but non-asbestiform actinolite, biotite, and talc failed to produce tumors. The relationship between fiber size and the development of mesothelioma was demonstrated, and it was concluded that fiber structure was a pre-eminent influence in the induction of malignant tumors of the pleura. Later experiments using various forms of asbestiform and non-asbestiform fibers, including fibrous glass and sundry fibrous clays, made it evident that carcinogenicity is related to the dimensional distribution of the fibers, which are longer than 8 m and have a diameter of 0.25 m.

For many years, it has been apparent that the likelihood of mesothelioma developing in chrysotile miners is less than in users of the finished product. It also became apparent that materials made from asbestos contained mixtures of different types, with varying proportions of amosite and crocidolite being added to Canadian

chrysotile before weaving. Epidemiologic studies of the frequency of mesothelioma have shown that the tumor occurs much more frequently in persons exposed to the amphiboles and that crocidolite is particularly dangerous in this regard.

Radioactivity

The excessive mortality of Schneeberg miners was shown by Harting and Hesse in 1879 to be caused by lung cancer, but it had been appreciated three centuries earlier that men working in these mines died prematurely. Lung cancer may have accounted for 40% of deaths in these miners at a time before the introduction of cigarettes to Europe. A similar problem was identified in the uranium miners of Joachimsthal in 1930. The cause of the increased risk for lung cancer in these miners was unknown. However, Kennaway and Lindsey subsequently showed that the air in these mines contained high concentrations of radon and other radioactive elements.

Since that time, radioactive contamination of air or water has been identified not only in uranium mines, such as those in Colorado, but also in several mines concerned with the production of nonradioactive substances, such as fluorspar mines in Canada, hematite and tin mines in the United Kingdom, hard rock mines in the United States, thorotrast mines in Denmark, and iron mines in Sweden.

Uranium

Uranium is mined in Colorado, Canada, Australia, Czechoslovakia, and Central Africa. It is mined on the surface and underground in the form of oxide or pitchblende, or as a compound oxide with vanadium and potassium known as *carnotite.* The ore, of which uranium constitutes 0.5%, also contains 5%–50% silica and hence is associated with a concurrent risk for silicosis.

After ore crushing, the uranium is extracted in the form of uranate known as *yellow cake.* This material is then packed for transport. Uranium is used mainly for the production of atomic energy (peaceful or otherwise), but it also has a minor use in the ceramic and chemical industries. The risk from uranium therefore applies to miners, uranium process workers, and users of the finished product, such as nuclear power plant workers and those who handle uranium in industry.

Mechanisms

Uranium itself is not, from a biologic point of view, dangerous, in that it emits mainly gamma rays, which are of such high energy that they pass through the human body. The problem occurs as uranium decays (Fig. 3). The first step in the decay series is from uranium 238 to radium 226, which in turn decays to radon 222. This element, which is one of the noble gases, decays into its daughters polonium 218 and 214, lead 214, and bismuth 214. Because these radon daughters are ionized metal atoms, they become attached to dust and water vapor. Thus, radon and its daughters can be inhaled into the respiratory tract, where they emit alpha radiation. Particularly important are the radon daughters that have a short half-life and so cannot be cleared from the respiratory tract before their energy is emitted. The alpha particles emitted have a range of 40 to 70 m, sufficient at the site of impaction to damage the mucosal cells and initiate carcinogenesis. This action has been confirmed experimentally when lung cancer has been induced in rats with cesium 14.

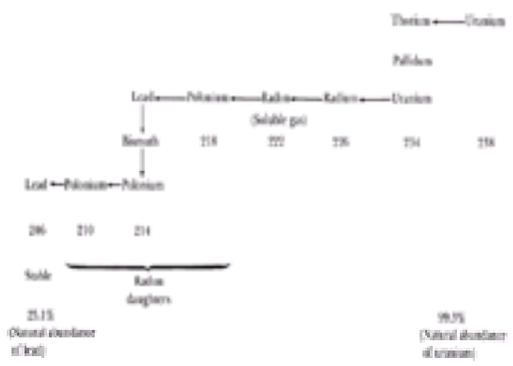

FIG. 3. Simplified natural decay series of uranium.

Epidemiology

Apart from the observations described earlier, several detailed studies have examined the effects of uranium on the lung. Mortality rates of Colorado miners were examined during a 17-year period, and a mortality more than six times greater than expected was demonstrated. Even those miners with low exposure for several years had a fourfold increased risk for lung cancer. A further finding was that the increased total radiation exposure was associated with increasing frequency of undifferentiated small-cell carcinomas.

The interaction between cigarette smoking and radiation is important. Because the incidence of smoking was so high in the initial studies, it was initially believed that smoking was a prerequisite for cancer in uranium miners. However, further studies have shown that although uranium miners who smoke have a higher risk, nonsmoking miners still have an increased risk for lung cancer. From various studies, it is clear that the amount of radiation is important, and for this reason an empiric unit, the *working-level month* (WLM), was derived. This unit is an exposure for 1 working month (170 hours) to a known concentration of radon daughters and thus reflects both intensity and duration of radiation. Risk factors were used to examine the problem in Swedish miners, and if normal nonsmokers had a risk for development of lung cancer of 1, then nonsmoking miners had a risk of 2.4. Smokers with no underground mining exposure had a risk of 6.8, and smoking miners had a risk of 18.2. Another study found that the excess cancer rate in nonsmoking miners was increased (18 observed deaths compared with 1.8 expected), but not as high as in smoking miners (32 actual, 11 expected). These figures suggest that the effects of smoking and exposure to radon daughters are additive. A further effect is the shortening of the induction-latent period, which results in an earlier appearance of cancer. This has been shown to be related to increasing age, increased exposure, and intensity of cigarette smoking, findings that have been confirmed in Sweden.

In summary, there is good epidemiologic evidence that the increased incidence of lung cancer in uranium miners is related to degree of exposure. However, increased incidence is also related to age and cigarette consumption.

Prevention

The atmospheric levels of radon daughters and exposure of workers to them must be kept to a minimum by providing ventilation, sealing off high-risk areas, and controlling water seepage. The work force should be monitored on an individual basis, and exposure should be controlled according to defined standards. In the United States, this is 4 WLM per year, with actual exposure levels being 1 to 2 WLM per year. Because the evidence suggests that the risks of smoking and uranium are at least additive, uranium workers must be strongly advised not to smoke. Some would even suggest that smokers not be employed in such high-risk situations. The question of surveillance is discussed elsewhere.

The preventative measures are not just for miners, but should also be applied to process workers, laboratory workers, and those employed in nuclear power plants.

Fluorspar

Fluorspar, or calcium fluoride, is used in the manufacture of steel and aluminum, in ceramics, and as a source of fluorine. The chief mining area of fluorspar is in Newfoundland, and it was here that the excess of carcinoma of the lung was first demonstrated. The cause of the increased mortality, which was 29 times that expected, was found to be related to radioactivity. Despite the fact that a nonradioactive material was being mined, radioactivity levels were comparable with those in uranium mines. The source was found to be radon daughters dissolved in water that had leaked into the mines.

Metal Mining

Lung cancer has been observed to be more common in certain metal miners. Mortality in hematite miners was found to be in excess compared with mortality in a control population of coal miners, and although initially it was thought that the carcinogens were iron and silica, these hematite mines were later found to be radioactive,

much in the same way as the fluorspar mines in Newfoundland. This same problem has been identified in hard rock miners in the United States, metal miners in Sweden, thorotrast miners in Denmark, and tin miners in Britain.

Nuclear Power Plants

Through the years, the use of nuclear power as a source of energy has been an emotional issue. This is particularly so in respect to possible increased risks for cancers in workers, their families, and surrounding populations. Earlier studies have shown no evidence of an increased risk for carcinoma in nuclear power workers; it should be noted, however, that the data are being amassed for impending court cases concerning the possibility of the development of lymphoma in children of men exposed to radiation at a nuclear power plant in Cumbria, United Kingdom.

Nickel lung cancer was first identified as being related to nickel exposure at the Mond Nickel Works in South Wales in 1958. The findings were later confirmed. These workers also were observed to have an increased incidence of nasal cancer. Their risk was calculated to be increased five times for cancer of the lung and 150 times greater than expected for cancer of the nose. When the study was repeated, the mortality figures had fallen. Studies of other nickel workers also have shown increased risks, especially in smokers.

The agent responsible was thought to be nickel dust, but because the incidence fell as arsenic was eliminated from the process, this also has been implicated. In one autopsy study, however, there was no evidence of arsenic in the lungs of workers who died of cancer. Overall, the evidence suggests that the risk is increased with exposure to several nickel salts, in particular, nickel subsulfide.

Chromates

Chromium is used in the production of alloys, electroplating, pigment production, tanning, and the chemical industry. It is mined chiefly in the former U.S.S.R., Turkey, and South Africa, but it is processed on a much wider scale. A link between chromates and lung cancer was reported early in this century, but epidemiologic study confirmed the association only in the 1940s. A death rate 16 times greater than expected was reported in the United States. The findings were confirmed in the United Kingdom, and the risk was later shown to fall when exposure was reduced.

The risk for carcinoma of the lung and the nose seems to be related to exposure to the salts of chromium, particularly hexavalent compounds such as dichromates and chromium pigments rather than trivalent salts.

Prevention depends on enclosure, extraction, and the use of respirators.

Earlier studies have been updated and have again shown an increased risk for carcinoma of the lung and nose in chromate workers, and the subject has been approached from a different perspective in a later study. When the nickel and chromate content of lung tissues in patients with lung cancer was examined using atomic absorption analysis, significantly higher levels of both metals were shown in the lungs of patients with cancer than in control subjects.

Chloroethers

Chloroethers are compounds encountered in the manufacture of bactericides and fungicides, and two compounds in particular, bischloromethyl and chloromethyl ether, have been shown to be important carcinogens. The other causes of occupational lung cancer were identified by observation and confirmed epidemiologically, but the chloroethers are unique in that their carcinogenic potential was first shown in animal experiments. The effect on humans has since been confirmed, and it has been shown that bischloromethyl ether in particular is associated with oat-cell carcinoma, with risk ratios of 10 to 12 being reported with heavy exposure.

Arsenic

Arsenic has been known as a carcinogen for many years. It was thought to cause scrotal cancer among copper workers as early as 1820, and it was thought that therapeutic arsenic was responsible for skin cancer. Lung and skin cancer were described in 1934 in workers manufacturing arsenical sheep dip. These men were later investigated in detail, and it was found that most workers also showed the clinical manifestations of arsenical poisoning, with hyperpigmentation, warts, and hyperkeratosis.

Nowadays arsenic exposure has been reduced, but a risk still exists in the use and preparation of some pesticides, in metal refining, and in the chemical industry.

Fossil Fuels

The products of fossil fuels, including coal, coke, coal gas, and coal tar, have been shown to be related to an increased incidence of carcinoma. In 1959, lung cancer was shown to be approximately 15 times greater than expected in two studies of Canadian and London gas workers, findings that were supported in a prospective study. Oven top workers in the U.S. steel industry had a 10-fold increase in mortality from carcinoma of the lung, and similar studies have shown this same problem in coke oven workers in the United Kingdom. However, the situation is likely to be improved following the introduction of natural gas. Coke plant workers in the Netherlands were shown to have increased death rates from lung cancer and nonmalignant respiratory disease, but the study failed to examine smoking habits fully. Another study of a cohort of 10,000 foundry workers covering a period of 40 years showed an increased incidence of both lung cancer (SMR 147) and stomach cancer (SMR 137) in comparison with the general population.

Mustard Gas

Mustard gas (bb'-dichlorodiethyl sulfide) has been used as a weapon in warfare. A mortality 10 times greater than expected was shown in Japan, where the gas was manufactured during World War II.

Vinyl Chloride

Vinyl chloride is well-known to produce angiosarcoma of the liver, but it also has been implicated in lung cancer. However, the association is weak, and other studies have attributed the problem to smoking.

Beryllium

Beryllium has not been proved to be a human carcinogen, although the OSHA has recommended that it should be regarded as posing a carcinogenic threat.

Materials Considered Suspect

At the end of any discussion of occupational carcinogens, some compounds should be mentioned that are suspected but not proved to be carcinogens.

Diesel Exhaust

Diesel exhaust fumes have not been proved to cause an excess of lung cancer; however, some studies suggest that exposure to diesel exhaust can increase the risk. A small study showed an increased risk in Swedish garage workers, and a large study of U.S. railroad workers showed increased numbers of deaths from lung cancer in men exposed for 20 years. Further studies have shown a possible association between diesel exhaust fumes and lung cancer, whereas others have failed to demonstrate any increased risk.

Animal studies have also addressed the problem; squamous metaplasia developed in rats exposed to diesel exhaust for 2 years and lung tumors occurred in 16%, compared with no tumors in the control groups. The same study also examined the effect of coal oven flue gas and found a similar increase in the incidence of lung tumors. The possibility that diesel exhaust is associated with lung cancer requires further investigation.

Formaldehyde

Debate is ongoing as to whether formaldehyde causes lung cancer, and the data from a large group of industrial workers exposed to formaldehyde have been

reanalyzed. According to the original interpretation of the data, excess mortality from lung cancer was not related to exposure to formaldehyde, but a repeated analysis suggested an association with formaldehyde. The final conclusion is that formaldehyde should be considered as a possible human carcinogen.

Other Materials

Several studies have examined the effects of silica and possible associations with lung cancer. Although it has been reported that the incidence of lung cancer is lower in miners with silicosis, other studies report increased numbers of deaths from lung cancer in men exposed to silica. Without more and better evidence, however, it is premature to conclude that exposure to crystalline silica has caused lung cancer in humans.

The links of several other compounds and processes with lung cancer remain doubtful. It has been suggested that cadmium is a carcinogen. Also, an increase in cancer has been noted in a group of workers exposed to magnesium.

Increases in lung cancer have been noted in the meat-processing industry and in Swedish bakers and pastry cooks, particularly those who work in small bakeries. Orchardists have been noted to have higher rates of lung cancer, although this is thought to be largely a consequence of cigarette smoking. A cohort of dry cleaners has been found to have a slightly increased incidence of cancer; however, the mortality was less than expected, and no significant increase in the numbers of lung cancers was found.

Isopropanol manufacture is associated with an increase in nasal cancer and possibly lung cancer. The agent suspected from animal studies is isopropyl oil. Suspicion also has been raised in Denmark and the United Kingdom about printing ink, as both printers and newspaper workers have been thought to have an increased incidence of carcinoma of the lung.

An increased risk for lung cancer was found in Swedish and Finish motor mechanics who had high blood levels of lead.

Several materials, such as glass fiber and fertilizers, have been studied and shown not to carry an increased risk for cancer. Cotton workers have been shown to have a decreased risk for lung cancer.

The subject of pulmonary occupational neoplasia is evolving. Further large, long-term studies must be carried out, and the constant review of the situation is necessary.

CHAPTER

37 Noxious Gases and Fumes

David R. Graham

D. R. Graham: Department of Respiratory Medicine, Whiston Hospital, Prescot, Merseyside L35 5 DR.

> “Gas! Gas! Quick, boys! An ecstacy of fumbling, Fitting the clumsy helmets just in time; But someone was still yelling out and stumbling And flound'ring like a man in fire or lime. . . Dim, through the misty panes and thick green light, And under a green sea, I saw him drowning.”
>
> —Wilfred Owen

INTRODUCTION

The deleterious effects of certain gases and fumes have been appreciated for many years. Indeed, several gases have been used specifically for their lethal effects as weapons of warfare. In the industrial setting, 20 or so gases and fumes may be encountered that are capable, after inhalation, of producing serious harm (Table 1 and Table 2).

TABLE 1. *Examples of inhaled chemicals known to cause pulmonary injury*

TABLE 2. *Summary of noxious gases and clinical correlations*

The SWORD (Surveillance of Work-related and Occupational Respiratory Disease) project, a register of cases of occupational lung disease in the United Kingdom, has shown that accidents involving inhalation account for approximately 10% of all industrial lung diseases.

MECHANISMS

The effects of a particular gas or fume can be anticipated by examining its physical and chemical properties. Inert gases cause harm by displacing oxygen, whereas toxic gases produce local irritation. The site of action of a toxic gas depends on its solubility. Soluble gases are absorbed in the upper airways, whereas those that are less soluble cause damage throughout the respiratory tract. Although brownian movement is a major factor in the dispersion of gases, the deposition of particulate matter is influenced more by gravity. Large particles (15 to 20 m) deposit in the nose and upper airways, smaller particles (7 to 15 m) deposit in the trachea and bronchi, and particles between 1 and 7 m may reach the alveoli. Particles <0.5 m are so small that they are influenced by brownian movement, and although deposition is limited, they are still able to cause harm.

The mechanisms by which toxic gases and fumes produce their harmful effects can be divided into four main groups.

1. Displacement asphyxia. The term *asphyxia* is derived from a Greek word that means “stopping the pulse.” The condition is produced by a deficiency of oxygen in respired air, blood, or tissues. Asphyxia resulting from toxic gases or fumes can occur in two ways. In the first mechanism, oxygen is displaced from inspired air by high concentrations of other gases, such as nitrogen, carbon dioxide, and methane.
2. Oxygen-transport asphyxia. The second mechanism involves chemical interference with the process of oxygen transport, preventing either delivery to the vital organs or cellular respiration itself. Carbon monoxide combines with hemoglobin, reducing its oxygen-carrying capability, whereas cyanides block the cytochrome oxidase system, preventing respiration and thereby causing asphyxia at a cellular level.
3. Local irritation. Most toxic gases and fumes cause harm by local irritation. The more soluble substances, such as ammonia, dissolve in the mucus of the nose and

upper airways, whereas the oxides of nitrogen, which are less soluble, exert their effects throughout the respiratory tract.
4. Toxic absorption. Some inhaled substances, in addition to producing immediate effects in the respiratory tract, are absorbed and may damage distant organs. Mercury and manganese damage the nervous system, whereas fluorides can harm the bones. Certain substances can produce long-term effects in the lungs; beryllium causes fibrosis, and cadmium has been associated with emphysema.

Displacement Asphyxia

Carbon Dioxide

Carbon dioxide is an odorless gas that is heavier than air and can be a hazard in any enclosed or ill-ventilated space. It is a particular hazard in coal mines when oxidation of the contaminants of coal occurs at unworked faces, particularly if a face is reopened.

Carbon dioxide was responsible for the deaths of 1700 people in Cameroon when a massive cloud of gas was released from Lake Nyos, a volcanic crater lake.

Inhalation of carbon dioxide causes hyperventilation, sweating, headache, and a bounding pulse with warm peripheries, followed by loss of consciousness. The treatment is to remove the patient from the source of the gas and administer oxygen. Mouth-to-mouth respiration is required if breathing has ceased. Carbon dioxide will extinguish a naked flame, and because of this property, safety lamps can be used to detect carbon dioxide in mines.

Nitrogen

Nitrogen constitutes approximately 80% of air; the remaining 20% is mainly oxygen. If the level of oxygen falls, as in oxidative processes that occur in mines, then the rest of the air is made up of nitrogen and carbon dioxide. If the oxygen level falls to 15%, dyspnea occurs on exertion. As the oxygen falls further to 10%, breathlessness occurs at rest, and at levels below this, collapse and even death may occur on minimal exertion. The way to detect a falling oxygen level again depends on the ability of the atmosphere to support combustion. The treatment is removal, administration of oxygen, and artificial respiration if required.

Methane

Methane, which is without taste or odor, is the product of decaying vegetable matter. It is known to miners as “firedamp” or “marsh gas.” Methane was feared by miners not only because of its asphyxiant properties, but also because of its explosive potential when mixed with air. In the past, methane explosions were the cause of many mining disasters. However, in 1816, Humphrey Davy introduced a lamp that was able to detect methane, which burned with a blue flame.

Methane produces asphyxia by displacement of oxygen, much in the same way as carbon dioxide. The treatment is the same.

Oxygen-Transport Asphyxia

Carbon Monoxide

Carbon monoxide (CO) is the most commonly encountered noxious gas, because it is formed during the incomplete combustion of any carbon-containing material. As well as being an occupational hazard in mines, kitchens, and gas works, around furnaces, and in any situation where high concentrations of motor vehicle exhaust may be present, it is an important cause of death in burning buildings. In the United States, the number of people who die of carbon monoxide poisoning each year is estimated to be above 3,800. In Britain, 1,000 people are estimated to die annually because of the effects of carbon monoxide, which is the most frequent cause of poisoning in children.

The gas is odorless and lighter than air. It causes hypoxia by reducing the oxygen-carrying capacity of the blood and by directly poisoning the cytochrome oxidase systems. The affinity of carbon monoxide for hemoglobin is a 200 times greater than that of oxygen. Carbon monoxide not only forms carboxyhemoglobin and prevents oxygen transport, it also shifts the oxygen dissociation curve to the left, making less oxygen available to the tissue. The tissues most affected by carbon monoxide are those with the highest metabolic rates. Warning symptoms include dizziness and headache, but rapid loss of consciousness without premonitory symptoms often occurs; in fact, it has been estimated that up to 70% of fire-associated deaths in the United States are not caused by smoke or heat of the fire but rather by carbon monoxide poisoning, explaining why individuals with the opportunity to escape fires often fail to do so.

Breathlessness is not necessarily a feature, and physical examination is not particularly helpful. Cyanosis does not occur despite the hypoxia, but a cherry-red coloration of the mucous membranes, caused by carboxyhemoglobin, may be present. The pulse rate is usually elevated.

The chest radiographic findings may be abnormal in acute carbon monoxide poisoning in up to 30% of cases, the usual pattern being diffuse shadowing with a peripheral predominance. If levels of carbon monoxide are insufficient to produce acute carbon monoxide poisoning, then chronic carbon monoxide poisoning can occur. Chronic exposure to carbon monoxide causes headache, muscular weakness, and nausea. If the central nervous system is affected, extrapyramidal or psychiatric symptoms can occur. These features may also be seen in patients who recover from acute poisoning.

The deleterious effects of carbon monoxide are related to its concentration in the inspired air, the duration of inhalation, and the oxygen requirement of the exposed person (and therefore the degree of exertion at the time of exposure). An estimate of the saturation of hemoglobin by carbon monoxide can be obtained for use in, for example, contaminated mines when the concentration is not too high with the formula $b = 4ate/100$, where b is the saturation, a the concentration in parts per million (ppm), t the exposure time in hours, and e the exercise factor (1 for rest, 2 for walking, 3 for working). Even low concentrations of carbon monoxide (0.5%) breathed for 2 hours can cause death. Symptoms begin when the carboxyhemoglobin saturation reaches 20%. Unconsciousness occurs at 60% and death at 80%. High concentrations of carbon monoxide can be produced quickly from vehicle exhaust fumes; a lethal concentration can be reached in a single car garage within 10 minutes. Normal individuals have carboxyhemoglobin saturation levels of 0.5%, whereas smokers have levels of 5%–10%. Nonsmoking London taxi drivers had levels of 0.4%–3%, presumably because of exposure to exhaust fumes.

The traditional means of detecting the presence of carbon monoxide in mines relied on the observation of canaries falling off their perches. Although this method has been largely superseded by detector tubes or infrared analyzers, most mines still keep canaries.

The management of carbon monoxide poisoning is important and consists of prompt administration of the highest concentrations of oxygen available. Normally, this will be 100% oxygen delivered by face mask, but if available, hyperbaric oxygen expedites the dissociation of carboxyhemoglobin. The hyperbaric chamber is undoubtedly the most effective treatment, and such chambers should be available where the risk for carbon monoxide poisoning is high.

The diagnosis of carbon monoxide poisoning is often overlooked (30% in one series). Hence, it is important to measure blood carboxyhemoglobin or breath carbon monoxide in both the industrial setting and in persons who have escaped from fires; this should be followed by prompt treatment with oxygen.

Cyanides

Cyanide poisoning caused by sodium or potassium cyanate can affect persons who are involved in gold extraction and electroplating or who work in chemical and photographic laboratories. The greatest risk, however, occurs with the use of acrylonitrile (vinyl cyanide) in the manufacture of synthetic rubber. The fumes may be inhaled or absorbed through the skin, and workers engaged in loading and unloading or in the industrial process itself are at risk. Cyanides derived from burning seats and furnishings in combination with carbon monoxide were thought to be the cause of death in victims of a recent airplane fire disaster, and elevated levels of cyanide have been identified in persons involved in residential fires.

Cyanide blocks the cytochrome oxidase system. Thus, oxygen can no longer be transferred to the tricarboxylic acid cycle. Asphyxia, therefore, occurs at the cellular level. The symptoms are usually dramatic, with dizziness, nausea, and rapid breathing. This is followed by vomiting, chest and abdominal pain, confusion, and finally coma. Because of the rapid onset of symptoms, the subject is fortunately warned of danger, allowing escape before a fatal dose is absorbed. The saturation of oxygen is not disturbed, and cyanosis is not a feature until respiration is depressed. The diagnosis can be made by the characteristic odor of “bitter almonds” on the breath.

Cyanide poisoning is a medical emergency. Two antidotes are available: nitrites and cobalt. Amyl nitrite, which is inhaled, or sodium nitrite, which is given intravenously, combines with hemoglobin to produce methemoglobin. This combines with cyanide, which in turn combines with thiosulfate to produce the harmless thiocyanate. Thiosulfate is given intravenously with nitrites to augment this conversion. A better alternative therapy is cobalt, which forms stable, inert complexes with cyanide (cobalt cyanides). Hydroxycobalamin can be given intramuscularly, but very high doses are required, so the chelated cobalt dicobalt edetate is the drug of

choice. It should be used only when the diagnosis is certain because of potential serious side effects.

A person poisoned with cyanide should be removed from the area, washed if the skin is contaminated, and given hydroxycobalamin intramuscularly and amyl nitrite to inhale as an immediate first aid measure. If the patient's condition remains severe (i.e., presence of neurotoxicity or depression of respiration), 300 to 600 mg of dicobalt edetate (Kelocyanor) should be given intramuscularly, with a further 300 mg if there is no recovery in 1 minute. Oxygen should be given in high concentration, as this has been shown to have a synergistic antidotal action, particularly when the nitrites are used. If the response is insufficient, then amyl nitrite should be inhaled every 2 minutes, with intravenous administration of sodium nitrite (10 mL of 3% solution) and sodium thiosulfate (25 mL of 50% solution). The patient may require inotropic support, artificial respiration, or even cardiac massage until the antidotes work.

Hydrogen Sulfide

Hydrogen sulfide has a characteristically unpleasant odor that has been used by generations of delighted schoolchildren to make stink bombs. In industry, it is a potential hazard in petroleum refining, the natural gas industry, tanning, the chemical industry, and in the preparation of fish meal.

Exposure to hydrogen sulfide causes conjunctivitis, blurred vision, keratitis, and blepharospasm, together with headache, dizziness, ataxia, nausea, and diarrhea. If the exposure is heavy or if the gas is inhaled, then cyanosis, confusion, pulmonary edema, convulsions, and coma occur. Severe acute exposure causes a greenish coloration of the face and chest. Coma and death result from toxicity of the central nervous system, because the gas binds iron and poisons the cytochrome oxidase system, preventing cellular respiration. Treatment consists of removal from the source with artificial respiration if required. Because the action of hydrogen sulfide is similar to that of cyanide, it would seem logical to give 10 mL of 3% sodium nitrite intravenously, as in cases of cyanide poisoning.

Irritant Gases

Ammonia

Ammonia is a widely used, highly irritant, highly soluble gas. It is utilized in refrigeration, fertilizer production, oil refining, and the manufacture of explosives and plastics. Exposure most commonly occurs as a result of industrial accidents in which tanks or pipes fracture.

The gas is very toxic, and because it is so soluble, its effects are manifested in the skin, conjunctivae, mucous membranes, and upper respiratory tract. Immediately following exposure, intense pain occurs in the eyes, nose, mouth, and throat, accompanied by a sense of suffocation. Stridor and aphonia are followed by cyanosis and ulceration of mouth, nose, and pharynx. Exposure to high concentrations for a minute or less will cause death.

Pathologic examination shows a severe acute inflammatory reaction characterized by edema, ulceration, and desquamation of mucous membranes. Death results from obstruction of the airway caused by edema of the larynx and blockage of the airways with desquamated epithelium. If the gas reaches the lungs, then the alveoli fill with blood and edematous fluid. Survivors have severe airways obstruction that can last for months, although in many cases the epithelial surface completely regenerates. Long-term impairment can occur and has been shown to be caused by bronchitis and bronchiectasis.

The treatment is rapid removal of the patient from the area by rescuers using breathing apparatuses. Weakly acidic mouth washes and eyewashes may help symptoms, but the main objective is to maintain oxygenation. All patients should be given oxygen therapy, and if the case is severe, tracheotomy and artificial respiration may be required. Severe ammonia burns require fluid to treat shock and antibiotics to prevent sepsis. The value of steroids and bronchodilators is unknown, but both tend to be used acutely.

Chlorine

Chlorine is another irritant gas that is widely used in industry in the manufacture of alkalis, bleaches, and disinfectants. It is less soluble than ammonia and is therefore more likely to affect the whole of the respiratory tract rather than just the upper airway. The gas is often stored or transported under pressure, and exposure occurs after accidents such as fracture of tanks or pipes.

Although the gas is less soluble, chlorine exposure still produces conjunctivitis and nasal irritation. However, the most serious effects occur in the lower respiratory tract. Acute exposure causes chest pain and breathlessness. Crackles and wheezes can be heard in the chest, and pulmonary edema with the production of a white or pink sputum can occur immediately or be delayed for several hours.

The degree of parenchymal damage is more severe than that produced by ammonia. Hence, the course of the acute illness is longer, with impairment of gas exchange for several days. Treatment is removal from the source and administration of oxygen, with intermittent positive-pressure ventilation if required. Steroids have been used, although benefit is not proved. Antibiotics are usually given to prevent infection, which may complicate the damaged respiratory mucosa.

Although chronic disability occurred in many victims of World War I gas attacks, this may have been a consequence of the sequelae of infection, as follow-up studies of persons poisoned by chlorine have not revealed permanent impairment of lung function. Nevertheless, there have been several recent isolated reports of persistent bronchial hyperreactivity and asthmatic symptoms (reactive airways dysfunction syndrome, or RADS) following a single large exposure to chlorine gas.

Similar situations have also been reported following a variety of particular smoke inhalations, such as from burning polyvinyl chloride (PVC). Thus, the development of prolonged obstructive airways disease after smoke inhalation is of concern to both fire victims and fire fighters.

Oxides of Nitrogen

Although nitrogen is capable of forming four oxides, the two forms of nitrogen dioxide, NO^2 and N^2O^4, are particularly hazardous. Nitrogen dioxide is a heavy, irritant, brown gas that is relatively insoluble. The gas occurs in several distinct situations in industry: silage production, arc welding, combustion of nitrogenous materials, and manufacture and transport of nitric acid.

Silage is used to feed livestock through the winter. It is produced from fresh green crops, such as grass, alfalfa, and corn, that are stored in a tower or pit at a controlled temperature of ⇀↽38°C. Nitrates derived from the soil or fertilizer are oxidized as a side reaction to the fermentation of vegetable matter, resulting in the production of nitrogen dioxide. The process begins within a few hours of filling the silo, peaks at 2 days, and subsides after a week or two. Farmers and their families are at risk for nitrogen dioxide poisoning at any time in the first week if the silo is entered or even simply approached. Poisoning has occurred up to 6 weeks after filling.

Arc welding, because of the very high temperatures involved, can cause atmospheric oxygen and nitrogen to combine to form nitrogen dioxide and causes a risk when carried out in confined spaces, such as inside tanks or ships' hulls.

Nitrogen dioxide also can be produced when nitrogen-containing materials are burned, as occurs during shot firing in coal and metal mines or the explosion of dynamite. In a particularly notorious episode of nitrogen dioxide poisoning at the Cleveland Clinic, the accidental burning of nitrocellulose radiographic film resulted in >100 deaths. The greatest risk from nitrogen dioxide fumes occurs in the chemicals industry, particularly in the manufacture, transport, and use of nitric acid. The hazard occurs after spills, as nitric acid gives off nitrogen dioxide on contact with organic material. There is also a risk when nitric acid is used to clean metals, in the handling of jet fuels, and in the nitrification of organic compounds.

In agricultural settings, nitrogen dioxide poisoning is known as *silo filler's disease.* However, the clinical features are similar whatever the source of the gas. The gas is not as irritating as ammonia, and low concentrations may produce only mild upper respiratory tract symptoms. The worker may be alerted to the danger by cough or by observing the characteristic brown gas. If the concentration of gas is high, choking and cough will cause the worker to leave the site. Choking and cough are followed by the production of frothy sputum, increasing dyspnea, and within an hour frank pulmonary edema; death may occur at this stage. Alternatively, the onset may be less acute, with cough and dyspnea developing during a few hours, followed by gradual improvement within 2 to 3 weeks. Despite an apparent improvement, there may be a sudden relapse, heralded by fever and chills and followed by cyanosis, dyspnea, and generalized crackles. Death resulting from respiratory failure also may occur in this second stage, but if the patient survives, then recovery is usual, although obstructive defects with impairment of gas transfer have been reported.

Radiographic findings in nitrogen dioxide poisoning are variable. In the acute stage, the radiographic features can be normal or display the appearance of pulmonary edema, which initially may have a nodular component. As the patient recovers, the radiograph clears, but if a second stage occurs, then miliary mottling develops, which at times becomes confluent. In the acute phase, pathologic examination reveals mucosal edema, inflammatory cell exudation, dilated capillaries, and blood in the alveoli. The delayed lesion shows bronchiolitis obliterans.

Management is mainly preventative. Farm workers should be warned of the dangers of recently filled silos, welders should not work in poorly ventilated enclosed spaces, and in addition to the obvious precautions that must be taken in chemical works, even small exposures should be reported and workers observed for late sequelae.

Medical management includes the use of oxygen and ventilation if required. Steroids have been beneficial in case reports, although no controlled trial has proved their benefit. Antibiotics are given to prevent superinfection, but their effectiveness is unproved. Bronchodilators may be of some use in the acute attack.

Ozone

Ozone (O_3) is a constituent of photochemical smog and can be found in the cockpits of aircraft flying above 30,000 feet. It is also produced by high-tension electrical discharges in arc welding.

Serious poisoning by ozone has not been reported, but abundant work in animals has demonstrated that ozone produces structural and functional changes. In humans, low concentrations of the gas (0.3 to 0.9 ppm) produce cough, chest discomfort, and impaired pulmonary function of an obstructive type. Tolerance, however, appears to develop in persons exposed to repeated low levels of ozone, possibly as a result of increased superoxide dismutase.

The evidence that ozone is detrimental to health is increasing. Recent studies have confirmed that ozone causes adverse effects on the pulmonary function of healthy individuals and is particularly harmful to asthmatic patients, potentiating the allergic response even at low concentrations. The subject requires further study.

Phosgene

Phosgene, along with chlorine, was responsible for many of the deaths caused by gassing in World War I. It is a heavy, colorless gas that has a faint odor of newly mown hay. Because it is not particularly irritant, it may be inhaled for long periods without great discomfort. Phosgene is a hazard in the chemical industry, being formed as an intermediate in the synthesis of isocyanates and other organic chemicals. It also occurs when chlorinated hydrocarbons are heated, and cases of phosgene poisoning have been reported following an accident with a carbon tetrachloride fire extinguisher.

Phosgene is toxic to the pulmonary capillaries and causes pulmonary edema (Fig. 1). An exposed worker begins to cough and within an hour becomes breathless. Crackles develop throughout the lungs, and shock follows. Phosgene also appears to cause constriction of the pulmonary vasculature, increasing transudation through the already leaky capillaries and compounding the hypovolemic shock.

FIG. 1. Posteroanterior radiograph of a 55-year-old man with acute phosgene poisoning. Extensive alveolar shadowing is present, with a normal-sized heart and no evidence of diversion of blood to veins of the upper lobes.

If the patient survives the acute episode, the pulmonary edema gradually subsides during a week. There is no definite evidence of long-term pulmonary damage.

Sulfur Dioxide

Sulfur dioxide occurs in the polluted urban atmosphere, being derived from the combustion of coal and gasoline. In industry, it is encountered in paper production, oil refining, and the manufacture of food preservatives and bleach.

Sulfur dioxide is a heavy, irritating gas with a solubility similar to that of ammonia. The effects are therefore severe irritation of the mouth, eyes, nose, and upper respiratory tract. This is quickly followed by violent paroxysms of coughing. Heavy exposure to sulfur dioxide can cause death from pulmonary edema.

The treatment is much the same as for the other irritant gases, although sodium bicarbonate may provide local symptomatic relief. There is some evidence that sulfur dioxide can exacerbate chronic bronchitis, and long-term complications have included the development of obliterative bronchitis and bronchiectasis. However, a 10-year study of a group of paper workers showed no increase in mortality from either respiratory or other diseases.

Toxic Fumes

Metal Fume Fever

Metal fume fever is an acute febrile illness caused by the inhalation of metal oxides. It is variously known as *brass founders' ague, copper fever, brass fever,* and *Monday morning fever.* The disease is most commonly associated with zinc, copper, and manganese, but it is also seen in persons who work with cadmium, iron, nickel, selenium, tin, and antimony. The industrial situations include ship building, welding, electrical metal furnaces, zinc smelting, and galvanizing.

Metal fume fever is thought to be caused by the inhalation of finely dispersed particles (<1 m in diameter) that are produced by heating the previously mentioned metals. The disease invariably has an acute onset, and repeated bouts are common. Metal fume fever is usually worse on the first day at work, as transient resistance develops after a few days exposure, although this effect quickly wanes—hence the term *Monday morning fever.* Attacks can occur on first exposure to fumes without prior sensitization, indicating that a direct toxic action, possibly involving chemotaxis of neutrophils, rather than an immunologic mechanism is the most likely basis for the condition.

The symptoms begin within 4 hrs of exposure and include sudden onset of thirst with a metallic taste in the mouth. This is followed by rigors, fever, and muscular aches and pains associated with generalized weakness. All the symptoms settle spontaneously within 24 to 36 hours. The diagnosis of metal fume fever is based on clinical findings, as no test is specific, although a leukocytosis is often present. The disease is so common that the diagnosis is often made by the workers, who are well aware of the condition. No medical treatment is available, but drinking milk, for no known reason, provides symptomatic relief.

Polymer Fume Fever

Polymer fume fever is a condition similar to metal fume fever and is known as “the shakes.” It occurs after exposure to the fumes produced during the manufacture of polytetrafluoroethylene (trademarks Teflon and Fluon). The condition, first described in 1951, begins several hours after exposure and is characterized by a sharp attack of chest tightness, choking, and a dry cough. Repeated attacks are common, as with metal fume fevers, and do not lead to permanent problems.

It is thought that inhalation of aliphatic and cyclic fluorocarbons, formed when polytetrafluoroethylene is heated to >250°C, causes leukocytes in the lung to degranulate and release endogenous pyrogens.

The vast majority of cases of polymer fume fever occur in smokers, and the incidence can be reduced if workers wash their hands before smoking. Better still, handlers

of polytetrafluoroethylene should be strongly advised not to smoke.

Osmium

Osmium is a very dense metal that is closely related to platinum. It is found in Russia, Canada, Colombia, Australia, and the United States as the ore osmiridium. Osmium is used as a catalyst, as an alloy with iridium in nibs and compass needles, in photography, and for the staining of histologic sections.

The metal is innocuous, but osmic acid (osmium tetroxide) produces effects similar to those of the halogen gases, including severe conjunctivitis, tracheitis, and bronchitis. Blindness can occur from corneal damage, and prolonged exposure causes nausea and vomiting.

Trimellitic Anhydride

Trimellitic anhydride (TMA) is used in a variety of industrial processes, such as the manufacture of plasticizers, as a constituent of alkyl resins, and as a curing agent for epoxy resins. Asthma and bronchitis were the first problems reported with trimellitic anhydride. However, hemorrhagic pneumonitis also has been described. Workers with pneumonitis were exposed to fumes of trimellitic anhydride when a mixture with epoxy resin was heated; they presented with cough and repeated hemoptysis. Chest radiographs often showed patchy infiltrates consistent with blood in the lung. All patients had hemolytic anemia as well as respiratory problems. Pulmonary function testing showed hypoxemia, and although the diffusing capacity (D_LCO) was occasionally raised initially because of blood in the lung, it was reduced as the anemia became more severe. Histologic examination in these cases showed a hemorrhagic pneumonitis with intravascular hemorrhage and alveolar cell hyperplasia.

Removal from the exposure usually results in resolution of symptoms. Treatment is supportive.

Mercury

The industrial hazard from mercury was appreciated as early as 1703 by Ramazzini, who reported that persons making mirrors became palsied and asthmatic from handling mercury. The inhalation of mercury vapor may cause inflammation throughout the respiratory tract, with tracheitis, bronchitis, bronchiolitis, and a pneumonitis. Exposure to this hazard occurs in extraction of the metal, in the manufacture of thermometers and tungsten-molybdenum wire, in the cleaning of tanks and boilers, and more recently, in the repair of sphygmomanometers.

Symptoms generally begin 1 to 4 hrs after acute exposure, with breathlessness and tightness of the chest. This is followed by development of paroxysmal cough, loss of appetite, fever, restlessness, rigors, and tremor. If the exposure is heavy, dyspnea can be severe and death may occur. If the exposure is small but repeated, the symptoms are of abdominal pain, diarrhea, erosion of the nails, gingivitis, and nonspecific neurologic symptoms such as tremor, irritability, or forgetfulness. Basal crackles may be heard in the lungs. The radiograph may show diffuse, patchy shadowing, and lung function tests show a mixed restrictive and obstructive defect. Mercury levels in the blood may be low, as it is fixed in the tissues. However, chronic exposure can be detected by finding raised levels in the urine. In severe cases, pathologic examination has shown tracheobronchitis and pneumonitis with alveolar edema and hyaline membrane formation. In infants, bronchiolitis and pneumothorax have been known to cause death. Occasionally, patients progress to pulmonary fibrosis. Management of the poisoning is supportive and includes oxygen and corticosteroids.

Manganese

Manganese is used as an alloy to harden steel. It is mined from a black ore containing manganese dioxide (pyrolusite) in Russia, India, Morocco, South Africa, and South America. Exposure to manganese occurs in smelting and the manufacture of dry-cell batteries and glass. The damage to the central nervous system caused by manganese is well-known; its effect on the lungs is not as clear. A high incidence of pneumonia and bronchitis has been observed in workers exposed to manganese, and animal experiments have confirmed its ability to cause pulmonary damage.

Cadmium

Cadmium is a soft, gray metal similar to zinc. It is produced chiefly in the United States, the metal being obtained from its own natural ore, greenockite, or from zinc, lead, and copper ores. Cadmium is also recovered from electrolytic zinc refining and from the fumes of lead and zinc smelting. Because it resists corrosion, cadmium is widely used for electroplating. It is also mixed with nickel and silver to form alloys used in nuclear reactors and batteries, and in the manufacture of jewelry.

Cadmium is toxic to humans. If the salts are ingested, nausea, vomiting, and diarrhea occur within 2 hrs. The most serious effects of cadmium, however, develop after inhalation of the fumes, which can occur at the time of smelting or if cadmium-plated metals are fired or welded. The effects can be either acute or chronic.

Acute exposure to high concentrations of cadmium fumes causes rhinitis, sore throat, cough, a metallic taste in the mouth, and retrosternal discomfort. Later, symptoms similar to those of metal fume fever develop, including malaise, rigors, and muscle pains, and, if the exposure is severe, dyspnea and hemoptysis. Physical signs include fever, tachypnea, cyanosis, and coarse or medium crackles in the chest. The chest radiograph shows vague infiltrates in the middle and lower zones or a pattern similar to that of pulmonary edema.

In fatal cases, pathologic examination shows damage to lung and kidney. The trachea and bronchi are inflamed, and the lungs are edematous. Histologic examination shows congestion with intra-alveolar exudate and hemorrhage. The kidneys are swollen with evidence of cortical necrosis. Glomerular vessels are often occluded by thrombi, and the tubules show widespread damage with proteinaceous and granular casts.

The effects of long-term exposure to cadmium are not as easily delineated. Nonrespiratory problems include anosmia, nasal ulceration, and discoloration of the teeth. Proteinuria occurs in 80% of workers with long-term exposure to cadmium and can be associated with severe tubular degeneration. Liver damage, anemia, and bone marrow depression have all been reported. The effect of long-term exposure to cadmium on the lungs is controversial. Some believe it causes emphysema, and although this may be the case, others argue that cadmium emphysema is in fact caused by cigarette smoking or is the aftereffect of an acute exposure. The situation is further complicated by the fact that cigarettes themselves contain cadmium. The symptoms of cadmium emphysema are much as expected, although there tends to be little in the way of accompanying bronchitis. Pulmonary function tests usually show obstruction, although one study by Smith and associates of heavily exposed workers showed a restrictive defect with evidence of pulmonary fibrosis in a minority of patients. These findings have not been observed by other investigators.

Pathologic examination of the lungs has shown marked emphysema without bronchitis, although there has not been unanimity concerning which type of emphysema is present, both panacinar and centrilobular patterns being reported.

No specific treatment is known for either acute or chronic cadmium poisoning, and both British antilewisite (BAL) and ethylenediamine tetra-acetic acid (EDTA) are thought to be contraindicated.

Vanadium

Vanadium is used to harden certain steels. It has been shown to cause industrial asthma, and after acute exposure, it can produce severe irritation of the eyes, nasal irritation, sore throat, cough, retrosternal discomfort, and bronchitis or a patchy bronchopneumonia.

Metal Fumes and Industrial Asthma

The list of substances that cause industrial asthma continues to increase and includes several metals, such as nickel, chromium, cobalt, and platinum salts. Industrial asthma is reviewed in Chapter 34.

MISCELLANEOUS AGENTS

Various agents are encountered in the workplace that do not necessarily fit into the classification of noxious gases and fumes discussed previously. Nevertheless, they deserve mention.

Diesel Emissions

Diesel emissions have been the subject of a number of investigations because they contain a complex mixture of harmful materials, including carbon monoxide, carbon dioxide, sulfur dioxide, formaldehyde, and nitrogen dioxide. However, despite the potential risks, several studies have failed to demonstrate serious effects. Coal miners showed no decrease in FEV_1 (forced expiratory volume in 1 second) or $FEF_{50\%}$ (forced expiratory flow, midexpiratory phase), railway workers exposed to short-term diesel exhausts showed no adverse effects, and iron ore workers in Sweden had no decrease in lung function after exposure to diesel fumes; an increased incidence of bronchitis was found in underground workers, although this was small compared with the effect of smoking.

Overall, diesel fumes, despite their hazardous potential, have not been proved to have any harmful effects, although surveillance should be maintained and any further complaints investigated. Diesel fumes are also considered in the chapter on occupational pulmonary neoplasms (Chapter 36).

Hexavalent Chromium Compounds

These compounds, used in pigments and tanning, cause nasal ulceration and perforation. In high concentrations they can induce severe tracheobronchitis and pneumonia. Recovery is usually rapid, but secondary infection can occur.

Hydrofluoric Acid

This acid is used in etching, in metal refining, and as a catalyst. It causes severe tracheobronchitis if inhaled.

Zinc Chloride

This compound can be a hazard in the manufacture of dry cells or in galvanizing. Its effects are similar to those of hydrofluoric acid.

Formaldehyde

This is a colorless, inflammable gas that has many industrial uses, including the manufacture of textiles, paper, rubber, adhesives, cosmetics, and insulation materials. It is used as a fixative and preservative in anatomy, in pathology laboratories, and by morticians. Formaldehyde is also present in cigarette smoke and automobile fumes. The irritant effects of formalin are well-known, with exposure causing lacrimation, nasal irritation, sneezing, sore throat, headache, and chest tightness. Evidence is increasing that formalin causes asthma. Formaldehyde has also been linked with cancer; this is discussed in Chapter 36.

Paraquat

This highly efficient herbicide is used worldwide, and although it becomes inactive on contact with soil, it is a serious occupational hazard. The devastating effects of ingestion of paraquat are well-known, producing an often-fatal pulmonary fibrosis. Occupational poisoning has occurred in agricultural workers spraying paraquat, and it is likely that absorption in these cases occurred through the skin. There is a single case report of a patient who survived poisoning by inhalation of aerosol.

Prevention is based on education of workers together with use of protective clothing and respirators. Treatment is supportive, including administration of steroids.

Methyl Isocyanate

Poisoning with methyl isocyanate (MIC) was not recorded until 1984, when a notorious accident occurred at a Union Carbide plant in Bhopal, India. This episode resulted in approximately 1,900 deaths, according to the official estimate of the Indian government; however, the true figure may have been as high as 2,500 to 5,000 deaths. Methyl isocyanate, which is used in the manufacture of pesticides, was thought to have escaped when water entered a tank of the gas. The exothermic reaction that resulted caused a massive escape in a densely populated area (100,000 people within a 1-km radius). The main effects were on the eyes and respiratory tract.

Pulmonary edema was followed by destructive lesions with cavitation, pneumomediastinum, and emphysema in affected individuals. Development of pulmonary hypertension has been reported in survivors, and the possibility of fetal damage and teratogenic effects has been raised. Because of the confusion following the disaster, records and data are incomplete, and many questions about the episode remain unanswered.

CHAPTER

38 Pulmonary Effects of Radiation

Robert A. Nonn · Nicholas J. Gross

R.A. Nonn and N.J. Gross: Departments of Medicine and Molecular Biochemistry, Stritch School of Medicine, Loyola University of Chicago, Maywood, Illinois 60153; and Medical Service, Hines Veterans Affairs Hospital, Hines, Ilinois 60141.

HISTORY

The discovery of x-rays in 1895 by Roentgen and a practical means of generating them led almost immediately to their use for diagnostic and therapeutic purposes. It also inaugurated the science of radiobiology. The first evidence of effects on the lungs came as early as 1898 in a study of guinea pigs by Bergonie and Teissier. The energy of therapeutic x-rays in the first decade of this century was so low that most was probably absorbed by the chest wall (even of guinea pigs), and the view at that time was that the lungs were relatively resistant to x-rays. During the second decade, however, higher-energy x-rays with more penetration were generated, and radiotherapists began to observe unusual lung reactions in their patients. It was the practice then to irradiate the chest wall of mastectomy patients with opposed anterior and posterior ports. The first suggestion of pulmonary reactions to this treatment was presented by Groover and colleagues in 1921 and described by them in the next 2 years. The same year as their first publication, 1922, Hines reported two cases with autopsy findings, and Tyler and Blackman reported seven cases, including some in which pleural changes were present; these were followed by Evans and Leucutia in 1925. There is some ambiguity in these reports, with early and late effects and pulmonary and pleural reactions being discussed simultaneously under the designation of “pulmonary fibrosis.” However, these were neatly sorted out by Desjardins at the Mayo Clinic in 1926 in the first review article on the subject. His descriptions of the clinical and roentgenographic features and their differential diagnosis leave little room for additions in these areas more than 60 years later. The discoveries of the previous century had clearly resulted in the first lung disorder that was entirely of man's own making.

Subsequent developments can be summarized. The first detailed descriptions of pathologic changes following irradiation were presented by Engelstad and by Warren and Spencer; these were followed by experimental and clinical reports of Jennings and Arden and Smith. Shortly thereafter, in 1966, Phillips suggested that the major change of pathogenetic consequence was the effect on pulmonary capillary endothelial cells, a view that is no longer current.

The physiological effects of pulmonary x-irradiation were investigated by McIntosh and Spitz in 1939 and Freid and Goldberg the next year. But it was not until the era of relative sophistication in pulmonary function testing that a coherent picture of the functional changes emerged.

In the clinical sphere, corticosteroids were first used for treatment of radiation effects on the lungs by Cosgriff and Kligerman and for prophylaxis by Friedenberg and Rubenfeld. Although these and clinical studies by Bluestein and Roemer, Rubin and colleagues, and Whitfield and Bond suggested that corticosteroids might be of benefit, the report by Moss and co-workers appears to have confirmed this experimentally.

RADIOBIOLOGY

The following discussion of the physical and biological effects of ionizing radiation is intended only to provide a superficial background for the understanding of clinical events. For a more detailed and accurate account of the effects of radiation on biological tissues, the reader is referred to any text on radiobiology or radiotherapy.

The two most commonly used forms of ionizing radiation are x- or gamma rays and accelerated particles, of which the only variety of significance for pulmonary effects at present is fast neutrons. (Fast electrons are also in clinical use but, because of their limited penetration, cannot produce effects in the lungs from an external source.) X-rays and neutrons ionize the target by indirect processes. When an x-ray collides with an electron in the target, some of its energy is transferred to the electron, which is accelerated out of its orbit. Neutrons are more likely to accelerate hydrogen nuclei. In either case, fast-charged particles so generated ionize the atoms or molecules they collide with, resulting in ion pairs. These in turn react with adjacent molecules to produce free radicals. In biological tissue, where most of the molecules are water molecules, most of the free radicals will be hydroxy radicals, ·OH, but free radicals also will be generated from more complex molecules. Free radicals,

particularly ·OH, have a great deal of excess energy because of their unpaired valence electrons. They can break covalent bonds to cause some of the biological effects of irradiation. It is in fact the free radical, which is much longer-lived and more energetic than the ion, that does the damage. However, the term *free-radical-forming radiation* is unlikely to displace the conventional term *ionizing radiation.* Although much damage can be rapidly repaired *in vivo,* the presence of oxygen in the target allows some of the free radicals to become oxidized. The result in the case of organic free radicals is an organic peroxide, which is less easily repaired than bond breakage without peroxide formation. Because the molecular injury is “fixed” by oxygen, most forms of radiation are much more damaging if the target is well oxygenated.

What is the target in biological systems? Although all molecules can be affected by the chain of events resulting from the absorption of ionizing radiations, the function of most of them is not important enough or not sufficiently altered to have serious consequences. Thus, a change in the viscosity of a mucopolysaccharide solution or an increase in permeability of a membrane could be corrected by replacement or repair of the damaged molecules. Doses in the range of thousands of rads are required to produce enough damage to nongenetic structures to seriously jeopardize the survival of most cells.

The damage to genetic material, DNA itself, is more important. Although the molecular events in genetic damage are not entirely clear, one can envision a number of points at which mutagenic or subsequently lethal effects could occur: single-strand breaks in DNA could be inadequately repaired, or base substitutions could be made in the repair process. Double-strand breaks could result in fragmentation or misalignment of the ends or cross-links between strands, all of which will occur in a small proportion of the population of irradiated cells. It is unlikely that such damage will be expressed in the cells until their next mitotic attempt. At that time, gross chromosomal damage may make it impossible for the chromatids to separate, resulting in anaphase arrest, or chromosomes may be divided unequally between the daughters, or major chromosomal aberrations such as ring forms, dicentrics, bridges, and fragments may appear. Equally fatal results may occur from deletions and point mutations. Genetic damage from radiation is therefore expressed as a loss of reproductive or clonogenic potential. This can occur at doses of a few hundred rads, in contrast to the thousands of rads needed to cause effects on nongenetic material.

Because ionizing radiations do not distinguish between normal cells and cancer cells, the history of experimental radiotherapy is the story of a search for methods to destroy the tumor cells without destroying the cells that make up the normal tissue around them and that will inevitably be irradiated in the process. This search has been considerably advanced by basic studies of the effects of radiation on cell survival (reproductive capacity). Loss of reproductive capacity is most satisfactorily studied in cultures of continuously dividing cells (i.e., HeLa cells, Chinese hamster cells, and mouse L cells), but similar experiments can be performed on the cells of certain organs *in vivo.*

Repair of Sublethal Damage

Following irradiation of cells *in vitro* or *in vivo* with different single doses of x-rays, a characteristic dose–response curve is generated (Fig. 1). There is an initial shoulder reflecting low doses, followed by a portion in which the fraction of cells that survive (divide) is inversely related to the dose. The initial shoulder indicates that a certain amount of radiation damage must be accumulated by cells for a lethal effect. This phenomenon is known as repair of sublethal damage. Above a certain threshold, reproductive death is a direct function of the dose absorbed. The amount of sublethal damage that can be repaired has been measured for many cell types, and there are techniques by which it can be measured *in vivo.* It has approximately the same value in many tissues and tumors *in vivo* and is equivalent to that produced by a notional dose (Dq) of 300 to 500 rads of x-rays (see Fig. 1); values for lung tissue also lie in this range. Furthermore, the survival curve following a second dose of x-rays given long enough after the first has the same shoulder as the first, indicating that sublethal damage must again be accumulated, and to the same extent, for a lethal effect. The phenomenon can be repeated indefinitely. The molecular mechanism of repair, like the mechanism of damage, is incompletely understood, but experiments in which the second dose follows the first by different times show that repair takes place rather quickly, within the first 4 to 6 hr and certainly within 24 hr. The fact that repair can be partially inhibited—for example, by low temperature—suggests it is a result of the activity of the cell's machinery. The implications of the repair phenomenon in the clinical situation are clear: the smaller the individual fractions, the larger is the total dose that can be administered in the course without destroying the organ, provided the fractions are separated by enough time for repair. Why a larger total dose in many fractions is good for the host cells and bad for the tumor cells may be related to the oxygen effect.

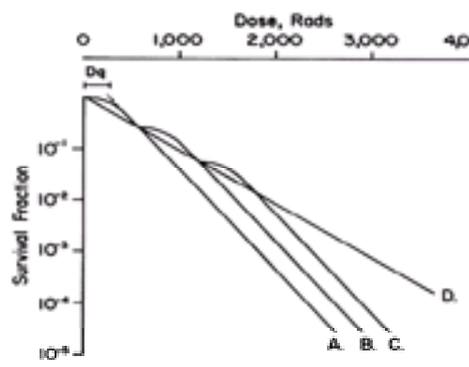

FIG. 1. Typical survival curves of cells in culture. Curve A represents survival (ability to reproduce) following various single doses of x-rays. The initial shoulder is due to sublethal damage, whose amount (Dq) can be calculated by extrapolation to the horizontal axis *(dashed line).* Curve B shows the effect of a second exposure on a culture previously exposed to 600 rads, and curve C the effect of a third such exposure. The line D is the resultant effective survival after successive 600-rad fractions. In this example, a single exposure to 1800 rads would reduce the proportion of surviving cells to less than 10 whereas the same total dose in three equal fractions would reduce the proportion to only 10 - 2, illustrating the sparing effect of dose fractionation.

Oxygen Effect

That ionizing radiations are more damaging to a well-oxygenated target has already been mentioned. This is well demonstrated in survival curves (Fig. 2), which typically show less reduction of reproductive potential of cells *in vitro* that lack oxygen at the time of irradiation. Tumor cells are quite likely to be poorly oxygenated because cells toward the center of the tumor are separated from their blood supply. In fact, tumor cells more than 150 to 200 m from stroma are likely to die of anoxia. Adjacent to the area of necrosis will be many tumor cells that are so poorly oxygenated that they will be relatively radioresistant; only at the periphery of the tumor will the cells have the same radiosensitivity as the surrounding stroma. X-irradiation will destroy the well-oxygenated cells at the periphery of the tumor, thus bringing the hypoxic cells closer to the blood supply at the periphery and rendering them more susceptible in turn. Fractionation of the total dose of x-rays thus “reoxygenates” the more isolated hypoxic tumor cells while minimizing the lethal damage in normal stromal cells. This is particularly important in the lung, which is the best oxygenated of all tissues. It also explains why small tumors (which have a relatively large surface of well-oxygenated cells) are more likely to be amenable to x-ray control than large ones and why there is an interest in pharmacologic agents that sensitize hypoxic cells to x-rays.

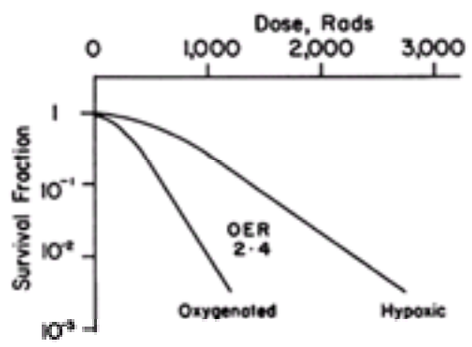

FIG. 2. Survival curves of cells in culture following exposure to various single doses of x-rays under hypoxic and oxygenated conditions. After each dose of x-rays, survival in the culture that was hypoxic at the time of exposure is 2.4 times greater than in the culture that was well oxygenated at the time of exposure. The oxygen enhancement ratio (OER) in this example is 2.4, a typical value for mammalian cells exposed to 250 kVp x-rays.

Radiation Energy and Neutrons

The foregoing discussion assumes that all ionizing radiations have the same energy. X-rays have a wide spectrum of energies, however; most experiments in radiobiology were performed at energies of 250 kV or less, but current radiotherapy is almost universally performed at energies in the megavoltage range. Higher-energy radiation is more penetrating, and the oxygen enhancement effect is in general less. Because penetration and less protection from hypoxia are bad for tumor cells and less bad for normal stromal cells, it is understandable that radiotherapy should move in the direction of higher energies. Fast neutrons, depending on the way in which they are generated, have mean energies up to one order of magnitude greater than conventional x-rays and therefore offer advantages over x-rays in tumor therapy (Fig. 3). Heavier charged particles, such as accelerated nuclei, would be even more advantageous, but for economic reasons, they are most unlikely to make the transition from experimental to therapeutic medicine in the time scale of this or the next edition of this text. For the present, fast neutrons are the only practical alternative to x-rays for deep therapy; experience with them is reviewed by Field. Although they appear to offer advantages in some tumor types, their use in lung tumors has been disappointing.

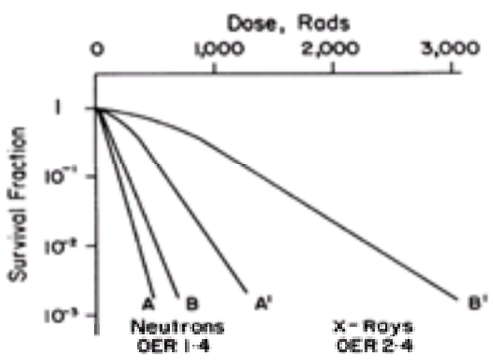

FIG. 3. Survival curves of cells in culture exposed to neutrons and 250 kVp, x-rays under oxygenated (A and A1) and under hypoxic (B and B1) conditions. Not only are neutrons more lethal than x-rays, dose for dose, but there is less sublethal damage (initial shoulder), and the oxygen enhancement ratio (OER) is less.

Units, Time, Dose, and Volume in Radiation Therapy

The unit of radiation exposure is the roentgen (R), but what matters to the patient is the amount of energy absorbed. This is a complex function of many factors, including density and thickness of the exposed tissue as well as energy of the radiation. In the case of x-rays, an exposure of 1 R to solid tissue results in an absorbed dose of approximately 1 rad, the unit of absorbed radiation. It is equal to 100 ergs absorbed energy per gram of tissue and has to be calculated on the basis of certain assumptions, tissue density, thickness, etc. It is important to note that the rad is the amount of energy absorbed per gram of tissue, so that a dose of 700 rads to both lungs is only a fraction of the energy absorbed when 700 rads is received by the whole body. The former would not produce any clinical effects; the latter would almost certainly be fatal. Another common misunderstanding is illustrated by the following: Suppose a patient received 5000 rads to a lung tumor and 5000 rads to the mediastinum. The total dose he or she has received is 5000 rads, not 10,000. The mass of tissue irradiated is thus quite as important as the dose of radiation because it is a determinant of the total energy absorbed. Because the only information that the clinician commonly receives, or takes notice of, is the total dose in rads, a unit, the megagram rad, was proposed. This is a mass integral of absorbed radiation energy and has been used in correlating dose with effect, for example, in pulmonary function. This logical unit enjoyed a brief vogue in previous years but is not widely used now. Radiation scientists and therapists now use a new unit, the Gray (Gy), which is equal to 100 rads, and current reports and treatment plans use this unit instead of the rad.

Important as the total dose is, the way in which it is delivered is as important. As Fig. 1 shows, the phenomenon of repair of sublethal damage indicates that fractionation of the total dose will minimize the damage to normal tissues. The importance of fractionation is well illustrated by a case reported by Whitfield and colleagues of a patient with breast cancer. Following mastectomy, she received 1500 rads in a single dose to the axilla and, inevitably, to the underlying lung. If this dose had been delivered in five to ten fractions, it would have been unlikely to produce any symptoms, even if delivered to the entire volume of both lungs. As a single dose, however, it produced a severe radiation reaction in the underlying lung tissue.

Biological response is thus determined to some extent by the number of fractions a total dose is delivered in. To take account of the effect of fractionation, an isoeffect dose can be expressed as the total dose modified by fractionation factors. Because much of the original work was done by Frank Ellis, the formula that relates tolerance to dose and fractionation is known by his name (the original equation has been rearranged for the purpose of this discussion):

$$\mathrm{NSD} = D \times N^{-0.24} \times T^{-0.11}$$

NSD stands for nominal standard dose; its unit is the ret (rad-equivalent therapy). Hypothetically, it is the number of rads equivalent to treatment as a single dose, but in reality, the formula cannot be extrapolated to fewer than about four fractions. It is the notional dose producing a certain biological effect, traditionally tolerance, resulting from a range of different dose-fractionation schedules. *D* is the total dose in rads, *N* the number of fractions, and *T* the overall treatment time. The Ellis formula (derived from experiments on skin) can be used to estimate the rets for tolerance in a large number of organs, including the lung. Phillips and colleagues reevaluated the exponents of *N* and *T* for the lung; in the equation form given here, they would be -0.377 and -0.058, respectively. (Actually, these will probably differ, if only to a minor extent, from one institution to another.) This formula indicates the importance of the number of fractions and, by comparison, the relatively small effect of the overall treatment time. It is used in treatment planning to calculate the total dose and fractionation to be used in irradiation of the entire lung, on the basis of the likelihood of pneumonitis. Thus, Wara and colleagues calculated that there is a 5% probability of clinical pneumonitis when 510 rets is delivered to the entire lung (Fig. 4). This dose is achieved by a wide range of alternative treatment schedules, for example, 1500 rads in 11 fractions over 20 days, 2000 rads in 24 fractions over 24 days, or 2500 rads in 38 fractions over 40 days. Each of these will have the same biological effect on normal lung but probably different effects on the tumor (because of such factors as reoxygenation). In addition, there may be regional variation in the response to irradiation, with high-grade pneumonitis more frequently being seen after treatment for lower-lobe than upper-lobe tumors in both animal and human models of study. Concomitant therapy with cytotoxic agents (see Contributory Factors) alters radiation sensitivity, adding yet another dimension.

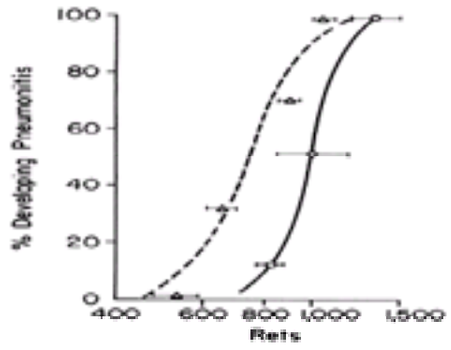

FIG. 4. The probability that pneumonitis will develop following whole lung irradiation at various nominal standard doses (rets) of x-irradiation, with (—D—) and without (-O-) concurrent actinomycin D therapy. (Redrawn from W. M. Wara et al. *Cancer* 1973;32:547. Reproduced from NJ Gross. Pulmonary effects of radiation therapy. *Ann Intern Med* 1977;86:81, with permission.)

The Ellis formula applies, of course, to x-rays. The search for an equivalent formula for neutrons has been reviewed by Field; the exponent of *N* for neutrons is now -0.04. The greatly diminished weighting of the fractionation factor in fast-neutron exposure would be expected from the fact that repair of sublethal damage is much less following neutron exposure (see Fig. 3).

It should be apparent from the foregoing discussion that a great many factors determine the amount of biological damage inflicted on the tumor and the normal

surrounding tissue by ionizing radiation and that all these factors have not been brought together into a single universal expression. There are also a number of assumptions and estimates about individual geometry and tissue density that will have to be made for each patient by each radiotherapist, with inconsistent degrees of success. Such judgments vary with the experience and knowledge of the therapist and must entail a degree of error. Add to these such imponderable factors as errors in localization and field placement, and radiotherapy appears to resemble a thunderbolt with Zeus not completely in control.

PATHOGENESIS OF RADIATION PNEUMONITIS

Histopathologic Cellular Effects

The major clinical effects of lung irradiation are conventionally divided into two stages: radiation pneumonitis and radiation fibrosis. Although the relationship between these is discussed in more detail later (Clinical Syndromes Following Lung Irradiation), we can regard pneumonitis as the episode during which the specific effects of lung damage are expressed, and fibrosis as the subsequent wound-healing phase. Death from radiation of the lungs almost invariably occurs during the time of pneumonitis, 80 to 160 days after treatment. Beyond this time frame, death from radiation itself is uncommon. Moreover, inhibition of collagen synthesis (i.e., fibrosis) does not greatly reduce mortality in irradiated rats, indicating that fibrosis is not a factor in mortality from lung irradiation. Consideration of the pathogenesis of radiation reactions in the lung therefore concentrates on the mechanisms of the acute episode of radiation pneumonitis and the events leading up to it, a process that is probably similar in humans and experimental animals.

One can regard the cellular mechanism of lung damage as being principally a result of genetic damage to lung cells, especially because it is so distant in time from the clinical sequelae. Genetic damage is primarily expressed as a loss of reproductive potential leading to depletion of that cell type in the tissue. The damage sustained by an organ will therefore reflect the reproductive activity of its constituent cells and be expressed when a critical level of certain crucial cell type(s) is reached. In tissues where reproductive activity is minimal, typically highly differentiated tissues such as muscle, a large amount of genetic damage will remain latent; muscle cells have no mitotic future and thus proportionately little likelihood of expressing their genetic damage; such tissues appear to be radioresistant. Rapidly dividing tissues composed of stem cells such as bone marrow and intestinal crypt cells will express their genetic damage as soon as they reveal their incapacity to produce fully functional progeny at the rapid rate required by those organs. Such tissues appear radiosensitive. The principle that radiosensitivity varies directly with the rate of proliferation and the number of future divisions to maturity and inversely with the degree of morphologic and functional differentiation of a cell type was expounded in 1906 by Bergonie and Tribondeau. Much subsequent work has confirmed this general principle.

Discussion of the cellular basis of radiation pneumonitis can begin, therefore, with consideration of the turnover of cell types in the respiratory tract. The data that exist have been reviewed and are quite variable. The cells of the airways make up 10% to 15% of the total lung cell complement if neural, blood, and lymphatic cells are excluded. Turnover rates of individual airway epithelial cell types have not been measured, although these cells are all presumably derived from bronchial basal cells. For the airway epithelium as a whole, a turnover time (100% replacement of the population) has been estimated at 1 to 3 weeks. Bronchiolar epithelium turns over more slowly than bronchial epithelium.

The cells of the lung parenchyma make up 85% to 90% of the total lung complement, of which only a small fraction are alveolar epithelial cells, types I and II pneumocytes. Type I pneumonocytes provide over 90% of the alveolar epithelial layer; their complex three-dimensional structure (a single cell will often form the epithelium of two and possibly more adjacent alveoli) makes it practically certain that they cannot divide. They are fixed postmitotic end cells incapable of mitosis in growth or regeneration. Type II cells, in contrast, undergo mitosis at a slow rate; their turnover time in growing rodents is 4 to 5 weeks, but in response to injury such as exposure to high oxygen concentrations, oxides of nitrogen, or radiation, they can revert to a rapid reproductive cycle, repopulate the alveolar epithelium, and subsequently redifferentiate into type I cells. Thus, in addition to its important and well-known function in the synthesis and secretion of surfactant, the type II cell acts as a stem cell for the alveolar epithelium, capable of replacing alveolar epithelium when type I cells are destroyed.

Capillary endothelial cells comprise about a third of all lung cells. Like type I cells, they have an extended cytoplasm, but unlike type I cells, they are in a continuous process of self-renewal. Their turnover time has been estimated at 8 weeks; however, in regenerating lung they appeared to have the same mitotic activity as type II cells.

Pulmonary mesenchymal cells make up the bulk of total lung parenchymal cells but are themselves a heterogeneous group, at least some of which are fibroblasts and macrophage precursors. No figures are available for their turnover rate. Alveolar macrophages form another small but important sector of the population with interesting origins. The cell type is almost certainly derived from the bone marrow via the circulating monocyte. The monocyte leaves the circulation and enters the interstitial space. There it divides one or more times, possibly even residing as a stem cell, and differentiates into a tissue macrophage. In the lung, this process entails an increase in size as well as the development of an appropriate complement of lysosomal hydrolytic enzymes. The differentiated macrophage leaves the interstitial space and appears fully fledged in the alveolar space. There it performs its important defense functions, ultimately to bow out either via the mucociliary escalator or, less probably, via the pulmonary lymphatics. The turnover rate of macrophage precursors in the interstitium is not known. Their turnover time in the alveolar space is about 1 week, but this is due to traffic through the alveolar space rather than division therein.

Nearly all the preceding data have been derived from small mammals that grow continuously from birth to death. The cytokinetics in adult human lungs may therefore be different. From these data it appears that prime targets for radiation damage would be, in order of reproductive rate, the epithelial cells of the airway, the type II and capillary endothelial cells, and the interstitial macrophage precursors. The histologic and other evidence of radiation damage given below accord to some extent with the reproductive activity of cell types in the lung. However, the disproportionate degree of damage sustained by capillary endothelial and type I alveolar cells suggests that there is considerable nongenetic damage in these cells. This possibly results from their very extended cell processes, regions not richly endowed with organelles and in which repair or replacement of damaged nongenetic macromolecular structures such as cell membrane is limited.

Cytokinetic Studies

In the lung, the long latent interval between irradiation and the occurrence of radiation pneumonitis some months later strongly suggests that critical depletion of a crucial cell type is the mechanism of pneumonitis. Because type II cells and capillary endothelial cells are undergoing constant replication (albeit usually at a slow rate), they are thus both candidates for radiation damage. Endothelial cells have been shown to be sensitive to ionizing radiation; in fact, the radiosensitivity of capillary endothelial cells in an organ has been viewed as the limiting factor in radiation tolerance of that organ. Both capillary endothelial cells and alveolar type II cells perform crucial functions in the lung, the failure of which could conceivably produce the changes associated with radiation pneumonitis. However, a complete explanation of radiation pneumonitis in terms of the depletion of either of these cell types has proved elusive. Relatively little is known about the number of these two cell types following irradiation of the lungs because the systematic morphometric analysis of lung cell types following radiation has not yet been reported in detail. However, recent reports suggest there is a general depletion in all cell types 12 weeks after x-irradiation.

Relevant information also can be obtained by cytokinetic studies. The incorporation of precursors of DNA into the nucleus of a cell is evidence of imminent mitosis, and the proportion of cells in that population that are about to enter mitosis, the labeling index, indicates the replicative activity of that cell type. Cytokinetic studies on lung cells following small doses of radiation to the thorax show mitotic arrest in all cell types in the first week after irradiation. Following this, the labeling index of capillary endothelial cells rises severalfold above control levels for a few weeks and then gradually declines to control levels. The labeling index of type II cells also rises above normal levels after the first week and returns to baseline some 4 weeks later. However, from about 6 weeks on, it begins a steady climb to levels about four- to sixfold above normal throughout the period when pneumonitis is occurring. It is therefore difficult to imagine how significant depletion of either endothelial cells or type II cells could occur unless their loss through death also was accelerated. For the latter, there is no evidence. Thus, an explanation of radiation pneumonitis in terms of classic concepts of radiobiology has not been successful, at least with respect to either type II cells or capillary endothelial cells. Some other crucial cell type may become depleted and be responsible for radiation pneumonitis, but this has neither been suggested nor ruled out.

Nevertheless, there is some radiobiological evidence to implicate type II cells and exonerate endothelial cells as the target in radiation pneumonitis. Butylated hydroxytoluene (BHT) has been used to selectively expose various lung cell types to radiations. Administration of BHT in mice results in a brisk inflammatory response in the lungs, during which type II cells are the predominant proliferative cell at 2 days. At 6 days, the proliferative response resides mainly in the interstitial cells and capillary endothelial cells. Thus, irradiation at either 2 or 6 days should intensify the damage to type II cells or interstitial and capillary endothelial cells, respectively. Irradiation at 2 days only resulted in enhanced radiosensitivity, reducing the mean duration of survival from about 170 days to about 30 days and reducing the median lethal dose (LD_{50}) from 9.5 to 2.7 Gy. Irradiation at 6 days had no such effect and actually increased the LD_{50} as compared to control mice not treated with BHT. This result argues in favor of the type II cell, and not the interstitial cell or capillary endothelial cell, as being the target for radiation pneumonitis, although it is possible that another unidentified cell type may have been stimulated to proliferate at 2 days and therefore was responsible for the enhancement of radiosensitivity following irradiation at that time.

Similarly, corticosteroids have been found to reduce the mortality of radiation pneumonitis (below). As they increase the replicative rate of type II cells in irradiated mice, it may be that their activity is functionally deficient in radiation pneumonitis (in the absence of corticosteroid stimulation). However, corticosteroids have many other effects on the lungs, for example, antiinflammatory effects (see below), and it may be that one of these other effects explains their protective role in radiation pneumonitis.

Biochemical Effects

Lipid studies are of interest because of the superficial resemblance between radiation pneumonitis and adult respiratory distress syndrome (ARDS) and because of histologic abnormalities in alveolar type II cells in the early stages of pneumonitis. Biphasic changes in lung total lipids of rats have been found in the first week after thoracic irradiation. Subsequent changes were not statistically significant, but the dose of x-rays, 800 rads, was well below that required to produce pneumonitis.

A transient increase in the content of lecithin has been noted in both lungs and alveolar fluid between 1 and 8 weeks after irradiation, and incorporation of precursors was probably constant throughout. These changes result from proliferation of type II cells, possibly as part of the regeneration of alveolar epithelium. At the stage of pneumonitis, 16 weeks after irradiation, the content of most phospholipids in the lung was increased up to 50%, and this increase was probably associated with increased phospholipid turnover. These changes were reflected in the alveolar lavage fluid; the degree of saturation of lecithin was normal throughout. These results do not suggest that radiation pneumonitis is associated with an abnormality of the surfactant system. Administration of corticosteroids from 2 to 3 weeks before the expected onset of pneumonitis further increased the phospholipid content of alveolar lavage fluid, increased the rate of incorporation of precursors into phospholipids, and normalized the surface tension properties of alveolar surface lining layer, both *in vitro* and *in situ.*

To identify patients at higher risk for radiation pneumonitis, a model was utilized that evaluated the production of free radicals in lipids after radiation exposure by measuring serum desferrioxamine-chelatable iron (free radical scavenger) and the percentage molar ratio of 9,11-linoleic acid and 9,12-linoleic acid (as an index of oxidation). After one week of radiotherapy, the group of subjects later developing pneumonitis exhibited significantly higher levels of desferrioxamine iron and a greater change in percentage molar ratio. This suggests that these assays might be useful indicators to identify patients more likely to develop radiation pneumonitis at a later time.

Coincident with pneumonitis, there is a five- to tenfold increase in microvascular leakage of plasma proteins into the interstitium and alveolar space, resulting in a chronic form of pulmonary edema. The amount of protein leakage is related to the dose of radiation, and its duration corresponds to that of pneumonitis. This probably explains the fall in lung compliance during pneumonitis. Corticosteroids had almost no effect on the amount of microvascular leakage, but mortality was substantially reduced. One speculates, therefore, that the steroid-mediated increase in surfactant phospholipids described earlier has a protective effect by promoting surfactant synthesis and delivery to the surface lining layer in sufficient amounts to counteract the inactivation or desorption of surfactant by plasma proteins. On the other hand, the beneficial effects of corticosteroids may be unrelated to surfactant production and may instead be secondary to some other action such as their antiinflammatory effect.

A cardinal feature of radiation pneumonitis is a fall in lung compliance that can be attributed to stiffness of the air–fluid interface of the alveolar lining. This may in turn be attributable to the leakage of plasma proteins into the alveoli with deleterious effects on the surfactant system as described above, a feature that radiation pneumonitis shares with any other forms of ARDS. It has now been shown that normal alveolar surfactant exists in several structural subtypes with different surface-active properties. The higher-density surface-active forms evolve into a lower-density form that is not surface active. The distribution of surfactant among these subtypes is greatly altered in radiation pneumonitis. Moreover, the metabolic evolution of surfactant subtypes, which is dependent on a unique serine protease that is secreted by the alveolar epithelium, is delayed in radiation pneumonitis. This may be the result of an 18-fold excess of a_1-antitrypsin (a serine-protease inhibitor) in the alveolar compartment that accompanies the microvascular leakage that characterizes this and other forms of ARDS.

Inflammatory Mechanisms

Following radiation to the lung there is an increase in the synthesis of prostaglandins and thromboxane, whereas in radiation pneumonitis there is an increase in the number of lymphocytes, possibly activated, in the bronchoalveolar lavage fluid. Experimental whole-body radiation results in early effects on cyclooxygenase products.

Phillips and co-workers were the first to show that corticosteroids reduced the mortality of experimental radiation pneumonitis, even when given many weeks after irradiation. Corticosteroids administered continuously to mice from 10 weeks after lethal thoracic irradiation substantially reduced mortality. However, if the corticosteroids were withdrawn during the period when pneumonitis was normally occurring, mortality increased and caught up with the mortality rate in the absence of corticosteroid administration. The protective effect of corticosteroids ceased after the time when pneumonitis normally occurs. Their effect, therefore, coincided with the phase of active radiation pneumonitis.

The inflammatory effects of irradiation can possibly be modulated by g-interferon. Lung lavage fluid cellularity and protein content were monitored in treatment and control groups of animals. After 35 days, animals that were irradiated but did not receive g-interferon had elevated protein and macrophage counts, whereas treated and irradiated animals did not vary significantly from unirradiated controls.

Studies carried out over 6 months after irradiation of rats are relevant to the mechanisms of late radiation damage. Among the findings were that prostacyclin (PGI^2) production by the irradiated lung increased progressively from a normal level at 2 months to a level two to three times higher than normal at 6 months. Coincident with this, there was a reciprocal decrease in perfusion of the irradiated lung. Because PGI^2 is a potent vasodilator and antithrombotic agent, the increase in its production is interpreted as consistent with a homeostatic response to impaired perfusion in the irradiated lung.

An alternative approach has been to study the effect of various antiinflammatory agents on mortality from experimental radiation pneumonitis when given well after irradiation but just before the time when pneumonitis normally occurs. The effect of corticosteroid administration is described above. The effects of a variety of agents that have more specific effects on arachidonate metabolism have been reported. In general, lipoxygenase inhibitors and leukotriene-receptor antagonists were markedly protective, more so indeed than corticosteroids. Cyclooxygenase inhibitors had variable effects; aspirin reduced mortality in a dose-dependent fashion, indomethacin markedly increased mortality, and other cyclooxygenase inhibitors had intermediate effects. These data were interpreted as suggesting that the protective effect of corticosteroids could be attributed to their antiinflammatory effects. They suggest that the mortality of radiation pneumonitis results from activity of the 5-lipoxygenase pathway and raise the possibility that clinical radiation pneumonitis can be mitigated by inhibitors or receptor antagonists of this pathway. This possibility has yet to be clinically tested.

PATHOGENESIS OF RADIATION FIBROSIS

The supposition in the past has been that radiation fibrosis was the natural consequence of lung damage expressed as pneumonitis. This is less clear now because of an apparent dissociation between some of the features of each. The connective tissue of the lung has been studied following x-irradiation both as a model of lung fibrosis and to determine the role of fibrosis in radiation reactions. Although the collagen content of the lungs is probably increased at the time of radiation pneumonitis, the increase at much later times is considerably greater, evidence that fibrosis is unlikely to play a major role in the pathogenetic mechanisms of pneumonitis.

One mechanism for the development of fibrosis is a progressive decrease in plasminogen activator activity that begins 1 to 2 months after lung irradiation. According to this hypothesis, the fibrinogen that leaks into the interstitial space as a result of radiation damage to the capillary endothelium, and is deposited as fibrin, is not adequately lysed by tissue fibrinolytic activity. The fibrin deposits act as foci for fibroblast stimulation and collagen secretion. Intricate cytokine and genetic pathways influencing fibroblast and fibrocyte maturation are well described. The ability of irradiation to induce a rapid and early maturation of fibroblasts as a result of genetic damage along with the enhanced production of cytokines by macrophages and type II pneumocytes has been substantiated. These stimuli together lead to an altered fibroblast-to-fibrocyte ratio, with an excess of fibrocytes favoring an increase in the production of collagen, leading in turn to fibrosis. Reduced fibrinolytic activity has also been demonstrated in irradiated lung and is caused by reduced plasminogen activator activity. Plasminogen activator is a product of both endothelial cells and alveolar macrophages. Either or both of these cells may be implicated in radiation fibrosis because endothelial cells irradiated *in vitro* exhibit impaired release of plasminogen activator and alveolar macrophages lavaged from irradiated rat lungs exhibit a time- and dose-related decrease in plasminogen activator activity.

The development of fibrosis in the lungs has been altered by a number of agents that affect collagen metabolism: triiodothyronine, colchicine, and b-aminopropionitrile. However, the best-studied agent is D-penicillamine, a reversible inhibitor of collagen cross-linking and maturation. Administration of D-penicillamine after irradiation of the rat hemithorax moderated late fibrosis in terms of histopathology, hypoperfusion, collagen accumulation, and lethality after 180 days, the latter being the conventional end of pneumonitis mortality. It also moderates the decrease in both angiotensin-converting enzyme and plasminogen activator activity described earlier. D-Penicillamine has been used in a number of other disorders in humans, but it has not been given prospective trials in patients undergoing radiation therapy to the lungs.

HISTOLOGIC CHANGES

Animals

The nature of radiation reactions in the lungs has been most often studied by microscopy. This is presented in summary form in Table 1. Changes are present at some

time in virtually every structure within the thorax; therefore, only the main features are discussed.

Site	Immediate or early (0–2 months)	Intermediate (2–6 months)	Late (6+ months)
Capillaries	24 hr: Vacuolation of endothelial cells. 2–7 days: Marked endothelial cell changes, separation from basement membrane, sloughing, obstruction of lumen with debris and thrombi, or normal. 1+ month: Many capillaries swollen and obstructed	Marked abnormalities with widespread obstruction by platelets, fibrin, and collagen. Capillary regeneration	Loss of many capillaries and regeneration of new ones
Type I pneumocytes	Early degenerative vacuolation, death, and sloughing, or normal	Decreased number	Further decrease in number
Type II pneumocytes	Early morphologic changes or normal redifferentiating into type I cells	Large increase in size and number, abnormal appearance	Return to normal size and number
Basement membrane	Early swelling, indistinct and later very irregular	Folded and thickened	Folded and thickened
Interstitial space	Edema and debris infiltrated with inflammatory cells and mast cells; slight increase in connective tissue	Infiltrated with mast cells, mononuclear cells, inflammatory cells, and collagen	Few inflammatory cells; large increase in collagen
Alveolar space	Fibrin, hemorrhages, and debris; increased number of alveolar macrophages, morphologically abnormal	Becoming smaller	Small, obliterated in places; distortion in architecture
Airway epithelium	Early transient inflammatory reaction, ciliary paralysis, increase in goblet cells, or normal	Epithelial proliferation	—

TABLE 1. *Pulmonary effects of radiation: Histologic changes in animals*

It seems clear that damage to capillary endothelial cells is a consistent and significant feature. There is some disagreement as to when this first appears, either within hours in the form of vacuolation and blebs in the extended cytoplasmic processes or several weeks later. An early increase in capillary permeability suggests a functional lesion, even if it cannot be seen. Within a few weeks at most, the endothelial cells look definitely sick, raised from the basement membrane in some places and attenuated in others. Some cells are sloughed, leaving a denuded basement membrane and choking the lumen with debris and platelet and fibrin thrombi and, subsequently, collagen. Obstruction of the microvasculature is widespread. Arteriolar and arterial lesions resembling an immune vasculitis may be present. Around the damaged vasculature there is edema, cellular infiltrate, and possibly the beginnings of collagen deposition. Within about 6 to 10 weeks, there is evidence of repair. Some capillaries are recanalized, and new capillaries enter adjacent tissues, although perfusion probably remains reduced and permeability is increased (see Physiological Changes). Endothelial lesions are, in fact, a common feature following x-irradiation in many organs; indeed, many consider the endothelial damage to be the single or most important factor that determines the radiation tolerance of an organ. Evidence of damage to the basement membrane that subtends the vasculature may also be important in view of its role in providing a scaffold on which regeneration occurs and without which architectural reconstruction is abnormal.

Coincident with the endothelial changes are alveolar epithelial changes that may or may not be as functionally significant. Early vacuolation and blebs are seen by some in the type I pneumonocytes, which, like endothelial cells, are probably shed from the basement membrane, cluttering the alveolar space with debris. Infection in experimental rodents may have something to do with these early changes. Unlike endothelium, alveolar epithelium appears to have regenerative potential. Experiments in which damage to type I cells has been inflicted with such diverse agents as NO^2, oxygen, and bleomycin, as well as x-rays, indicate that the alveolar epithelium can be repopulated by type II cells that subsequently redifferentiate into type I cells. The large increase in the size and number of type II cells may reflect their role in regeneration of the alveolar epithelium. These cells appear to be relatively radioresistant by comparison with endothelial and type I cells. Nevertheless, the fact that they are stem cells and have important secretory functions warrants suspicion that they may play a role in the pathogenesis of radiation pneumonitis, as already discussed.

Some other features of the histologic changes are mentioned briefly. Cellular activity in the alveolar septum (interstitial space) is present early after irradiation: increased numbers of mast cells and mononuclear cells. There appears to be a paucity of acute inflammatory cells, although occasionally a brisk inflammatory response has been seen. Fibroblast activity can be seen within the first 2 months, when all the changes previously noted are at their height, but little collagen is laid down until about 6 months. At a later stage, dense fibrosis of alveolar septa dominates the histologic picture.

Little attention has been paid to the airway epithelium. The relatively rapid turnover of its cells, noted previously, would suggest early and extensive damage. This has only rarely been observed, however.

In summary, there are no characteristic histologic features; lesions in all cell types have been reported, but damage to capillary endothelial cells and alveolar epithelial type I cells is fairly consistent. These changes can be found in damage from a wide variety of physical and chemical agents.

Humans

The picture in humans is complicated. Early and serial samples are not, of course, available, but at a late stage the dense fibrosis is entirely nonspecific. Again, material obtained at autopsy is likely to show superimposed changes from terminal heart failure or infection and postmortem artifacts. Changes in virtually all pulmonary structures have been reported in material obtained 4 to 12 weeks after completion of radiotherapy. As in the experimental studies, vascular damage is present. Arteriolar lesions are, however, more commonly mentioned. Changes in the alveolar epithelium are also present. Atypia, hyperplasia, sometimes bizarre, and desquamation into the alveolar space are noted, as well as other debris in the alveolar space and fibrin-rich exudate or hyaline membranes. Some observers considered them to be one of the most common and persistent of the abnormalities seen. Although animal studies frequently indicate abnormalities in the alveolar space, hyaline membranes as such are not reported. Possibly they are a terminal feature or secondary to other pathologic developments in humans.

The interstitial space is frequently thickened by edema and hypercellular because of a mononuclear infiltrate. A variable excess of collagen may be present, but inflammatory cells are usually absent. At 4 to 12 weeks after completion of a course of radiotherapy, abnormalities may be present in the airway walls. These include focal necrosis and squamous metaplasia.

Again, it can be seen that there is little that is characteristic about the histologic appearance in radiation pneumonitis. This is unfortunate because one of the more common clinical problems in diagnosis is the differentiation of a radiation reaction from tumor recurrence and infection. Now that the treatment of each of these alternatives is more aggressive, and lung biopsy by one or another route is so readily available, criteria for their differentiation would be most useful. Some criteria that have been suggested for diagnosis of radiation pneumonitis are (1) the presence within the sample of regions of greatly varying pathologic changes and (2) a combination of atypical alveolar epithelial cells, vascular changes, and widespread hyaline membrane formation. Possibly the absence of much evidence of inflammation and the presence of mast cells adjacent to regions of capillary damage can be added to the preceding features. It is highly unlikely that reactions will be found outside the irradiated regions, although there may be exceptions (see Associated Complications). A precise knowledge of the field placement and biopsy site is thus important.

Six months or more after the completion of a course of irradiation, the major abnormality is the huge amount of fibrosis interspersed with obliteration of alveolar spaces and vasculature, a picture that resembles end-stage lung damage of any etiology.

OCCURRENCE

It is difficult to assess how commonly radiation reactions occur in the lungs. No prospective studies have been performed to our knowledge, although in some studies this complication of treatment had obviously been anticipated in the investigative protocol and is reported in the subsequent publication. Published reports necessarily represent a population of patients highly selected by factors such as interest, awareness, and technique. The evolution of radiation therapy itself accounts for another factor of uncertainty. The trend toward more energetic and penetrating radiation deposits more energy in the lung and less in superficial tissues, but at the same time, dosimetry and field placement have become much more sophisticated. These and other technical factors are constantly evolving. Another difficulty in determining the occurrence of radiation reactions is semantic: some authors, particularly in the radiology literature, use the term radiation pneumonitis to denote a roentgenographic appearance; by others, particularly clinicians, it is used to denote the clinical syndrome, which is probably less common. Occasionally, the term is used without attempt at definition or distinction between pneumonitis and fibrosis. In fact, occurrence rates from 0% to 100% have been reported, raising the question of whether any incidence data are meaningful without definition of technical, clinical, and roentgenographic factors.

The principal conditions for which radiotherapy may expose the lungs to radiation are breast cancer, lung cancer, Hodgkin's disease, and lymphoma. The lungs may be exposed in treatment of other tumors such as cancer of the esophagus, but data are scant. The figures given below are based on selections from the literature that seem to provide some guide to occurrence in the era of megavoltage therapy.

Breast Cancer

The technique of tangential therapy of breast cancer minimizes damage to underlying lung, although wound healing, rib fractures, and chest wall necrosis are

correspondingly more troublesome. The occurrence of roentgenographic changes in the lungs adjusted for numbers in each series is about 45%. The proportion of the total who had symptoms that may have represented radiation pneumonitis was 10%. Fatal reactions were not reported.

Lung Cancer

Although in lung cancer patients the occurrence of each of the radiation reactions is similar to that seen in patients with other malignancies, the incidence of lung cancer is extremely high (about 150,000 new cases per year in the United States). Because the majority receive lung irradiation at some stage, this group forms the largest portion of the population with potential or actual radiation damage.

Hodgkin's Disease and Lymphoma

Close cooperation between clinicians and radiation therapists in a number of large study groups has contributed to technical improvements in the treatment of Hodgkin's disease and lymphoma. A search for factors identifying patients at higher risk for radiation pneumonitis was undertaken by retrospectively evaluating 24 series of patients with over 1900 total subjects. The overall incidence of radiation pneumonitis was found to be 7.8%. Multivariate analysis suggested that fraction sizes greater than 2.67 Gy, once-daily dosing, and the total dose of radiation were associated with an increased risk of radiation pneumonitis. Field shaping (to fit the tumor) and field reduction during the course of treatment minimize the amount of normal lung exposed as it is brought into the field by the rapid reduction in size of the tumor mass.

The three malignancies just discussed contribute nearly all the cases of radiation reactions in the lungs. The figures in Table 2 indicate that roentgenographic changes are common in the early stage. Only a proportion of patients, maybe up to 15%, have clinical radiation pneumonitis, still a very large number. A small percentage of the total will die of radiation pneumonitis. In view of the number of patients who receive lung irradiation, radiation pneumonitis is a clinical problem of considerable size.

Primary diagnosis	Roentgenographic changes[a]	Clinical features[a]	Fatality due to radiation pneumonitis[a]	Roentgenographic changes of fibrosis[a]
Breast cancer	24.5	8		57
	20	13		60
	56	14		
	70	5		
	87			
Lung cancer	13 at 3 months	4.6	5	66 at 12 months
	33 at 6 months	15	2	100 at 30 months
	6	3	0.7	100
	100	5		
Hodgkin's lymphoma	65	0.4–33[b]	0.25–5.9[b]	65
		5		

[a] Figures are percentages of total number of patients in the series.
[b] Higher figures refer to cases with contributory factors, e.g., previous irradiation.

TABLE 2. *Pulmonary effects of radiation: Occurrence of radiation reactions in the lungs (from selected reports)*

Brachytherapy and Interstitial Implantation of Isotopes

There is considerable interest in direct implantation of g-emitting isotopes into the lesion. This innovation offers improved control of the dose and field. The usual isotope is iodine-125, which has a half-life of 60 days and a small volume of irradiation. Multiple sources are inserted directly into the lesion and not removed. Radiation pneumonitis was found in 9% of 46 patients receiving brachytherapy but was attributed to the external beam radiation delivered concomitantly. Experience with this form of radiotherapy is limited, and unfavorable reactions to it are as yet uncertain.

Accidental Irradiation with Isotopes

Intrapleural administration of isotopes with b-emission, such as radioactive gold, produces a local pleural reaction only. Inhalation of dust or particles containing g-emitting isotopes can produce radiation damage. In the event of a nuclear disaster, this could be a long-term consequence. There is also a report of probable radiation pneumonitis, ending fatally, in a worker employed for 3 years in the production of radioactive luminous paint. The treatment with iodine-131 of thyroid malignancy, metastatic to the lungs, also has been associated with fatal radiation pneumonitis.

In patients being treated for inoperable hepatic tumors with intraarterial yttrium-90 microsphere infusions, five of 80 patients developed a syndrome resembling radiation pneumonitis 2 to 4 months after therapy. Technetium-labeled macroaggregated albumin studies were performed before the treatments, and the degree of intrahepatic shunt was quantified. Those who did not develop radiation pneumonitis had shunts of less than 1% to 15% with a median of 6%, whereas five of nine patients with shunts greater than 13% developed radiation pneumonitis. No patients developing radiation pneumonitis demonstrated shunts less than 13%.

CLINICAL SYNDROMES FOLLOWING LUNG IRRADIATION

Radiation Bronchitis

Courses of radiotherapy that typically call for 40 to 60 Gy take several weeks to administer and often include the central airways in the field. Dry irritant cough is very common toward the end of the course or during the next few weeks. From the cytokinetics of bronchial mucosa and the few histologic reports (see Histologic Changes), it seems conceivable that these symptoms are caused by radiation bronchitis. If symptoms are severe, the course of treatment may need to be suspended for a week or two, much as for radiation esophagitis. We are not aware of any detailed investigations into this possibility. No serious complications ensue, and treatment is symptomatic.

Radiation Pneumonitis

Radiation pneumonitis develops insidiously. Although the symptoms can sometimes be traced back to a month or so after the completion of radiation therapy, it is uncommon for the patient to present less than 6 to 8 weeks after completion unless a contributory factor is present (see Contributory Factors). Roentgenographic changes may, however, be detected in advance of this if routine x-ray films are taken (Fig. 5). A useful rule of thumb is that roentgenographic changes can be expected 8 weeks after 40 Gy to a significant volume of lung and 1 week earlier for each 10-Gy increment above 40 Gy. Roentgenographic changes generally precede clinical features but do not, of course, make them inevitable. The early appearance of roentgenographic changes or symptoms, however, generally signifies a particularly severe episode.

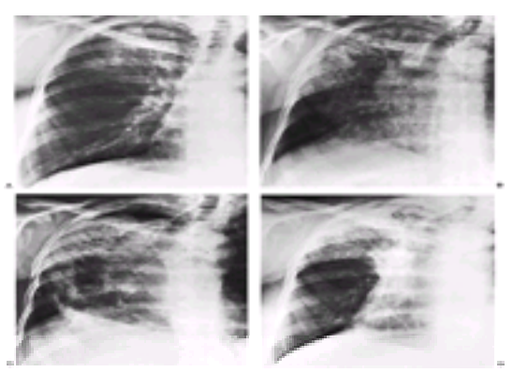

FIG. 5. Roentgenograms of a 54-year-old woman who had a right radical mastectomy for breast cancer and subsequent radiation therapy. **(A)** 3-19-73. Three weeks after completion of radiation therapy **(B)** 4-10-73. More extensive changes in parenchyma with retraction indicated by tracheal deviation, diaphragmatic elevation, and air bronchograms. Patient was symptomatic at this stage. **(C)** 4-30-73. More extensive changes of radiation pneumonitis with pneumothorax at right apex and a fluid level. Pneumothorax resolved spontaneously. **(D)** 12-11-74. Late roentgenographic appearance showing resolution of changes in mid and lower zones, radiation

fibrosis at apex, marked tracheal deviation, and mediastinal shift. (Reproduced from NJ Gross. *Ann Intern Med* 1977;86:81.)

The cardinal symptom of radiation pneumonitis is dyspnea. Mild and occurring only on exertion at first, it may progress in the course of a week or two to severe dyspnea on minimal effort or even at rest. Occasionally, the progression from mild dyspnea to severe respiratory distress may occur in only a few days, particularly if the lesion involves a large volume of lung. In our experience, these patients do badly. Other symptoms coincide with dyspnea but are overshadowed by it. Cough is common and initially dry and harsh. Small amounts of clear or pink sputum may be produced later, but purulent sputum or frank hemoptysis should be attributed to another cause. The sensation of a limitation of inspiratory capacity (doorstop sign) and fever, usually low grade but occasionally high and spiking, may be present. Vague chest pain is common but rarely troublesome unless caused by rib fracture (see Associated Complications).

The dominant physical signs are respiratory distress and tachypnea, particularly on mild effort, with or without central cyanosis. Finger clubbing may have been present because of underlying malignancy but does not develop at this stage. Examination of the chest often fails to elicit any signs. It is worth looking for the tattoo marks on the chest that radiotherapists sometimes use to outline the field and to compare these with the roentgenogram because the close correspondence between these and the roentgenographic changes is highly suggestive of a radiation reaction (see Roentgenographic Changes). However, there is no correlation between the severity of skin reactions such as pigmentation and desquamation and the presence of an underlying lung reaction. Occasionally, a pleural friction rub or rales are present over regions of pneumonitis. In a severe advanced case, features of respiratory distress syndrome with or without right-sided heart failure are present. Acute cor pulmonale is particularly ominous and usually indicates a fatal outcome. The typical course of radiation pneumonitis is protracted over several weeks or months, even if symptoms are mild. Commonly, symptoms persist for a month or more and subside even more gradually than they appeared.

The leukocyte count and red cell sedimentation rate are frequently raised, but not by very much. Blood gas studies are discussed in more detail under Physiological Changes; they commonly show arterial hypoxia and hypocapnia. Other data, such as results of enzyme studies, rheumatoid factor, and complement levels, are lacking. Pulmonary function abnormalities and roentgenographic abnormalities are discussed later; these are very likely to be present at the stage of radiation pneumonitis.

Radiation Fibrosis

Although fibrosis can be diagnosed with certainty only on histologic grounds, the term *radiation fibrosis* has come to be used in situations in which reasonable clinical grounds for it exist. Fibrosis is very likely, if not inevitable, in any region of the lung that has received therapeutic doses of radiation, whether or not radiation pneumonitis has occurred. Histologic (see Table 38-1), biochemical, and physiological evidence (see Physiological Changes) indicates that fibrosis begins as early as 2 months after irradiation and may take several months or years to become fully established. Whether or not pneumonitis was previously present, the roentgenographic features of fibrosis will gradually appear from 6 to 24 months after irradiation and will persist almost without change for the rest of the patient's life.

Clinical features are usually minimal. In a few patients—those with preexisting pulmonary function abnormalities and those who have experienced an episode of severe radiation pneumonitis—the additional burden of pulmonary fibrosis will result in chronic respiratory failure with dyspnea on effort and abnormal gas exchange. Some patients so affected may even develop chronic cor pulmonale, but this is uncommon. More likely than this is a moderate exacerbation of preexisting symptoms such as a decrease in exercise tolerance. The majority will have no symptoms at all. Physical signs, if present, are explained on the basis of contraction of lung tissue in the region of fibrosis, for example, diaphragmatic elevation, mediastinal shift in the case of unilateral fibrosis, and loss of inspiratory excursion. Finger clubbing may develop.

ASSOCIATED COMPLICATIONS

Pleural Effusion

The possibility of pleural reactions following x-irradiation is most frequently suspected when the radiation given for breast cancer, possibly because of the tangential technique. The complication has been noted in 5.5% to 14% of patients so treated.

It is important to distinguish between a malignant effusion and a reaction to radiation. Radiation-induced effusions are invariably associated with and usually appear at the same time as pneumonitis. They may persist for long periods of time. Once they appear, they usually remain stable and rarely increase in size, unlike malignant effusions. The fluid is exudative in character but not blood-stained. Pleural biopsy specimens appear normal apart from a few nonspecific changes.

The mechanism of pleural effusions following radiation is unknown, but they occur with striking regularity in experimental radiation pneumonitis.

Pneumothorax

When pneumothorax occurs, it tends to be a feature of radiation pneumonitis and is found in the same side as pneumonitis. A typical case is illustrated in Figure 5. One would anticipate problems with expansion of the lung, but most reported pneumothoraces have reexpanded spontaneously.

Infection

In addition to its well-known suppressive effects on immunity, radiation impairs clearance mechanisms. In mice there is a transient drastic reduction in the number of alveolar macrophages between 1 and 8 weeks after a single dose of x-rays to the thorax. In addition, impaired phagocytosis and killing of microorganisms have been demonstrated. Although the morphology of macrophages is altered (they become transiently much larger), their individual functional abilities (phagocytosis, etc.) are retained. Thus, increased susceptibility to infection, which is present at this stage, is probably related to the transient reduction in their number.

Data in humans are hard to find. Furthermore, there often are other factors that more potently predispose to opportunistic infection, such as lymphoreticular malignancy or combination chemotherapy. No particular organisms have been associated with infections following irradiation.

Rib Fractures

Rib fractures may occur shortly after completion of the course of irradiation. They are found within the field of irradiation and appear to be more common when radiation is given for breast cancer. Possibly this is because the technique of tangential irradiation of the chest wall delivers more radiation to the rib cage than do opposed anterior and posterior fields. For the same reason, the fractures occur independently of radiation pneumonitis. They may be single or multiple and are usually painful. They heal spontaneously, although slowly if extensive necrosis of the chest wall is present.

Pneumonitis Outside the Field of Irradiation

One of the characteristic features of radiation pneumonitis is that it is confined to the region of lung that was irradiated. Nevertheless, there are a few reports of radiation reactions well outside the field and sometimes in the contralateral lung. This unusual and unexpected occurrence has raised speculations that include obstruction of the lymphatic drainage of the lungs and the induction of autoimmunity to lung tissue. Neither theory explains why the damage should be so widespread in a small number of patients and confined in the vast majority of cases. Hypersensitivity to radiation has been suggested, particularly when a severe reaction follows an apparently small exposure.

Of 17 patients evaluated by bronchoalveolar lavage (BAL) following lung irradiation, 13 (75%) exhibited bilateral lymphocytosis, with two demonstrating a more marked response leading to clinical radiation pneumonitis. In the remaining 25%, no lymphocytosis or immune response was detected. Changes in BAL lymphocyte populations as well as increases in radiolabeled gallium uptake were demonstrated bilaterally. It is proposed that these bilateral findings result from cytokines released from $CD4^-$ helper T lymphocytes recently activated in the irradiated lung exerting their effects in a widened area, which is more consistent with a hypersensitivity pneumonitis pattern. When large numbers of patients are treated according to strictly supervised protocols and closely observed, the number of cases of hypersensitivity diminishes to a fraction of a percent. One rare instance in which abnormal radiosensitivity has been established (ataxia-telangiectasia) is discussed later (see Contributory Factors).

Radiation Carcinogenesis

It is reasonably well established in experimental animals that irradiation of the lungs enhances the formation of pulmonary metastases. The enhancement occurs briefly

and transiently after each exposure and is thought to be related to changes in vascular perfusion or permeability. The phenomenon may be of considerable clinical importance in relation to prophylactic lung irradiation and postoperative irradiation for breast cancer.

An equally important but apparently unrelated phenomenon is the late appearance of a new primary tumor in a previously irradiated lung field. Figure 6 illustrates this phenomenon. If such cases are not coincidental, one can only speculate whether the mechanism involves radiation carcinogenesis, or is related to scar cancer.

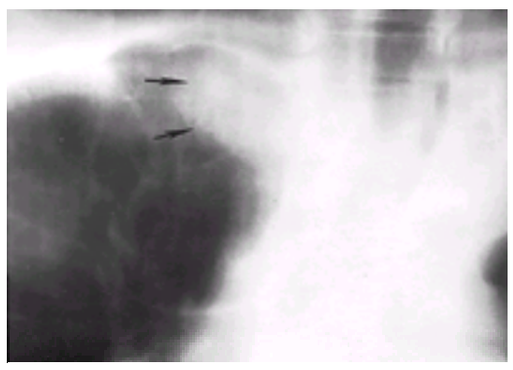

FIG. 6. Radiation carcinogenesis? The patient presented in 1968 with Hodgkin's disease of the right supraclavicular region, for which he received mantle irradiation with x-rays. Details of the treatments are not available, but the field probably resembled that shown in Fig. 8. He returned 8 years later with a lesion in the paramediastinal region of the right upper lobe, shown in this tomogram (*arrows*). The lesion was resected and found to be a primary lung carcinoma within the fibrotic region of previous irradiation. A few months later the patient was also found to have a malignant thymoma, again within the field of previous irradiation.

Miscellaneous Complications

Acute obstruction of a large airway may occur when a tumor that occupies a large portion of its lumen is irradiated. This is because of edema of the tumor and can be prevented by administration of corticosteroids during the first few days of irradiation. Such cases may be mistakenly diagnosed as hyperacute radiation pneumonitis or pneumonia.

Hyperlucency of a lung after unilateral x-irradiation has been reported. Arteriograms show this to be related to hypoplasia of the pulmonary artery without obvious obstruction of its lumen.

Secondary pulmonary effects of cardiac damage from x-rays are, of course, not uncommon, but such a discussion falls outside the scope of this chapter.

Thoracic irradiation given before lung surgical procedures appears to cause few technical problems. In some series, however, there was a much higher incidence of complications related to delayed healing in previously irradiated tissues, i.e., bronchopleural fistula and empyema. At later stages after irradiation, a surgical procedure may be technically difficult because of fibrosis in the chest wall, pleura, and lung.

Phrenic and recurrent laryngeal nerve paralysis and Horner's syndrome do not occur following conventional radiation treatment of the lungs. Spinal cord damage, however, is a complication. Necrosis and cavitation of the lung do not occur except as a result of tumors, although radiation can cause fistulas between hollow viscera. Reactivation of granulomatous disease is rare.

PHYSIOLOGICAL CHANGES

In view of the delicate balance between the structure of the lung and its function, any pathologic condition that involves more than a very small portion will likely produce detectable abnormalities in overall function. Of the considerable number of reports in the literature, those that give the best picture of physiological events in humans concern patients with breast cancer. These patients, unlike those with lung cancer and Hodgkin's disease or lymphoma, can be presumed to have essentially normal lungs before irradiation.

Two principal lesions can be identified, the vascular lesion and the mechanical lesion, with resultant effects on gas transfer.

Vascular Changes

Changes in perfusion of the lungs have been studied by means of isotopes, either ^{131}I-labeled macroaggregates of albumin or xenon-133. A decrease in perfusion has been detected in the first few hours after irradiation, particularly following large single doses. This change appears to be transient and is of questionable clinical relevance (in view of the size of the dose needed to produce it). In the period from a few days to 14 days after irradiation. Some authors reported an increase, whereas others reported a decrease, in pulmonary perfusion. A transient increase in diffusion capacity at this time supports increased perfusion. Permeability changes at this time are quite complex.

All authors have agreed that pulmonary perfusion is decreased from about 14 days on. Hypoperfusion is confined to the irradiated region and persists for a very long period, probably indefinitely. It is more marked following 15-MeV neutrons than g-irradiation. The decrease in perfusion corresponds well with the capillary damage seen histologically and bears on the blood gas changes discussed below. In animals at the stage of pneumonitis there is a marked decrease in perfusion and a marked increase in permeability of the pulmonary vasculature that results in pulmonary edema. The mechanism of this is unclear, but a modest reduction in the perfusion defect can be brought about by long-term administration of the collagen antagonist D-penicillamine.

Mechanical Changes

Studies of pulmonary mechanics in both humans and experimental animals have uniformly shown a dose- and time-related fall in static compliance following irradiation (Fig. 7). This change is first evident at about 40 days, becomes more marked at the time of pneumonitis, and persists for many years. Static compliance of the thorax is the result of the compliance of three parallel elements: the thoracic wall, lung tissue, and lung surface. Studies of excised or exposed lungs of animals showed that the fall in total compliance was related entirely to a fall in the compliance of the lung itself rather than of the thoracic wall. And this in turn was shown to result, at the stage of radiation pneumonitis, in increases in the surface tension of the alveolar surface. In fact, the alveolar fluid obtained by pulmonary lavage of irradiated mice behaves abnormally *in vitro,* and the stability of expressed lung bubbles is impaired. The abnormal behavior of alveolar fluid can be explained by the presence in the alveolar fluid of a large amount of protein of circulatory origin. It is known that extraneous protein, particularly fibrinogen, impairs surface activity. There is an alteration in the distribution of surfactant subtypes in radiation pneumonitis.

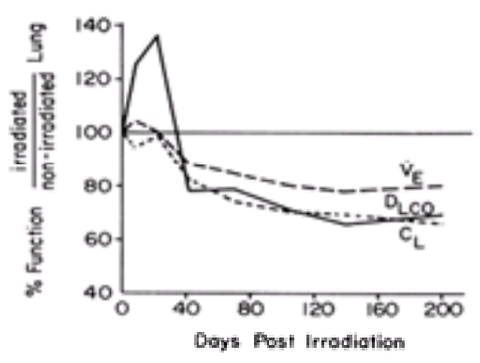

FIG. 7. Physiological effects of irradiation on one lung of dogs. Changes in diffusion capacity (D_LCO, *solid line*) compared with the preirradiation level of that lung. Changes in ventilation (VE, *long-dash line*) and compliance (CL, *short-dash title*) compared with those in the nonirradiated lung. (Redrawn from CD Teates. *J Appl*

Physiol 1965;20:628. Reproduced from NJ Gross. *Ann Intern Med* 1977;86:81.)

At later stages, low lung incompliance appears to result from development of fibrosis and a fall in static compliance of the lung tissue. This change can be regarded as permanent because it is present many years later.

Associated with the fall in lung compliance is a dose-related increase in the respiratory rate and a decrease in lung volumes, again long-lasting. Regional lung studies in patients have shown that volume loss was confined to the region of irradiation, where decreased perfusion also was present. The extent of overall changes in lung function in humans is therefore a function of the amount of lung affected by radiation. Airway resistance is normal or only minimally raised. Consistent with the fall in lung compliance, where present, the elastic work of breathing in humans is raised, and consequently, tidal volume tends to fall, and frequency tends to increase, resulting in a moderate overall increase in minute ventilation. However, decreases in lung volumes may not occur at all despite a successful response to radiation therapy.

Gas Transfer

Overall, gas transfer and blood gas changes again reflect the amount of lung affected. Within the irradiated region, perfusion changes are more severe than ventilatory changes, resulting locally in a high ventilation– perfusion ratio, little change in local gas transfer, and redistribution of pulmonary blood flow to other, unaffected regions. Where the volume of irradiated lung is small and the function of unirradiated lung is normal, overall gas transfer is not impaired, and blood gases are normal. If the volume of affected lung is large and/or the function of unirradiated lung is marginal, some abnormalities of gas transfer are found. In this situation, arterial blood gases typically show mild to moderate arterial hypoxemia with normal or reduced $P^{a}CO^{2}$, a reduced diffusion capacity for carbon monoxide, and an increased alveolar–arterial oxygen gradient. This is the most likely blood gas abnormality in patients with symptomatic radiation pneumonitis. Use of SPECT and CT scanning allows changes in local ventilation and perfusion to be determined relative to the three-dimensional dose distribution of the irradiated lungs. Standard pulmonary function testing noted a 20% decrease in vital capacity and 1-sec forced expiratory volume (FEV_1). The average reduction of local ventilation and perfusion after radiation for all patients was approximately 10% below baseline values and was greater in those with clinically evident radiation pneumonitis. Correlations were demonstrated between decrease in perfusion, decrease in FEV_1, and the presence of radiation pneumonitis. In more severe degrees of radiation pneumonitis, greatly increased stiffness (decreased compliance) of the lungs may superimpose hypoventilation on mismatching, resulting in carbon dioxide retention and severe hypoxia, but this can be regarded as a terminal effect.

Symptoms of radiation pneumonitis are therefore a function of the volume of affected lung and are attributable to changes in the mechanical properties of the lung and associated blood gas abnormalities. Where only the apex of the lung is irradiated, as in postoperative irradiation for breast cancer, the symptomatic and physiological effects will be less because ventilation and perfusion are both lower at the lung apex. It may be possible, using modern refinements of radiation techniques, to ablate the gas exchange effects entirely.

It seems probable that routine clinical tests of pulmonary function such as lung volumes, diffusion capacity, and arterial blood gas tensions could provide early warning of symptomatic radiation pneumonitis, if they were regularly performed in patients at risk.

ROENTGENOGRAPHIC CHANGES

For detailed information on radiation effects in the lungs, the reviews of Rubin and Casarett and Libshitz and colleagues are recommended. As shown in Table 2, roentgenographic changes are very commonly seen following lung irradiation, more commonly than symptoms. They are also present before the clinical episode that may or may not subsequently occur.

The commonly recognized roentgenographic changes are first seen 4 to 8 weeks after completion of radiotherapy, possibly as much as 2 to 3 weeks before symptoms, if the latter should occur (Fig. 8). Initially, the lesion has a ground-glass or soft appearance, and the lung markings are hazy and indistinct. As the lesion evolves, the opacification may become micronodular and harder, with linear branching streaks a centimeter or more in length. These are usually radially oriented and may resemble Kerley B lines if the lesion is peripheral. Symptomatic pneumonitis is very likely to be present if and when these features are present. In the most severe lesions, the affected region may become densely opacified as the nodules and streaks become confluent. Air bronchograms may appear within this region, and pleural and interlobar effusions may occur. The outline of the mediastinum and cardiac shadow becomes indistinct when the lesion is adjacent to these structures. A most striking feature is a marked volume loss in the irradiated region. This is particularly obvious when irradiation was unilateral, as the trachea and mediastinum shift toward the lesion; elevation and tenting of the diaphragm and narrowing of the intercostal spaces are further evidence of contraction of the lesion. Cavitation is not seen in lung tissue, although it may occur in an irradiated tumor.

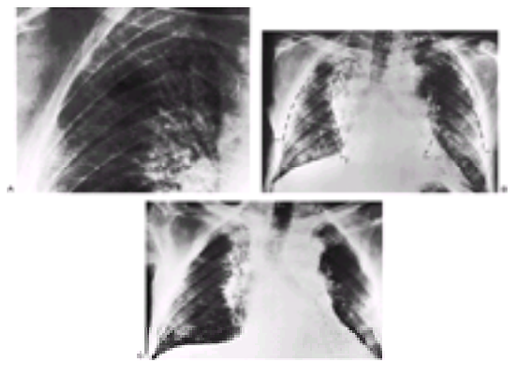

FIG. 8. Roentgenograms of a 64-year-old man with stage IIA Hodgkin's disease. **(A)** 5-15-72. Detail of right apex showing early appearance of radiation pneumonitis 5 weeks after completion of mantle irradiation. **(B)** 5-28-71. The outline of the lung shields from a treatment film (taken supine) has been traced onto a diagnostic roentgenogram (taken erect) to show the close topographic correspondence between roentgenographic changes and the field of irradiation around the lung shields. The patient had dyspnea, cough, and pyrexia at this stage. **(C)** 1-18-73. Roentgenographic changes of radiation fibrosis in the paramediastinal, apical, peripheral, and left basal regions, again corresponding to the irradiated regions of the lung. (Reproduced from NJ Gross. *Ann Intern Med* 1977;86:81.)

A cardinal feature of radiation pneumonitis is that the roentgenographic abnormality is limited sharply by the radiotherapy port (see Fig. 8). Roentgenographic changes outside the port are minor and adjacent to the port; if not caused by uncertainty of the port margins, they may be the result of scattered or oblique irradiation. Because the field of irradiation corresponds to the neoplastic lesion, the roentgenographic abnormality does not usually correspond to anatomic boundaries in the lung. It is therefore of utmost diagnostic value for the clinician to have the treatment films or at least an accurate graphic description of the ports and to observe the skin marks corresponding to the port margins. With this technical information—chronology of treatment and symptoms and evidence of the evolution of lung changes—the diagnosis of radiation pneumonitis can usually be made with confidence. As with the clinical features described, the early appearance and rapid progression of the roentgenographic lesion generally signify a more severe clinical episode.

Like the clinical episode, the roentgenographic features of pneumonitis persist for long periods, possibly months. Depending on the extent and severity of the lesion, the roentgenographic changes gradually resolve and evolve into those of radiation fibrosis. The chest roentgenogram may not stabilize in less than 1 to 2 years. The irradiated region assumes a dense roentgenographic appearance, still limited to the margins of the treatment port but often contracted and further condensed (Fig. 5, Fig. 8, and Fig. 9). There may be linear streaks extending outside the port, but these are centered on the irradiated region, with compensatory hyperinflation in the adjacent or contralateral lung. Irradiated regions may adopt a bronchiectatic, cystic, or even honeycomb appearance and may be mistaken for active pulmonary tuberculosis. Calcification of lymph nodes has been reported, but hilar node enlargement does not occur. Conventional perfusion scans of the lung, whether with ^{131}I aggregates or ^{133}Xe, show decreased perfusion of the irradiated region in the stage of radiation pneumonitis. Hypoperfusion is likely to persist indefinitely.

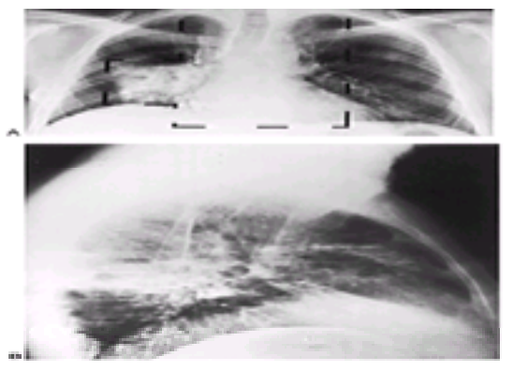

FIG. 9. Posteroanterior **(A)** and lateral **(B)** roentgenograms of a patient who initially presented with inoperable primary carcinoma of the right-lower-lobe bronchus, for which he received radiation therapy. These roentgenograms were taken on routine follow-up 7 months after therapy—the patient was asymptomatic. The outline of roentgenographic changes exactly follows the margin of the port, allowing for contraction due to fibrosis and the fact that treatment films are taken supine. The lateral picture **(B)** shows the opacity running the full depth of the lung, again corresponding to the x-ray beam. The patient received no further treatment and remained asymptomatic without roentgenographic progression of the lesion. Diagnosis: radiation fibrosis.

In summary, roentgenographic changes of some sort are more likely than not to be present following irradiation of the thorax. These are usually strictly limited to the radiotherapeutic port and may or may not be associated with symptoms of pneumonitis. In the great majority, if not all patients, the roentgenographic changes of fibrosis will become evident over the subsequent year.

CONTRIBUTORY FACTORS

The enhancement of the effect of radiation by oxygen has already been mentioned. A number of other factors with similar effect but different actions are also known. Awareness of these is clinically important in modifying treatment planning as well as in recognition of unexpected complications.

Concomitant Chemotherapy

It has been recognized at least since 1959 that administration of actinomycin D enhances the undesirable effects of radiation on the lung. At equivalent radiation doses, pneumonitis is about 30% more likely to occur in patients who receive concomitant actinomycin D therapy (see Fig. 4). In view of the more aggressive current approach to tumor management and, in particular, the combination of multiple drugs with radiation therapy in treatment protocols, the phenomenon of unfavorable interactions has become one of increasing importance.

Lamoureaux reported a small number of lung cancer patients randomized into two groups. One group received mechlorethamine, procarbazine, and vincristine concurrently with radiation therapy; the other received radiation only in the same dose and schedule. All five of the chemotherapy patients had symptomatic radiation pneumonitis as compared to only one of the six patients in the nonchemotherapy group. Which of the three drugs was responsible for enhancing the effects of radiation is uncertain. In the nervous system, vincristine has been implicated, and the experiments of Phillips' group, discussed below, are consistent with such an effect in the lungs. Einhorn and colleagues reported severe radiation pneumonitis in five of 13 patients who received concomitant chemotherapy; three of these cases were fatal. Chemotherapy consisted of bleomycin, doxorubicin (Adriamycin), cyclophosphamide, and vincristine. Patients given chemotherapy alone suffered no pulmonary effects, nor did a further 20 patients who received radiation and the same chemotherapeutic treatment without bleomycin. Einhorn and associates therefore implicated bleomycin as the agent responsible for the extremely common occurrence of pneumonitis, a conclusion not supported by others. Soble and Perry reported a case in which fulminant fatal pneumonitis and bone marrow hypoplasia occurred 4 weeks after a course of 4000 rads to the mantle for Hodgkin's disease. The interesting feature was that the patient had received busulfan (480 mg total) over the previous 6 years. Although both pneumonitis and aplastic anemia can occur following busulfan in this dosage (15% to 20% probability), the sudden appearance of both complications shortly after radiation suggested to the authors that they were induced by interaction with radiation. It is possible that doxorubicin, which has marked effects on the myocardium, also may enhance radiation effects in the lungs. In the foregoing reports, pneumonitis started earlier than usual, was severe, sometimes preceded radiologic changes, and was evident outside the ports of irradiation.

Phillips and co-workers reported that significant enhancement of pulmonary lethality occurred with actinomycin (0.075 mg/kg of body weight), cyclophosphamide (75 mg/kg), and vincristine (0.5 mg/kg) given 2 hr before irradiation, but not with bleomycin, hydroxyurea, or BCNU. With actinomycin D there was significant enhancement of lethality, even when a small dose (0.015 mg/kg) was given 30 days before irradiation but not 30 days after it. Interestingly, the effect of these agents is not consistent between different organs. Nor is the list of drugs that potentiate the effects of radiation the same as the list that can cause pneumonitis in the absence of irradiation.

There is no obvious relationship between the mode of action of these agents and their potentiating effects on lung irradiation. Information on the time of administration of drug in relation to radiation, dose, and fractionation is fragmentary, although of clear clinical importance.

Corticosteroid Withdrawal

There is some controversy about the role of steroids in the treatment of radiation pneumonitis (see Management), and in clinical practice prophylactic steroid therapy is not used. Nevertheless, if steroids are being administered, their inopportune withdrawal appears to be capable of precipitating radiation pneumonitis. Cycles of chemotherapy that included prednisone are likely to be followed by episodes of pneumonitis. Thus, corticosteroids should be administered either continuously or not at all in the period following radiation. In lethally irradiated mice, deaths were markedly reduced by prophylactic prednisolone but occurred rapidly after its withdrawal at 160 days. The phenomenon can be interpreted either as unmasking of steroid-suppressed pneumonitis or, less likely, as precipitation, by the withdrawal itself, of a reaction that would not have been present at all if steroids had not been given.

Previous Radiation Therapy

It has been recognized from the earliest reports that retreatment is likely to precipitate radiation pneumonitis. For example, reirradiation of the mediastinum for inadequately treated Hodgkin's disease resulted in pneumonitis far more frequently than did a first course and that the episode occurred earlier and was more severe. It is not clear whether the phenomenon is a function of the total dose received or whether the lung is more susceptible after the first course.

Ataxia Telangiectasia

The rare disorder, ataxia telangiectasia, appears to be associated with abnormal sensitivity to ionizing radiation. This hereditary syndrome is characterized by cerebellar ataxia, oculocutaneous telangiectasia, immunologic deficiencies, and an increased occurrence of reticuloendothelial malignancy. Increased radiosensitivity can be demonstrated at the molecular, cellular, and clinical levels. Conventional doses of radiotherapy for the malignant complications are likely to be followed by severe radiation reactions. It has been postulated that the radiosensitivity results from defective DNA repair, which also accounts for another feature of the condition: chromosomal instability. This raises the possibility, as yet undemonstrated, of enhanced radiosensitivity in two other disorders characterized by chromosomal instability and predisposition to malignancy, Bloom's syndrome, and Fanconi's syndrome.

Other Contributory Factors

Age has been considered a factor that might modulate a patient's response to radiation. It is mentioned in many reviews but supported by only scant data. Gas transfer appears affected more in older patients. There appears to be an age-related increase in frequency and severity of roentgenographic changes in irradiated breast cancer patients. The grading was made on roentgenograms taken from 7 weeks to 30 months after the end of treatment. Whether atherosclerosis plays a role also has been considered, but data on this are absent. It does seem possible, however, that the lungs of children recover better than those of older adults from the effects of x-rays.

Underlying infection such as that which may be associated with chronic bronchitis also has been considered to be a predisposing factor to radiation intolerance. However, when patients with and without chronic bronchitis were compared, no change in the incidence of minor and major reactions was found, nor were subsequent functional changes different in the two groups. The commonly held view that patients with chronic obstructive lung disease tolerate radiotherapy poorly should be qualified: such patients are not more likely to experience radiation pneumonitis. Radiotherapy will add a certain amount of functional impairment to their already abnormal physiological state, but no more than in normal subjects. It is of interest that radiotherapy has been employed in emphysematous patients without malignancy

as a means of reducing their excessive lung compliance—with only marginal success, but equally without much harm.

DIFFERENTIAL DIAGNOSIS

In a typical clinical setting, the patient who has received radiation therapy for a malignancy and subsequently develops pulmonary problems presents a diagnostic challenge. The differential diagnosis invariably includes radiation reactions, recurrent malignancy, infection, and possibly other entities such as drug-induced lung disease and thromboembolism. In view of the divergent therapeutic requirements of these conditions, their differentiation is of utmost clinical importance. It can often be made on the basis of clinical features and radiologic appearances.

The differentiation of radiation-induced pleural effusion from other effusions has been discussed (see Associated Complications). Differentiation of radiation pneumonitis from tumor recurrence is facilitated by the following criteria: recurrent malignancy is suggested by an interval of more than 4 months between radiation therapy and symptoms; steady progression of the roentgenographic changes, metastases elsewhere, anemia, and hemoptysis. Lymphangitic spread of tumor is usually associated with very severe symptoms, particularly dyspnea, and is more marked at the lung bases, where septal lines and long linear streaks from the hilus to the pleura are seen. Unlike radiation reactions, tumor recurrence is often roentgenographically manifest outside the field of irradiation.

Infections may present a more difficult problem. Criteria for differentiation of radiation reactions from tuberculosis have been suggested but have not been found to be particularly helpful. Usual features of other infections, pyrexia, leukocytosis, and purulent sputum, may or may not be prominent in infected patients who have been compromised by chemotherapy, corticosteroids, and tumors as well as by previous radiation therapy. The diagnosis rests on a combination of immunologic studies, stains, and cultures of bronchopulmonary secretions, and possibly histologic and microbiological studies of lung tissue.

The diagnosis of radiation reactions is greatly simplified by excellent roentgenograms and knowledge of the precise chronology, dose, field margins, and dose schedules in relation to the onset of subsequent problems. Microbiological backup is most helpful, but histologic samples obtained by bronchoscopy or open lung biopsy are particularly important in difficult cases. Even when these are available, differentiation between the various possibilities is not always straightforward.

MANAGEMENT

Because radiation pneumonitis rather than fibrosis is the major life-threatening event, management is principally directed toward this problem. Early recognition is important, as early treatment may affect the course of pneumonitis.

Untoward reactions following radiation could probably be anticipated in a large proportion of patients by roentgenographic monitoring and the more discriminating tests of lung function at the appropriate time. This has been considered impractical for routine purposes because of the extended time over which reactions can occur. Furthermore, the appearance of abnormalities does not necessarily inevitably lead to pneumonitis. Possibly patients who are at increased risk because of an unavoidable contributory factor should be so monitored.

Symptomatic

Patients whose symptoms are not severe or rapidly progressive and develop late (i.e., 10 to 12 weeks after completion of radiotherapy) will probably have a mild clinical course. For these patients, symptomatic therapy is all that is required: restriction of activity, cough suppressants, and observation during the 2- to 4-week period.

If an early reaction occurs and symptoms progress rapidly, additional therapy may be required, as follows.

Corticosteroids

The place of corticosteroids in the management of radiation pneumonitis remains controversial; no controlled clinical trials have been carried out to our knowledge. However, corticosteroids are widely used in clinical practice, and animal studies support their use.

Early clinical studies suggested that relatively small doses might be protective if given prophylactically, before the onset of pneumonitis, or early in its course. They were less beneficial if delayed much beyond the onset of symptoms. Pneumonitis may appear shortly after withdrawal of steroids, but there is a dramatic response of all patients shortly after restitution of prednisone, 20 to 80 mg/day.

Although early animal studies gave divergent views on the use of corticosteroids, it is now fairly clear that when corticosteroids are given before the onset of pneumonitis, mortality is significantly reduced. In a detailed analysis of this phenomenon in lethally irradiated mice, it was found that prednisone (4.0 mg/kg per day starting 10 weeks after irradiation but before deaths from pneumonitis normally occur) significantly reduced the mortality of radiation pneumonitis and was as effective as a larger dose in this respect. However, if steroids were withdrawn during the period when pneumonitis normally occurs, death rapidly occurred and caught up with that of mice that did not receive corticosteroids. But corticosteroids could be withdrawn at 30 weeks (after the usual period of pneumonitis) without resultant mortality. Prednisone had a lesser protective effect when given after the onset of pneumonitis. Steroids, therefore, reduce the mortality of lethally irradiated mice during the period of pneumonitis, even if commenced well after irradiation, a finding that suggests that their beneficial action is related to the suppression of the radiation response. There is evidence that their effect might be a result of suppression of the microvascular leakage that is characteristic of radiation pneumonitis.

The foregoing clinical and experimental data can be synthesized into a hypothesis concerning the place of steroids in radiation pneumonitis: There is a stage, probably following irradiation but preceding established pneumonitis, during which steroid administration prevents the progression of unfavorable cellular or biochemical antecedent(s) or trigger(s) to an abnormal physiological state. The antecedent event remains suppressed or deferred as long as steroids are administered. But once the event occurs, either primarily or because of steroid withdrawal, the physiological and clinical sequelae of radiation pneumonitis follow, and these are not amenable to steroid therapy. However, the antecedent event may occur over a long time span, several weeks, and the physiological sequelae may reverse spontaneously, if slowly. Use of steroids early in the period of emergent physiological derangement prevents further changes from occurring and allows normal repair processes to proceed. This hypothesis would explain the (1) protective effect of steroids, (2) unmasking of latent injury on steroid withdrawal, (3) abrogation of pneumonitis by early use of corticosteroids, and (4) relative inefficacy of steroids in reversing established pneumonitis. Current practice agrees with this hypothesis.

Prophylactic corticosteroids are rarely used in clinical practice. In general, large doses for long periods would be required to abolish all pneumonitis. If and when symptomatic pneumonitis occurs, and especially if early onset and rapid progression suggest a severe reaction, large doses of corticosteroids, for example, prednisone (100 mg/day in an adult), should be instituted as early as possible and maintained for several weeks. When symptoms have been absent or not clinically troublesome for a week or more, the dose can be cautiously reduced, but it must be raised promptly if relapse occurs. Subsequent tapering should be prolonged over several weeks. If respiratory failure ensues, the patient should be maintained by mechanical ventilation and supplemental oxygen in the expectation that the condition will ultimately remit spontaneously, provided the patient can be kept alive. It is, however, unlikely that corticosteroids will be of benefit to the patient who first comes under treatment at the stage of established respiratory failure. There are thus many instances in the literature and in common experience in which even large doses of corticosteroids failed to alter the course of radiation pneumonitis. The ideal would be to recognize pneumonitis early in its course, anticipate its severity, and treat appropriate cases as early as possible with large doses of corticosteroids. Agreement is universal that corticosteroids have no place at the stage of radiation fibrosis.

Other Forms of Therapy

A large number of other agents and procedures have been suggested or exposed to trial in the management of radiation pneumonitis. These are reviewed briefly.

It might have been anticipated that anticoagulants could prevent radiation pneumonitis in view of the prominence of the vascular damage that precedes pneumonitis. Daily injections of heparin given to rats from the time of irradiation did not provide protection against the physiological sequelae. We know of no controlled clinical trial, but oral anticoagulants were given without benefit to one series of patients.

Although there is experimental evidence of transient impairment of lung defense mechanisms, prophylactic antibiotic administration has also proved unable to offer protection against physiological changes or to alter mortality in experimental radiation pneumonitis. Administration of antibiotics to patients also would raise the possibility of superinfection with insensitive opportunistic organisms. When infection occurs as a complication of pneumonitis, it should be treated with the appropriate antibiotic.

Oxyphenbutazone, an antiinflammatory agent, also has been used prophylactically in one prospective double-blind trial on 116 patients receiving cobalt radiation therapy. Patients who received oxyphenbutazone experienced significantly less frequent or severe pneumonitis and fibrosis by roentgenographic criteria. As mentioned above, animal experiments strongly suggest that other antiinflammatory agents, particularly those that inhibit or antagonize the leukotriene pathway, may have a

markedly beneficial effect on the survival from radiation pneumonitis.

L-Triiodothyronine has been given prophylactically to dogs, with small and nonsignificant effects on postirradiation thoracic compliance. b-Aminopropionitrile (BAPN), an inhibitor of collagen maturation, also has been studied as a prophylactic agent in rats. Although an increase in the collagen content of the lungs was prevented as long as BAPN was administered, mortality was not significantly diminished. Another inhibitor of collagen metabolism, D-penicillamine, also moderates the late effects of radiation on the lungs.

Pneumonectomy has been performed for severe unilateral radiation pneumonitis, and single lung transplantation might be considered in the current era.

CHAPTER

39 Clinical Evaluation of Individuals with Suspected Indoor Air Quality Problems

Clifford S. Mitchell · Jonathan M. Samet

C.S. Mitchell: Department of Environmental Health Sciences, Johns Hopkins School of Public Health, Baltimore, Maryland 21205.
J.M. Samet: Department of Epidemiology, Johns Hopkins School of Public Health, Baltimore, Maryland 21205.

INTRODUCTION

The recognition of indoor air pollution as relevant to the practice of pulmonary medicine reflects the increasing time spent indoors, significant contributions of indoor environments to exposures to pollutants, the sealed environments of modern buildings, and the emergence of new clinical syndromes linked to indoor air pollution. Total personal exposure to pollutants represents a weighted average of the exposures received in indoor and outdoor environments, locations having homogeneous characteristics during the time that exposure is received. For many pollutants, indoor microenvironments make dominant contributions, e.g., radon and volatile organic compounds (VOCs). Even for some pollutants regulated in outdoor air, e.g., particles and nitrogen dioxide, exposures in indoor microenvironments may outweigh exposure received outdoors.

The spectrum of adverse respiratory effects of indoor air pollution is broad, ranging from symptoms and exacerbation of preexisting respiratory disease to acute and even fatal conditions that can be readily linked to indoor air pollution. The illnesses directly associated with indoor air pollution can be grouped as specific building-related illnesses and sick-building syndrome. The former includes such well-defined entities as hypersensitivity pneumonitis and Legionnaires' disease. The latter is a nonspecific syndrome, often having both respiratory and nonrespiratory elements. Indoor air is also widely contaminated by respiratory carcinogens: radon, environmental tobacco smoke (the mixture of sidestream smoke and exhaled mainstream smoke), and asbestos. Pulmonary physicians may be consulted concerning the risks posed by these agents and asked for guidance concerning control strategies.

SOURCES OF INDOOR AIR POLLUTION

Indoor air pollution has myriad sources including the materials from which the space is constructed, its furnishings, processes operating within the environment, biological agents, and even the occupants. Outdoor air pollutants can also penetrate indoors, as can soil gas. The broad source headings are combustion, evaporation, abrasion, biological, and radon. The principal combustion sources are gas cooking stoves, burning cigarettes, fireplaces, wood stoves, and unvented space heaters. Evaporation of volatile organic compounds from materials and products leads to ubiquitous contamination by these agents. Abrasion of friable asbestos is a principal source for this indoor contaminant. The biological agents are heterogeneous, extending from infectious organisms to pets and the occupants themselves. Radon comes primarily from soil gas.

The concentration of an indoor contaminant depends on the strength of its source, the rate of removal, the volume of the space, and the rate of exchange of air between the space and outdoors. This “mass-balance” formulation indicates that the concentration of a contaminant might be reduced by limiting source strength, increasing removal rate, or increasing exchange between indoor and outdoor air.

In the typical modern building, the exchange of indoor with outdoor air is accomplished by a central heating, ventilating, and air-conditioning (HVAC) system. These systems are diverse, although all have the same purpose: the delivery of air of acceptable quality to building occupants. The volume of air to be delivered follows the recommendation of standards set by the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE). In the majority of newer buildings, occupants can no longer control the temperature of the work environment, and in most buildings, occupants cannot open windows to increase air exchange. Most residences still rely on natural ventilation.

EVALUATING THE PATIENT

A patient presents to a pulmonary physician with nonspecific complaints, perhaps cough and sore throat. When should indoor air pollution be suspected as a cause? How can the link to indoor air pollution be established? The same questions face the clinician for specific disease entities also caused by indoor air pollution, such as hypersensitivity pneumonitis, Legionnaires' disease, and worsening of asthma. For each, the diagnosis should raise questions about the role of the indoor environment.

For the physician evaluating and treating an individual patient, indoor air pollution often presents unusual challenges. First, the physician needs to think beyond diagnosis and management of the individual, to diagnosis and management of the specific environment. Interaction with other health and safety professionals may be needed to deal with problems of indoor environments. Second, because cases involving indoor air pollution often revolve around a workplace, physicians will frequently find themselves dealing with employers, unions, and other organizational entities and with complex nonmedical issues such as return to work, workers' compensation, risk communication and risk management. In some cases these “nonmedical” issues play a substantial role, and physicians should be familiar with the kinds of questions that will be asked (Fig. 1).

FIG. 1. Evaluation and management of indoor air quality problems.

There is no “typical” presentation for individuals suspected of having health problems related to the indoor environment (Table 1). Patients may report the onset of new symptoms or exacerbation of a preexisting condition. In some cases patients will ask the physician about the possible relationship between symptoms and indoor air. In other cases, the clinician must be alert for diseases or patterns of symptoms that the patient does not necessarily link to a specific exposure or environment. In

managing the patient, the physician's role includes five elements: first, diagnosing the clinical syndrome; second, characterizing the nature and magnitude of any exposures; third, deciding whether the clinical picture is consistent with the likely exposure; fourth, treating the condition; and fifth, managing nonmedical issues such as return to work, compensation, and protection of other potentially affected individuals. Thus, the clinician will often need to consult with industrial hygienists, indoor air quality experts, public health officers, or others who can assist in characterizing indoor environments as well as employers, unions, and regulatory agencies in resolving issues such as return to work and workers' compensation. The physician's role may be complicated by tensions between involved parties such as employee unions and employers and the threat or presence of litigation.

Clinically evident diseases	Diseases for which the usual methods of clinical evaluation can establish a causal link to an indoor air pollutant.
Exacerbation of disease	The clinical status of already established disease is exacerbated by indoor air pollution.
Increased risk for diseases	Diseases for which epidemiologic or other evidence establishes increased risk in exposed individuals. However, the usual clinical methods indicative of injury typically cannot establish the causal link in an individual patient.
Physiological impairment	Transient or persistent effects on a measure of physiological functioning that are of insufficient magnitude to cause clinical disease.
Symptom responses	Subjectively reported responses that can be linked to indoor pollutants or are attributed to indoor pollutants.
Perception of unacceptable indoor air quality	Sensing of indoor air quality as uncomfortable to an unacceptable degree.
Perception of exposure to indoor air pollutants	Awareness of exposure to one or more pollutants with an unacceptable level of concern about exposure.

TABLE 1. *Classification of the adverse effects of indoor air pollution*[a]

Although patients may in some cases be convinced not only of the diagnosis but also of its relationship to a specific indoor exposure or environment, the physician should remain a “diagnostic skeptic.” It is especially important to identify specific treatable and preventable conditions, not only for the patient but for others who may be potentially exposed to the same conditions.

A thorough history is the first and most important step in the clinical evaluation. In addition to the symptoms reported by the patient, the physician should elicit the temporal relationship between putative indoor exposure and the onset of symptoms. Do symptoms improve over weekends and vacations? Is there a pattern related to certain activities or locations? An attempt should be made to distinguish between upper and lower respiratory tract symptoms. For example, the presence of lower respiratory tract symptoms points away from sick-building syndrome and toward intrinsic lung disease such as asthma.

Physical examination should focus on the presence or absence of inflamed conjunctivae, sinus tenderness or congestion, signs of allergic rhinitis, nasal polyps, wheezing, and rales. In cases involving possible multiple chemical sensitivity or sick-building syndrome, symptoms may involve many organ systems, and a thorough physical examination is mandatory.

Laboratory testing should focus on the diagnosis of specific conditions, based on the presenting symptoms. Spirometry can be very useful in separating obstructive from restrictive physiology in relation to symptoms that involve only the upper respiratory tract. The presence of an elevated white count may suggest infection or hypersensitivity pneumonitis. Total serum IgE may be elevated in allergic disorders such as asthma and rhinitis. For allergic conditions in which an exposure is well documented or a particular agent is suspected, the use of specific antibody testing through RAST or epicutaneous tests is appropriate. However, the use of broad antigen panels, although they identify individuals with a range of allergies, may not help determine the specific agent to which the person is reacting in the indoor environment.

Because sick-building syndrome and multiple chemical sensitivity are diagnoses of exclusion, when these conditions are being considered there may be a tendency to “exclude everything” and to use tests that have not been adequately validated clinically. Use of appropriate diagnostic testing in sick-building syndrome and multiple chemical sensitivity is considered in more detail below.

Characterizing the responsible exposure will often require consultation with an industrial hygiene professional, an indoor air quality expert, and a heating, ventilation, and air-conditioning (HVAC) engineer. The evaluation of the indoor environment will in most cases involve interviews with the occupants, a walk-through evaluation, and sampling for common indoor pollutants including organics, bioaerosols, and, in some cases, particular substances such as pesticides or combustion products. Measurements of temperature and humidity should be compared with ASHRAE standards. Ventilation rates, including air velocity and air changes per hour, should be measured. The HVAC system should be inspected carefully, including the air supply ducts, air-handling units, cooling towers, and air intakes (which can sometimes inadvertently be located near external sources of pollutants). The building should be examined for water leaks and other defects that often contribute to the development of bioaerosols and other indoor air pollutants. Other potential sources of indoor pollutants include photocopy machines (ozone, toner, VOCs), building construction material such as resin-containing particle boards (formaldehyde), and carpeting. Measurements of indoor air quality are rarely informative by themselves. If the setting is a workplace, and exposure to a particular chemical agent is at issue, the material safety data sheets should be reviewed. These are required under the U.S. Occupational Safety and Health Administration's hazard communication standard. Other factors may also be involved, including lighting of work areas, noise and/or vibration, ergonomics, and, importantly, work organization.

MANAGING INDOOR AIR QUALITY PROBLEMS

There are three aspects to successful management of indoor air quality problems: first, medical management of the affected individual or individuals; second, administrative management of both the individuals and the problem environment; and third, risk communication, a key aspect of medical and administrative management. Medical management depends on the diagnosis.

Whether the patient can return to work is of considerable significance. Patients with multiple chemical sensitivity or sick-building syndrome are often apprehensive that a return to the workplace will exacerbate their symptoms. However, although short-term removal from work may help to reduce symptoms and may also be useful diagnostically in linking symptoms to the workplace, there is a great deal of controversy over whether a return to the offending environment ultimately leads to increased morbidity. Some patients may benefit from supportive counseling or other psychological interventions to facilitate a return to an environment that produced symptoms.

Management of indoor air quality problems often involves more than individual medical therapy. When possible, the diagnosis of a building-related problem should prompt correction of the underlying problem. This generally requires the involvement of building engineers, HVAC professionals, and industrial hygienists. In cases in which a specific causal agent can be identified, the corrective action will usually be apparent. In most cases, however, an iterative approach is required, involving assessment of the design, operation, and maintenance of the HVAC system as well as appropriate decontamination or source control.

Communication is a critical component of successful management of indoor air quality problems. Communication with the patient should address (1) medical issues such as the diagnosis and recommended therapy and (2) administrative issues related to return to work. Although some physicians shy away from advising patients about workers' compensation, the physician should consider whether the employee is aware of workers' compensation and of what he or she should do to gain access to the system. This is particularly important because of the statute of limitations for some compensation claims.

Communication with the employer should include: (1) clear information on the ability of the employee to return to work, including any restrictions and need for follow-up; (2) if the condition is thought to be work-related, any recommendations related to identifying and fixing the source of the problem; and (3) whether there is a need to evaluate other employees who may potentially have been exposed.

The physician should consider not only the individual patient but whether other building occupants may have concerns about their risks. This includes individuals who may not be experiencing symptoms themselves. The communication program should include, at a minimum, disclosure of the findings from the evaluation of the building as well as a discussion of the clinical significance of the findings to the potentially exposed population.

RESPIRATORY HEALTH EFFECTS OF INDOOR AIR POLLUTION

As noted above, the spectrum of clinical responses to indoor air pollution is diverse. Table 2 describes some of the major categories of clinical responses, the responsible agents, and the setting in which they may be found. This section briefly describes these clinical responses, aspects of which are considered in greater

depth elsewhere in this volume.

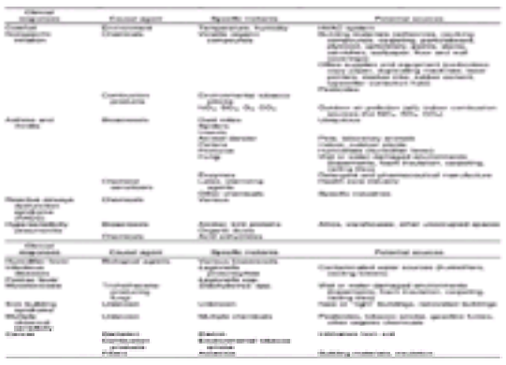

TABLE 2. *Pulmonary responses commonly associated with indoor air pollution*

Asthma

Indoor air pollution both causes and exacerbates asthma. Exposure in the home to house dust mite antigen and to environmental tobacco smoke contributes to asthma. Similar exposures to these and a wide array of other biological agents, antigens from pets, rodents, cockroaches, molds, and fungi, may exacerbate asthma in the workplace. There may be exposure to molds and fungi that have contaminated moist surfaces of heating, ventilating, and air-conditioning systems. Volatile organic compounds, low-molecular-weight agents such as formaldehyde that are released from materials, furnishings, and office processes, may worsen asthma. Smoking adds particles and irritant gases to the air of public and commercial buildings.

Respiratory Infections

Indoor microenvironments are the principal locale for transmission of infectious respiratory diseases, including tuberculosis, influenza, and Legionnaires' disease. Risks reflect occupant density and the level of ventilation provided. Contamination of cooling towers and water systems, which aerosolize bacteria, has been linked to episodes of pneumonia and nonpneumonic disease caused by *Legionella* species. Diagnosis of Legionnaires' disease or Pontiac fever should prompt consideration of the source of the infection. Airborne transmission of tuberculosis has occurred in such diverse enclosed environments as ships, airplanes, and shelters for the homeless.

Lung Cancer

Three agents causally linked to lung cancer may contaminate indoor environments: radon, derived from decay of naturally occurring uranium and entering buildings in soil gas; asbestos fibers released from building materials; and environmental tobacco smoke from the smoking of occupants. Radon is estimated to cause approximately 14,000 lung cancer deaths a year, approximately 6000 to 7000 in never-smokers, and the estimate for mortality from environmental tobacco smoke is 2000 to 3000 lung cancer deaths annually in the United States. Exposures to asbestos in public and commercial buildings are generally low, and the associated cancer risks are likely far lower than for the other carcinogens. As yet, there are no specific markers for lung cancer caused by these agents.

Chronic Rhinitis

Chronic rhinitis related to indoor air pollutants can be a significant cause of morbidity and decreased quality of life for many patients. Causes of chronic rhinitis include annoyance reactions, allergic reactions, chemical irritation, and chemical corrosion. The estimated prevalence rate of allergic rhinitis is between 15% and 20%.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis, caused by inhalation of organic dusts and immunologically active chemicals, has usually been associated with building air-handling systems, although room humidifiers have also been implicated in some cases. Humidifier fever has been considered a separate entity because of the absence of chest x-ray findings in the latter condition.

SICK-BUILDING SYNDROME

Sick-building syndrome is a widely used term to describe a constellation of symptoms associated with exposure to an indoor environment, typically a modern office building. The syndrome is characterized by mucous membrane irritation, respiratory complaints, and sometimes skin, central nervous system, or gastrointestinal effects. There is no generally agreed on case definition, and no unifying pathophysiological mechanism has been advanced to account for all of the symptoms (Table 3). Although occupants of buildings where sick-building syndrome (SBS) has occurred often have a very high symptom prevalence, there is no consensus regarding the percentage of occupants who must be symptomatic in order for the building to qualify as a “sick” building. Affected occupants may be only a minority of the total occupants, but they may be clustered geographically in one area of the building.

Component	World Health Organization	American Thoracic Society
Symptoms	1. Sensory irritation in eyes, nose, and throat 2. Neurotoxic or general health problems 3. Skin irritation 4. Nonspecific hypersensitivity reactions 5. Odor and taste sensations	1. Eye irritation 2. Headaches 3. Fatigue 4. Throat irritation 5. Chest burning, cough, sputum production in the absence of exposure to tobacco smoke 6. Wheezing or chest tightness 7. Malaise 8. Rhinitis
Population affected	Majority of occupants	Substantial proportion of a building's occupants, or of the occupants of a particular space within a building

TABLE 3. *Proposed case definitions for sick building syndrome*

The prevalence and incidence of SBS have been studied in a number of different indoor environments. In several studies of office building workers, the prevalence of symptoms was quite high, over 80% for at least one SBS symptom. However, as noted above, there is no agreement that a certain percentage of occupants must be affected in order for the building to qualify as “sick.” Risk factors associated with the development of symptoms consistent with sick-building syndrome include female gender, a history of asthma or rhinitis, occupation (clerical workers are at increased risk compared with managers), high psychosocial stress, and jobs involving use of carbonless copy paper and visual display terminals.

Thus far, the etiology of sick-building syndrome remains uncertain, although volatile organic compounds, bioaerosols such as bacterial endotoxins or b-1,3-glucan, work organization and other psychosocial factors, and unpleasant odors have all been suggested as possible causal or contributing factors (Fig. 2). There is also disagreement whether and under what circumstances the amount of building ventilation affects the development of sick-building syndrome. However, poor maintenance of the HVAC system has been found in many buildings with occupants affected by SBS.

FIG. 2. Contributing factors in sick-building syndrome.

The clinical presentation of SBS is highly variable. Patients may complain only of irritation, or they may have a wide range of symptoms. Sick-building syndrome is characterized by the presence of symptoms in the building and resolution when exposure ceases. The persistence of symptoms outside the suspected building should increase suspicion that another underlying process is involved. In some individuals, symptoms will initially be present only in the building, but over time the symptoms become more generalized, triggered by a variety of chemical exposures. Eventually, some of these patients may become indistinguishable from patients with multiple chemical sensitivity. Individuals with sick-building syndrome usually do not have evidence of any abnormality of respiratory function. The upper respiratory tract has been the focus of considerable attention as a likely target organ. The presence of lower respiratory tract symptoms, particularly cough, wheeze, or dyspnea, should prompt examination for the presence of airways hyperresponsiveness.

Sick-building syndrome is a diagnosis of exclusion. A careful history and physical examination should be conducted. Keys in making the diagnosis are an appropriate relationship between symptoms and occupancy of the building and an appropriate epidemiologic context with similar problems in other persons working in the same building. The physician should be particularly alert for signs or symptoms of allergic disorders because these may be misdiagnosed as SBS and not adequately treated.

There is no specific medical treatment for SBS. Rather, the physician must consider management issues related to the individual patient, the building, and the work environment (including, frequently, psychosocial aspects of the environment). Management of the individual patient often involves some form of reassurance that the problem is being addressed seriously, that there is no long-term health threat, and that, where appropriate, additional therapeutic modalities such as supportive psychological counseling will be available. Symptoms should not be minimized or trivialized, either by the physician or by the building management. Some patients may insist that the cause of the problem be identified and removed, and these patients may require considerable reassurance and support if they are to successfully return to work.

One of the most important aspects of management is effective communication among patient, physician, and employer. Resolution of SBS may require that the physician contact the employer; this needs to be done with the patient's knowledge and approval. If several occupants appear to be affected, and industrial hygiene or building engineering is undertaken to correct a problem, the affected individuals should be kept informed of all findings and corrective actions, along with appropriate interpretations of the probable clinical significance of the findings.

Prevention of SBS requires both proper building design and maintenance, particularly of the HVAC system. Changing uses of the building should prompt careful analysis of the impact on occupants. Overloading of HVAC capacity by increasing occupant density or adding new equipment may lead to SBS, as may failure to address moisture problems, which facilitate microbial growth. Use of low-emission products and allowing emissions from new building materials to dissipate before occupying the building may also reduce the likelihood of SBS. This can be accomplished through a bake-out period before occupancy.

MULTIPLE CHEMICAL SENSITIVITY

The earliest references to multiple chemical sensitivity (MCS) as a distinct clinical entity date to 1987, although some clinicians have for years postulated that there are certain individuals who have a “sensitivity” or “allergy” to environmental chemicals. Other terms for this condition have included “environmental illness” or “chemical hypersensitivity or hypersusceptibility.” The most common clinical and epidemiologic definition used for MCS was developed by Cullen:

> [An] acquired disorder characterized by recurrent symptoms, referable to multiple organ systems, occurring in response to demonstrable exposure to many chemically unrelated compounds at doses far below those established in the general population to cause harmful effects. No single widely accepted test of physiologic function can be shown to correlate with symptoms.

Patients with MCS may consult pulmonary physicians because of respiratory symptoms.

There is no scientific consensus regarding the etiology and pathogenesis of MCS. Physiological, psychological, psychophysiological, and sociologic models have been proposed to explain MCS. It has been described as a chemical sensitization of the central nervous or immune system, a conditioned response, a panic attack, or a posttraumatic stress response to odors, as a misdiagnosis of psychological or physical illness, and as an illness “belief system.” Clinical studies of patients diagnosed with MCS have not found any consistent abnormalities in physiological, immunologic, neurologic, or psychological parameters.

The upper respiratory tract has been the focus of considerable attention as a likely site involved in the pathogenesis of MCS. Attention has focused on inflammatory changes detected in some patients by rhinolaryngoscopy and on the possible role of a hypothesized but as yet unconfirmed relationship between inflammation and distant neurophysiological effects.

Typically, a patient will present with symptoms in a number of organ systems that are triggered by exposure to perfumes, cigarette smoke, cleaners, automobile and truck exhaust, and other chemicals with strong odors. Common symptoms include headache, fatigue, confusion, memory problems, shortness of breath, arthralgias/myalgias, and nausea. Symptoms may also be triggered by a particular location such as an office, and it may be difficult to distinguish MCS patients from patients with sick-building syndrome. Although many patients report that their condition was triggered by a specific inciting event, some state that the condition developed gradually.

The evaluation of patients with symptoms characteristic of MCS (Table 4) is often time-consuming, and consultation with a specialist in occupational medicine may be helpful. Because symptoms are by definition multisystem, patients with symptoms in only or primarily one organ system should be carefully evaluated for another diagnosis. The presence of concomitant or explanatory psychiatric diagnoses should be established. Some patients with symptoms characteristic of MCS may also meet many of the criteria for chronic fatigue syndrome, but there is as yet no consensus regarding any relationship between the two entities.

A. History
Detailed exposure history (workplace and other environmental exposures)
Industrial hygiene data (Material Safety Data Sheets, results of exposure monitoring, etc.)
Current and past medical illnesses and results of previous diagnostic workups and treatments
Review of prior medical records
B. Physical examination
Rule out other illnesses in the differential diagnosis
C. Diagnostic testing
There is no established diagnostic testing for MCS
Rule out other illnesses in the differential diagnosis
The following tests are currently not validated for clinical use to confirm the diagnosis of MCS:
Environmental challenge testing (unblinded, uncontrolled)
Quantitative electroencephalography
Brain electrical activity mapping
Evoked potentials (brainstem, visual, sensory)
Positron emission tomography scanning
Single photon emission computed tomography scanning
Immunologic testing
Measurement of trace concentrations of volatile organic compounds or pesticides in blood (parts per billion)
Neuropsychological testing
D. Consultation
Occupational and environmental medicine specialist
Psychiatrist
Other specialists as appropriate to rule out other medical conditions in the differential diagnosis
E. Other
Symptom diary
Short-term removal from exposure

[a] Adapted from Sparks PJ, et al. Multiple chemical sensitivity syndrome: a clinical perspective. In: J Occup Med 1994;36:718–730.

TABLE 4. *Diagnostic evaluation of patients with multiple chemical sensitivity*[a]

Treatment of patients with MCS is typically difficult and best accomplished by a multidisciplinary team that includes a psychologist or psychiatrist. Many patients are

concerned about any possible chemical exposures, and it is not uncommon for patients to resort to increasing social isolation in an attempt to prevent exposure. Just as there is no agreed-on case definition, there is also no agreed-on therapeutic regimen. Most treatment has been aimed at relief of symptoms, which can of itself have a significant salutary effect. The issues that have engendered the greatest controversy over management of patients with MCS are (1) whether to remove patients from exposure, and if so for how long; (2) the use of behavioral therapies; and (3) the role of desensitization or chemical detoxification. In the experience of the authors and of most of the scientific literature, short-term removal from exposure may be helpful both as a diagnostic test and therapeutically, but there is little evidence that long-term removal improves clinical outcome. The use of behavioral therapies has been hotly debated. There have been no controlled trials of behavioral therapy, although case reports suggest that some patients respond favorably to the use of biofeedback or other supportive modalities. No controlled trials have validated the use of chemical desensitization (sometimes termed “neutralization”) therapies.

CHAPTER

40 Bronchial Asthma

Jeffrey M. Drazen

J.M. Drazen: Department of Medicine, Harvard Medical School, Respiratory Division, Brigham and Women's Hospital, Boston, Massachusetts 02115.

INTRODUCTION

Asthma is a clinical syndrome defined physiologically by episodic reversible airway narrowing and hyperresponsiveness of the airways to a variety of stimuli (Table 1). It is also defined pathologically by the presence of certain recognizable microscopic features including infiltration of the airways with eosinophils, hypertrophy and hyperplasia of airway smooth muscle, hypertrophy and hyperplasia of mucous secretory apparatus, and overall thickening of the airway wall.

1. Episodic airway obstruction
2. Airway hyperresponsiveness
3. Airway inflammation

TABLE 1. *Characteristics of asthma*

Our current knowledge of the molecular pathogenesis of asthma is minimal. Indeed, our current knowledge of asthma may be likened to our knowledge of anemia before the elucidation of the various molecular events leading to the clinical syndromes that are recognized as distinct forms of anemia. On the basis of our current clinical understanding of asthma, it seems likely that multiple molecular causes for the syndrome will be identified in the future.

Given the uncertainties embodied in the absence of molecular understanding, the Global Initiative for Asthma and the National Asthma Education Program defined asthma as follows: "Asthma is a chronic inflammatory disorder of the airways in which many cells play a role, in particular mast cells, eosinophils, and T lymphocytes." In susceptible individuals, this inflammation is reflected physiologically as recurrent episodes of wheezing, breathlessness, chest tightness, and cough. These symptoms are usually associated with widespread but variable airway narrowing, which causes airflow limitation that is at least partly reversible either spontaneously or with treatment. The inflammation is also associated with an increase in airway responsiveness to a variety of stimuli.

This is a useful definition for health care professionals interested in asthma, but it lacks the precision needed for use in epidemiologic studies. As a result, many epidemiologists have found it necessary to create their own definition of asthma for use in the populations they wish to study. As methods for quantifying the asthma phenotype become more codified, the definition of asthma from group to group has become more uniform, thus allowing comparisons among various studies. In reviewing asthma studies, it is worthwhile to query whether the definition was based on clinical criteria (for example, the presence of wheeze or a doctor's diagnosis of asthma), on the presence of airway obstruction or hyperresponsiveness, or on pathologic criteria such as analysis of sputum or airway biopsy material. In most circumstances asthma definitions are based on a combination of a characteristic clinical history and physiological evidence of reversible airway obstruction. In cases in which the diagnosis is not clear from these two criteria, airway responsiveness testing is quite often added. Very few clinical studies of asthma have used pathologic characteristics of materials obtained from patients to define asthma.

ASTHMA EPIDEMIOLOGY

Asthma Prevalence

Asthma is a very common disorder that affects approximately 5% of the population of the United States and Europe; it affects men and women equally. It is well established that the prevalence of asthma below age 20 is greater than that above age 20, which suggests a “remission” from asthma some time in the midteen years. Indeed, clinical remission of asthma is common in the peripubertal period, but many adults who develop asthma had a history of asthma in childhood. Worldwide, the prevalence of asthma in children is between 8% and 30% in more affluent countries and on the order of 0% to 5% in less well-developed countries.

There is reason to believe that the prevalence of asthma is increasing. For example, according to data obtained from England and Wales, there has been a doubling of hospital admissions for asthma in individuals of all ages over the past 15 years: in 1990, individuals over age 15 had approximately 12 hospital admissions per 10,000 patients, children aged 5 to 14 approximately 40 admissions per 10,000, and children under age 4 approximately 100 admissions for asthma per 10,000. In comparison, in 1980, the admission rate per 10,000 patients for children under 4 was approximately 40, i.e., 2.5-fold fewer.

Asthma Mortality

Mortality rates from asthma are difficult to estimate because of the difficulty of establishing asthma as the cause of death. For example, evaluation of death certificates indicates that patients with chronic obstructive lung disease may be improperly coded as having asthma. Despite these limitations, most sources indicate that the death rate from asthma in individuals aged 5 to 34 is between 0.2 and 1 per 100,000 population per year, with the lowest rates occurring in the United States, France, Japan, and Canada and the highest rates occurring in Australia, New Zealand, England, and Wales. It is important to note that death rates from asthma, which were very high in New Zealand over the period from 1975 to 1990, have recently fallen to levels consistent with those found in other countries with similar overall socioeconomic status.

“Natural History”

The “natural history” of asthma is not well established. Although we know that asthma is more common in individuals under age 20 than in older individuals, the odds of a given person's having a clinical remission are not established, and new-onset asthma has been documented in every decade of life. What is not known is in what fraction of individuals asthma will progress to chronic airflow obstruction and whether this progression can be altered by appropriate treatment. There is now evidence, from both longitudinal and cross-sectional epidemiologic studies, to suggest that asthmatic individuals with high levels of airway responsiveness lose lung function at a more rapid rate than asthmatic individuals without elevated levels of airway responsiveness. It is not known whether medications that modify airway responsiveness will be associated with a change in the rate of loss of lung function.

PATHOLOGY OF ASTHMA

Morphologic evaluation of endobronchial biopsy specimens from asthmatic volunteers has contributed to understanding the pathobiology of asthma. It is now well established that the airways of patients with even mild asthma are inflamed; some data suggest that asthma severity parallels the degree of inflammation. The airway inflammation in asthma can be classified into three distinct components (Table 2), each of which is considered separately.

Alterations in airway constitutive cells: Cells ordinarily present in the airway wall, such as epithelial cells, smooth muscle cells, and mast cells, are enhanced in number or express a more proinflammatory phenotype than these cell types in normal individuals.
Increased numbers of infiltrating cells: Leukocytes, such as eosinophils, monocytes, TH_2 lymphocytes, and basophils, are found in the airway wall in greater numbers than in normal individuals.
Changes in the noncellular components of the airway wall: The airway wall is thickened beyond that which can be accounted for on the basis of resident and infiltrating cells alone. These noncellular structural alterations in the airway include changes in the epithelial basement membrane and increased amounts of airway wall and luminal liquid.

TABLE 2. *Airway inflammation in asthma*

Alterations in Airway Constitutive Cells

Both hyperplasia and hypertrophy of the airway epithelial cell layer are present in asthma and contribute to the thickening of the airway wall. Within the epithelial layer there are increased numbers of surface secretory cells as well as hypertrophy and hyperplasia of airway mucus glands. Thickening of the airway smooth muscle layer also occurs. In addition, there is reason to believe that mast cells in the asthmatic airway express a more proinflammatory phenotype than those in the normal airway. These changes result not only in thickening of the airway wall, which promotes airway hyperresponsiveness on a simple mechanical basis, but also in an altered phenotype of the resident cells, which produces a microenvironment whereby activating stimuli enhance the production of prophlogistic mediators and cytokines. These mediators and cytokines in turn contribute to the airway obstruction and hyperresponsiveness that characterize asthma.

Infiltration by Inflammatory Cells

The airway wall in asthma is infiltrated by T lymphocytes bearing the T-helper-2 (TH_2) phenotype. These cells can produce a limited panel of cytokines including interleukin (IL)-3, IL-4, IL-5, and granulocyte–macrophage colony-stimulating factor (GM-CSF). Although the primary signals resulting in the infiltration of the asthmatic airways by this lymphocyte subset have not yet been established, the net effect of the cytokines elaborated is to promote the synthesis of immunoglobulin E (IgE) through the actions of IL-4 on immunoglobulin isotype switching and to enhance the differentiation and migration of eosinophils through the actions of IL-5. There is abundant evidence that IgE and the eosinophil are critical elements in the pathobiology of asthma. We are also beginning to appreciate the potential importance of other proinflammatory cytokines and chemokines, such as IL-1, tumor necrosis factor (TNF)-a, and macrophage inhibitory protein (MIP)-1a, in asthma.

Alterations of the Noncellular Component of the Airway Wall

It is well established that the airway wall is thickened in asthma. Although some of the thickening can be ascribed to the cellular components noted above, other components of the thickened airway are not cellular in nature. The basement membrane is increased in thickness and exhibits alterations in the structure of its collagen components; such thickening promotes airway obstruction and hyperresponsiveness. Liquid that infiltrates the airway wall and surrounding tissues as a result of local inflammation further amplifies airway obstruction.

Potential Schema Linking Airway Inflammation and Asthma Pathobiology

Although the anatomic changes in the asthmatic airway wall are now well established, the mechanisms that link airway inflammation and the altered physiology of asthma remain speculative at best; one potential schema linking the known alterations in the airway wall with the clinical changes that occur in asthma is presented in Fig. 1.

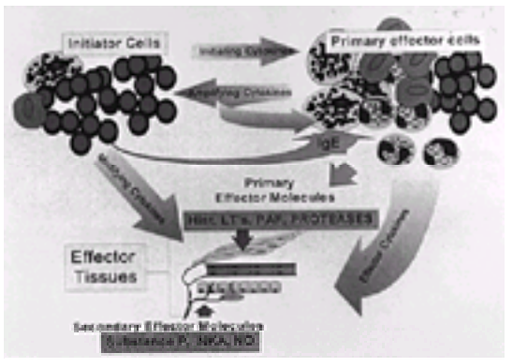

FIG. 1. Schema relating airway inflammation, shown in the top half of the figure, to airway obstruction, shown in the bottom half of the figure. *See Color Plate 17.*

As described above, allergen exposure,[1] via mechanisms that are not fully understood, results in the accumulation in the airway of lymphocytes bearing the TH_2 phenotype. The cytokines elaborated by these cells (and perhaps mast cells, which can also produce IL-4 and other TH_2-type cytokines as well as TNF-a) favor the synthesis of IgE and promote the recruitment of additional T cells, eosinophils, monocytes, and basophils. In addition, the binding of IgE results in immunologically specific sensitization of mast cells, monocytes/macrophages, eosinophils, and basophils. When activated, these cells elaborate mediators of inflammation including histamine, leukotrienes, lipoxins, platelet-activating factor (PAF), and various proteases into the local microenvironment. These molecules, termed *primary effector molecules,* have the capacity to stimulate airway smooth muscle, to alter microvascular permeability, and to promote the release of mucins from airway glands and surface secretory cells. The primary effector cells also secrete cytokines, which amplify the response and perpetuate the asthmatic phenotype by aiding in the recruitment of more inflammatory cells and by having additional proinflammatory effects on smooth muscle and other resident cells. Primary effector molecules can contribute to the inflammatory nature of the lesion (for example, PAF and LTB_4 are potent chemoattractants for eosinophils), and they can also stimulate sensory nerve fibers within the airway, leading to the release of *secondary effector molecules* including substance P and neurokinin A. Nerve stimulation also initiates the release of both vasoactive intestinal peptide and nitric oxide.

The initiation and perpetuation of inflammation in the asthmatic airway thus result in an expansion of the number of primary effector cells and the sensitization of these cells for IgE-dependent mediator release. This process greatly enhances the local production of both primary and secondary effector molecules. Moreover, the effects of some of the products of airway inflammation initiate airway epithelial disruption, which further promotes the asthmatic phenotype.

PATHOGENESIS: LINKS BETWEEN PATHOLOGIC AND PHYSIOLOGICAL FINDINGS

The pathologic changes noted in the airway wall result in the availability in the airway microenvironment of a number of molecules whose presence is thought to be responsible for many of the physiological changes that we recognize as asthma. In general, these molecules fall into three broad categories (Table 3): neurotransmitters, chemical mediators, and cytokines/chemokines. Each of these categories is reviewed separately.

Neural links
Cholinergic neurotransmission via M_3 receptors
Peptidergic nerves
Substance P and neurokinin A: bronchoconstrictor peptides
Vasoactive intestinal peptide: bronchodilator peptides
Nitric oxide
Inflammatory mediators
Histamine
Platelet-activating factor
Leukotrienes
Proteases
Cytokines/chemokines
IL-4
IL-5
TNF-α
Eotaxin
RANTES

TABLE 3. *Molecular links betweeninflammation and asthma*

Neurotransmitters

Cholinergicis

Acetylcholine is released from intrapulmonary motor nerves. The acetylcholine so released can directly stimulate muscarinic receptors of the M_3 subtype found on airway smooth muscle, which cause airway smooth muscle constriction. In addition, it is now established that autonomic ganglia near the airway contain inhibitory autoreceptors, which, when activated, inhibit neurotransmission and thus serve as an endogenous down-regulatory mechanism. Although the specific nature of the human inhibitory autoreceptor is not established on a molecular basis, it is clear that such receptors exist and, if appropriately blocked, may prevent down-regulation of nerve stimulation, hence enhancing airway responses.

Peptidergic Nerves

Peptidergic nerves in the lung are predominantly sensory. Sensory nerve endings contain neuropeptides including substance P and neurokinin A, which, when stimulated by specific action at irritant receptors, result in release of these peptides in the airway microenvironment. At the same time, action potentials are conducted toward the central nervous system to convey the presence of this irritant stimulus. However, as these action potentials cross the terminal ramifications of the airway nerves, antidromic conduction causes the release of the sensory peptides throughout the territory innervated by the specific axon dendrite. This action results in an effective local axon reflex in which sensory nerves serve a motor function. It is well established that both substance P and, to an even greater degree, neurokinin A can constrict airway smooth muscle, thus contributing to the asthmatic diathesis. In addition, these peptides can mediate bronchovascular leak, which may contribute to the pathobiology we recognize as asthma.

In this setting it is important to understand an endogenous down-regulatory mechanism that keeps the physiological effects of these peptides in check. The membrane-bound enzyme neutral metalloendopeptidase (NEP, E.C. 3.4.24.11) is present in the microenvironment where the peptides are released from nerves. It has been shown in both animals and humans that the ability of this enzyme to cleave and inactivate the neuropeptides competes with the ability of neuropeptides to stimulate their specific receptors. It is thought, therefore, that the action of NEP is similar to the action of acetylcholinesterase on acetylcholine; i.e., it is a physiologically important enzyme limiting the expression of the biological actions of neuropeptides. It is of interest to note that conditions such as viral infections and exposure to certain pollutants are associated with decreased NEP activity, which would allow peptides cleaved by NEP not to be cleaved and their “proasthmatic” actions to be amplified.

Vasoactive intestinal peptide (VIP) is a 28-residue peptide found in airway nerves, which can relax airway smooth muscle and may serve as an endogenous bronchodilator. It can be cleaved and inactivated by NEP, which thereby limits its physiological actions. It can also be cleaved by the mast-cell enzyme tryptase, found in enhanced amounts in the asthmatic airway after allergic activation. Inactivation of VIP by tryptase may contribute to enhanced airway responses in the setting of allergic activation.

Nitric Oxide

Nitric oxide is an endogenous molecule with both proinflammatory and bronchodilator actions. It has been shown by a number of groups that nitric oxide can be produced by airway nerves, as indicated by the presence of the neural form of nitric oxide synthase in airway nerves in both normal and asthmatic subjects. However, the role of nitric oxide released from airway nerves in asthma is not known. Nitric oxide can also be produced in large quantities by airway epithelium that has been

stimulated by inflammatory cytokines; nitric oxide released in this setting likely serves a proinflammatory role.

Inflammatory Mediators

Inflammatory mediators are molecules produced by inflammatory cells in the asthmatic lesion that have the capacity to mediate physiological effects consistent with the abnormalities seen in asthma; a mediator is distinct from a hormone in that a mediator's activity occurs near the site of its production or release.

Histamine

Histamine, or b-imidazolylethylamine, is formed by mast cells found in the airway lumen or in the airway wall. Histamine can cause airway narrowing when given by inhalation in normal and asthmatic subjects; patients with asthma are more sensitive to the effects of histamine than normal subjects. Although histamine is present in the airway, agents that inhibit the action of histamine, i.e., antihistamines, have not been very successful in asthma treatment. This observation has been interpreted to indicate that histamine plays a secondary role in the biology of asthma.

Platelet-Activating Factor

Platelet-activating factor is a phospholipid that differs from other phospholipids in that it has an ether rather than an ester link in the *sn*-1 position and an acetyl moiety in the *sn*-2 position; phosphatidylcholine is found in the *sn*-3 position. Experiments in animals and humans have shown that platelet-activating factor is a bronchoconstrictor of modest potency and can sensitize airways to the effects of other bronchoconstrictor mediators. Although a number of clinical trials have been conducted in patients with asthma to determine whether antagonists of the action of platelet-activating factor at its receptor will improve asthma control, none of the trials performed to date has been successful in demonstrating such an effect. Therefore, it remains an open question as to whether platelet-activating factor has a significant role in the biology of asthma.

Leukotrienes

The cysteinyl leukotrienes known as LTC_4, LTD_4, and LTE_4, as well as the dihydroxyleukotriene, LTB_4, are derived by the sequential lipoxygenation of arachidonic acid, which is released from cell membrane phospholipids during cellular activation. 5-Lipoxygenase, a cytosolic protein known as the 5-lipoxygenase activating protein, and LTC_4 synthase are the enzymes required to produce the cysteinyl leukotrienes, whereas LTA_4 hydrolase rather than LTC_4 synthase is needed to produced LTB_4. Mast cells, eosinophils, and alveolar macrophages each have the capacity to produce cysteinyl leukotrienes when appropriately activated. Cysteinyl leukotreines may also be formed by transcellular metabolism in which the first components of the reaction (e.g., LTA_4) are contributed by one cell type, such as polymorphonuclear leukocytes, and other components are provided by other cell types, such as pulmonary epithelial cells.

The major physiological role of LTB_4 is that of a chemotactic factor, whereas the predominant physiological role of the cysteinyl leukotrienes is that of bronchoconstrictor mediators. The cysteinyl leukotrienes are known to play a partial role in mediating the constrictor biology of asthma, and agents that inhibit the synthesis of leukotreines or their action at leukotreine receptors are now established to have a beneficial effect in asthma. These benefits include chronic bronchodilation, improved asthma symptoms, and a decreased need for steroid rescue treatments.

Proteases

A number of proteases are produced by mast cells when activated. Although these enzymes themselves cannot be considered mediators, their biological effect is to cleave active mediators from substrates in the airway microenvironment. Enzymes such as tryptase, chymase, and kallikreins are found in mast cells. Although the endogenous substrates and the molecules formed through cleavage by the action of tryptase and chymase are not known, kallikreins cleave kinins from kininogen. Kinins, such as bradykinin, are potent bronchoconstrictor molecules and can induce microvascular leak. In trials in human subjects, aerosols generated from bradykinin solutions have been shown to induce symptoms consistent with asthma.

Cytokines/Chemokines

The putative role for cytokines and chemokines is to amplify and modify the inflammatory cellular response. These effects are detailed in the previous section. However, there is reason to believe that cytokines may also modify the capacity of effector tissues to respond to stimulation.

PHYSIOLOGICAL ALTERATIONS IN ASTHMA

The predominant physiological effect observed in asthma is airway obstruction, which results from celluar infiltration of the airway wall, thickening of the airway wall by the presence of edema and other liquids, and smooth muscle constriction. When these anatomic events (airway wall stiffening and luminal narrowing) take place, airflow obstruction occurs. From the physics of flow limitation, we know that maximal expiratory airflow rates vary directly with the airway area (smaller areas lead to decreased flows) available for airflow to the third power, whereas increasing airway wall stiffness increases maximal airflow rates to the first power. Therefore, decreasing airway diameter has a much more powerful effect on airflow than increasing airway wall stiffness. The effects of narrowing and stiffening of airways are a decreased forced expiratory volume in the first second (FEV_1) as well as decreased flow rates throughout the vital capacity. Because of the nonhomogeneous nature of airway narrowing, when a maximal expiratory flow–volume maneuver is performed, airflow proceeds first from those units that are least obstructed and then from those that are most obstructed, thus resulting in a characteristic “coved” shape to the flow–volume curve, with the less obstructed units emptying higher in the vital capacity. Administration of a bronchodilator improves flow rates throughout the vital capacity and straightens this expiratory coving. Physiological studies indicate that, during a spontaneous acute asthmatic episode, airway obstruction occurs originally in airways of all sizes, but resolution occurs first in the large airways and later in the peripheral airways. This series of events is reflected in asthma as the airflow rates normalize first high in the vital capacity and later low in the vital capacity. Indeed, it is quite common to find a patient with very mild asthma and a normal FEV_1 whose flow–volume curve will be concave toward the volume axis. In such individuals, the major physiological abnormality is that flow rates low in the vital capacity are substantially depressed; this is reflected by a low maximum midexpiratory flow rate on spirometric tracings.

Because asthma is a disease of the airways, there are no primary changes in the static pressure–volume curve of the lungs. However, during an acute asthmatic episode it is common for airway narrowing to be so severe as to result in complete airway closure. Because individual lung units tend to close at a volume that is close to their maximal volume, this trapped gas results in a change in the static pressure–volume curve of the lung such that for a given volume of gas contained within the thorax, there will be reduced elastic recoil. The physiological consequence of this elastic recoil is to depress expiratory flow rates by reducing the effective driving force for airflow.

Additional factors influence the mechanical behavior of the lungs during an acute attack of asthma. During normal ventilation, as the diaphragm descends, pleural pressure drops from its value of –3 to –5 cm H_2O at functional residual capacity to –5 to –10 cm H_2O at the end of a normal inspiration. However, because there is airflow obstruction in asthma, it is necessary for a larger negative inspiratory pressure to be generated to create airflow. During expiration, as the patient tries to force air from his or her lungs, pleural pressures become quite high. Therefore, the pressure swings, and the subsequent energy that must be expended during a ventilatory cycle, are much greater in patients with asthma than in normal subjects. During acute episodes of asthma, increased respiratory rate, coupled with increased airway resistances, results in a work of breathing that may be more than ten times greater than in normal subjects.

The airway obstruction in asthma causes a maldistribution of ventilation relative to perfusion. Under normal circumstances, most units have a ventilation to perfusion ($\dot{V}/Q$) ratio (when ventilation and blood flow are both measured in liters/min) on the order of unity (i.e., numerically equal to 1). In patients with asthma, many units have $\dot{V}/Q$ ratios far below unity, a maldistribution that results in arterial hypoxemia, which can usually be corrected with small amounts of supplemental oxygen. This is of more than passing therapeutic interest, because administration of oxygen mixtures containing a high F_IO_2 promotes absorption atelectasis. Therefore, only the minimal amount of oxygen required to achieve saturations on the order of 92% to 93% should be administered to such patients.

Irritant stimuli that impinge on the airway in asthma result in tachypnea, which in turn causes hyperpnea out of proportion to that required to maintain normal ventilatory needs. Indeed, most patients with asthma have partial pressures of CO_2 in the arterial blood that are below normal. It has been demonstrated that the P_aCO_2 in patients with asthma decreases in direct proportion to the fraction of the predicted value recorded for the FEV_1 until an FEV_1 on the order of 25% of predicted is achieved. For example, a patient with an FEV_1 45% of predicted will have a lower P_aCO_2 than a patient with an FEV_1 65% of predicted. When the FEV_1 falls below 45% of predicted, the mechanical load to ventilation is so great that the P_aCO_2 increases.

CLINICAL PRESENTATION

A number of the most common distinct clinical presentations of asthma are reviewed separately.

Acute Asthma

During an acute asthmatic episode, the patient experiences airway obstruction that causes symptoms of breathlessness and anxiety, commonly accompanied by wheezing and on occasion cough. The resolution of these symptoms and physical findings usually occurs within 1 to 3 days without specific therapy and may occur within hours if specific therapy is given. During the intervals between episodes of airway obstruction, airflow is normal, and the patient is asymptomatic. A number of distinct conditions associated with airway obstruction are reviewed.

Exercise-Induced Asthma

Individuals who exercise for brief periods of time, on the order of 15 to 20 min, commonly develop airway obstruction after the cessation of exercise. Obstruction usually begins 5 to 10 min after the completion of exercise and resolves in 1 to 4 hrs. Exercise stimuli such as skiing, playing ice hockey, or running in the cold are commonly known to bring on exercise-induced asthma, whereas other forms of exercise such as swimming do not predispose to airway obstruction, probably because of the temperature and high humidity of the air being inspired. Patients with this condition can often prevent exercise-induced asthma symptoms by inhaling a b-adrenergic agonist before exercising.

Cold-Dry-Air-Induced Asthma

This asthma is induced by a change from breathing in a relatively warm atmosphere laden with water to one that is dry and cool. For example, when one exits a heated house into cold dry outdoor air in the winter in northern climates or, conversely, when one goes from warm and humid outdoor air into a dry air-conditioned environment in the summer (mall asthma), asthma attacks may be provoked. In taking a history from a patient with potential asthma, it is worth inquiring whether shortness of breath is induced by this type of environmental change.

Allergen-Induced Asthma

Allergen-induced asthma is one of the best-understood forms of asthma; it likely results from the direct effects of mediators released from inflammatory cells as a consequence of clustering of IgE receptors on the surface of effector cells. Common allergens inducing asthma are cat allergen (Fel D1), house dust mite allergen (der P1), and tree and grass pollens. Because of the high prevalence of cat and house dust mite allergy, specifically asking whether patients develop shortness of breath in the presence of a cat is worthwhile. Furthermore, patients with house dust mite allergy often develop asthmatic symptoms on entering rooms with high concentrations of this allergen, for example, a carpeted bedroom where the humidity is relatively high.

Virus-Induced Asthma

Many individuals with a history of asthma will be relatively asymptomatic until they contract a viral illness, when asthma may occur without other known inciting stimuli. In the absence of therapy, it may take weeks or months for lung function to return to normal.

Occupational or Environmental Asthma Without Simple Allergy Mechanisms

A wide range of conditions can cause asthma in the workplace. The important historical clues relate to the onset of asthma in relationship to workplace exposure. An early response can occur within a few hours, a late response within 8 to 12 hrs. It is important to note that many cases of occupational asthma do not resolve quickly when the patient leaves the workplace environment; therefore, the absence of this finding does not make occupational asthma less likely.

Aspirin-Induced Asthma

Approximately 1% to 10% of patients with moderate-to-severe asthma have aspirin-induced asthma, which consists of symptoms of moderately severe airway obstruction, rhinorrhea, sneezing, tearing, dermal changes, and, in some patients, GI changes (cramping, nausea, or vomiting) after exposure to aspirin or other agents with the capacity to inhibit prostaglandin H synthase type I (PGHS-1 or cyclooxygenase type I). This syndrome has a characteristic onset in the second to third decade of life and is associated with sinusitis and nasal polyposis. Aspirin-induced asthma is an important specific diagnosis to make for two reasons: first, patients may have life-threatening asthma if they take aspirin or even other cyclooxygenase inhibitors; second, there is a relatively specific treatment for this entity, namely inhibition of the 5-lipoxygenase pathway through the use of leukotriene receptor antagonists or synthesis inhibitors.

Acute Severe Asthma

Acute severe asthma is a more severe and prolonged version of an acute asthmatic episode. Quite often individual acute asthmatic episodes will run together, and the patient may give a history of many days to weeks of shortness of breath with diminishing response to therapy. Patients often treat themselves repeatedly with b-adrenergic agonists and finally seek acute medical attention when airway obstruction is so great as to make normal ventilation impossible and collapse and asphyxia are imminent. This syndrome is not pathogenetically distinct from acute asthma but rather represents a more severe prolonged form of acute asthma.

Chronic Stable Asthma

Chronic stable asthma is the name given to the syndrome characterized by episodes of asthmatic symptoms and airflow obstruction that recur. Although there may be one or two severe episodes over the course of many months, most episodes of asthma are of moderate severity. Asthmatic symptoms can be controlled through chronic medication use.

PHYSICAL EXAMINATION

Vital Signs

Patients with asthma have tachypnea, with respiration rates often 25 to 40 breaths/min, accompanied by tachycardia, with pulse rates of about 100 as well as pulsus paradoxus, an exaggerated inspiratory fall in the systolic blood pressure. It is now well established that the magnitude of the fall in systolic blood pressure reflects the magnitude of a negative inspiratory swing in pleural pressure and thus is proportional to the severity of the asthma attack.

Thoracic Examination

During an acute attack of asthma, the chest is hyperinflated, which can be appreciated on inspection. During asthma attacks patients use their accessory muscles of inspiration. Because of the substantially negative pleural pressure generated during inspiration, the skin over the intercostal spaces may be retracted during the inspiratory phase. The expiratory phase is active, with the patient making efforts to expire air from the thorax, which causes expiratory bulging of the skin over the intercostal spaces.

Percussion of the thorax demonstrates hyperresonance, with loss of the normal variation in dullness from diaphragmatic movement.

The cardinal physical finding in asthma is wheezing. Wheezing is commonly heard during both inspiration and expiration; it tends to be louder during expiration. Wheezing is polyphonic (more than one pitch can be heard simultaneously) and is to be distinguished from monophonic wheezing, which suggests airway obstruction by fixed bronchial or tracheal lesions.

It is important to note that not all patients with asthma have wheezing. Some individuals have normal chest examinations even though they may have airflow obstruction. Second, not all wheezing illnesses are asthma (see Table 4). In addition to wheezing, rhonchi may suggest the presence of free secretions in the airway lumen, and rales suggest a condition other than simple asthma, such as localized infection or cardiac failure, and should prompt appropriate diagnostic tests. Absent or

low-intensity breath sounds indicate severe airflow obstruction.

Acute bronchiolitis (infectious, chemical)
Airway obstruction by masses
Central thoracic tumors
Metastatic cancer
Primary lung tumors
Substernal thyroid
Aspiration (foreign body)
Bronchiolitis obliterans organizing pneumonia (BOOP)
Bronchial stenosis
Carcinoid syndrome
Cardiac failure
Chronic bronchitis
Cystic fibrosis
Endobronchial sarcoid
Eosinophilic pneumonia
Pulmonary emboli
Systemic mastocytosis
Systemic vasculitis (polyarteritis nodosa)

TABLE 4. *Differential diagnosis of wheezing illnesses other than asthma*

LABORATORY FINDINGS

Pulmonary Function Testing

Decreased airflow rates throughout the vital capacity are the most common pulmonary function abnormality in mild asthma, as reflected by abnormalities in the peak expiratory flow rate (PEFR), the FEV_1, and the maximum mid-expiratory flow rate (MMEFR; $FEF_{25–75}$). As mentioned previously, when tests of forced expiration are presented in a flow–volume configuration, the curve is characteristically coved (Fig. 2).

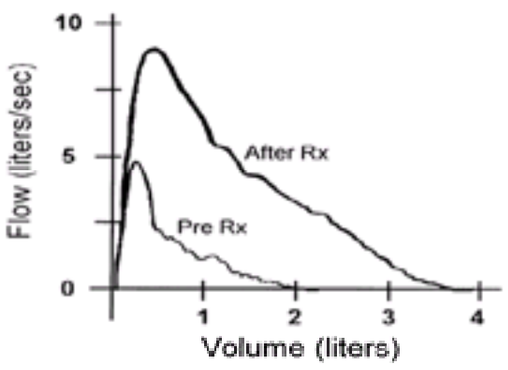

FIG. 2. Actual flow volume curves from a 28-year-old woman with moderate asthma before (pre-Rx) and after (after Rx) treatment with inhaled steroids. Because absolute lung volumes were not measured, curves were “matched” at total lung capacity. Note that treatment increased flows over the entire vital capacity and resulted in a straightening of the curve over the lower 50% of the vital capacity.

The severity of asthma attacks must be assessed by accurate and reproducible objective measures of airflow. Even in the patient who has asthma so severe that an entire spirogram cannot be recorded, a forced expiration of 1-sec duration will allow the FEV_1 to be measured; forced expirations of even shorter durations are all that is required to measure the peak expiratory flow rate. These measures will allow the physician to assess the adequacy of current therapy and the need for further therapy, prolonged attention at an emergency service, or admission to hospital.

As the attack resolves, the peak expiratory flow rate and the FEV_1 both increase while the MMEF usually remains substantially depressed. Even after substantial resolution of the attack leading to normalization of both the FEV_1 and the peak expiratory flow rate, the maximal expiratory flow rate may be depressed to 60% of predicted. Indeed, it may take weeks to months for this index to return to normal.

Airway Responsiveness Testing

Airway responsiveness testing measures the bronchoconstrictor response elicited by a standard stimulus. A schematic diagram of the airway responsiveness test (Fig. 3) shows the response in normal subjects and patients with mild or moderate severe asthma. In this test, the patient is asked to inhale an aerosol generated from solutions containing graded amounts of a bronchoconstrictor agonist, most commonly methacholine and histamine; the FEV_1 response is measured after administration of the agonist. If, after a given dose of agonist, a response of the proposed magnitude is not achieved, the dose is increased by a factor of 2 or 3, and the challenge is repeated. This cycle is repeated until the FEV_1 falls 20%. The interpolated concentration of agonist that would have decreased the FEV by 20% is termed the PC_{20}. The test is used diagnostically when it is not clear from a patient's history or response to medication whether asthma is the correct diagnosis. If the patient's FEV_1 before the test is less than 60% of predicted, the test carries additional risk and should be performed only by laboratories experienced in this testing maneuver. Airway responsiveness is not a fixed entity but rather reflects the inflammatory microenvironment of the airway wall, as noted in the asthma pathology section. Therefore, it will change in response to specific treatment.

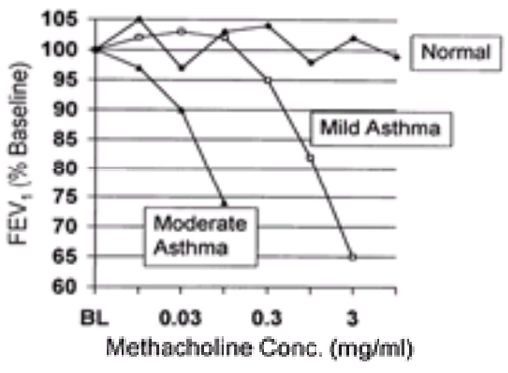

FIG. 3. Schematic methacholine dose–response curves for normal subjects, patients with mild asthma, and patients with moderate asthma. The calculated PC_{20} values for the patients with asthma are approximately 0.08 mg/ml and 1.2 mg/ml. Note that a PC_{20} cannot be calculated for the normal subjects.

Arterial Blood Gases

Analysis of arterial blood carbon dioxide and oxygen tensions need not be undertaken in individuals with mild asthma. However, if the asthma is sufficiently severe to merit prolonged observation, then arterial blood gas analysis is indicated. As noted above, hypoxemia and hypocarbia are the rule. For a patient with a mild attack of asthma, the P_aO_2 is usually between 55 and 75, and the P_aCO_2 between 25 and 35. It is important to note that, if an asthma attack is chronic, the hyperventilation associated with the attack results in a compensatory metabolic acidemia in which the kidneys excrete bicarbonate to normalize pH. Thus, an individual with a prolonged

attack of asthma may have only a slightly alkalotic pH but at the expense of a low serum bicarbonate level. If such a patient deteriorates so that he or she is no longer able to defend a low P_aCO_2, the pH will fall more rapidly than it would in a normal individual. Thus, patients with asthma who show signs of moderately severe airway obstruction but have normal carbon dioxide tensions require very close monitoring.

Other Findings in the Blood

Patients with asthma frequently have atopy; therefore, blood eosinophilia on the order of 4% to 8% is common. In addition, elevated serum levels of IgE are often used as an index of the atopic state. Indeed, epidemiologic studies indicate that asthma is unusual in subjects with low IgE levels. Furthermore, as indicated by the patient's specific history, specific radiooligosorbent tests (RAST) can be conducted to determine the amount of IgE specifically directed against an offending antigen.

Severe cases of asthma can be associated with elevated serum concentrations of aminotransferases, lactate dehydrogenases, muscle creatinine phosphokinase, transcarbamylase, and antidiuretic hormone. Furthermore, therapy with b-adrenergic agonists, may create low serum potassium levels.

Radiographic Findings

In most cases, chest radiographs in patients with asthma are normal. Therefore, unless specifically indicated by adventitious findings on chest examinations or other physical findings suggestive of an infectious illness, or by unusually severe asthma, chest radiography is not indicated. If a patient's asthma is severe enough to merit hospital admission, a chest radiograph is advised. In patients with severe asthma, the x-ray may show hyperinflation, indicated by depression of the diaphragm, and abnormally lucent lung fields. Complications of severe asthma include pneumomediastinum and pneumothorax, which may be detected only radiographically.

Electrocardiographic Findings

In most cases of asthma, the electrocardiogram is remarkable only for sinus tachycardia. In severe attacks right axis deviation, right bundle branch block, P pulmonale, or even ST-T wave abnormalities may occur. If these abnormalities resolve as the asthma attack resolves, they will require no further follow-up. In individuals with substantial cardiac risk factors or a cardiac history, electrocardiographic findings of myocardial infarction should be monitored because of the stress induced by the attack.

Sputum Findings

Between acute asthma attacks, in the absence of infection, the sputum of patients with asthma is usually clear. During an acute asthma attack, even without infection, the sputum may be green to yellow from eosinophil peroxidase. Indeed, the presence of yellow-green sputum does not necessarily indicate infection, and examination of a Gram stain and Wright stain of the sputum is indicated to determine whether the sputum contains asthmatic or infective findings. Asthmatic findings include eosinophils, Charcot-Leyden crystals (crystallized eosinophil lysophospholipase), Curschmann's spirals (bronchiolar casts composed of mucus and goblet cells), or Creola bodies (clusters of airway epithelial cells with identifiable, quite often beating, cilia).

ASTHMA TREATMENT

Asthma treatment is undergoing substantial evolution as we learn how to use most effectively agents that are currently available and those that are being newly introduced. The treatment of asthma is aimed at alleviating asthma symptoms by treating airway obstruction and modifying various aspects of the previously described inflammatory events. It cannot be overemphasized that it is necessary to follow the progress of asthma treatment by using objective measures of airway obstruction; this is critical so that the success or failure of a treatment can be documented. Asthma therapy is best approached by a standard format: first, the severity of the patient's asthma is assessed; second, treatment appropriate for the severity is initiated; third, the response to this therapy is monitored; and fourth, the therapy is modified, if need be, depending on the response. Before specific treatment outlines are reviewed, we will discuss the medications available for use.

Inhaled b-Adrenergic Agonists

Inhaled medium-acting b-adrenergic agonists are the mainstay of bronchodilator treatment for asthma. These agents relax airway smooth muscle, which is constricted as a result of stimuli in the asthmatic microenvironment. b-Adrenergic agents with varying degrees of b_2 selectivity are available for use in inhaled (by metered-dose inhaler or nebulizer), oral, or parental preparations. b-Adrenergic agents, with selective b_2 action are also available in medium-duration and long-duration formulations (Table 5).

Short acting (onset less than 5 min; duration 2–3 hr)
Epinephrine—α and β agonist, not β_2 selective
Isoproterenol—nonselective β agonist
Medium acting (all are β_2 selective; onset 10–15 min; duration 4–6 hr)
Albuterol
Bitolterol
Isoetharine
Metaproterenol
Pirbuterol
Terburtaline
Long acting (onset 1–2 hr; duration 10–14 hr)
Salmeterol

[a] As of June 1, 1995.

TABLE 5. *Inhaled b-agonist for asthma treatment available in the United States*[a]

Because these agents are commonly administered by metered-dose inhaler, it is worthwhile to review the steps required for appropriate use of a metered-dose inhaler. Patients should be instructed to exhale to a comfortable volume in the expiratory reserve volume, to breathe in slowly (approximately 0.5 L/sec), to actuate the inhaler as they inspire, then to complete a slow inspiration to near total lung capacity and hold their breath for 5 sec. Because most individuals have a vital capacity of several liters, this will mean that the inspiratory effort should take 3 to 6 sec; inhaling too rapidly is a common mistake, and care should be taken to ensure that patients inspire slowly. Patients need to have specific instruction in inhaler use and should be asked to demonstrate their technique. Particular attention should be paid to female patients who historically do not use their inhalers as well as male patients. Patients who have difficulty coordinating the onset of inspiration with firing the metered-dose inhaler should be given aerosol “spacers” available from many manufacturers.

The “best” use for long-acting b-agonists has not been established. One use, which is well accepted, is to provide overnight bronchodilation for individuals with nocturnal asthma symptoms. Patients need to be specifically instructed not to use these agents for the relief of acute bronchospasm.

Theophylline

Theophylline and aminophylline are bronchodilators of moderate potency with a long history of use in asthma. The mechanism by which they exert their effect has not been established with great certainty, but it is likely related to the inhibition of certain forms of phosphodiesterase. One of the major difficulties with using theophylline is its relatively low therapeutic-to-toxic ratio because of substantial variations in the rate of its metabolism both in a single individual over time and among individuals in a population. Because of this variability, monitoring of plasma theophylline levels is indicated so that patients who are taking theophylline get adequate medication to achieve a bronchodilator response without excess risk of toxicity. Acceptable plasma levels for therapeutic effects are between 10 and 20 µg/mL; higher levels are associated with gastrointestinal, cardiac, and central nervous system toxicity, including symptoms such as headache, nausea, vomiting, diarrhea, cardiac arrhythmias, and seizures. Because catastrophic complications may occur without any mild adverse effects when plasma levels exceed 20 µg/mL, careful monitoring of plasma level is very important. Indeed, many physicians aim for a steady therapeutic level of 10 to 12 µg/mL, which allows for a decrease in the rate of metabolism without toxicity but does not maximize the therapeutic benefits of theophylline.

Theophylline comes in a variety of preparations, including a number of oral preparations that can be taken only twice a day and preparations for intravenous use. The prior practice of using rectal theophylline suppositories to treat nocturnal asthma has been superseded by longer-acting oral preparations of theophylline as well as

longer-acting b-adrenergic bronchodilators.

Systemic and Inhaled Corticosteroids

Corticosteroids are a widely used and effective treatment for moderate to severe asthma. Although they are effective, their mechanism(s) of action in asthma has not been established but appears to be linked to their ability to inhibit a wide variety of inflammatory processes. Indeed, it may be that the multiple potential mechanisms of steroid therapy account for their effectiveness in many patients with asthma. Despite the effectiveness of steroids during therapy, the disease will usually exacerbate again when treatment is stopped.

There is no consensus on the specific type, dose, or duration of corticosteroids to be used in the treatment of asthma. In nonhospitalized patients with asthma that is not responding to standard treatment, a steroid “pulse” with initial doses of prednisone on the order of 40 to 60 mg/day is indicated. This dose is tapered to zero over the ensuing 1 to 2 weeks. If the patient's asthma reexacerbates during this period, the dose is increased, and the process is restarted. In the occasional rare patient whose asthma is so severe as to require continuous treatment with steroids, it is far superior to find a regimen of treatment on an every-other-day rather than every-day basis, as such alternate-day treatment tends to diminish many of the severe adverse effects of oral steroid therapy.

For patients whose asthma requires in-hospital treatment but is not considered life-threatening, methylprednisolone, 20 mg given every 6 hrs, will have a therapeutic effect observable within the first 12 to 18 hrs. In attacks of asthma that are considered life-threatening, intravenous methylprednisolone, 125 mg every 6 hrs has been advocated. Although the data touting the superiority of this dosage over the smaller dose have not been established through clinical trials, clinical experience suggests that it is effective. In each case, as the patient improves, oral therapy is substituted for intravenous therapy, and the oral dose is tapered over 1 to 3 weeks, with inhaled corticosteroids added to the regimen while oral steroids are being tapered.

Inhaled corticosteroids, which have many fewer systemic adverse effects than oral corticosteroids for a given level of therapeutic effect, are important therapeutic agents in asthma. A large number of clinical trials indicate that inhaled steroids are effective asthma therapy. With the steroids available for asthma treatment in the United States, dosage begins with four “puffs” a day. If the patient fails to respond, the steroid dose may be increased up to 1.5–2.0 mg/day. Although inhaled steroids at the lower doses are highly likely to be safe for long-term asthma therapy, the safety of long-term treatment with high-dose inhaled steroids has not been well established. The major adverse effect of inhaled steroids is oral thrush, which can be prevented by good oral hygiene and the use of aerosol spacers. On the basis of the relative risks of oral and inhaled steroid therapy, there is no question that inhaled steroid therapy is far safer.

Other Nonbronchodilator Antiasthma Drugs

Disodium chromoglycate and nedocromyl sodium are agents whose specific mechanism of action is not yet established. Both are used in the prophylaxis rather than in the acute treatment of asthma. Indeed, both of these agents are most useful when identifiable stimuli such as exercise or allergen exposure can be shown to elicit an asthmatic response; they tend to be more useful in pediatric than in adult populations.

Cyclosporine or methotrexate has been shown in research studies to be useful as adjunct therapy for patients with severe chronic asthma who cannot otherwise discontinue treatment with oral corticosteroids. The use of these agents in asthma is still experimental and should be confined to the asthma specialist with experience in their use.

Receptor Antagonists

Antihistamines

H_1 receptor antagonists such as astenizole, ceterazine, loratidine, and terfenidine have been shown to have a measurable, but not marked, effect on asthma symptoms. These agents are not used in the treatment of asthma directly but are generally reserved for patients with concomitant allergic diathesis.

Anticholinergics

Although atropine can be shown to have a bronchodilator effect in patients with mild to moderate asthma, it is not as effective as a b-adrenergic bronchodilator. The availability of ipratropium bromide by metered-dose inhaler, provides an alternative asthma therapy for those individuals who find b-adrenergic adverse effects intolerable.

Agents Active on the 5-LO Pathway

Agents (montelukast, pranlukast, and zafirlukast) have been developed that can inhibit the action of cysteinyl leukotrienes at their receptor ($CysLT_1$ receptor) or can prevent the synthesis of leukotrienes (zilestun). Studies in patients with chronic stable asthma show that treatment with these agents results in persistent bronchodilation, reduced asthma symptoms, reduced medication use, reduced awakenings from sleep at night, and diminished need for prednisone rescue therapy. Because they have just recently become available by prescription, specific roles in asthma treatment has not been codified; their use is advocated for the treatment of chronic persistent asthma.

SPECIFIC TREATMENT SCENARIOS

These treatment guidelines have been adapted from the National Asthma Education Program and from the Global Initiative on Asthma. They represent a broad overview of the detailed guidelines, which can be found in the specific source documents available from the United States National Institutes of Health or from the World Health Organization.

Management of Mild Intermittent Asthma

Most patients with asthma have mild asthma and require only intermittent therapy. These are patients who usually have up to twice-weekly episodes of dyspnea, cough, and wheezing. They tend to be asymptomatic between exacerbations but may develop symptoms with strenuous physical activity. They are awakened from their sleep less than twice a month by asthmatic symptoms. Such individuals usually have FEV_1 values or peak flow values greater than 80% of predicted when they are asymptomatic; when they are symptomatic, these flow rates may fall. The treatment for these people is one or two puffs of an inhaled b agonist by metered-dose inhaler before participation in events known to precipitate asthma or when asthmatic symptoms have been precipitated. Patients should be instructed to monitor peak flow rates during such attacks to ensure that they return to normal with inhaled agonist use.

Current data indicate that patients with very mild symptoms should be treated with inhaled b-agonists on an “as needed” only basis. If symptoms occur intermittently and lung function can be normalized with intermittent b-agonist this treatment is adequate. Indeed, if asthma can be controlled totally (symptoms and flow rates) by use of a single 200-actuation b-adrenergic agonist each month no additional treatment is warranted.

Management of Mild to Moderate Persistent Asthma

Patients with mild to moderate persistent asthma have symptoms more than twice a week that usually affect their ability to sleep through the night. Patients can perform the more sedentary activities of daily life but are often limited by asthma symptoms in activities requiring higher levels of exertion. These patients have asthma exacerbations that last 2 to 3 days and need to seek emergency care on occasion. Most important, patients in this category will have FEV_1 values of 60% to 80% of predicted when they are only mildly symptomatic and substantially greater decrements in airflow when they are more symptomatic. Primary treatment for this group of individuals should consist of either inhaled corticosteroids or antileukotriene. The starting dose should be that recommended by the package insert for the product to be used. The dose of inhaled steroids may be increased or anti-leukotriene and inhaled steroid therapy combined until the patient has asthma symptoms and lung function more characteristic of mild than of moderate disease. Patients should be instructed to use their b-agonist inhalers on an as-needed basis. If asthma cannot be controlled through the use of inhaled steroids and b-agonists, additional therapy including sustained-release theophylline, or oral b-agonists should be added. Specific evidence based on treatment guidelines indicating which of these agents is most effective have not been drafted, and it is currently a matter of choice for patients and their physicians.

Severe Persistent Asthma

Patients with severe persistent asthma have continuous symptoms; the activities of daily life are always limited by their asthma. These individuals often have difficulty sleeping through the night and have exacerbations with even very mild exercise. Lung function monitoring shows FEV_1 or peak flow values less than 60% of predicted but varying widely depending on the patient's activity and exposure. In addition to the medications used for chronic moderate asthma, oral corticosteroids are often required daily or every other day. Here the goal of treatment is to reduce the patient's asthma severity to that of chronic moderate asthma.

The guidelines given above are for adult patients, and pediatric guidelines are different; the interested reader is referred to source documents for specific treatment scenarios.

Asthma in the Emergency Room

When a patient with asthma presents for acute emergency care, objective measures of the severity of the asthma attack must be obtained, including measurements of airflow such as the peak expiratory flow rate or FEV_1. If this rate is less than 40% of predicted, but the attack does not appear to be life-threatening, inhaled b-agonists (such as albuterol given by nebulizer 2.5 mg every 20 min) should be used. If there fails to be an objective response (FEV_1 or peak flow) to treatment within 60 min, intravenous steroids (40 to 60 mg of methylprednisolone) should be administered. Inhaled treatment should continue at 20- to 30-min intervals until the peak flow rate or FEV_1 rises to more than 50% of predicted values. If this point is not reached within 2 hrs, admission to the hospital for further treatment is strongly advocated.

For the patient who has peak expiratory flow rates and FEV_1 values greater than 60% of predicted on admission to the emergency room, treatment with inhaled b-agonists alone is likely to achieve a salutary therapeutic response. Again, this should be documented by an objective improvement in airflow rates. If significant improvement takes place in the emergency room, these patients can usually be treated as outpatients and given inhaled b-agonists plus inhaled corticosteroids. The dose of inhaled steroids should depend on the severity of the attack and the rapidity of response to treatment; common recommended doses are 200 to 400 µg twice a day for at least 2 weeks following the acute attack. In those patients whose asthma is intermediate in severity between the two scenarios given above, the treatment plan should be intermediate in complexity and duration.

Acute Severe Asthma

The patient with asthma whose FEV_1 or peak flow does not increase to greater than 40% of the predicted value with treatment, whose $PaCO_2$ is within the normal range in the presence of severe airflow obstruction, or who develops life-threatening complications such as pneumothorax or pneumomediastinum should be admitted to the hospital in a setting where they can be closely monitored. These patients should be given frequent treatment with inhaled b-agonists, intravenous amyinophylline at doses yielding maximum safe plasma levels (i.e., 15 to 20 µg/mL), and high-dose intravenous steroids. Oxygen should be titrated to achieve S_pO_2 values between 92% and 94%; higher levels promote absorption atelectasis, which may be detrimental. A search for specific objective evidence for bacterial infection should be made, and appropriate treatment administered only if clear evidence is found. If the patient fails to respond despite intensive inhaled therapy, it may be necessary to institute endotracheal intubation and mechanical ventilation. Remember that asthma is a difficulty of expiratory airflow, and ventilators provide only inspiratory assistance. Because it is quite easy to achieve a state of chronic pulmonary overdistention in the process of mechanical ventilation, one should administer mechanical ventilation just adequate to sustain life and not to normalize arterial blood gases. For example, a PCO_2 of 50 to 70 torr is acceptable in a patient with status asthmaticus; this approach is known as “permissive hypercapnia.” Indeed, in these individuals it is quite often necessary to institute heavy sedation or in extreme cases pharmacologic muscle paralysis to achieve the appropriate stage of relaxation to permit mechanical ventilation.

---

[1] Other activation mechanisms such as neural or physical activation of mast cells could initiate the secretion of IL-4, which subsequently could aid in the recruitment of lymphocytes through alteration in the expression of cellular adhesion structures. The details of such mechanisms have not been elucidated.

CHAPTER

41 Bronchiectasis

Thomas O'Riordan · Adam Wanner

T. O'Riordan and A. Wanner: Division of Pulmonary/Critical Care Medicine, University of Miami, Florida 33101.

INTRODUCTION

Bronchiectasis is defined as a permanent dilatation of those airways that have a normal diameter of >2 mm. Bronchial dilatation frequently occurs in association with acute pneumonias and with some types of atelectasis, but in these cases the dilatation resolves (90% within 3 months). Bronchiectasis can be localized or generalized, and within an individual segment, the severity of disease affecting individual subsegments may vary widely. Rather than being a single disease process, bronchiectasis is best regarded as the end result of a number of different pathologic processes. Infection is implicated in the majority of cases, and defects in local and systemic host responses can be present.

Postinflammatory bronchiectasis continues to be a common problem in developing countries, but in developed countries the reduction in frequency and duration of childhood pneumonia, through vaccination and antibiotics, has dramatically reduced the incidence of focal bronchiectasis. Cystic fibrosis is now the most common cause of fatal generalized bronchiectasis in Europe and North America. For patients with established bronchiectasis, regardless of etiology, antibiotics have significantly altered prognosis and life expectancy.

PATHOLOGY AND PATHOPHYSIOLOGY

In addition to the pathognomonic remodeling of the airways that characterizes bronchiectasis, there are, in the majority of cases, two associated pathologic developments that may account for the major clinical features of the disease. First, an anatomic and functional derangement of the mucociliary apparatus causes a self-perpetuating cycle of infection and inflammation. Second, marked hypertrophy of the bronchial circulation may be associated with the development of systemic-pulmonary shunts that impair gas exchange and are prone to rupture, with consequent life-threatening hemorrhage.

Remodeling of the Airway

A condition resembling bronchiectasis occurs in association with most cases of acute bacterial pneumonia wherein the airways dilate as the surrounding airless tissue retracts. This dilatation of the airways is temporary and in the majority of cases resolves within 3 months. True bronchiectasis, on the other hand, is generally a permanent condition. The remodeling of the airways was classified by Reid into grades of increasing severity that correlate with the severity of bronchographic abnormality (Fig. 1):

FIG. 1. A: Bronchogram showing normal anatomy of right lung and cylindrical bronchiectasis (left lung). **B:** Saccular bronchiectasis of right lung. (Reproduced courtesy of Manuel Viamonte, M.D., Department of Radiology, Mount Sinai Medical Center, Miami Beach, Florida.)

Grade 1. Cylindrical bronchiectasis: uniform dilatations that end abruptly (Fig. 1A and Fig. 2A)

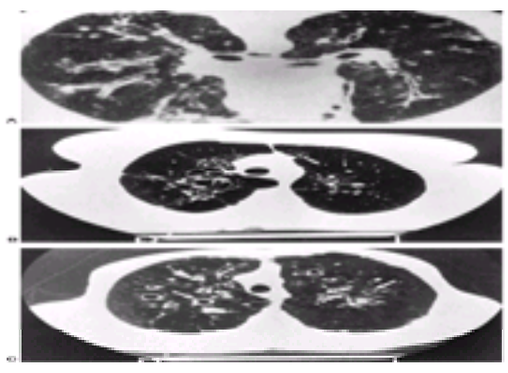

FIG. 2. CT demonstrating cylindrical bronchiectasis with thickened bronchial walls (“tram lines”) in a patient with cystic fibrosis. **B:** Proximal varicose and cystic bronchiectasis in a patient with ABPA. **C:** Two examples of a “signet ring” sign. (Reproduced with permission from Hansell and Strickland. High-resolution computed tomography in pulmonary cystic fibrosis. *Br J Radiol* 1989;62:1–5.)

Grade 2. Varicose bronchiectasis: dilatations that have an irregular contour (Fig. 2B)

Grade 3. Saccular or cystic bronchiectasis: dilated segments that are pus-filled cavities, with destruction of the distal airways (Fig. 1B and Fig. 2B)

The pathophysiology of bronchial dilatation is not understood, but several mechanisms are believed to be involved. The wall of the bronchus becomes weakened with loss of its muscular and elastic elements. The catalyst for this weakening appears to be related either to infection or the host response to infection (inflammation). In most cases, there appears to be a factor that prolongs either the infection or the inflammatory process. For example, regional clearance of infected secretions can be inhibited by an obstructing lesion. Alternatively, the cilia may be abnormal (e.g., primary ciliary dyskinesia) or the secretions may be abnormal (e.g., cystic fibrosis). Immune deficiency can impair the ability to kill micro-organisms and thus prolong the infective process. In contrast, tuberculosis is a chronic condition that in an immunocompetent host can provoke an intense local inflammatory response that can impair airway integrity. The inflammatory products produced by micro-organisms and host defenses include proteases, collagenases, and free radicals. All these substances are capable of impairing the integrity of the airway wall. Further, many inflammatory mediators may impair local mucociliary clearance by inhibiting ciliary beating and altering the composition of secretions. Impaired mucociliary clearance prolongs and aggravates local inflammatory processes. With the progression of bronchiectasis and the attendant loss of airway wall muscle mass and elasticity, medium-sized bronchi (>2 mm in diameter) dilate because of the elastic recoil of surrounding lung.

In addition to weakening of the airway wall, three other mechanisms may contribute to airway distention. First, loss of volume in adjoining lung parenchyma, caused by both impaction with secretions and inflammatory bronchiolar obliteration, may contribute to increased elastic recoil. Second, scarring that may develop in the parenchyma surrounding the airways may contribute to a further increase in elastic recoil pressures. Third, local obstruction may give rise to a mucocele that distends the airway. However, provided the mucus does not become infected, this is reversible.

Mucociliary Dysfunction

Most patients with bronchiectasis have a productive cough. Their sputum is commonly both purulent and copious. Examination of the lungs at necroscopy or at open lung biopsy reveals dilatation and hypertrophy of the bronchial glands. Goblet cell metaplasia of bronchiolar epithelium develops. (Goblet cells are found only in the central airways in normal subjects.) Squamous metaplasia is frequently seen.

Studies in which the clearance of radiolabeled airway mucus was used as an index of tracheobronchial mucociliary function have found that clearance is reduced in patients with bronchiectasis compared with normal volunteers. Several factors are likely to cause the mucociliary impairment that occurs in bronchiectatic airways. The frequency of the ciliary beat, and the composition and rheologic features of lower airway secretions, can be affected by bacterial products or by the host response to infection, especially the response of neutrophils, which are the predominant cell type found in bronchiectatic sputum. Neutrophil elastase, which is present in increased amounts, has been reported to inhibit ciliary function in vitro and is also a potent secretagogue and chemotactic agent. Bacterial and inflammatory cell products may also have a detrimental effect on the mucociliary apparatus. Soluble bacterial and leukocyte products disrupt mucociliary interaction and clearance. For example, in an isolated human nasal cilia preparation, investigators have found that supernatants obtained from *Pseudomonas aeruginosa* and *Haemophilus influenzae* cause a decrease in the frequency of the ciliary beat. Animal data suggest that bacterial products, such as pyocyanin and 1-hydroxyphenazine, inhibit mucociliary function by activating phagocytes and other cells and releasing reactive oxygen species. Furthermore, mucosal biopsy specimens taken from the airways of patients with purulent respiratory infection have revealed impaired ciliary beating in vitro, with a return of ciliary function to normal after antibiotic therapy. Recurrent episodes of bacterial pneumonia can also induce secretory changes in the airways that are characterized by an increase in the quantity and a change in the glycoprotein content of mucus and augmented ion secretion.

Remodeling of the Vasculature

The bronchial circulation is part of the systemic circulation and supplies the bronchi. The pulmonary circulation supplies the lung parenchyma, and anastomoses between the two circulations account for a small physiologic (1%) shunt. However, in bronchiectasis, the bronchial vessels become hypertrophied and flow increases through both existing and newly formed anastomoses (Fig. 3). At the same time that flow through the bronchial circulation is increasing, flow through the pulmonary circulation is decreasing as a response to alveolar hypoxia. The reduction in pulmonary vascular cross-section and the equilibration of pulmonary and systemic pressures have been implicated in the development of right ventricular overload and cor pulmonale. The tortuous, hypertrophied bronchial vessels are prone to hemorrhage, especially in the setting of acute exacerbations of bronchial infection, and hemorrhage is a frequent occurrence in advanced bronchiectasis.

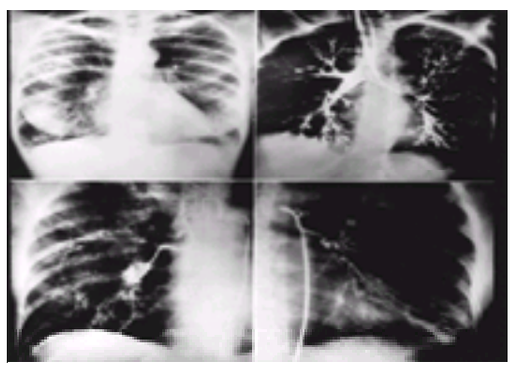

FIG. 3. Plain chest radiograph showing right-sided infiltrate (*upper left panel*) and bronchiectasis confirmed by bronchography (*upper right panel*) in a patient presenting with severe hemoptysis. Bronchial angiography (*lower panels*) demonstrates bilateral tortuous and hypertrophied bronchial circulation, significantly more severe in the right lung, suggesting that this was the source of hemorrhage. (Reproduced courtesy of Manuel Viamonte, M.D., Department of Radiology, Mount Sinai Medical Center, Miami Beach, Florida.)

Anatomic Distribution of Bronchiectasis

In a series of 3000 patients with bronchiectasis reported from South Africa (which excluded patients with prior tuberculosis), the anatomic distribution of bronchiectasis was, in order of decreasing frequency, as follows: (1) left lower lobe, (2) middle lobe, (3) lingula, (4) entire left lung, (5) right lower lobe, and (6) entire right lung. Interestingly, left lower lobe bronchiectasis was twice as common as right lower lobe bronchiectasis, whereas right upper lobe bronchiectasis was four times more common than left upper lobe bronchiectasis (excluding the lingula). Isolated basal segment bronchiectasis was rare but was most common in the right medial basal segment.

The reasons for this pattern of distribution are speculative and may relate in part to relative risks for aspiration and the role of gravity in clearing aspirated material or excessive secretions. In the erect position, the right medial basal segment is the most likely site for deposition of aspirated material. During sleep, in either lateral position, the right upper lobe and the lingula are the most likely repositories for aspirate. In the supine position, the apical segments of the lower lobes are the most likely sites.

When pneumonia develops, there is a tendency for the lung parenchyma to shrink, with consequent distortion of the bronchi. In some cases, this distortion may facilitate clearance by gravity (e.g., left upper lobe), but in others, the distortion may make clearance more difficult (left lower lobe). Additional factors in the various bronchi can predispose to the development of bronchiectasis. For example, the right middle lobe bronchus is not only long and narrow, but also susceptible to compression by lymph modes at its orifice. Although the left main bronchus is less likely to be a receptacle for aspirated material than the right, its angulation, greater length, and smaller diameter may make clearance of aspirated material more difficult.

In contrast to nontubercular postinflammatory bronchiectasis, posttubercular bronchiectasis predominantly involves the upper lobes (Fig. 4). Allergic bronchopulmonary aspergillosis (ABPA) tends to affect the central airways of the upper lobes. Cystic fibrosis usually causes generalized bronchiectasis, but the upper lobes tend to be more severely affected.

FIG. 4. Bronchiectasis and fibrosis of upper lobes. The most common cause of bilateral upper lobe bronchiectasis is tuberculosis. (Reproduced courtesy of Manuel Viamonte, M.D., Department of Radiology, Mount Sinai Medical Center, Miami Beach, Florida.)

CONDITIONS ASSOCIATED WITH BRONCHIECTASIS

Bronchial Obstruction

Bronchial obstruction can be caused by intraluminal, intramural, or extramural factors. Obstruction by an aspirated foreign body or a benign tumor has been described as a cause of bronchiectasis. Malignant tumors of the lung are not a common cause of bronchiectasis, probably because of the relatively short duration of the obstruction. Other causes include bronchial stricture resulting from prior tuberculosis and extrinsic compression of the right middle lobe bronchus by lymphadenopathy.

Childhood Pneumonia

The incidence of childhood infections, especially measles and pertussis, has been dramatically reduced in developed countries by vaccination. These infections can lead to severe pneumonia, complicated by bronchiectasis, in a significant minority of cases. Why bronchiectasis develops in some patients and not others subjected to the same insult is not known. Clearly, shortening the course of a bacterial superinfection with antibiotics may prevent bronchiectasis. Failure to provide antibiotic therapy, together with impairment of host defenses through malnutrition, may be among the reasons why bronchiectasis is more common in regions with poor access to health care. The reporting of clusters of patients with bronchiectasis in areas with a high frequency of intermarriage may suggest a role for genetic impairment of host defenses. Finally, others have speculated that cofactors may be involved in the development of bronchiectasis in certain settings. For example, it has been suggested that coinfection with herpesvirus or adenovirus may predispose to bronchiectasis in children with rubeola pneumonia.

Antibiotic therapy has reduced the incidence and duration of complicated pneumonia induced by necrotizing organisms such as *Staphylococcus aureus* and *Klebsiella,* with a concomitant reduction in postinflammatory bronchiectasis.

Aspiration and Inhalation of Irritants

A severe chemical pneumonia resulting from aspiration, with or without bacterial superinfection, can cause bronchiectasis, most frequently in the dependent segments of the lung. A similar syndrome has been described in patients who have been exposed to certain toxic fumes (e.g., ammonia). Although chronic microaspiration can cause asthma, it has not been established that this condition causes bronchiectasis. Aspiration of a foreign body should always be considered in the differential diagnosis of localized bronchiectasis.

Tuberculosis and Other Granulomatous Infections

Tuberculosis, active or inactive, is a common cause of bronchiectasis, typically in the upper lobes (Fig. 4). It is frequently described as being a “dry” bronchiectasis, because sputum may be produced only during acute infective exacerbations. Hemoptysis is frequent and thought to be related to infection in many instances. When a patient with a radiograph suggestive of previous tuberculosis presents with hemoptysis, the differential diagnosis includes reactivation of tuberculosis, exacerbation of bronchiectasis with aerobic bacteria or atypical mycobacteria, mycetoma, broncholith, and scar carcinoma.

Identical presentations can occur with other granulomatous infections, including those caused by fungi (histoplasmosis, coccidioidomycosis) and *Nocardia.* Atypical mycobacteria can colonize existing areas of bronchiectasis. Whereas these organisms used to be thought of as innocent commensals, it has recently become apparent that they can play a pathogenic role and also perpetuate the bronchiectatic process.

Cystic Fibrosis

In developed countries, cystic fibrosis is now the most common cause of generalized fatal bronchiectasis. Cystic fibrosis is associated with a defect in the cystic fibrosis transmembrane receptor (CFTR) gene, which is transmitted by a mendelian recessive mode of inheritance. However, although specific genetic defects have been identified, the mechanism by which these genetic defects lead to clinical disease remains a matter of speculation. This gene codes for a chloride channel that is present on a wide variety of cells. In the airway, this defect leads to decreased chloride secretion into the lumen and increased sodium and water reabsorption from the lumen. A similar defect in chloride secretion may lead to impaired acidification of glycoprotein in the Golgi apparatus of glandular mucous cells. These abnormalities may result in the production of dehydrated mucus that is suboptimally cleared and prone to bacterial colonization and infection.

The morphology of the lungs in cystic fibrosis is normal at birth. Recent studies, however, show that even when lung function is still normal, marked inflammation may be present in the airways of infants. The earliest pathologic lesions are dilatation and hypertrophy of the bronchial glands and goblet cell metaplasia of bronchiolar epithelium. The ensuing recurrent infections of airway mucus are thought to be responsible for the development of progressive bronchiectasis. The earliest infections are usually caused by *S. aureus,* but eventually the airways become permanently colonized by various strains of *P. aeruginosa.*

Radioaerosol studies show impairment of mucociliary clearance in patients with cystic fibrosis. Rheologic studies of the sputum reveal increased viscosity. The

predominant cell in the sputum of patients with cystic fibrosis is the neutrophil, and neutrophil elastase is present in increased amounts. Elastase inhibits ciliary function and is a potent secretagogue. Some of the mucociliary impairment in cystic fibrosis is caused by bacterial products that impair ciliary function and change the volume and composition of secretions. If the condition is suspected, a sweat test should be performed. The radiologic features of cystic fibrosis (Fig. 2A) are similar to those of other types of severe bronchiectasis. However, upper lobe predominance can be seen, and the lungs in early disease show radiologic features, and evidence on pulmonary function testing of hyperinflation.

Primary Ciliary Dyskinesia

The cilia of normal respiratory epithelial cells are approximately 6 µm in length and beat at 10 to 15 Hz, with a fast forward stroke and a slower recovery stroke. Their internal structure consists of nine pairs of microtubules surrounding two central tubules. Dynein, a protein with adenosine triphosphatase activity, mediates the sliding of ciliary tubules that causes ciliary bending. Ciliary dysfunction can be a primary defect or it can be secondary to the effects of inflammation, infection, or toxins. In the primary ciliary dyskinesia syndrome, characteristic ciliary defects have been noted that are believed to result in impaired clearance of mucus by ciliated epithelia and the development of bronchiectasis, sinusitis, and otitis media. In addition, male infertility occurs as a consequence of sperm tail immotility; sperm tails contain the same microtubules as cilia. The most common defect in ciliary structure is the absence of the outer dynein arms of the cilia. Approximately 20 other abnormalities of ciliary structure have been described, and these appear to produce identical clinical presentations. The condition occurs worldwide, with a prevalence of 1/20,000 in Europe and North America. The syndrome has been found to cluster in remote populations with a tendency to inbreed. It is thought to be transmitted by a mendelian recessive mode of inheritance.

Dextrocardia or situs inversus (Fig. 5) is associated with the dyskinesia in 50% of cases. The combination of bronchiectasis, sinusitis, and situs inversus is called *Kartagener's syndrome.* There is an infrequent association with congenital heart disease.

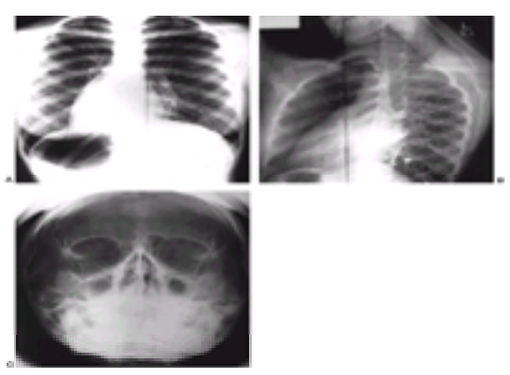

FIG. 5. Primary ciliary dyskinesia in a female patient with situs inversus, bronchiectasis, and sinusitis. **A:** Plain radiograph shows that the cardiac silhouette and stomach bubble are on the right side. An infiltrate silhouettes the left border of the heart. **B:** Bronchogram of left lung confirms bronchiectasis. **C:** Sinus radiograph is consistent with sinusitis. (Reproduced courtesy of Manuel Viamonte, M.D., Department of Radiology, Mount Sinai Medical Center, Miami Beach, Florida.)

Mucociliary clearance is markedly reduced in these patients, and clearance of mucus from the airway is primarily mediated by cough. Primary ciliary dyskinesia is associated with much slower rates of mucociliary clearance than is cystic fibrosis. Nevertheless, patients with primary ciliary dyskinesia, on average, have less severe pulmonary disease than patients with cystic fibrosis.

Young's Syndrome

Young's syndrome is characterized by bronchiectasis, sinusitis, and obstructive azoospermia. The latter affects the tail rather than the head of the epididymis. The converse is the case with obstruction caused by sexually transmitted infection. There is no association with dextrocardia or situs inversus. Radioaerosol mucociliary clearance is markedly impaired. Although the syndrome mimics primary ciliary dyskinesia, the cilia reveal no structural abnormality. The condition has been most frequently reported in the United Kingdom, France, and Australia; it has not been reported in the United States. It has been suggested that the condition may be a sequela of childhood mercury poisoning from teething powders, a suggestion based on epidemiologic data regarding mercury poisoning in the United Kingdom. Mercury-containing teething powders were banned the United Kingdom in 1955, and the incidence of acute mercury poisoning, and apparently of Young's syndrome, subsequently decreased.

Allergic Bronchopulmonary Aspergillosis

The clinical syndrome of ABPA is presumed to be caused by an intense inflammatory response to the presence of noninvasive *Aspergillus fumigatus* in the airways. Similar syndromes have been described much less frequently with other fungal species. The lung parenchyma surrounding the involved bronchi may demonstrate patchy areas of eosinophilic pneumonia. The condition has a predilection for segmental and subsegmental bronchi, the lumina of which may become occluded with inspissated mucus, with resultant segmental atelectasis that gives rise to the distinctive radiologic abnormalities of this condition.

Acute clinical exacerbations of the syndrome are characterized by chest radiographic infiltrates, asthmatic symptoms, peripheral blood eosinophilia (>1000/mm^3), very high levels of serum IgE (>1000 ng/mL), immediate cutaneous hypersensitivity to *Aspergillus* antigen, the presence of fungal elements in sputum, and proximal bronchiectasis (Fig. 2B). The bronchiectasis may progress, if untreated, to respiratory failure and cor pulmonale.

Diffuse bronchospasm frequently but not invariably accompanies acute exacerbations. The asthmatic symptomatology may be of new onset or predate the development of ABPA. However, the asthmatic symptoms usually worsen with the onset of ABPA. In some patients, a form of chronic, glucocorticosteroid-dependent asthma can develop.

Between exacerbations, the radiographic infiltrates resolve and the peripheral blood eosinophilia and serum IgE levels decrease. IgE levels may be the most clinically useful indicator of disease activity. ABPA responds readily to large doses of systemic glucocorticosteroids, but relapse is common once steroids have been discontinued.

Immunoglobulin Deficiency

Immune deficiency syndromes are discussed in detail in Chapter 53. IgA deficiency is common (1/500 individuals) but rarely associated with significant pulmonary disease. However, if a deficiency of IgA is associated with a deficiency of an IgG subclass, sinopulmonary infection, including bronchiectasis, may occur. Immunoglobulins of the IgG2 subclass are involved in opsonization and phagocytosis of encapsulated organisms, such as *Streptococcus pneumoniae* and *H. influenzae.* Deficiency of an IgG subclass can also occur in the presence of normal IgA levels. If total IgG levels are within normal range in the presence of severe infection, when elevated levels would be expected, deficiency of an IgG subclass should be suspected.

The relatives of patients with IgA deficiency have an increased incidence of a much rarer and more serious condition, called *common variable immune deficiency,* that is characterized by a deficiency of all major immunoglobulins. Because the same major histocompatibility complex (MHC) haplotypes are involved in both IgA deficiency and common variable immune deficiency, it has been suggested that these two conditions may represent extremes of the same spectrum of disease. In addition to recurrent, severe bacterial infection and chronic sinopulmonary disease, fever and lymphadenopathy may be presenting manifestations of common variable immune deficiency.

Secondary immunoglobulin deficiency, which can lead to a predisposition to severe pulmonary infection, can be the initial manifestation of lymphoma and multiple myeloma. Bronchiectasis may develop if the course of the underlying disease is prolonged.

Human Immunodeficiency Viral Infection

There have recently been a series of reports of bronchiectasis in patients with acquired immunodeficiency syndrome (AIDS). Most of these patients had advanced

disease and low $CD4^+$-lymphocyte counts. Bronchorrhea was a frequent finding, and the diagnosis was made by computed tomography (CT).

a_1-Protease Inhibitor Deficiency

a_1-Protease inhibitor deficiency is the the second most common fatal inherited lung disease, after cystic fibrosis. In a_1-protease inhibitor deficiency, which is inherited by a mendelian recessive mechanism, the hepatic synthesis and/or secretion of a_1-protease inhibitor is impaired. Although the typical clinical manifestation is emphysema, a significant minority of patients have coexisting bronchitis and bronchiectasis. Smoking may be a predisposing factor for bronchiectasis in this population, as may be a history of childhood respiratory tract infection. Experimental data may provide a rational basis for the development of bronchiectasis. Elastase, which is inhibited by a_1-protease inhibitor, is a potent secretagogue and may also have a role in the impairment of mucociliary transport. Replacement of a_1-protease inhibitor is indicated for certain patients with emphysema, but bronchiectasis is not an approved indication for replacement therapy at the present time.

Yellow Nail Syndrome

Yellow nail syndrome is characterized by yellow discoloration of the nails and lymphedema, most likely caused by lymphatic hypoplasia. Although the most prominent pulmonary manifestation of the syndrome is recurrent pleural effusion, associations with bronchiectasis and chronic sinusitis have been reported.

Rheumatoid Disease

Rheumatoid disease is associated with pulmonary fibrosis, pulmonary nodules, pleural effusion, Kaplan's syndrome (severe fibrosis in rheumatoid patients who worked as coal miners), and bronchiectasis. There is an association between rheumatoid arthritis and bronchiectasis, but the histocompatibility leukocyte antigen (HLA) associations are different from the HLA markers associated with other types of rheumatoid-associated lung disease. The cause of the association is not known. See Chapter 53.

Structural Abnormalities of the Tracheobronchial Tree

In Macleod's syndrome (unilateral hyperlucent lung), hypoplasia of the pulmonary arterial branches leads to hypoperfusion, hyperaeration, and hypoventilation of the involved area. Bronchiectasis of central airways that taper abruptly is seen. However, purulent infections are rare. This condition can develop at any age and the etiology is unknown.

Bronchial cartilage deficiency (Williams-Campbell syndrome) is a rare congenital condition that leads to expiratory collapse of airways. Bronchiectasis develops in most cases. Symptoms usually begin in infancy.

Mounier-Kuhn syndrome is characterized by dilatation of the trachea (diameter 20 mm) and large bronchi, with folds of redundant mucosa and fibromuscular tissues that resemble diverticula. The syndrome is associated with recurrent respiratory tract infections. The cause of the condition is unknown, but it is thought to be most likely of congenital origin.

Bronchopulmonary sequestration is a congenital anomaly in which a portion of the lung is supplied by the systemic circulation alone. The terminal bronchioles do not develop and the proximal airways become dilated. If the sequestered area communicates with the rest of the bronchial tree, bronchiectasis usually develops.

CLINICAL FEATURES

The classic symptom of bronchiectasis is a cough productive of large quantities of mucopurulent sputum, less frequently mucoid sputum (occasionally 200 mL in 24 hrs). However, sputum production is not invariably present or necessary to make the diagnosis. Patients with prior tuberculosis and residual upper lobe bronchiectasis may produce little or no sputum and may exhibit instead intermittent hemoptysis. Chronic bronchitis and bronchiectasis frequently coexist in the same patient, especially in cigarette smokers.

Hemoptysis is a common presentation of bronchiectasis. Usually, small amounts of blood-streaked mucopurulent sputum are expectorated, often heralding the onset of an infective exacerbation. Larger amounts, sometimes resulting from hemorrhage of a bronchopulmonary anastomosis, can be produced in advanced localized or generalized bronchiectasis. Hemoptysis can be chronic and intermittent or occur as a single massive and potentially fatal event.

Pleuritic chest pain is a frequent symptom, especially during exacerbations. Patients may have intermittent wheezing, particularly in ABPA, cystic fibrosis, and IgA deficiency. Dyspnea on mild to moderate exertion occurs with advanced disease.

Symptoms of sinusitis are frequently found in patients with bronchiectasis. There are a number of reasons for this association. First, the ciliated epithelia of the nose and the lung can be affected by the same disease process (e.g., ciliary dyskinesia or cystic fibrosis). Second, the incidence of atopy is increased in certain bronchiectatic populations (cystic fibrosis, ABPA). Third, aspiration of nasopharyngeal secretions can contribute to recurrent or chronic respiratory tract infection, including bronchiectasis.

Patients may offer a history of “recurrent pneumonia,” childhood pneumonia, or tuberculosis, or a family history of cystic fibrosis or other sinopulmonary symptoms. Patients with cystic fibrosis may have symptoms of malabsorption or recurrent cramping abdominal pain.

Physical examination in advanced cases typically reveals cachexia, cyanosis, clubbing, cor pulmonale, and diffuse rales and wheezes on chest examination. Milder cases may have no physical findings. Inspiratory rales may be noted on auscultation of the chest. Primary ciliary dyskinesia may be associated with situs inversus, dextrocardia, and rarely congenital heart disease.

COMPLICATIONS OF BRONCHIECTASIS

The complications of bronchiectasis include recurrent pneumonia, lung abscess, empyema, hemoptysis, pneumothorax, cor pulmonale, and metastatic intracranial infection (cerebral abscess or ventriculitis). Amyloidosis may occur in longstanding, extensive disease.

RADIOLOGIC STUDIES

Plain Chest Radiograph

The plain chest radiographic findings are rarely normal in advanced disease, but the plain chest radiograph is not a reliable screening test in milder cases. The number of bronchial vascular markings may be increased. Parenchymal shrinkage leads to crowding of bronchial markings. Occasionally, the thickened walls of a dilated airway, resembling “tram lines,” can be seen. Advanced end-stage bronchiectasis may reveal honeycombing and cystic changes (Fig. 6). The plain chest radiograph is not reliable in assessing the extent of disease.

Mount Sinai Medical Center, Miami Beach, Florida.)

Bronchography

Until the advent of CT, bronchography was the definitive investigation in cases of suspected bronchiectasis. With the decline in the incidence of bronchiectasis and the advent of CT, the procedure is now rarely performed, except perhaps as a preoperative assessment in candidates for lung resection. Bronchography can be performed either with a fiberoptic or rigid bronchoscope. The procedure is unpleasant—hence the preference by some investigators for general anesthesia. Endobronchial examination is performed to define anatomy and to look for aspirated foreign bodies or other cause of bronchial obstruction. This is followed by aspiration of excess secretions. Generous local anesthesia is required to prevent coughing. Up to 20 mL of an oily contrast material is injected through a catheter advanced over a guide wire placed by fiberoptic bronchoscopy or through a rigid bronchoscope with the patient lying in a lateral position (side to be studied is dependent). Viscous contrast material may cause ventilation-perfusion mismatch, but this is usually transient. An attempt is made to remove the contrast material at the end of the examination. Some investigators then study the contralateral side at the same sitting. Others defer the second examination to another day. Complications are very rare with experienced investigators but include pneumothorax, bronchial rupture, and allergic reaction to the contrast materials.

Computed Tomography

High-resolution CT has in recent years replaced bronchography as the radiologic procedure of choice for the investigation of suspected bronchiectasis. Cylindrical bronchiectasis appears on high-resolution CT as dilated bronchi with thickened walls that extend to the lung periphery; these are sometimes described as resembling “tram lines” (Fig. 2A). On cross-section, the diameter of the bronchus is larger than that of the accompanying branch of the pulmonary artery. (In normal subjects, the diameter of the bronchus and that of the artery should be similar.) On cross-section, the juxtaposition of a dilated bronchus and pulmonary artery is referred to as a “signet ring” (Fig. 2C). In varicose bronchiectasis, the walls of the bronchus show irregular “varicosities” (Fig. 2B). In cystic bronchiectasis (Fig. 2B), the bronchi are grossly dilated and can be thin-walled. Changes on high-resolution CT are specific, but sensitivity varies with the thickness and intervals of cuts. The use of 4-mm contiguous cuts has been recommended. Other authors recommend 1.5-mm cuts at 10-mm intervals.

LABORATORY INVESTIGATIONS

In seeking to determine the cause of localized bronchiectasis confined to the upper lobes, sputum should be induced, stained, and cultured, not just for *Mycobacterium tuberculosis* but also for atypical mycobacteria, *Nocardia,* and fungi. If *Aspergillus* is found in sputum, it may represent saprophytic mycetoma, ABPA, or, if the patient is immunosuppressed, the possibility of invasive disease. The characteristic appearances of a saprophytic fungus ball on chest radiograph or CT should differentiate this entity from ABPA. If ABPA is suspected, serum IgE, eosinophil count in peripheral blood, skin testing with *Aspergillus* antigen, and sputum culture for *Aspergillus* may be indicated.

In patients <50 years of age with unexplained diffuse bronchiectasis or with sputum culture revealing mucoid strains of *P. aeruginosa,* iontophoresis (“sweat test”) is indicated to rule out cystic fibrosis. A sweat chloride level of 60 mEq/L in a child or 80 mEq/L in an adult is highly suggestive of cystic fibrosis.

Serum protein electrophoresis should be considered in patients with unexplained bronchiectasis and in patients with lymphoma or multiple myeloma in whom recurrent respiratory tract infections develop. As discussed earlier, quantification of IgG subclasses may be indicated in some patients.

If primary ciliary dyskinesia is suspected, biopsy of the nasal mucosa and electron microscopic assessment of ciliary morphology are indicated.

Other investigations that are not routinely ordered but that may be indicated in an individual patient include serology for human immunodeficiency virus (HIV) and rheumatoid factor, and a_1-protease inhibitor quantification and phenotyping.

PULMONARY FUNCTION STUDIES

Parameters of pulmonary function may be normal or show a restrictive pattern, an obstructive pattern, or a combination of both. In advanced bronchiectasis, restriction is often the dominant finding. In cystic fibrosis, obstruction and hyperinflation predominate. In early bronchiectasis, obstruction is often partially reversible. Diffusing capacity for carbon monoxide tends to decrease as disease progresses. Results of arterial blood gas analysis should be normal in mild to moderate disease. Respiratory acidosis and hypoxemia develop in the terminal phase of the disease.

Pulmonary function testing may of value in predicting long-term survival. For example, in cystic fibrosis, an FEV_1 (forced expiratory volume in 1 second) value that is 25% of predicted has been reported to herald a 50% mortality within 2 years and constitute an indication for lung transplantation.

FIBEROPTIC BRONCHOSCOPY

Endobronchial examination with a fiberoptic bronchoscope should be considered in cases of localized bronchiectasis. Obstruction by an aspirated foreign body or a benign tumor has been described as a cause of bronchiectasis. Bronchial strictures from prior tuberculosis are an important cause of localized bronchiectasis in some populations. Malignant tumors of the lung are not a common cause of bronchiectasis because of the relatively short duration of the obstruction.

TREATMENT

Antibiotics

Antibiotic therapy is the mainstay of the management of bronchiectasis. Initial therapy should include intermittent antibiotic therapy for infective exacerbations. Empiric therapy should be ideally based on results of previous sputum cultures, even though cultures do not always predict clinical response. Ampicillin/sulbactam or amoxicillin/clavulanate, second- and third-generation cephalosporins, the newer macrolides (azithromycin or clarithromycin), or trimethroprim/sulfamethoxazole will cover most strains of *H. influenzae, S. pneumoniae,* and *Branhamella catarrhalis.* For patients with *Pseudomonas* colonization, the oral quinolones (ciprofloxacin, olfloxacin) permit outpatient therapy. Another outpatient alternative is the use of aerosolized antibiotics; these are of proven efficacy in mild exacerbations of cystic fibrosis, but the data for other types of bronchiectasis are unclear. For the intravenous treatment of *Pseudomonas* bronchiectasis, the ideal regimen is a combination of a broad-spectrum anti-*Pseudomonas* penicillin (e.g., mezlocillin or piperacillin) and an aminoglycoside. The combination is synergistic and may help to prevent the development of drug resistance. Eradication of colonization with *Pseudomonas* may not be possible. Nevertheless, antibiotic therapy has been shown to reduce clinical symptoms and improve pulmonary function.

The use of antibiotics to prevent exacerbations is more controversial. “Rotating” courses of prophylactic oral antibiotics in relatively asymptomatic patients are empirically prescribed by some physicians, although the efficacy of this strategy has not been documented. In patients with severe generalized disease, especially those with cystic fibrosis, who have established chronic infection that cannot be eradicated, long-term administration of oral or aerosolized antibiotics has an established role in diminishing daily symptomatology.

Atypical mycobacteria may require prolonged therapy (several years with combinations of potentially toxic drugs). Therefore, the decision to initiate therapy is not taken lightly. Accepted treatment practices would be to seek out and treat other potential pathogens (*M. tuberculosis,* gram-negative aerobic or anaerobic bacteria) as causes of a patient's symptoms before initiating therapy for atypical mycobacteria, to document the presence of atypical mycobacteria in at least three sputum samples, and to follow objective clinical or radiologic markers of disease progression and response to therapy.

Bronchodilators

In addition to their bronchodilator effects, b-adrenergic agonists and methylxanthines stimulate mucociliary clearance in patients with chronic airways disease. The mechanism of action by which these agents increase mucociliary clearance could include an increase in frequency of the ciliary beat, a change in airway secretion, or both.

Glucocorticosteroids

The role of systemic or inhaled glucocorticosteroids in most forms of bronchiectasis is controversial. Glucocorticosteroids, especially when combined with bronchodilators, may be useful as an adjunct to antimicrobial therapy in patients with partially reversible obstruction of air flow or acute exacerbations.

Systemic glucocorticosteroids are particularly important in the management of bronchiectasis caused by ABPA. A staging system has been proposed to guide treatment: stage 1, acute; 2, remission; 3, exacerbation; 4, corticosteroid-dependent asthma; 5, fibrotic end-stage disease. Stages 1 and 3 require high doses of oral glucocorticosteroids (0.5 mg of prednisone per kilogram daily for at least 2 weeks, followed by the same dose on alternate days for 3 months), whereas stage 4 usually requires lower doses of oral steroids that need to be determined on an individual basis.

Mucolytics and Agents Altering the Composition and Volume of Secretions

The rheologic properties of expectorated sputum in patients with bronchiectasis are often abnormal. Many agents have been evaluated with the intent of optimizing the rheologic properties of lower airway mucus. Unfortunately, most of the agents that exhibit in vitro activity tend to be ineffective in vivo. One reason for the disappointing *in vivo* data may be the lack of objective tests to assess drug efficacy clinically. The ideal test should be able to quantify and define the distribution of secretions in the lower airways before and after drug administration, as the goal of mucolytic therapy is to facilitate ciliary and cough clearance of excessive lower airway secretions. Such a test is currently not available. Therefore, drug effects are evaluated indirectly by sputum volume, mucociliary clearance, pulmonary function, and symptom scores. These yield incomplete, nonspecific, or subjective information.

N-acetylcysteine and *S*-carboxymethylcysteine break disulfide bonds, thereby depolymerizing the glycoconjugate molecule and changing the rheologic properties of sputum, especially by reducing its viscosity. These compounds effectively liquify sputum *in vitro.* Aerosolized *N*-acetylcysteine has been used for more than three decades. Although several authors report that it is an effective mucolytic agent in clinical practice, there are no controlled studies showing that administration of *N*-acetylcysteine improves mucociliary clearance in humans. The clinical usefulness of *N*-acetylcysteine is limited because it can provoke significant bronchospasm in patients with airways disease—a complication that can be prevented by pretreatment with a b-adrenergic agonist. Because of the irritating effects of inhaled *N*-acetylcysteine, oral formulations were developed for long-term maintenance therapy. Their clinical usefulness has been difficult to establish, and studies in bronchitic patients have yielded conflicting results.

Deoxyribonucleic acid (DNA) released from degenerating neutrophils accumulates in the sputum of patients with cystic fibrosis and bronchiectasis. DNA can induce significant changes in the rheologic properties of sputum. Bovine pancreatic DNase was introduced for inhalation 30 years ago but was discontinued because it causes bronchospasm. Recently, human DNase has been manufactured using recombinant DNA technology. In vitro testing of DNase demonstrates a significant reduction in the viscosity of expectorated purulent sputum. The drug appears to be well tolerated compared with inhaled *N*-acetylcysteine. Clinical studies with DNase have revealed symptomatic improvement, as demonstrated by results of questionnaires and a modest improvement in spirometric values that persists for a few weeks after the drug is started. There is as yet no evidence that mucociliary clearance is improved by DNase. Evidence that the number of respiratory tract infections is decreased with this therapy in cystic fibrosis has been reported. Data on the use of this agent in other types of bronchiectasis are currently not available.

A recent study suggested that bromhexine, an oral agent that fragments acid mucopolysaccharide but not deoxyribonuclease fibers, may be useful in patients with exacerbations of bronchiectasis in combination with antibiotic therapy.

Iodinated glycerol produces subjective symptomatic improvement in patients with chronic bronchitis, but no controlled data are available for bronchiectasis. Guaifenesin (glycerol guaicolate) has been used as an expectorant for many years, but clinical studies have not demonstrated consistent objective or subjective improvement in chronic bronchitis or bronchiectasis.

Amiloride, a drug used systemically for many years as a potassium-sparing diuretic, selectively blocks sodium absorption in the airway when administered topically, thus increasing the hydration of mucus. Aerosolized amiloride increases radioaerosol mucociliary clearance. Preliminary clinical data suggest that when administered by aerosol, amiloride may slow the decline in pulmonary function in patients with cystic fibrosis. Data in other types of bronchiectasis are lacking. Hypertonic saline increases mucociliary clearance of radiolabeled mucus in patients with chronic bronchitis and is used to induce sputum in patients who do not have a productive cough. However, hypotonic or hypertonic aerosols can provoke bronchospasm in patients with airway disease. There are no controlled studies demonstrating that sustained use of hypertonic saline improves lung function in patients with obstruction of air flow. Although saline aerosol therapy is commonly used to treat children with upper airway infection, there is no evidence that aerosol therapy is superior to humidification. Despite the fact that patients with bronchitis and bronchiectasis are often exhorted to drink more fluid to facilitate expectoration, a controlled clinical study demonstrated no benefit.

Aerosolized indomethacin has been reported to reduce sputum volume in patients with bronchorrhea. Preliminary data suggest that systemically administered ibuprofen may reduce the rate of decline in pulmonary function in patients with relatively mild lung disease associated with cystic fibrosis.

Intravenous Immunoglobulin Replacement

Therapy of documented IgG deficiency is with intravenous immunoglobulin replacement. IgG subclass deficiency may require treatment with intravenous immunoglobulin. However, an associated IgA deficiency may complicate the administration of IgG because of an increased risk for immune reactions. Furthermore, it is not clear whether replacement is appropriate for all patients with an IgG subclass deficiency or only for those who have been shown to be unable to mount a normal response to specific bacterial antigens.

Physical Therapy

The objective of physical therapy is to move excessive secretions, either directly or by augmenting cough mechanisms. Some of these maneuvers may also have an effect on mucociliary clearance, but this is probably of lesser importance. Physical therapy protocols involve one or a combination of the following: gravity (postural drainage); forced breathing maneuvers, including directed cough; and external oscillation (vibration, either manual or with external devices). Most published studies have been performed in patients with chronic bronchitis or cystic fibrosis, but the findings are probably applicable to bronchiectasis.

Directed Cough

In patients with chronic bronchitis and bronchiectasis, spontaneous expectoration of secretions is an important adjunct to mucociliary clearance. It has been suggested that directed cough, in which patients are trained and encouraged to perform deep coughs, is just as efficacious and more cost-effective than a more complex regimen of postural drainage and percussion administered by a therapist.

Postural Drainage

In patients who produce at least 25 mL of sputum per day, postural drainage alone will improve clearance of secretions by moving secretions to the central airways, where cough clearance is more effective. Although postural drainage adds significantly to the efficacy of other methods of physical therapy (forced expiration, cough, vibration), it is not particularly successful by itself and should be combined with another method.

Forced Expiration Technique

The maneuver involves repetitive, forced exhalation from middle to low lung volumes. It is believed to clear mucus by gas-liquid interaction. In patients with chronic bronchitis (with or without bronchiectasis) who produced a large amount of sputum, mucous clearance was found to improve with a combination of forced expiration and postural drainage. It was also demonstrated that sputum volume and clearance of radiolabeled mucus improved with forced expiration and postural drainage in comparison with cough alone and with postural drainage alone.

Simple devices that facilitate positive airway pressure expiration during spontaneous breathing seem to augment expectoration in patients with cystic fibrosis. Commercial devices include both fixed and variable resistor valves against which patients exhale. The mechanism of action of these maneuvers may be that they cause the equal pressure point (at which expiratory dynamic airways collapse takes place) to move more distally. The fluttering motion that occurs in these areas as the airways transiently but repetitively collapse may mobilize mucus that is adherent to the airway walls.

External Oscillation

The role of manual chest percussion and vibration has been questioned by several investigators. For patients with cystic fibrosis and chronic bronchitis whose disease is stable, there appears to be no additional advantage over the forced expiration and postural drainage combination as assessed by radioaerosol studies or sputum production. The inconvenient requirement for an assistant to perform this service makes the equivalent results of forced expiration and postural drainage seem more attractive.

The failure of manual percussion may be a consequence of the relatively low frequencies achieved with this technique. Mechanical devices can significantly increase frequency. These systems can be subdivided into methods that involve the application of forces to the chest wall and those that provide oscillations at the airway opening. In the case of the latter, animal studies suggest that the use of asymmetric expiratory and inspiratory flow rates may be optimal. In short-term studies, mechanical vibrators appear to be equivalent in efficacy to standard chest physical therapy. However, one long-term study found that whereas FEV_l declined gradually during a period of traditional chest physical therapy, FEV_1 stabilized during a period of high-frequency chest compressions.

Nutrition

With the advent of antibiotic therapy and improved survival of patients with postinfectious bronchiectasis, malnutrition is seen much less frequently. Nevertheless, severe malnutrition can develop in patients with advanced disease. Malnutrition can directly compromise host immune responses and also lead to respiratory muscle dysfunction. Patients who are candidates for lung resection should have their nutritional status optimized to reduce postoperative morbidity. Patients with cystic fibrosis may require pancreatic enzyme supplements to treat malabsorption.

Bronchial Arterial Embolization

Massive hemoptysis (500 mL in 24 h) is a frequent complication of advanced bronchiectasis. If hemopytsis does not resolve with conservative management, including parenteral antibiotics, fiberoptic bronchoscopy may be helpful in localizing the site of bleeding. However, definitive therapy requires either surgery or bronchial arterial embolization. The development of isotonic contrast material has made angiographic assessment less hazardous. The availability of increasingly fine-bore catheters makes localization more precise, and the development of nonirritating embolization materials has also reduced complications. Complications of embolization include spinal arterial embolization and subsequent quadriplegia, necrosis of the chest wall, and necrosis of multiple segments of the lung. Frequently, a site of bleeding is not identified and empiric embolization of suspected vessels is performed. Serial procedures may be required to control a single episode of bleeding. Serial embolization of several small vessels is preferable to embolization of a single large vessel, which is associated with a risk for extensive necrosis.

Surgical Resection

Recent studies suggest that with careful selection, the majority of patients who undergo surgical resection of bronchiectatic tissue experience significant symptomatic improvement, and many are cured. Indications for surgery in a patient who according to pulmonary functional status can tolerate resection include the following: (1) localized disease with severe symptomatology, (2) resectable disease with severe hemoptysis from a segmental or lobar source, (3) resectable disease causing recurrent acute episodes of infection. The main determinant of resectability is the predicted postoperative pulmonary function. Ideally, all affected segments should be resected, because even mildly affected segments tend to deteriorate with time. However, in patients with more generalized disease, resection of the more severely affected regions may convey significant symptomatic relief. When the major portion of a lung needs to be removed, it is desirable to leave a few healthy segments behind. If these segments expand to fill the hemithorax postoperatively, the risk for infection of the hemithorax will be significantly reduced. In the majority of bronchiectatic patients, the lower lobes, middle lobe, and lingula are most often involved, and it may be possible to preserve the unaffected upper lobes and (more controversially) the apical segments of the lower lobes. Extensive resection is usually performed only if the affected lobes are shrunken and if the remaining lung tissue has expanded to fill each hemithorax. The resected lobes in such cases were likely to be making a negligible contribution to pulmonary function. The risks of surgery are much increased if the resected lobes are aerated, as the loss of pulmonary function then could be significant.

In selecting candidates for surgery and planning the extent of resection, meticulous radiologic staging is essential. Bronchogram remains the gold standard in the characterization of bronchiectasis. However, recent studies suggest that high-resolution CT may be an acceptable substitute. Surgery should not be performed in asymptomatic individuals, even if extensive bronchiectasis has been documented radiologically. In preparing a patient for surgery, antibiotics and physical therapy should be employed to reduce the level of infection and volume of lower airway secretions. Nutritional status should be optimized. Spirometry and quantitative perfusion lung scanning are useful in determining the patient's ability to withstand resection.

Bilateral resections are sometimes performed as a two-stage procedure. Some surgeons prefer to operate initially on the more severely affected side, because the reduction in symptoms may obviate the need for a second operation. Other surgeons prefer the converse, operating on the less affected side first so as to be in a better position to evaluate the patient's pulmonary status and ability to withstand the more extensive second resection.

A further consideration in selecting candidates for surgery is the need to ensure that the segments being considered for resection are permanently bronchiectatic. Two circumstances require special consideration. First, in children <3 years old, normal lung tissue surrounding the bronchiectatic area may significantly increase in size to replace shrunken regions lost to bronchiectasis; thus, surgery should be deferred to beyond the age of 3 years. Second, in patients who have undergone a necrotizing pneumonia, the radiologic abnormalities may resemble those of bronchiectasis. However, as this is a transient defect, some investigators recommend that serial high-quality bronchograms, several months apart, should be performed before surgery is undertaken.

Transplantation

The dramatic improvement in survival rates following lung transplantation during the past decade now means that patients with advanced generalized bronchiectasis should be considered for transplantation. The most extensive experience in bronchiectatic patients has been with cystic fibrosis. Fears that complication rates would be higher in patients with cystic fibrosis because of pre-existing pleural disease (predisposing to hemorrhage during cardiopulmonary bypass) and pre-existing infection (predisposing to tracheal anastomotic breakdown) than in other patients have not been realized to date with the exception of those patients colonized with *B. cepacia.*

In contrast to most other lung diseases, which can be treated with single lung allografts, purulent lung disease requires a double lung transplant to reduce the risk for contamination of the allograft. Heart-lung transplantation was the initial treatment of choice. A shortage of donor organs and the risks for cardiac rejection prompted the development of bilateral lung transplants. However, this procedure also requires cardiopulmonary bypass and carries the risk for pleural hemorrhage. Bilateral sequential transplantation avoids the need for bypass, and initial results are promising.

Candidates for lung transplantation should be at significant risk of dying within 2 years without transplantation. Evidence of such a risk includes an FEV_1 value that is 30% of predicted, a 12-minute walking distance of 500 m, a Schwachman-Kulczycki score (a rating scale based on chest radiograph, physical examination, physical activity, and nutrition) of 40/100 in children, hypoxemia, and signs of failure of the right side of the heart. Poor nutritional status is associated with increased postoperative mortality. The current survival rates for adult patients with cystic fibrosis after lung transplant are approximately 70% at 1 year and 50% at 3 years, with somewhat worse results in children.

CHAPTER

42 Anatomic and Pathophysiological Correlations in COPD

Dennis E. Niewoehner

D. E. Niewoehner: Pulmonary Section, Minneapolis Veterans Affairs Medical Center, and Department of Medicine, University of Minnesota, Minneapolis, Minnesota 55455.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is characterized functionally by a decrease in maximal expiratory flow rates. In addition, patients with COPD have uneven ventilation, which results in arterial hypoxemia and hypercapnia. These functional abnormalities can be detected and quantified by relatively simple pulmonary function tests. Similarly, pathologic lesions in lungs of patients with COPD have been described in some detail, and efforts have been made to quantify the severity of the lesions observed. Structure–function relationships in COPD are imperfectly understood. Optimally, a pathologist could accurately predict the nature and severity of dysfunction from gross and microscopic examination of lung tissue. Unfortunately, this ideal has not been realized because there may be striking discrepancies between the extent of disease as determined by the pathologist and the severity of dysfunction as measured by physiological tests. These disparities can partly be attributed to the formidable methodologic problems that one faces in studying a structurally complex organ such as the lung. It also indicates that the pathophysiological mechanisms occurring in COPD are simply not well understood. This chapter reviews the basic pathology of COPD; it describes the functional and roentgenographic abnormalities associated with this disease; and it attempts to show how the pathology and physiology are interrelated.

PATHOLOGY

Emphysema

Emphysema is defined by expert committees as “a condition characterized by abnormal enlargement of the air spaces distal to the terminal bronchiole, accompanied by destruction of their walls, and without obvious fibrosis.” Air space enlargement may be secondary to actual departitioning of alveolar walls or to destructive changes that result in simple rearrangement of acinar shapes without fenestration. Air space enlargement is also observed in conditions other than emphysema, and distinctions are not always possible. For example, the aging lung is characterized by progressive enlargement of the alveolar ducts with effacement of adjacent alveoli. The enlarged alveolar ducts in aged lungs can be readily identified on whole-lung sections, and this condition has at times been termed “senile emphysema.” It is probably best to view this condition as a normal aging process, but because destructive emphysema is primarily a disease of older persons, the two conditions frequently merge imperceptibly.

Two principal subtypes of emphysema are recognized (Fig. 1 and Fig. 2). Centriacinar emphysema is characterized grossly by discrete, enlarged air spaces, usually measuring 1 to 10 mm in diameter. At the microscopic level, these lesions are seen to involve the respiratory bronchioles, the partly alveolated structures immediately distal to the terminal bronchiole. The structure of more distal alveoli within an acinar unit is largely preserved, though with advanced disease an enlarged air space may encompass much of the acinus. It is not uncommon to observe focal areas of inflammation, fibrosis, and black pigment in the structures bordering the emphysema lesion. The earliest centriacinar emphysema lesions tend to occur in the more cephalad lung regions, but they may be seen throughout the lung with severe disease.

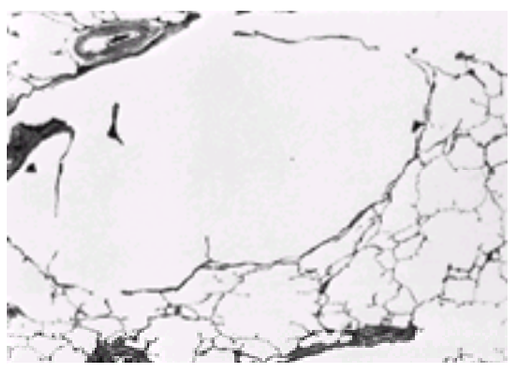

FIG. 1. Centriacinar emphysema. Air-space enlargement is centered about the proximal respiratory bronchiole. More distal lung parenchyma is normal.

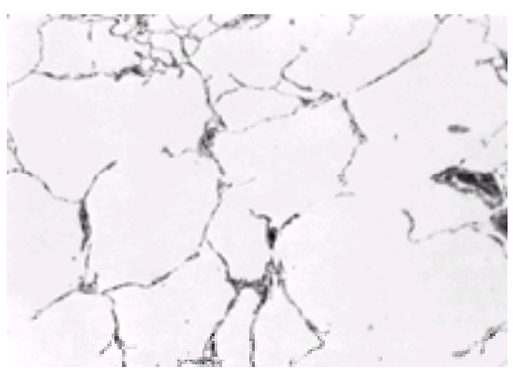

FIG. 2. Panacinar emphysema. The pattern is of diffuse air-space enlargement involving the entire acinus. A small region of normal alveoli is visible at top center.

Panacinar emphysema, as the name implies, more uniformly involves the entire acinar structure. Viewed grossly, mild panacinar emphysema consists of nothing more than a subtle, relatively diffuse enlargement of air spaces. In more advanced disease, single lesions may measure up to several millimeters in diameter. Microscopically, the alveolar architecture is distorted such that alveolar ducts appear enlarged, and it may be difficult to identify individual alveoli. In contrast to centriacinar emphysema, early panacinar emphysema may involve any portion of the lung with some disposition to involve lung bases more severely.

The lung contains abundant quantities of elastin, and this protein is instrumental in maintaining normal alveolar architecture and in conferring organ elasticity. It is now widely accepted that emphysema develops because of damage to the elastic fiber network and that this is caused by an elastase–antielastase imbalance within the distal structures of the lung. The two most powerful arguments in favor of this hypothesis are: (1) proteases with activity against native elastin produce emphysema-like lesions when instilled into the lungs of experimental animals, and (2) many persons with inherited, severe forms of a_1-antiprotease deficiency develop advanced, predominantly panacinar emphysema at a relatively young age. a_1-Antiprotease has a high level of activity against neutrophil elastase as well as other related enzymes, and it is the most abundant antiprotease within the lower airways of the lung. Severe forms of a_1-antiprotease deficiency are relatively uncommon, being found in only a few percent of patients with COPD. The most common known cause of emphysema, cigarette smoking, may upset the normal elastase–antielastase balance in a variety of ways. Most notably, regular cigarette smoking causes a low-grade inflammatory reaction in the distal airways, and the principal cells involved in this reaction, alveolar macrophages and polymorphonuclear leukocytes, are both rich sources of elastases. It is also possible that cigarette smoke may exert its effects by suppressing normal antielastase activity, by inhibiting the production of connective tissue proteins, and by other unknown actions.

Mucus Hypersecretion

One proposed definition of chronic bronchitis is a “clinical disorder characterized by excessive mucus secretion in the bronchial tree, manifested by chronic or recurrent productive cough on most days for a minimum of 3 months per year for not less than two successive years.” Experts arrived at this definition when excessive mucus secretion was thought to play a central role in the development of airflow obstruction in COPD. This is now known not to be true, but the definition continues in use. Many patients with COPD do have mucus expectoration, and the pathologic correlates of this symptom have been well described.

Mucus lines the lumina of the bronchial tree, and it serves an important role in host defense against the environment. Seromucous glands are found within airway walls throughout the central bronchial tree, and their mucus products empty into the bronchial lumen through ducts. In addition, mucus-secreting goblet cells are present as specialized epithelial cells throughout the bronchial tree. Both mucus-secreting elements may become enlarged in disease states. The volume of bronchial mucous gland may increase by 50% to 100% in severe cases of chronic bronchitis (Fig. 3). The population of epithelial goblet cells may also expand, particularly in the more distal airways, where few goblet cells are normally seen. In addition to enlargement of the mucus-secreting elements, it is not uncommon to see a low-grade inflammatory response, smooth muscle enlargement, and squamous metaplasia.

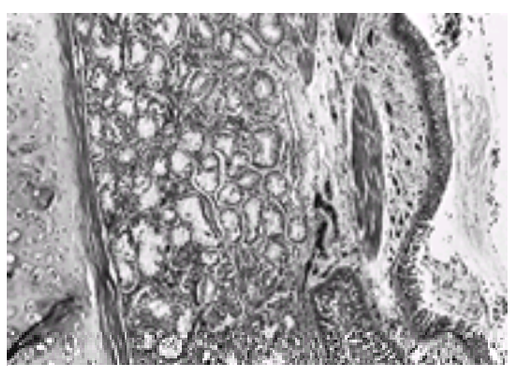

FIG. 3. Bronchial mucous gland enlargement. The markedly enlarged mucous glands from a case of chronic bronchitis occupy about twice their normal volume. Some mucus is visible in the bronchial lumen.

Peripheral Airways Disease

Descriptive changes in the peripheral airways of patients with COPD date back to Laennec's treatise in the 19th century. In the modern era, greater attention has been paid to this element of disease in COPD, as there has been a better appreciation of the functional impact. The abnormalities seen in COPD are multiple and nonspecific in nature (Fig. 4, Fig. 5, and Fig. 6). These include collections of brown-pigmented macrophages within the walls and air spaces of the distal lung passages, a low-grade inflammatory and fibrotic response involving the walls of the terminal bronchiole, goblet cell and squamous cell metaplasia of the lining epithelium, smooth muscle hypertrophy, and increased amounts of luminal mucus. These abnormalities are caused in part by cigarette smoke, but they are also observed to some extent in the lungs of elderly nonsmokers. Little is known concerning the specific pathogenetic mechanisms.

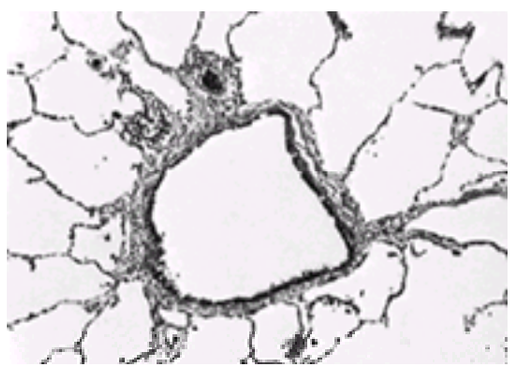

FIG. 4. Normal peripheral bronchiole. The airway lumen is only about 0.5 mm in diameter, and its patency is dependent on the tethering effect of surrounding lung parenchyma.

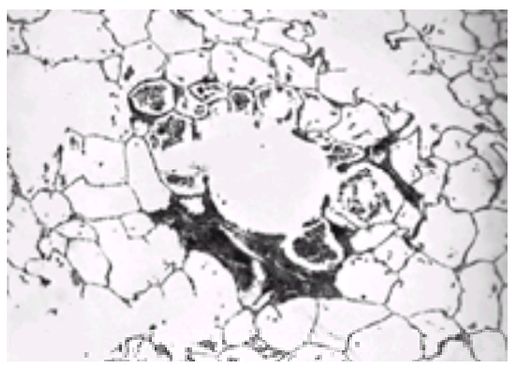

FIG. 5. Section through the junction of a terminal and respiratory bronchiole in a lung from a youthful cigarette smoker. Clusters of pigmented macrophages are visible in the respiratory bronchiole. There is also a mild inflammatory reaction in the wall of the bronchiole and in the adjacent alveoli.

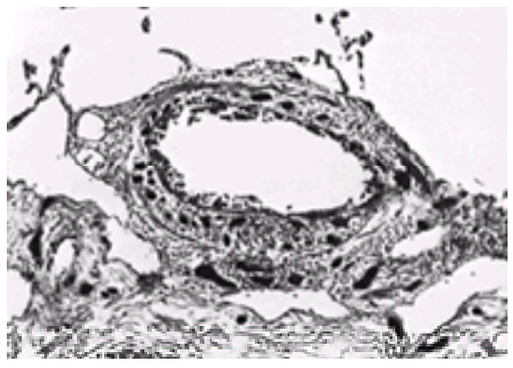

FIG. 6. Severely diseased bronchiole from a patient with COPD. The airway wall is thickened from edema, fibrosis, and smooth muscle enlargement, and a low-grade inflammatory response is visible throughout.

PHYSIOLOGICAL ABNORMALITIES

Lung Mechanics

The most practical and useful physiological test of airflow obstruction is spirometry, in which maximal expiratory flow rates are measured as a function of time. This information can be displayed as either the volume–time or the flow–volume relationship (Fig. 7). Both plots contain the identical information. Conventional parameters of maximal expiratory airflow include the forced expiratory volume at 1 sec (FEV_1), the expiratory flow rate between 200 and 1200 mL of the forced vital capacity ($FEF_{200–1200}$), the midexpiratory forced expiratory flow rate ($FEF_{25–75}$), and other less frequently used indices. Maximal breathing capacity (MBC), or maximal voluntary ventilation (MVV), is an older technique for demonstrating airflow obstruction that has now fallen out of favor. Airflow obstruction also may be evaluated by measurement of total pulmonary resistance or airway resistance. These measurements require more sophisticated instrumentation than does spirometry, and although they may be useful for some clinical investigations, they provide little practical information in the clinical management of patients with COPD. For most purposes, the FEV_1 (particularly when expressed as the percentage of predicted) or the ratio of the FEV_1 to the forced vital capacity (FEV_1/FVC) provide the best quantitative measures of airflow obstruction.

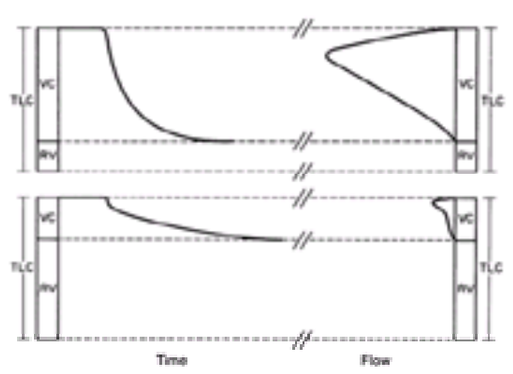

FIG. 7. Characteristic spirometric and lung volume abnormalities in a patient with severe COPD (*lower panel*). Spirometry is shown on the left as a volume–time relationship and on the right as a flow–volume relationship. In comparison with the normal subject (*upper panel*), the patient with COPD has a reduction in expiratory flow rates, a decrease in the forced expiratory vital capacity (FVC), and a corresponding increase in the residual volume (RV). TLC, total lung capacity.

Lung volume abnormalities are also characteristic of COPD and they include (1) a decrease in the forced vital capacity (FVC), (2) an increase in the residual volume (RV) and in the residual volume–total lung capacity (RV/TLC) ratio, (3) an increase in the functional residual capacity (FRC), and (4) a variable increase in the TLC (Fig. 7). Lung volumes are measured either by the washin or the washout of tracer gases such as helium or by plethysmography. Because tracer-gas methods require long equilibration times in the presence of severe COPD, plethysmography is the more accurate method. Surprisingly accurate estimates of TLC can also be made from the standard chest roentgenogram. The measurement of lung volumes may sometimes be useful in differentiating interstitial fibrosis and other forms of restrictive lung disease from COPD. However, these distinctions are usually evident from other clinical and roentgenographic findings, and in most patients with COPD, the determination of lung volumes adds little useful information. Increases in the RV/TLC ratio are observed relatively early in the natural history of COPD, and the magnitude of these changes continues to parallel spirometric abnormalities in more advanced stages of the disease.

Mechanisms of Maximal Expiratory Airflow Limitation

The interaction of air molecules with each other and with the internal surface of a cylinder impedes their movement, so that energy in the form of a pressure difference is necessary to cause flow through the cylinder. Flow resistance is defined as the ratio of the longitudinal pressure difference to the flow rate that pressure differential produces ($R = P/V$). The magnitude of flow resistance depends on the physical properties of the gas and on the length and diameter of the cylinder. The bronchial tree has many generations of branching, and each airway can be viewed as a resistive element existing in series and in parallel with tens of thousands of similar elements.

The energy necessary to move air through this resistive network is provided by the bellows action of the thoracic cage. For a constant resistance, flow through the conducting airways is proportional to applied pressure. In Fig. 8, transairway (alveolar–airway opening) pressure is plotted against flow rate at a constant lung volume in a normal subject. With inspiration, the relationship of flow to pressure is nearly linear, meaning that resistance is relatively constant over a wide range of applied pressures. Therefore, inspiratory flow is limited only by the magnitude of the applied pressure, which is largely dependent on respiratory muscle strength. However, the relationship is quite different during expiration. At low values for flow and pressure, the relationship is nearly linear, but beyond a certain critical point, flow remains constant despite further increases in pressure. This phenomenon is described as flow limitation, which indicates that expiratory airflow resistance increases dynamically as greater effort is expended.

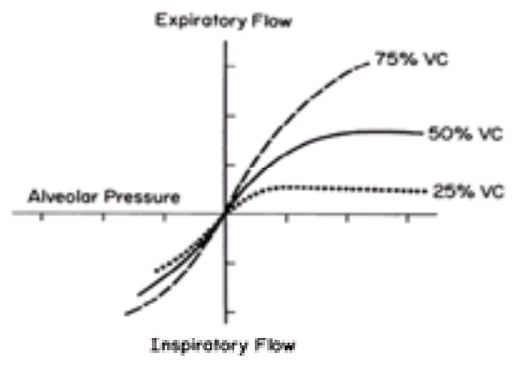

FIG. 8. Inspiratory and expiratory airflow as a function of alveolar pressure at various lung volumes. With inspiration, flow increases as the driving pressure between airway opening and alveolus increases. With expiration, flow increases with pressure only to a point beyond which flow remains constant despite further increases in pressure. This is called flow limitation, and the effect is most marked at small lung volumes. VC, vital capacity.

Flow limitation can be demonstrated by a simple experiment utilizing flow–volume curves. Figure 9 shows a series of flow–volume tracings in a normal subject who was instructed to expire repeatedly from total lung capacity (TLC) to residual volume (RV) with progressively greater efforts. With minimal effort (A), flow rates are low and relatively constant over much of the vital capacity. With increasing efforts (B through D), flow rates at large lung volumes increase correspondingly. However, the tracing from each submaximal effort contains an inflection, and below that volume the flow tracing superimposes on those from previous, lesser efforts. In other words, flow rates at any particular volume over the lower two-thirds of the vital capacity have a maximum that is relatively independent of the effort applied. As will be described, this phenomenon is largely determined by the intrinsic mechanical properties of the lung.

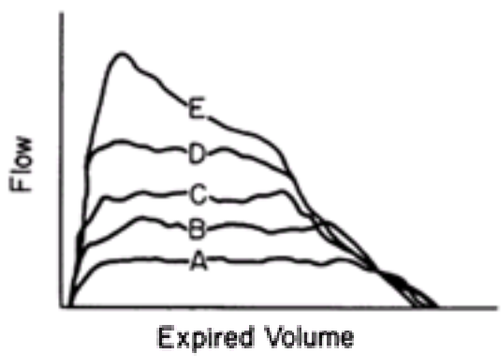

FIG. 9. Flow–volume relationships in a normal subject who expired from total lung capacity to residual volume with progressively greater effort (*A*–*E*). The latter portion of the maximal effort is superimposed on the tracings from lesser efforts, demonstrating flow limitations at smaller lung volumes.

The clinical significance of flow limitation can be appreciated by comparing flow–volume curves in a normal subject to those in a patient with COPD. Figure 10 shows inspiratory and expiratory flow–volume relationships during tidal ventilation and during maximal efforts. In the normal subject, minute ventilation can be increased severalfold in response to increased metabolic demands so that ventilatory capacity is not a limiting factor, even with vigorous exercise. In contrast, the maximal inspiratory and expiratory flow rates are greatly diminished in the patient with COPD, with expiration being more severely affected than inspiration. With severe disease, tidal expiration may be nearly superimposed on the tracing from a maximal forced effort. Such an individual has little ventilatory reserve and can increase total ventilation only marginally in response to exercise demands. This largely accounts for the cardinal symptoms of dyspnea and diminished exercise capacity in patients with COPD.

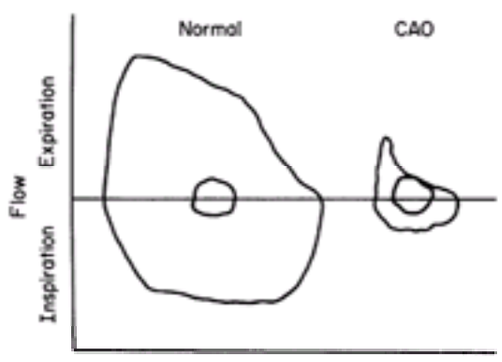

FIG. 10. Expiratory and inspiratory flow rates as a function of lung volume in a normal subject and in a patient with severe COPD. The outer envelopes represent maximal efforts; the inner tracings represent tidal breathing. The patient with COPD has very limited ability to increase ventilation with exercise.

The decrease in ventilatory capacity results not from decreased expiratory effort but rather from abnormal lung mechanics. Models of graded complexity have been used to analyze the physical behavior of the lung during forced expiratory maneuvers. A simple model, shown in Fig. 11, consists of a distensible balloon, representing the gas-exchanging regions of the lung, contained within a box, representing the thoracic cage. The balloon is connected to the environment by a compliant tube (conducting airways) and is surrounded by a space between the balloon and box (intrapleural space). Respiratory muscles, which actively alter intrapleural pressures, are represented by a bellows situated at the bottom of the box. If the lung is inflated above its resting volume, it will deflate to its original volume unless this tendency to recoil is opposed by an outward-acting transpleural pressure difference. The transpleural pressure required to keep the lung statically inflated at a particular volume is referred to as elastic recoil pressure (P_{el}). Alveolar pressure (P_{alv}) is at all times greater than intrapleural pressure (P_{pl}) by the amount of P_{el}; $P_{alv} = P_{el} – P_{pl}$. For air to flow through the conducting airway, there must be a pressure gradient between the alveolus and the airway opening (P_{ao}). With no flow, P_{alv} is equal to P_{ao}, and P_{pl} is negative, equal in magnitude but opposite in sign to P_{el}, in order to keep the lung distended. At functional residual capacity in normal subjects, P_{pl} is typically 4 to 3 cm H_2O less than ambient pressure. Inspiration creates a more negative P_{pl}. Because P_{alv} is the algebraic sum of P_{pl} and P_{el}, P_{alv} becomes negative with respect to P_{ao}, and air is drawn into the lung. Expiration reverses this process: P_{pl} becomes less negative, P_{alv} becomes positive with respect to P_{ao}, and air flows out of the lung. During the normal breathing cycle, pressure fluctuations in the pleural space are only a few centimeters of water, and during expiration, P_{pl} ordinarily remains negative with respect to ambient pressure. During expiration, pressure at all points within the conducting airways is positive with respect to ambient pressure. Hence, during tidal expiration, there is a net pressure gradient acting outward on those conducting airways that are exposed to pleural pressure. However, with forced expiration, this transmural pressure gradient may be reversed; it is these compressive pressures acting on compliant bronchi that narrow the airway lumen and limit maximal expiratory flow rates.

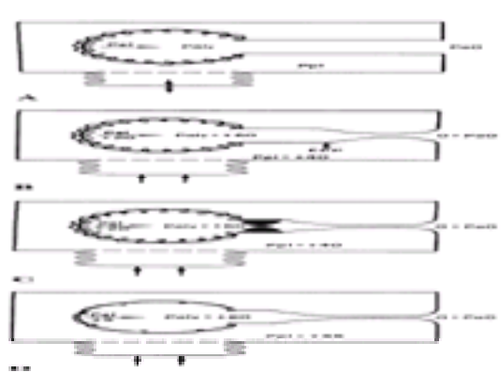

FIG. 11. Model of forced expiratory airflow. See text for explanation. **A** and **B** represent the normal relationships. **C** illustrates the effects of intrinsic airways obstruction on forced expiratory airflow. **D** demonstrates the effects of decreased lung elastic recoil, as might occur with emphysema. P_{el}, elastic recoil pressure; P_{alv}, alveolar pressure; P_{ao}, airway opening pressure; P_{pl}, intrapleural pressure; EPP, equal-pressure point.

Representative pressure relationships during a forced expiration are shown in Fig. 11B. Assume that P_{el} is –20 cm H_2O, P_{pl} is –40 cm H_2O, and P_{alv} is –60 cm H_2O. The alveolar driving pressure is dissipated by flow resistance along the length of the airway so that intraairway pressure progressively decreases to that of ambient pressure at the airway opening. Because P_{pl} is –40 cm H_2O, and intraairway pressure varies from –60 to 0 cm H_2O, there is a point at which intraairway pressure is equal to P_{pl}, and the transmural pressure gradient is zero. Distal (meaning in the direction of the alveolus) to this “equal-pressure point,” pressures within the airway are positive with

respect to P_{pl}, and this outward-acting force distends the airway lumen. Proximal to the equal-pressure point, intraluminal pressures are negative with respect to P_{pl}, creating a compressive force. Because bronchi are not rigid tubes, inward-acting transmural pressure gradients tend to compress the airway lumen, which in turn increases flow resistance. As P_{pl} increases, $P_{alv} - P_{ao}$ increases by the same amount and would, for a constant resistance, cause an increase in expiratory flow. However, increases in P_{pl} subject the proximal bronchi to greater compressive pressures, which narrow their lumina even more. The increase in driving pressure between alveolus and airway opening is balanced by the increase in flow resistance so that flow rates remain relatively constant. Thus, it is the flow-limiting segment of the conducting airways, usually located in the more proximal bronchi, that sets an upper limit to expiratory flow rates.

From this simple model several factors are recognized that might affect the mechanical behavior of the flow-limiting segment and in turn set the magnitude of maximal expiratory flow rates. One factor relates to the intrinsic elastic behavior of the flow-limiting segment itself. It is evident that the same compressive pressure might cause greater flow resistance in a highly compliant airway than in an airway with relatively rigid walls. Experimental studies support this suggestion, but whether such changes play a significant role in COPD is unclear.

The mechanical behavior of the flow-limiting segment is also influenced by flow resistance in more distal portions of the conducting airways. This is illustrated in Fig. 11C, which shows narrowing of the distal airway. Under these conditions, a relatively greater portion of the alveolar driving pressure, $P_{alv} - P_{ao}$, is dissipated over the obstructed segment of airway. Compared to the conditions presented in Fig. 11B, intraairway pressures at each point between the obstruction and the airway opening are necessarily less positive, and the compressive pressures must be correspondingly greater. Because a longer segment of normal airway is exposed to larger compressive forces, airflow resistance would be greater, and maximal expiratory flow rates would be less. Intrinsic airway narrowing may occur from pathologic conditions such as inflammation and fibrosis in airway walls and from excessive luminal mucus, all of which are frequently seen in lungs from patients with COPD. As discussed below, lesions are thought to be a significant cause of airflow obstruction in this disease.

The pathologic condition that may be most important in causing airflow obstruction, emphysema, involves the lung parenchyma and not the conducting airways. How do abnormalities of the lung parenchyma give rise to expiratory airflow obstruction? Emphysema is characterized by destruction of alveolar walls and disruption of the normal parenchymal architecture. These morphologic changes are associated with a loss of lung elastic recoil, which may be viewed as the primary functional defect in emphysema. The loss of elastic recoil affects both the dimension of intrapulmonary airways and the behavior of the flow-limiting segment. Intrapulmonary airways are surrounded by lung parenchyma and are intimately connected to the elastic and collagen fibers in the alveolar walls. As the lung is inflated, alveolar walls become increasingly stressed, and this creates a tethering effect on airways at their points of attachment. As lung volume increases, so do the lengths and diameters of the intraparenchymal airways. This mechanism accounts for the volume dependence of airflow resistance in the lung, the resistance being greater at small volumes and less at large volumes. With loss of lung elastic recoil, the distending forces acting on the airway at any particular volume would diminish, and airflow resistance would increase correspondingly.

Lung elastic recoil also influences maximal expiratory flow rates through an indirect effect on the mechanical behavior of the flow-limiting segment. This mechanism can best be appreciated by again considering the model. In Fig. 11D, the effect of emphysema has been simulated with a decrease in P_{el} from +20 cm H_2O to +5 cm H_2O. For the sake of the argument, let P_{pl} increase from +40 cm H_2O to +55 cm H_2O, a change that could be realized simply by more forceful chest constriction. The sum of P_{el} and P_{pl} in this example provides the same driving pressure between alveolus and airway opening, +60 cm H_2O, as in Fig. 11B. Although the driving pressure is the same, pressure relationships across the airway wall are different. Because P_{pl} has increased by 15 cm H_2O, external pressures at each point on the airway in Fig. 11D are necessarily increased by the same amount. The larger compressive forces on the flow-limiting airways would, in comparison with Fig. 11B, cause greater luminal narrowing, resulting in decreased maximal expiratory flow rates. Thus, P_{el} may be viewed as effectively opposing the compressive forces of P_{pl} on intrathoracic airways. In experimental models of emphysema, it has been demonstrated that the decrease in maximal expiratory flow rates is nearly proportional to the decrease in P_{el}.

Ventilation Distribution and Gas Exchange

An early and characteristic physiological abnormality in COPD is arterial hypoxemia. Mild hypoxemia may be detected in the early stages of COPD, when spirometric values are normal or nearly normal. As COPD worsens, hypoxemia also tends to worsen, although the severity of COPD and the degree of hypoxemia are imperfectly concordant. Some degree of hypercapnia is also usually present in more advanced disease, and there may be sustained elevations of the P_{CO_2} to 70 mm Hg or more in the most severe cases. It is believed that the principal mechanism underlying arterial blood gas derangements in COPD is the mismatching of ventilation and perfusion in regional lung units. As described below, the uneven distribution of inspired ventilation is thought to be the primary event, with alterations in pulmonary blood flow being secondary.

Uneven ventilation in COPD can be demonstrated by several techniques. The single-breath oxygen test is one such method (Fig. 12). The subject inspires a single breath of pure oxygen and then slowly exhales while nitrogen concentration at the mouth is plotted as a function of expired volume. A positive slope in phase III, the “alveolar plateau,” indicates that different portions of the lung with different concentrations of residual nitrogen empty asynchronously. In normal subjects, the slope of phase III is usually no more than a 2% rise in nitrogen concentration per liter of expired volume, but this value may rise to as much as 10% to 15%/L in patients with COPD. A variety of techniques to measure the washin or washout of tracer gases also detect inhomogeneous ventilation. Though difficult to quantify, external scanning after inhalation of radioactive xenon may allow the best visual appreciation of disordered ventilation distribution in COPD.

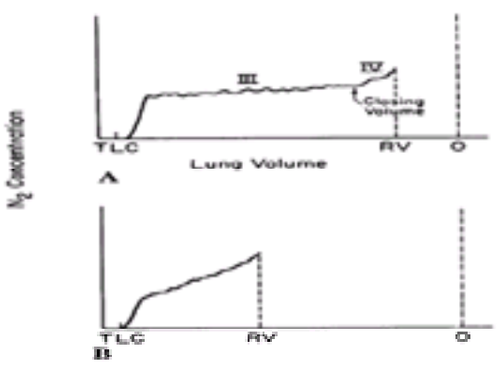

FIG. 12. Representative tracings from the single-breath oxygen test in a normal subject **(A)** and a patient with COPD **(B)**. In normal subjects, the slope of phase III (the “alveolar plateau”) is no more than a 2% change in nitrogen fraction for each liter of expired air. Phase III is delineated from phase IV by an inflection point, the “closing volume.” In the patient with COPD, the slope of phase III is much steeper, suggesting less even ventilation, and frequently the closing volume can not be identified. TLC, total lung capacity; RV, residual volume.

Mechanisms of Deranged Gas Exchange

In patients with COPD, ventilatory capacity may be a limiting factor in determining oxygen uptake and carbon dioxide excretion during exercise. However, even at rest, most patients with COPD have evidence of impaired gas exchange. With mild COPD, impaired gas exchange may be manifest only as mild arterial hypoxemia. However, with severe disease, hypoxemia may be profound, and it, along with hypercapnia, contributes to the clinical signs and symptoms of this disorder. Certain of the mechanisms that impair gas exchange in COPD are intuitively obvious. For example, widespread emphysema is associated with a substantial loss of alveolar capillary surface area. With extensive destruction of parenchyma, the lung simply does not function effectively in exchanging oxygen and carbon dioxide.

However, current thinking suggests that mechanisms other than a simple loss of surface area are more important as a cause of hypoxemia and hypercapnia. These other mechanisms relate principally to the distribution of ventilation and perfusion within the lung. Gas exchange is most efficient when the ratio of ventilation to perfusion ($\dot{V}/\dot{Q}$) is uniform. To the extent that regional $\dot{V}/\dot{Q}$ deviates from unity, the exchange of both oxygen and carbon dioxide is impaired.

If an alveolar region is ventilated but not perfused ($\dot{V}/\dot{Q}$ = ¥), no gas exchange occurs. Relatively overventilated alveolar regions that receive some blood flow behave functionally as though a portion of that region were normally perfused and the remainder received no blood flow. The excess ventilation in both situations is wasted, a condition that is described as a high $\dot{V}/\dot{Q}$ abnormality or “alveolar dead space.” High $\dot{V}/\dot{Q}$ abnormalities are detected as an increase in the dead space to tidal volume ratio (V_D/V_T). In normal subjects, V_D/V_T is no more than 0.3 to 0.4, but in patients with severe COPD, it may be as high as 0.7 to 0.8. In such patients, the major portion of each inspired breath contributes nothing to gas exchange. Alveolar regions that are perfused but not ventilated ($\dot{V}/\dot{Q}$ = 0) also do not participate in gas exchange.

The proportion of the cardiac output that passes through unventilated lung zones is termed the shunt fraction, and the admixture of shunted blood with other pulmonary venous blood results in arterial hypoxemia. If an alveolar region receives some ventilation but is underventilated relative to its blood supply, arterial oxygen desaturation will also ensue. Underventilated alveolar regions, termed low $\dot{V}/\dot{Q}$ abnormalities, are thought to be the principal cause of hypoxemia in COPD. Theoretically, pathologic states affecting the pattern of either ventilation or perfusion may cause the regional $\dot{V}/\dot{Q}$ to deviate from unity.

Abnormal ventilation and perfusion patterns in COPD are readily demonstrated by radioactive scanning and by other methods. Regional hypoperfusion to some extent may be directly attributed to loss of the capillary bed accompanying emphysema. However, abnormal perfusion patterns in COPD also may represent normal homeostasis in the pulmonary vasculature. According to this concept, pathologic changes in COPD create regions of hyperventilation and hypoventilation. Regions that are underventilated develop relative hypoxia, which in turn initiates a local vasoconstrictor response. The reduction in blood flow tends to restore the regional $\dot{V}/\dot{Q}$ ratio toward unity. Over long periods of time, hypoxic vasoconstriction may induce permanent histopathologic changes in the pulmonary arteries, leading to irreversible pulmonary hypertension and cor pulmonale. Because changes in the pulmonary vascular bed may be regarded as secondary, attention in this discussion is directed at those pathologic mechanisms that alter the distribution of ventilation.

Ventilation is the process by which ambient air is transported to the alveolar–capillary interface and alveolar air is removed to the environment. Regional ventilation may be defined as the volume of ambient air that reaches a given lung region relative to the volume of gas that resided in that same region at the beginning of the breath. Regional ventilation is determined by the relative volume expansion of that region and by the manner in which inspired air mixes with resident gas. Expansion of alveolated zones depends on both the elastic behavior of that region and external forces acting on it. Distending forces are closely equated to transpleural pressure. For the same change in transpleural pressure, compliant regions expand more than do noncompliant regions and, other things being equal, receive more ventilation. Therefore, any pathologic state causing nonhomogeneous elastic behavior in various lung regions might be expected to cause uneven ventilation.

Emphysema is the prototype of diseases that alter lung elastic behavior. In most instances, emphysematous involvement is not uniform; severely diseased regions lie adjacent to histologically normal lung tissue. Therefore, one would anticipate abnormal ventilation patterns in emphysematous lungs, and this is observed. Whether emphysematous regions are overventilated or underventilated is not so apparent. This statement may seem surprising in view of the fact that emphysematous lungs are generally said to be overly compliant and that compliant lungs should theoretically receive more ventilation. This seeming paradox can be understood by comparing pressure–volume curves in normal and emphysematous lungs (Fig. 13). With emphysema, there is a loss of lung elasticity with a consequent upward and leftward shift of the pressure–volume curve. At low volumes, the emphysematous lung undergoes a greater volume change for any transpleural pressure change than does the normal lung. However, at large volumes, the emphysematous lung is less compliant than the normal lung and undergoes less volume change for the same change in transpleural pressure. Thus, relative differences in the pressure–volume relationships and in the magnitude of external forces acting on each region would determine the distribution of ventilation between normal and emphysematous zones. Existing evidence suggests that emphysematous areas are usually underventilated compared with normal lung parenchyma. However, if perfusion were even more severely impaired than ventilation, emphysematous regions might still represent high-$\dot{V}/\dot{Q}$ zones.

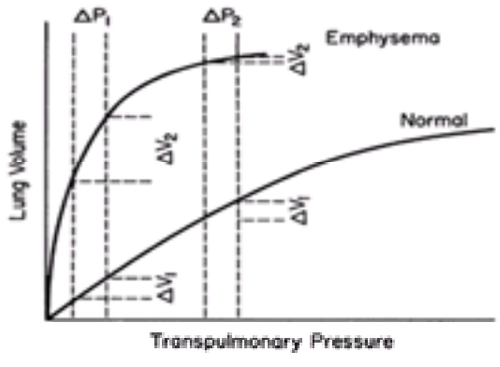

FIG. 13. Pressure–volume relationships in normal and emphysematous lungs. At small lung volumes, the emphysematous lung is more compliant than the normal lung, but the reverse is true at large lung volumes. D*P*, change in pressure; D*V*, change in volume.

The volume change that a lung region undergoes during the respiratory cycle exceeds the volume of effective ventilation. At the end of expiration, all gas-transport pathways contain alveolar gas. With the next inspiration, the “dead space” gas within the conducting airways precedes ambient air into the gas-exchanging zones. Dead-space gas represents a significant portion of each tidal breath, so its distribution and mixing with ambient air may have pronounced effects on gas exchange. Gas is transported from the airway opening to the alveolar–capillary interface by two mechanisms: convection and diffusion. Gas is thought to move through the proximal airways principally by convection, but in the distal alveolated zones diffusion predominates. At the beginning of inspiration, one can imagine a front forming at the airway opening with ambient air on the proximal side and resident gas on the distal side. If no mixing occurs across the interface, the front would migrate distally as inspiration proceeds. The location of this front at the end of inspiration marks the limit of convective flow, and beyond this point gas transport is solely dependent on diffusion. (In reality, of course, mixing between ambient air and residual gas begins at the airway opening, but the notion of a convective front is conceptually useful.) Calculations based on known dimensions of the respiratory tract suggest that, with tidal breathing, this imaginary convective front penetrates to the level of the alveolar ducts. From there gas diffuses radially into the alveoli and axially into more distal alveolar ducts and alveoli. Because distances are short, radial mixing between the alveolar duct and alveoli probably is complete within a fraction of a second. However, axial pathways are much longer. Theoretical studies suggest that because distal pathways are of uneven lengths, mixing between gases in the proximal and distal alveolar ducts may not be complete within the span of a single breathing cycle, even in the normal lung. If so, proximal alveolated regions would represent high-$\dot{V}/\dot{Q}$ zones, whereas more distal regions would represent low-$\dot{V}/\dot{Q}$ abnormalities. Transport pathways within the alveolated zones of the lung may be a critical factor in gas-mixing efficiency, and any pathologic state that alters the dimensions of those airways might have profound effects on overall gas exchange.

Two examples illustrate how these functional abnormalities might occur. Centriacinar emphysema primarily involves the respiratory bronchiole, leaving more distal portions of the acinus intact (Fig. 14). To reach normal alveoli, gas molecules must pass through the increased dead-space volume of the pathologically enlarged respiratory bronchiole. With inspiration, ambient gas preferentially fills the proximal emphysema lesion, while distal regions tend to be filled by resident dead-space gas. This creates a region of relative alveolar hypoxia in the distal acinus but a high-$\dot{V}/\dot{Q}$ zone within the emphysema lesion itself.

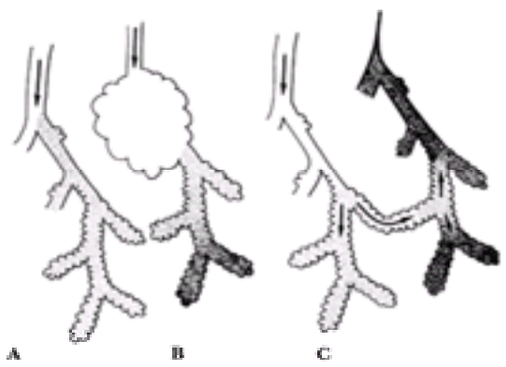

FIG. 14. Postulated mechanisms of uneven ventilation in COPD. (*Shading* represents resident dead-space gas.) **(A)** Normally inspired air is mixed evenly with resident gas throughout the acinus. **(B)** A disproportionate amount of inspired air remains within a proximally located centriacinar emphysema lesion, while the distal acinus contains relatively more dead-space gas. **(C)** Alveolated regions distal to an obstructed bronchiole are ventilated through a collateral channel. Because the pathway for gas transport is longer, mixing between inspired air and resident gas is incomplete.

Another mechanism by which a specific structural abnormality might impair gas exchange is depicted in Fig. 14C. Adjacent acini are shown; one is ventilated through a normal bronchiole, but the other bronchiole is occluded by a mucus plug. If the latter bronchiole remained occluded throughout the respiratory cycle, and if no other

bronchial connections existed, the distal acinus would become atelectatic as gas was absorbed. Atelectasis probably does not occur because some ventilation is supplied to the obstructed acinus via collateral channels. However, the collateral pathways are likely to be longer than normal, with a corresponding increase in the dead-space volume. In the example shown, alveolated regions behind the obstructed bronchiole would function as a low-$\dot{V}/\dot{Q}$ abnormality, whereas portions of the unobstructed acinus might represent regions with a high $\dot{V}/\dot{Q}$ ratio.

These examples illustrate how specific anatomic abnormalities might give rise to abnormal ventilation distribution. Other examples might also be cited, but the relative importance of specific pathologic lesions as causes of $\dot{V}/\dot{Q}$ disturbances in COPD is simply not known. Gas exchange may also be dependent on factors relating to the distribution of pulmonary blood flow, to neural control of breathing, to chest wall mechanics, to systemic hemodynamics, to systemic metabolic demands, and to respiratory muscle function. The final common expression of disordered gas exchange in COPD, arterial hypoxemia and hypercapnia, represents the summation of multiple, complex mechanisms.

PHYSIOLOGICAL CORRELATES OF EMPHYSEMA

Emphysema is by definition an anatomic entity, and its presence and severity can best be directly determined only in specimens obtained at surgery or autopsy. Accurate quantification of emphysema severity requires that lungs be fixed in an inflated state. Assessments of emphysema severity can be made either from whole-lung slices or from histologic sections. The paper mounting of whole-lung slices is one of the more common methods employed. Specimens to be graded are compared to a standard picture panel depicting progressively more severe grades of emphysema. This method is fairly reproducible, and it is also quite sensitive in detecting mild grades of emphysema. Some investigators have assessed emphysema by variations of this method and by point-counting techniques. Emphysema severity also can be assessed by more direct measurements of air-space size from histologic sections. A test line of known length, contained within the eyepiece reticule, is superimposed over lung parenchyma at multiple sites. The number of intersections of the test line with alveolar walls is counted, and from this is calculated the average distance between alveolar walls (mean linear intercept). Provided that adequate attention is given to sampling considerations, the mean linear intercept can be reproducibly determined with an error of only a few percent. The correlations between estimates of severity from the panel-scoring method and from the mean linear intercept are reasonably good in lungs involved by moderate to severe grades of emphysema, but the histologic method lacks sensitivity when estimating milder grades of emphysema. Milder forms of emphysema are usually focal in their distribution, and although these abnormalities can be recognized from visualization of whole-lung slices, these abnormalities may be difficult to detect against the normal background variability of the mean linear intercept.

The problem in assessing emphysema presence and severity is further compounded by the presence of morphologic subtypes, the most important of which are centriacinar and panacinar. The panacinar form of emphysema predominates in the severe a_1-antiprotease deficiency state, whereas centriacinar emphysema appears more closely linked to cigarette smoking by etiology. In their earlier stages, these two forms of emphysema can usually be distinguished, but mixed forms are the rule in most cases of advanced COPD, and the relative proportion of each is difficult to quantify. In most studies, assessment of emphysema has been made without reference to morphologic subtype, and it remains unclear whether either form of the disease is associated with any distinguishing clinical or physiological features.

Patients with physical impairment from COPD nearly always have emphysema, but severity varies widely. Occasionally, emphysema may be absent or present in only trace amounts. Advanced grades of emphysema may be suspected from certain types of pulmonary function abnormalities, but it bears emphasizing that none of the available pulmonary function tests is capable of predicting emphysema severity with a high degree of precision. The enlargement of the air spaces in emphysema is accompanied by loss of alveolar and capillary surface areas available for gas exchange. This factor, coupled with ventilation and perfusion inhomogeneities, might impair oxygen and carbon dioxide exchange between ambient air and capillary blood. However, anatomic emphysema correlates poorly with abnormalities in arterial blood gas measurements. It appears to correlate somewhat better with decreases in the diffusing capacity for carbon monoxide (D_LCO), but even in this case, the literature contains conflicting results. Some studies found correlation coefficients as high as –0.70 (meaning that about 50% of the variance in the D_LCO could be explained by emphysema), whereas other investigators found no significant relationship between emphysema severity and decreases in the D_LCO. These discrepant results might partly be explained by selection biases and by the generally small sizes of the studies. One may reasonably conclude that emphysema probably does cause some reduction in the D_LCO but that the predictive power of the test was too weak to allow valid judgments about the extent of emphysema in the individual patient.

Severe emphysema is also associated with characteristic abnormalities in the lung pressure–volume relationships, which include an increase in maximal lung capacity and a decrease in lung elastic recoil pressure at each lung volume. Efforts have been made to use the pressure–volume relationship and parameters derived from it as tests for emphysema severity. When pressure–volume relationships have been measured in excised human lungs, correlations with emphysema grade and or the mean linear intercept have been fairly close in some studies. Similarly high-order relationships have been shown in animal models of emphysema. Unfortunately, these relationships have been less consistent when the pressure–volume relationships have been measured in live humans and compared to emphysema severity in excised lungs. Correlations generally were found to be of a low magnitude, and they were not always statistically significant. These disappointing results are in part caused by the inherent variability of pressure–volume relationships in live subjects. Additionally, human disease frequently contains mixed elements of panacinar and centriacinar emphysema, and these two subtypes of emphysema may have different effects on lung elasticity. It has also been suggested that loss of lung elastic recoil may relate only indirectly to air-space enlargement and more directly to other, more subtle abnormalities in the lung's connective-tissue skeleton.

In a preceding section it was pointed out that emphysema would be expected to cause a reduction in maximal expiratory flow rates both because of a loss of lung elastic recoil and because of the loss of intraparenchymal airway tethers. Several correlative studies have shown that with increasing emphysema severity, maximal expiratory flow rates do decrease. Spirometric variables usually distinguish those patients with severe emphysema from those with no or trivial air-space enlargement, but in general, the correlation coefficients are surprisingly poor, so that spirometric abnormalities are not a good predictor of emphysema severity.

Total lung capacity is increased on average in patients with severe COPD, as are the vital capacity, functional residual capacity, and residual volume. The hyperinflation that is so characteristic a clinical and physiological feature of COPD is frequently attributed to emphysema. However, correlative studies have again proved disappointing in that none has shown a close correlation between any of the lung volumes and emphysema severity.

Thus, the principal conclusion to be drawn is that no currently available physiological test provides an accurate estimate of emphysema severity. In most studies, emphysema severity has been shown to correlate most closely with the D_LCO and less well with spirometric variables, lung volumes, and parameters of the pressure–volume relationships.

PHYSIOLOGICAL CORRELATES OF AIRWAYS DISEASE

The diverse pathologic conditions that affect the conducting airways in COPD are frequently lumped together as chronic bronchitis. Because not all of these lesions can be described as bronchial inflammation, and because chronic bronchitis has another, clinical definition, the practice of using this term to describe a variety of histopathologic changes in the conducting airways is not entirely logical. In this discussion we describe the entire complex of lesions affecting the conducting airways in COPD airways disease or, to clearly distinguish this category of disease from emphysema, intrinsic airways disease.

As discussed in the previous section, the importance of emphysema as one morphologic cause of airflow obstruction is well established even though the extent of anatomic emphysema does not correlate closely with any single pulmonary function test. Occasionally, patients with well-documented, severe COPD are found to have little emphysema when the lungs are examined at autopsy. Conversely, widespread emphysema is sometimes an incidental finding at autopsy in persons without known respiratory symptoms. Had careful pulmonary function testing been carried out in these individuals, some impairment of lung function might well have been found. Yet it is clear that the same amount of emphysema may be associated with severe disability and death in one person and cause few, if any, symptoms in the next.

This indicates that other morphologic factors must act in concert with emphysema to determine the severity of airflow obstruction. It has long been suspected that the most important of these other factors is the presence and severity of intrinsic airways disease. Earlier descriptions emphasized hypertrophy and hyperplasia of the mucus-secreting elements (i.e., bronchial mucous glands and epithelial goblet cells) as being an essential pathologic feature of COPD. It was suggested that excessive mucus predisposed to recurrent infection and that other pathologic changes, such as inflammation and fibrosis, were secondary phenomena. Because mucus hypersecretion was considered of paramount importance in the pathogenesis of COPD, chronic bronchitis was defined by the clinician as the presence of a productive cough, and to the pathologist it became virtually synonymous with bronchial mucous gland enlargement.

Other investigators described abnormalities in the peripheral airways of patients with COPD. These abnormalities included mural thickening and inflammation in many noncartilaginous bronchioles of lungs from patients with COPD. Morphometric and radiographic methods were employed to show that the peripheral airways from diseased lungs contained regions that were tortuous and modestly narrowed. It was also noted that inflammation and fibrosis of the membranous and respiratory bronchioles were more prevalent in lungs with centriacinar emphysema than with panacinar emphysema. It was suggested that lesions in the peripheral airways might contribute to the airflow obstruction and air trapping observed in COPD, but their mere presence gave no clue to their functional significance.

Earlier efforts to correlate the extent of intrinsic airways disease with the severity of airflow obstruction in COPD proved largely unsuccessful. The relationship between ventilatory dysfunction and mucous gland enlargement was most thoroughly investigated. In most such studies, the extent of mucous gland enlargement was assessed at autopsy by the Reid index or by other quantitative methods and was compared to pulmonary function measured within 1 or 2 years before death. Many such studies failed to show a consistent and compelling relationship between ventilatory function and the extent of mucous gland enlargement. This conclusion is further substantiated by studies of lung mechanics and morphology in postmortem lungs where no relationship was found between bronchial gland volume and any of the flow-resistive properties of the conducting airways. Also, epidemiologic studies demonstrated no significant relationship between excessive sputum production, the clinical correlate of mucous gland enlargement, and long-term changes in spirometric function. Correlative studies were similarly unsuccessful in showing that other disease features, including inflammation, fibrosis, and goblet cell metaplasia, involving either the large or small airways significantly related to antemortem spirometric abnormalities. Although these largely negative studies suggested that airways disease played only a small role in the causation of airflow obstruction, it is important to keep in mind that pathologic features such as inflammation and fibrosis do not lend themselves readily to quantitative assessment. Sampling is another potential problem because a single lung may contain as many as 30,000 separate airways. Hence, the results of these earlier studies should be regarded as inconclusive.

With tidal breathing, most patients with COPD have an elevated pulmonary resistance. The increase in airflow resistance, particularly when measured on inspiration, correlates with clinical status but not with the extent of anatomic emphysema. This measurement is thought to reflect more directly intrinsic airways disease than does spirometry, which, for reasons previously outlined, is also closely dependent on lung elastic recoil. An important clue to the site and nature of increased airflow resistance in COPD was provided by studies in which a retrograde catheter was positioned in the bronchial tree of postmortem lungs. This catheter then permitted airflow resistance to be partitioned between central airways and those peripheral airways of less than 2 mm internal diameter. The measurements obtained suggested that in normal lungs, peripheral resistance was negligible in comparison with the central component. However, in lungs from patients with COPD, central airways resistance was on average increased only slightly, but the peripheral component was increased between ten- and 20-fold. These observations added enormously to our understanding of the pathophysiology of COPD. Contrary to the opinion prevailing at that time, these studies indicated that it was disease in the distal airways and not the large bronchi that was principally responsible for increased flow resistance in COPD.

In addition, novel ideas were introduced concerning the natural history and pathophysiology of COPD. If peripheral resistance was negligible in the normal lung but predominated in severe COPD, quiescent disease might exist in the distal airways for many years before clinical symptoms of airflow obstruction became manifest. It was further suggested that routine spirometric tests may not be sufficiently sensitive to detect early disease in the distal airways. This premise provided the impetus to develop and evaluate a variety of so-called tests of small airways disease, such as the frequency dependence of dynamic compliance and the closing volume. Whether any of these newer tests offer any advantages over spirometry for either clinical or investigational purposes remains conjectural. Available evidence from epidemiologic and correlative studies indicates that standard spirometric tests, such as the FEV_1, are as sensitive as the specialized tests for detecting both early COPD and small airways disease.

This appears to be true because it is now known that the component of peripheral resistance in the normal lung is substantially greater than was suggested by the original retrograde catheter studies. In a population of largely normal lungs, it was found that pulmonary resistance and maximal expiratory flow rates correlated closely with the diameter of the membranous bronchioles and not with any other morphologic variable. For example, pulmonary resistance was correlated to average bronchiole diameter with a coefficient of –0.85, whereas the correlations between pulmonary resistance and both bronchial gland mass (r = –0.10) and large airways diameter (r = –0.21) were not statistically significant. Subsequent studies with the same retrograde catheter technique confirmed that the peripheral component of airways resistance in normal lungs was seriously underestimated in the original study.

This finding has important implications concerning the pathophysiology of COPD. If the peripheral airways are an important determinant of ventilatory function in the normal lung, it logically follows that lung function may be critically vulnerable to minor degrees of pathologic narrowing in those same airways. The sensitivity of ventilatory function to minor degrees of bronchiolar narrowing can be appreciated in Fig. 15, which shows the frequency distribution of internal bronchiole diameters in two normal adult lungs from persons of the same age. The average diameter in one lung is nearly twice that in the other. Because airflow resistance through cylinders varies with the fourth power or greater of diameter, seemingly modest differences in average bronchiole diameter are associated with pronounced functional differences. Pulmonary resistance in the second lung is more than five times greater than that in the first lung, and maximal expiratory flow rates are correspondingly less. Subtle pathologic changes that diffusely affect the distal air passages may have profound functional consequences.

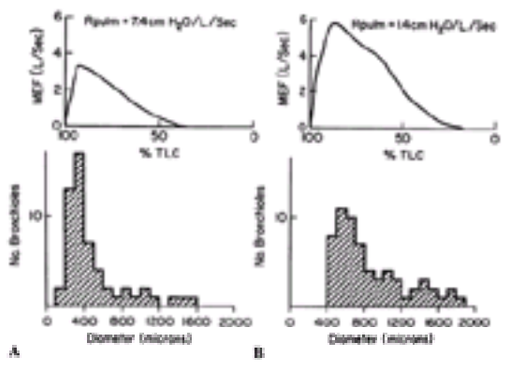

FIG. 15. Ventilatory function is sensitive to minor degrees of narrowing in the membranous bronchioles. Postmortem flow–volume loops and pulmonary resistance (R_{pulm}) were measured in two normal lungs **(A,B)** from men 40 years old. The *lower panel* shows the distribution of internal bronchiole diameters in the same two lungs. Note that R_{pulm} is substantially higher, and MEF is lower, in the lung with slightly smaller bronchioles. TLC, total lung capacity; MEF, maximum expiratory flow.

The suggestion that disease in the peripheral airways might antedate the clinical manifestations of COPD has been largely substantiated by physiological and pathologic studies. Most such studies have been directed at young smokers, a logical choice because cigarette smoking causes COPD, but usually only after at least 20 years of habitual consumption. Subtle ventilatory dysfunction in young smokers has been detected by a variety of pulmonary function tests. The pathologic lesions thought to be responsible for these minimal physiological abnormalities have been identified in studies of lungs from youthful victims of sudden death. The characteristic lesion in cigarette smokers (Fig. 5) is located in the respiratory bronchiole and consists of clumps of brown-pigmented macrophages lying within the air spaces while edema, epithelial hyperplasia, and minimal fibrosis involve the adjacent alveolar and bronchiolar walls. Frequently, a sparse mononuclear inflammatory infiltrate is seen within the walls of the terminal membranous bronchioles. These lesions are present in all lungs from cigarette smokers, but they are noted only occasionally in the lungs of nonsmokers.

Functional and morphologic correlative studies provide additional direct evidence linking peripheral airways disease with airflow obstruction in COPD. Lung tissue was obtained from patients undergoing thoracotomy in whom extensive pulmonary function tests had been performed immediately before surgery. A few subjects had normal pulmonary function, but most had mild to moderate COPD. Emphysema was quantified from thick lung slices, and the extent of small airways disease was assessed on multiple histologic sections from each lung. Each bronchiole was individually evaluated and assigned a score appropriate to the severity of each morphologic abnormality, including luminal mucus, squamous and goblet cell metaplasia involving the epithelium, and inflammation, fibrosis, pigment, and smooth muscle hypertrophy in the airway wall. A weak but consistent relationship was found between composite scores for small airways disease and the severity of airflow obstruction as assessed by various physiological tests. Functional disturbances related most closely to fibrosis and inflammation within the walls of the bronchioles, and they correlated less well with epithelial abnormalities and with the amount of intraluminal mucus. Other studies in which postmortem pathology was compared to antemortem pulmonary function tests yielded similar results.

RELATIVE IMPORTANCE OF EMPHYSEMA AND AIRWAYS DISEASE

From the foregoing discussion it is reasonable to conclude that both emphysema and small airways disease play significant roles as causes of airflow obstruction in COPD. Both are clearly more important than chronic bronchitis and mucus hypersecretion. Lungs from patients with COPD usually contain elements of both emphysema and peripheral airways disease, but numerous studies have yielded conflicting results as to which component might be the more important. This might be a function of case selection and the severity of the clinical disease. When pathologic studies were performed on autopsied lungs, emphysema has generally emerged as the single closest correlate of airflow obstruction. When pathologic studies were performed on lungs resected at surgery, peripheral airways disease has usually appeared to be somewhat more important. Patients undergoing thoracotomy clearly have less severe disease than those patients who are subjected to autopsy. On the basis of such studies, it has been suggested that peripheral airways disease might dominate during the earlier clinical stages of COPD but that emphysema might play a greater role in those patients who are severely incapacitated and who eventually die of respiratory insufficiency. No firm conclusions can be drawn until more complete information becomes available. A summary of the principal pathologic changes found in COPD and their relationship to clinical and physiological

abnormalities is provided in Table 1.

	Symptoms	Pathology	Physiology
Chronic bronchitis	Cough and sputum expectoration	Inflammation and enlargement of mucus-secreting elements in central airways	Little or no effect on spirometry
Emphysema	Dyspnea and exercise intolerance when severe	Air space enlargement with destruction of alveolar walls	Adverse effects on spirometry and arterial blood gases Loss of elastic recoil Decrease in DLCO
Small airways disease	Dyspnea and exercise intolerance when severe	Inflammation, goblet cell metaplasia, fibrosis, and smooth muscle enlargement in distal airways	Subtle spirometric abnormalities in young smokers Contributes to airflow obstruction and blood gas abnormalities in severe COPD

TABLE 1. *Pathologic features of COPD and their relationship to symptoms and pulmonary function abnormalities*

CLINICAL AND PATHOLOGIC SUBTYPES

Patients having in common irreversible airflow obstruction may exhibit otherwise variable clinical and physiological features. Based on clinical, roentgenographic, and physiological criteria, two contrasting categories of disease, the so-called emphysematous and bronchial subtypes of COPD, were described. As implied by the descriptive terms applied to each subgroup, it was presumed that extensive anatomic emphysema provided the principal morphologic basis for dysfunction in the first group, whereas enlargement of the mucus-secreting elements was the major pathologic lesion in patients with bronchial disease. There is general agreement as to the basic clinical and physiological features of each syndrome; whether distinguishable patterns of lung pathology underlie these subtypes of COPD is somewhat less clear.

The patient thought to have predominant emphysema (type A disease) has been described in rather vivid terms as a “pink puffer.” He is said to be a cachectic, elderly man who relates a long history of progressive and unrelenting breathlessness. Sputum production and recurrent chest infections are notable by their absence and, except in the preterminal stages of the disease, heart failure (cor pulmonale) is not clinically evident. The chest roentgenogram reveals a small cardiac silhouette along with the roentgenographic signs of advanced emphysema: lung hyperinflation, attenuated peripheral lung markings, and frequently the thin ring shadows pathognomonic of bullae. At rest, arterial blood gas values reveal mild hypoxemia with little elevation in the arterial carbon dioxide tension. The hematocrit is seldom greater than 45% to 50%, reflecting the relative absence of arterial oxygen desaturation. In addition to the decrease in expiratory flow rates, pulmonary function studies show large lung volumes, with TLC being 130% or more of the predicted value. Because of the loss of alveolar tissue, lung elastic recoil is decreased, and the D_LCO is severely impaired. Pulmonary resistance measured during tidal breathing is normal or only slightly elevated.

The patient considered to have predominant bronchial disease (type B patient) was described as a “blue bloater.” In contrast to the asthenic appearance of the pink puffer, this patient is described as a stocky and sometimes overweight individual with a plethoric facies and pronounced cyanosis. Because enlargement of the mucus-secreting elements has been thought the principal cause of airflow obstruction in these individuals, the presence of chronic cough and sputum production has been considered an essential feature of type B disease. The other essential feature is cor pulmonale, which appears early and remains a prominent feature throughout the course of the disease. Cor pulmonale is manifest clinically as peripheral edema, cardiac enlargement, and classic electrocardiographic signs of right ventricular enlargement. Arterial blood gas values show evidence of severe arterial oxygen desaturation and a strong tendency to carbon dioxide retention. Secondary polycythemia with a hematocrit in excess of 55% commonly develops as a consequence of severe, chronic hypoxemia. As with the type A patient, spirometry shows severe airflow obstruction, but there is less hyperinflation of the lung. Because alveolar tissue is thought to be preserved, lung elastic recoil is normal, as is the D_LCO.

The clinical features that distinguish COPD subtypes can be recognized in some patients, but most patients with COPD appear to have features of both groups and cannot be categorized. It has been proposed that the population of COPD patients represents a spectrum, with the type A patients at one end and the type B patients at the other. Because of extensive overlap between the two groups, clinical investigations have compared only those patients at the extreme ends of the spectrum.

In general, type A patients were found to have larger lung volumes, more nearly normal arterial blood gases, and a larger volume of total ventilation per unit of oxygen uptake. Consistent differences were noted between the two groups with regard to pulmonary vascular hemodynamics and systemic oxygen transport. In the type A patients, cardiac output was subnormal both at rest and with exercise, whereas this physiological variable was normal under both conditions in the blue bloaters. Calculated pulmonary vascular resistance was not significantly different in the two groups, but because cardiac output was higher in the type B group, mean pulmonary artery pressures also were greater. Pulmonary hypertension developed in the type A patients only in response to exercise. Despite a greater degree of arterial oxygen desaturation, systemic oxygen transport was better preserved among the type B patients because of their secondary polycythemia and because of their higher cardiac output. With exercise, minute ventilation in relation to oxygen consumption and to carbon dioxide excretion was higher in the type A patient than in the type B patient. Maximum work load and the exercise level associated with anaerobic metabolism tended to be less in the type A patient.

Ventilation–perfusion relationships have also been compared in patients with type A and type B disease. In general, patients with type A disease had predominantly high abnormalities with relatively few areas of low-$\dot{V}/\dot{Q}$ abnormalities. There was a greater tendency for low-$\dot{V}/\dot{Q}$ patterns to be found in type B disease, but most patients with this clinical syndrome had mixed patterns of both high- and low-$\dot{V}/\dot{Q}$ disturbances.

Though type A and type B patients are recognized clinically, much less is known about the causes and mechanisms of those differences. It is emphasized that subgroup distinctions have usually been made on clinical and physiological grounds, and the pathology has only been inferred. Where efforts have been made to correlate lung pathology with the clinical subtype of COPD, the findings have been contradictory and inconclusive. Many of the criteria used to categorize clinical subtypes are descriptive and not quantitative. It is evident that selection criteria are not uniform among different studies, and sometimes not even among the same groups of investigators at different times. These factors may partly explain the relative lack of success in correlating clinical COPD subtypes with pathology.

Cor pulmonale is generally considered an essential feature of the type B patient but not the type A patient. Clinical right-sided heart failure relates closely to right ventricular enlargement, and this morphologic feature can be accurately assessed at autopsy. One can conclude from the available evidence that the presence of emphysema alone is not the predominant factor in the pathogenesis of cor pulmonale. Numerous autopsy studies compared right ventricular size with emphysema severity. The correlation was variously reported as positive, negative, or not statistically significant. However, even with a positive correlation, only about 25% of the total variance in right ventricular weight could be explained by emphysema severity. The methods for assessing emphysema and right ventricular size are reproducible, so that the poor correlations cannot be attributed to measurement error. It also has been suggested that right ventricular enlargement might be more closely related to the morphologic type of emphysema. Even here the evidence is conflicting; some reports show that right ventricular size is related to centriacinar emphysema, but others report an association with panacinar emphysema. Estimation of emphysema severity by CT also bears no significant relationship to arterial blood gas abnormalities, cardiac output, mean pulmonary artery pressure, or pulmonary vascular resistance.

The dissociation between the severity of emphysema and right ventricular size supports the idea that type A patients have little tendency to develop cor pulmonale. However, a number of earlier efforts to relate bronchial mucous gland enlargement, thought to be the essential pathologic feature in type B patients, with pulmonary hypertension and cor pulmonale were equally unsuccessful. These negative findings are not surprising in light of the previously cited evidence that bronchial mucous gland enlargement is also unrelated to airflow obstruction.

Peripheral airways disease might be more closely associated with cor pulmonale than is either emphysema or mucous gland enlargement. The severity of peripheral airways disease, as assessed from histologic studies, from bronchial casts, or from bronchography, has been compared to right ventricular weights or to the characteristic changes of hypertension in the pulmonary arterioles. Although the association was not strong, and it varied from study to study, a reasonably consistent relationship has been found between indices of peripheral airways disease and the development of pulmonary hypertension.

Certain patients with COPD do have a greater predisposition toward developing hypoxemia, hypercapnia, and pulmonary hypertension, so that the terms pink puffer and blue bloater may have some validity as clinical descriptive terms. However, it is largely unknown why these differences exist. Because they have no clearly defined anatomic basis, there is no justification for describing such patients as having either the emphysematous or bronchitic type of COPD.

ROENTGENOGRAPHIC CORRELATES

A chest roentgenogram is an essential part of the initial medical evaluation of all patients with an undiagnosed complaint of dyspnea. However, its chief diagnostic value may lie in what it does not reveal, namely, roentgenographic signs that suggest some cause for dyspnea other than COPD. The chest roentgenogram is a relatively insensitive test for COPD, and it may appear normal or near-normal in the face of severe airflow obstruction. The criteria for the roentgenographic diagnosis of COPD fall into two main categories: lung hyperinflation and irregular radiolucencies of the lung fields.

Lung Hyperinflation

The standard chest roentgenogram in a patient with severe COPD reveals a diaphragm that is depressed with an altered contour (Fig. 16). The diaphragm is abnormally low if the dome is at the level of the anterior aspect of the seventh rib or below, and it is considered flattened if the maximum curvature is less than 1.5 cm. It has also been suggested that the sternodiaphragmatic angle on the lateral chest film may be a useful sign. In normal subjects, this angle is acute, but in patients with COPD, it is frequently greater than 90°. Lung hyperinflation is also indicated by an increase in the retrosternal clear space. This distance is measured horizontally between the posterior edge of the sternum and the most anterior portion of the ascending aorta. Some experts consider a distance of 2.5 cm or more to be abnormal, but others believe a value of 4.5 cm to be a more specific criterion for COPD.

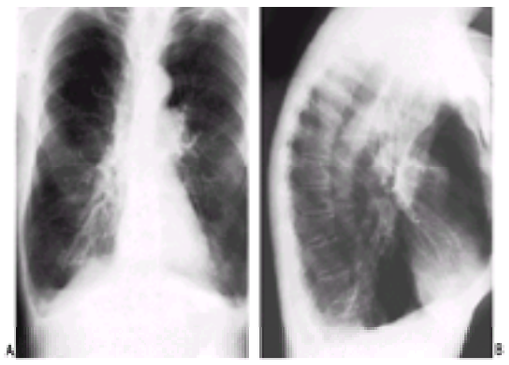

FIG. 16. Chest roentgenogram from a patient with severe COPD. In the posteroanterior projection (*left*), the lungs appear hyperinflated with attenuation of the peripheral lung markings. The lateral projection (*right*) shows loss of the normal contour of the hemidiaphragms and an increase in the retrosternal clear space.

Irregular Radiolucencies of Lung Fields

Emphysema results in a loss of alveolar tissue and a diminution in the number of blood vessels. As a consequence, affected areas are less dense, and these abnormalities can be appreciated roentgenographically as areas of radiolucencies in the peripheral lung fields. On the standard chest roentgenogram, these changes may be quite subtle, and the presence of radiolucencies can be appreciated only by comparison against more normal-appearing regions. The edges of bullae can frequently be identified by the presence of thin, curved lines on the plain chest roentgenogram, and these changes are pathognomonic for bullous emphysema.

The irregular radiolucencies associated with emphysema are much better seen with tomography, particularly with the superior resolution provided by computed tomography (CT). When regional variations in lung tissue density are quantified by CT scans, remarkably good correlations with the extent of anatomic emphysema have been demonstrated. Precise information concerning the anatomic distribution and severity of emphysema has no clinical implications except in those few patients where consideration is given to surgical ablative therapy.

VARIANT FORMS OF COPD

Bullous Emphysema

Bullous emphysema is considered separately because it has certain distinctive pathologic and roentgenographic features and because surgery may be of benefit to the patient. Bullae are abnormally enlarged air spaces, measuring more than 1 cm in diameter, resulting from destruction of alveolar walls. Bullae are thought to represent a variant form of emphysema in which the destructive changes are exaggerated within focal areas. Most patients with bullae have some emphysema in other lung regions, but extensive bullous disease may be present with little pathologic change in other lung regions. Small bullae, occurring singly or in clusters, are sometimes seen at the apices of otherwise normal lungs, particularly in tall young adults. They may spontaneously rupture into the pleural space and cause a pneumothorax. Whether these small apical bullae are the forerunners of more extensive bullous disease in older patients is not known. Giant bullae may occur singly, but they are more commonly multiple, and they frequently involve both lungs. They are located immediately below the pleural surface and occur most commonly in the upper portions of the lung. The predilection for bullae to occur in lung apices might be explained by gravitational effects, which result in greater tissue stresses in the more cephalad lung regions. However, bullae occur in all parts of the lung, and a basal location is more frequently observed in patients with severe a_1-antiprotease deficiency.

Bullous disease, when extensive, can usually be recognized on the plain chest roentgenogram as regions of absent or decreased vascular markings demarcated by curving hair-thin shadows. These thin lines represent the walls of the bullae and, when visible, are virtually pathognomonic. Bullae are visualized much better with the CT scan, and this is the preferred method if there is need to define location and extent. The displacement of the pulmonary vasculature away from areas of bullous involvement can be demonstrated elegantly by pulmonary angiography, but this procedure is rarely necessary. Radioisotope scanning can also be utilized to assess the location and severity of bullous disease, as the involved areas have markedly diminished ventilation and perfusion.

Patients with bullae frequently have reduced maximal expiratory flow rates, an increase in TLC, FRC, and RV, and a decrease in the D_LCO. The extent to which bullous disease is responsible for these functional disturbances is uncertain because patients usually have coexisting diffuse emphysema and airways disease. Bullae are largely avascular, and because they also are underventilated, they contribute little to overall gas exchange. Bullae are frequently viewed as enclosed air spaces that, because of pressure differentials, particularly during expiration, compress and impair function in more normal adjacent lung regions. However, most bullae have some communications with surrounding air spaces, and it therefore seems improbable that large pressure differentials could exist across the walls of the bullae during tidal breathing. Bullae probably impair lung function merely as space-occupying structures that do not permit more normal areas of the lung to expand fully.

The suspicion that bullae may contribute directly to impaired lung function has guided surgical efforts for their removal or ablation. Overall, these efforts have not yielded encouraging results, and as might be anticipated, surgery in this group of patients has a high attendant morbidity and mortality. Despite the generally disappointing results, surgery does confer substantial objective and subjective benefits for a few selected patients. The problem is in knowing how to identify those individuals who are most likely to benefit. Based on the case analysis of published reports, only general guidelines can be offered to predict the response to surgery. The larger and more localized the bullae, the more likely there will be a favorable result from surgical ablation. Patients with the worst preoperative pulmonary function have the poorest chance of appreciable objective improvement. The presence of diffuse severe emphysema, as indicated by a very low D_LCO, is associated with a particularly poor surgical success rate. However, if bullae are localized, if they involve at least one-third to one-half of a hemithorax, if the patient is severely disabled from dyspnea, and if overall lung function is reasonably well preserved, then consideration should be given to surgical ablation.

Unilateral Hyperlucent Lung Syndrome

Swyer and James first described the unilateral hyperlucent lung syndrome in 1953; this report was followed shortly by descriptions of similar cases by MacLeod. Hence, the condition is sometimes described as the Swyer–James or MacLeod syndrome. The diagnosis is principally a roentgenographic one, and many cases are first recognized from routine chest roentgenograms in asymptomatic persons. The principal feature is an abnormal degree of radiolucency involving one lung or one lobe within a lung that results from attenuated vascular markings and not from overexpansion. In addition, there is usually a smaller-than-normal hilar shadow on the affected side. Severe airflow obstruction is present on the affected side, and this is evident with fluoroscopy or with inspiratory and expiratory chest roentgenograms. With inspiration, the mediastinum shifts toward the affected lung, and there is only minimal movement of the rib cage and diaphragm on the involved side. With expiration, the mediastinum shifts toward the normal lung as it empties, while the volume of the affected lung changes little if at all. Pulmonary angiograms show a relatively small pulmonary artery on the affected side, with marked attenuation in the number and size of the smaller arterial branches. The decrease in ventilation and

perfusion in the radiolucent lung can also be readily appreciated from external radioisotope scans.

Originally it was thought that this syndrome represented a congenital or acquired vascular abnormality similar to hypoplastic pulmonary artery, but it is now known that diffuse obstruction in the peripheral airways is the primary lesion, and the vascular changes are secondary. Roentgenographic and pathologic studies demonstrate severe bronchiolar disease, which is responsible for airflow obstruction and air trapping. Bronchograms of affected lungs show largely normal proximal bronchi but dilation and beading of the more distal airways. Many of the terminal airways fail to fill completely with contrast material. The clubbed and tapered peripheral airways are described as having a “broken bough” appearance. Pathologic studies of these same lungs reveal widespread inflammation and fibrosis of the nonalveolated bronchioles with narrowing or complete obliteration of their lumina. Emphysema of varying severity is present in the parenchyma of some of the affected lungs. Small pulmonary arterioles are narrowed, but they are not occluded by thrombi, and they are not involved by an endarteritis. The large pulmonary arteries are normal by histologic examination.

Many patients with the unilateral hyperlucent lung syndrome have a history of severe childhood pneumonia, and other cases have been described following *Mycoplasma pneumoniae* infection, measles, pertussis, tuberculosis, radiation, foreign-body aspiration, and hydrocarbon exposure. The clinical and pathologic observations are consistent with the idea that severe inflammation in the small airways, induced by infection or toxin, causes severe airflow obstruction. Hypoperfusion occurs secondarily because of relative alveolar hypoxia, and over time these vascular changes become irreversible.

The affected lung receives some ventilation (atelectasis would occur if it did not), but minute volume and oxygen uptake on the affected side are usually less than 25% of the total and may be much less. Mixing time for inert gases is greatly prolonged because of the marked disparities in the amounts of ventilation received by the two lungs. Because perfusion is reduced roughly in proportion to ventilation, the $\dot{V}/\dot{Q}$ of the involved lung remains near unity so that severe arterial oxygen desaturation does not usually occur unless the patient exercises. Spirometry characteristically shows a modest reduction in the forced vital capacity and mild airflow obstruction. If the opposite lung is relatively free of disease, pulmonary function test results may be surprisingly normal.

Unilateral hyperlucent lung syndrome usually presents few difficulties in differential diagnosis provided that fluoroscopy or inspiratory and expiratory roentgenograms are obtained. Most patients have no symptoms directly attributable to the disorder, so that no specific treatment is required. If the opposite lung is also involved to a lesser degree, severe airflow obstruction and a clinical picture indistinguishable from COPD may be present. Rarely, recurrent infections in the affected lung may be an indication for surgical removal.

Partitioning of pulmonary impedance in excised human and canine lungs. *J Appl Physiol* 1983;55:1733–1742. *This is a reprise of the retrograde catheter study by Hogg and associates. This study also demonstrated that peripheral resistance is markedly elevated in lungs from patients with COPD, but the study also indicates that the peripheral component of resistance may be as high as 75% of the total in normal human lungs.*

CHAPTER

43 Clinical Aspects of Chronic Obstructive Pulmonary Disease

Bartolome R. Celli

B.R. Celli: Pulmonary and Critical Care Division, St. Elizabeth's Medical Center, and Department of Medicine, Tufts University, Boston, Massachusetts 02135.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) has recently been defined by the American Thoracic Society (ATS) as a disease state characterized by the presence of airflow obstruction secondary to chronic bronchitis (airways disease) or emphysema (parenchymal destruction with air-space enlargement). The airflow obstruction is generally progressive, may be accompanied by hyperactivity, and may be potentially reversible. This definition is very similar to that expressed by other international respiratory societies in similar statements. Inherent to the definition is the acknowledgment that many patients with COPD may show a significant reversible component in their airflow obstruction and that patients with asthma may go on to develop irreversible airflow obstruction indistinguishable from COPD.

Chronic bronchitis is defined in clinical terms as the presence of chronic cough with phlegm production for 3 months in each of two consecutive years, without other specific causes of cough (asthma, bronchiectasis, cystic fibrosis, etc.). Emphysema, on the other hand, is defined pathologically as abnormal air-space enlargement as has been discussed in the previous chapter. Figure 1 graphically represents the interrelation of the different nosologic components that lead to COPD and helps the reader to better understand the concepts. Most patients with asthma have significant reversible airways constriction and respond well to inhaled and systemic antiinflammatory therapy and therefore do not have COPD. As stated before, a small minority of asthmatics go on to develop minimally reversible airflow limitation indistinguishable from COPD. This group of patients do have COPD and are treated as such.

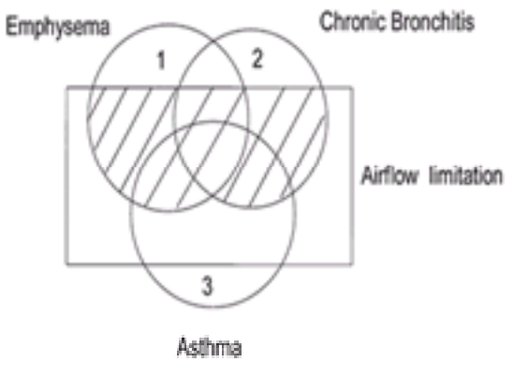

FIG. 1. Nonproportional Venn diagram. Each *circle* represents a nosologic entity. The *rectangle* represents airflow limitation as documented in a forced spirometry. The *shaded area* corresponds to patients diagnosed as having COPD. Notice that a patient (subset 1) may present with emphysema without COPD (patient with bullae on chest roentgenogram without airflow limitation). Similarly, he or she may present with sputum production and normal spirometry (subset 2, with simple bronchitis). Finally, an asthmatic may present without airflow limitation (subset 3) and will be diagnosed only after a bronchoprovocation test.

EPIDEMIOLOGY OF COPD AND RISK FACTORS

It is estimated that in the United States, close to 14 million people suffer from COPD. This number has increased 42% since 1982. Although between 1979 and 1986 the prevalence varied from 4% to 6% of adult men and 1% to 3% of women, it had increased more for the women than for men. There were 85,544 deaths from COPD in 1991 (death rate of 18 per 100,000 persons); COPD ranks as the fourth leading cause of death, but it was the fastest rising one (33%) between 1979 and 1991. When adjusted by age, the death rate from COPD rose 72% between 1966 and 1986. This is particularly important when death rate for all causes decreased 22% and rates from heart and cerebrovascular disease declined 45% and 85%, respectively. Fortunately, there has been a progressive decline in the percentage of the population who smoke (Fig. 2). This should result in decreased mortality from COPD in the near future. It is interesting that most of the decrease is attributable to

smoking cessation in men and not in women. Even greater efforts must be devoted to smoking cessation because the habit is still practiced by 75 million citizens in the United States alone. If the same prevalence exists around the world (there is evidence that it may actually be more), there is an astonishing total of 1.2 billion human beings exposed to the ravages of cigarettes.

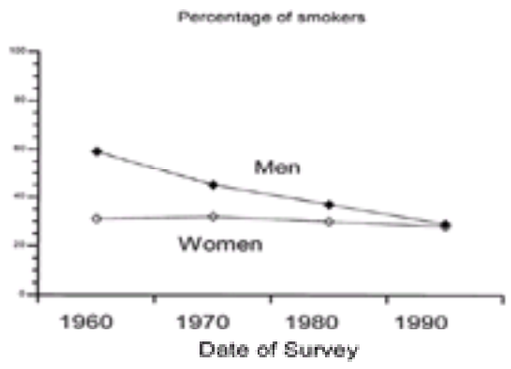

FIG. 2. Prevalence by decade of smoking habit in the general population of the United States.

As shown in Table 1, the most important cause of COPD is cigarette smoking. Other possible causes may act as independent risk factors in its genesis, but their importance dwarfs in comparison with the role of cigarette smoking. The only other risk factor comparable to the importance of smoking for an individual is a_1-antitrypsin (AAT) deficiency, but AAT accounts for fewer than 1% of COPD cases.

Established	Probable	Possible
Cigarette smoking	Air pollution	Low birth weight
Occupational exposure (work smoke)	Poverty	Childhood respiratory infections
α_1-Antitrypsin	Childhood exposure to smoke	Family history
	Alcohol	Atopy
	Hyperreactive airways	IgA nonsecretor
		Blood group A

TABLE 1. *Risk factors for the development of COPD*

Children exposed to cigarette smoke manifest a higher prevalence of respiratory symptoms and diseases than do children of nonsmokers. They also show a measurable decrease in pulmonary function tests. Whether this leads to COPD remains unclear, but it is very possible. Air pollution is harmful to patients with heart and lung disease and may be an important factor in certain areas. Studies in nonsmoking persons who use solid fuels for indoor cooking and lack adequate ventilation have shown presence of COPD in some of the patients studied. This evidence does support some role for pollutants in the genesis of COPD, but it would be small in comparison to cigarette smoking in countries with better pollution control. Expoto polluting agents in the environment may probably operate in the same way and may certainly worsen the function of patients with airflow obstruction. Morbidity and mortality rates from COPD are higher for whites than for nonwhites and in blue-collar than white-collar workers; COPD also aggregates in families independent of a_1-antitrypsin deficiency.

Atopy, hyperresponsive airways, and asthma may play a role in the genesis of COPD. Since it was first proposed by researchers in The Netherlands, the Dutch hypothesis has been the subject of interesting analyses. It has been shown that airway hyperactivity is inversely related to FEV_1 and that it is predictive of an accelerated rate of decline of lung function in smokers. In the Lung Health Study of COPD, there was a rather significant proportion of men (59%) and even more women (81%) who manifested airways hyperactivity. This suggests that hyperactive airways may be an important factor contributing to FEV_1 decline in some patients with COPD, but its true importance remains to be determined.

The only host factor proven to lead to COPD is deficiency of a_1-antitrypsin. This serum protein is made by the liver, and its main role is the inhibition of neutrophil elastase. It is a glycoprotein coded for by a single gene on chromosome 14. The normal value of AAT is 150 to 350 mg/dl (commercial standard) or 20 to 48 mg/dl (laboratory standard). There are rare instances of patients with normal levels of dysfunctional AAT. Most of the persons with severe deficiency are homozygotic for the Z allele (PiZZ) and have very low levels of AAT (mean 18% of the value seen in normals). The threshold protective level of AAT is around 80 mg/dl (35% normal), and heterozygotes (PiSZ) with these levels rarely develop emphysema. Severe AAT deficiency leads to premature emphysema, often with chronic bronchitis, nonspecific airway hyperactivity, and occasionally with bronchiectasis. The onset of disease is accelerated by smoking, and dyspnea begins at the median age of 40 in smokers and 50 in nonsmokers. Not all patients with AAT deficiency will develop emphysema, especially if not exposed to cigarettes or pollution. Patients should be screened for AAT deficiency if they present with premature onset of COPD (before age 50), predominance of basilar emphysema (by x-rays), presence of nonremitting asthma in a young person, and liver cirrhosis without apparent risk factors.

NATURAL HISTORY OF COPD

The decline in lung function with time is shown in Fig. 3. Normal nonsmokers lose between 25 and 35 mL of their FEV_1 yearly. The rate of decline is steeper for smokers than for nonsmokers. The heavier the smoking, the steeper the decline; likewise, the lower the initial FEV_1, the faster will FEV_1 drop. The FEV_1 of patients with COPD decreases around 90 mL a year. The Lung Health Study showed that patients who stopped smoking had a mean postbronchodilator FEV_1 increase of 57 mL at the first annual visit compared with a mean FEV_1 decline of 38 mL for those who continued to smoke. This indicates not only that the decline will decrease but that lung function may actually improve after smoking cessation. The natural rate of decline accelerates dramatically in susceptible smokers. The rate of decline returns toward normal soon after smoking cessation in most of the patients, whereas the development of symptoms with minimal activities will occur much earlier in current than in ex-smokers.

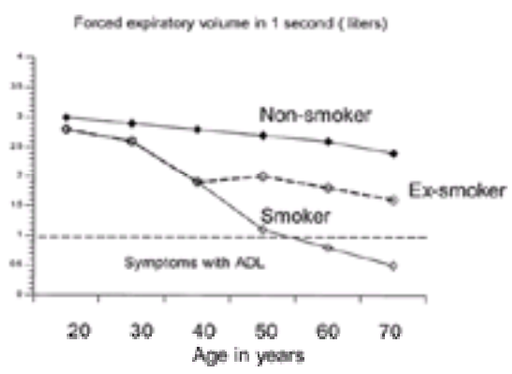

FIG. 3. Rate of decline of lung function according to smoking habit. Notice that the rate of decline is steeper for current smokers and tends to return to the normal rate after smoking cessation. The onset of symptoms related to COPD will be delayed whenever smoking stops.

CLINICAL FEATURES

History

The typical patient with COPD has smoked more than 20 pack/years before symptoms develop. They commonly present with productive cough or an acute chest illness at around the fifth decade. Dyspnea usually begins around the sixth or seventh decade, but it may become the dominant feature. Dyspnea may become crippling and lead to deconditioning as ever less intense exercise precipitates worsening of the symptom. This vicious cycle is one of the most important problems in patients with advanced COPD. Breaking the cycle leads to improvement in the functional status of the patient.

Sputum initially occurs only in the morning and is usually mucoid. During exacerbations, it may become purulent. Acute chest illnesses characterized by increased cough, purulent sputum, wheezing, dyspnea, and occasionally fever may occur intermittently. The history of wheezing and dyspnea may lead to the erroneous diagnosis of asthma. As the disease progresses, the intervals between exacerbations shorten. Late in the course, the patient may develop hypoxemia, which, if severe enough, may result in clinical cyanosis; this is accentuated by erythrocytosis. Development of morning headache suggests hypercapnia. Weight loss occurs in some patients, and cor pulmonale with right heart failure and edema may develop in patients with hypoxemia and hypercapnia. Most episodes of hemoptysis result from mucosal erosion and not carcinoma. However, because bronchogenic carcinoma occurs with increased frequency in smokers with COPD, an episode of hemoptysis raises the possibility that a carcinoma has developed, and it should prompt an evaluation to rule out this possibility.

Physical Examination

Initially, the chest exam may show wheezes only on forced expiration. As obstruction progresses, hyperinflation becomes evident, and the anteroposterior diameter of the chest increases. The diaphragm is depressed and limited in its motion. Breath sounds are decreased at this stage, and heart sounds often become distant. Coarse crackles are often heard at the lung bases. An excessively prolonged forced expiratory time (over 4 sec with the stethoscope over the trachea) may be seen in patients with a significant degree of airflow limitation. The patient with end-stage COPD may adopt positions that relieve dyspnea, such as leaning forward with weight supported on the arms. The accessory respiratory muscles of the neck and shoulder girdle are in full use. Expiration often takes place through pursed lips and with forced contractions of the abdominal muscles. Paradoxic indrawing of the lower costal interspace with inspiration is a classic finding first described by William Stokes in 1837. An enlarged tender liver indicates heart failure. Neck vein distention, especially during expiration, may be observed in the absence of heart failure because of increased intrathoracic pressure. Cyanosis may be present, and asterixis may be seen with severe hypoxemia and hypercapnia.

LABORATORY FINDINGS

Chest Radiography

Because emphysema is defined in anatomic terms, posteroanterior and lateral chest roentgenograms provide evidence of its presence. Hyperinflation is indicated by a low, flat diaphragm, an increased retrosternal air space, and a long, narrow heart shadow. Rapid tapering of the vascular shadows accompanied by hypertransparency of the lungs is a sign of emphysema; bullae, presenting as radiolucent areas larger than 1 cm in diameter and surrounded by arcuate hairline shadows, suggest its presence. However, bullae reflect only locally severe disease and are not necessarily indicative of widespread emphysema. Studies correlating lung structure and the chest radiograph show that emphysema is consistently diagnosed when the disease is severe but that diagnosis is not as accurate when the disease is mild or even moderate. Right ventricular hypertrophy does not result in cardiomegaly in COPD. Comparison with previous chest radiographs may show the enlargement. The hilar vascular shadows are prominent, and the heart shadow encroaches on the retrosternal space as the right ventricle enlarges anteriorly. Lung cancer and heart disease are associated with the same risk factor as COPD, namely, smoking. Therefore, a chest roentgenogram is indicated, not only to find evidence of emphysema but, equally important, to rule out the presence of any of the diseases that may present with similar symptoms.

Computed Tomography

Computed tomography, especially a high-resolution CT scan (collimation of 1 to 2 mm), has much greater sensitivity and specificity than standard chest radiography. However, because this rarely alters therapy, CT has no place in the routine care of patients with COPD. It is the main imaging tool for evaluating the benefit of pulmonary resection for giant bullous disease and for diagnosing bronchiectasis. It also is gaining ground as a good tool to evaluate potential candidates for lung volume reduction surgery.

Pulmonary Function Tests

Determination of a forced vital capacity is necessary for the diagnosis and assessment of the severity of disease and helpful in following its progress. The FEV_1 is easily measurable, has less variability than other measurements of airways dynamics, and is more accurately predictable from age, race, gender, and height. Roughly comparable information can be obtained from the peak flow measurement or from the forced expiratory flow–volume curve. None of these tests can distinguish between chronic bronchitis and emphysema. The FEV_1 and the FEV_1/FVC ratio fall progressively as the severity of COPD increases. In the laboratory, about 30% of patients have an increase of 20% or more in their FEV_1 following a b-agonist or ipratropium bromide treatment.

Lung volume measurements show an increase in total lung capacity, functional residual capacity, and residual volume. The vital capacity may be decreased. The single-breath carbon monoxide diffusing capacity (D_LCO_{sb}) is decreased in proportion to the severity of emphysema because of the loss of alveolar capillary bed. The test is not specific, nor can it detect mild emphysema. If the D_LCO_{sb} is disproportionally low in comparison with changes in other function tests, emphysema is more likely to be the cause of the obstruction. The presence of a low D_LCO_{sb} has correlated with exercise oxygen desaturation in patients with COPD.

Arterial blood gases reveal hypoxemia without hypercapnia in the early stages. As the disease progresses, hypoxemia becomes more severe, and hypercapnia supervenes. Hypercapnia is observed with increasing frequency as the FEV_1 falls below 1 liter. Blood gas abnormalities worsen during acute exacerbations and may worsen during exercise and sleep. Erythrocytosis is infrequently observed in patients living at sea level who have P_aO_2 levels of >55 mmHg; the frequency of erythrocytosis increases as P_aO_2 levels fall below 55 mmHg.

Sputum Examination

In stable chronic bronchitis, sputum is mucoid, and the predominant cell is the macrophage. With an exacerbation, sputum usually becomes purulent with an influx of neutrophils. The Gram stain usually shows a mixture of organisms. The most frequent pathogens cultured from the sputum are *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis.* However, cultures and even Gram stains are rarely necessary before antimicrobial therapy is instituted in the outpatient setting.

DIAGNOSIS AND MONITORING

In patients suspected of COPD, a forced spirometry provides the basic physiologic assessment needed to quantify obstruction. Arterial blood gases in patients with severe COPD (stage III) help to identify the presence and severity of hypoxemia and hypercapnia. The effect of inhaling a b-agonist or ipratropium on the FEV_1 should be determined. Bronchodilators should not be withheld on the basis of this test. Measurements of lung volumes, diffusing capacity, or physiological responses to exercise usually add little unless the diagnosis is in doubt or an assessment of operative risk is being made. Arterial blood gas measurements are not needed with mild or moderate disease unless symptoms or specific clinical findings suggest a need for them. With severe disease (FEV_1 < 1 L), serial measurements of FEV_1 become relatively unimportant because of the difficulty of interpreting small changes. Serial blood gas measurements become the major test for monitoring the course of the disease.

STAGING OF COPD

There is no well-accepted staging or severity scoring system for patients with COPD. An ideal system would allow categorization of patients with COPD for epidemiologic and clinical studies, health resource planning, and prognosis. It would also facilitate communication between professionals. As discussed before, the strongest prognostic indicators for mortality are the age of the patients and FEV_1, followed by the presence of hypoxemia and hypercapnia. Obviously, death is not the only morbidity attributable to COPD. At present, we are limited to grade the severity of COPD on the basis of some objective physiological measure of pulmonary

function, usually the FEV_1. However, the impact of COPD on the ability of patients to perform the normal activities of daily living is incompletely described by the FEV_1. The cardinal symptom of COPD is dyspnea, which often limits functional activity and ability to exercise and frequently causes the patient to seek medical attention. Because COPD is a chronic disorder that limits the patient's ability to work and in severe cases impairs the activities of daily living, a staging system that includes some attribute of this limitation is highly desirable. Therefore, an ideal classification would include elements of all three factors (FEV_1, capacity to perform ADL or capacity to exercise, and dyspnea); unfortunately, this tool has yet to be developed. The current staging system as suggested by the ATS attempts to classify patients according to the degree of FEV_1 value (Table 2). This staging system is designed to help the clinician and health care provider identify the possible level of care and complexity of the patient. It also provides a rough estimate of the patient's prognosis.

	Stage I	Stage II	Stage III
FEV_1 (predicted)	≥50%	30% to 49%	≤30%
Usual findings	Most of the patients May be symptomatic Small impact on health-related quality-of-life issues Usually managed by primary care physicians	Minority of patients Symptomatic Moderate impact on health-related quality-of-life issues May be hypoxemic May be helped by evaluation by specialist	Small minority of patients Severe symptoms Large impact on health-related quality of life Hypoxemic, may show hypercapnia Best managed by professionals familiar with COPD

TABLE 2. *Staging of COPD*

QUALITY OF LIFE

Not all the problems associated with the development of COPD are described by physiological variables (FEV_1 or arterial blood gases). Furthermore, only weak associations have been described for FEV_1 and quality of life or FEV_1 and dyspnea. Because of the capacity of certain questionnaires to provide an accurate estimation of a patient's quality of life in chronic diseases, there has been a recent interest in adding this dimension to the evaluation of patients with COPD. These tools acquire particular importance in the comprehensive evaluation of different forms of treatment because there need not be an association between physiological results and how patients perceive the effect of the intervention. A typical example is that of pulmonary rehabilitation. Several controlled trials have shown significant improvement in patient's perceived quality of life without demonstrable evidence of changes in lung function. Table 3 shows different quality-of-life questionnaires that have been validated and are widely used. Some are generic in nature and are applicable to all forms of chronic diseases. They may not be sensitive enough to detect changes that may arise from improvement secondary to benefits in the respiratory domain. For this reason, there has been recent interest in the development of disease-specific quality-of-life questionnaires. In particular, the ones shown in Table 3 have been validated and proven to be of use when evaluating patients with COPD. They have proven useful in research and may find a role in the everyday management of patients.

Quality-of-life assessment tools	
General	Disease specific (pulmonary)
Quality of Well-Being Scale	The St. George's Respiratory Questionnaire (SGRQ)
Sickness Impact Profile	Chronic Respiratory Disease Questionnaire (CRQ)
Nottingham Health Profile	Pulmonary Functional Status and Dyspnea Questionnaire (PFSDQ)
Medical Outcomes Study—Short Form (MOS SF-36)	
Dyspnea assessment tools	
Functional	Exercise related
Baseline Dyspnea Index (BDI)	Borg Scale
Transitional Dyspnea Index (TDI)	Visual Analog Scale (VAS)
Physiological tools	
Complex	Simple
Cardiopulmonary Exercise Test	6- and 12-min walk test
Pulmonary Function Testing	Walk up stairs
Graded Exercise Test

COMPREHENSIVE MANAGEMENT OF COPD

The airflow obstruction of COPD is largely irreversible. This physiological fact has generated an unjustified nihilistic therapeutic attitude in many health care providers. The evidence accumulated suggests otherwise, and an optimistic attitude toward these patients goes a long way in relieving patient fears and misconceptions. In contrast to many other diseases, some forms of interventions significantly prolong life (Table 4), and others improve symptoms and the quality of a patient's life once the diagnosis has been established. The overall goals of treatment are to prevent further deterioration in lung function, to alleviate symptoms, and to treat complications as they arise. Once diagnosed, the patient should be encouraged to participate actively in the management. This concept of collaborative management may improve self-reliance and esteem. Although not proven, it may also help improve compliance with treatment. All patients should be encouraged to lead a healthy life and exercise regularly. Preventive care is extremely important at this time, and all patients should receive immunizations including pneumococcal vaccine and yearly influenza vaccines. An algorithm detailing this comprehensive approach is shown in Fig. 4.

Interventions that improve survival	Interventions that improve symptoms
Smoking cessation	Pharmacotherapy
Oxygen therapy if hypoxemic	Rehabilitation
	Education
	Training and exercise
	Psychological support
	Nutrition
	Surgery (pneumoplasty)

TABLE 4. *Therapy of patients with symptomatic COPD*

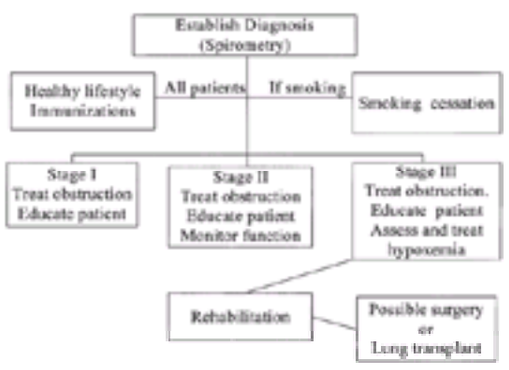

FIG. 4. Algorithm that shows the overall management of patients with COPD.

SMOKING CESSATION

Because smoking is the major cause of COPD, smoking cessation is the most important component of therapy for patients who still smoke. It should become part of our counseling for any patient who smokes. Because secondary smoking is known to damage lung function, limitation of exposure to involuntary smoke, particularly in children, should be encouraged. Although most patients agree that smoking is risky, they seem unaware of its true significance. Continuous abstinence in pulmonary patients who have participated in smoking cessation programs may be as low as 27% in follow-up periods ranging from 6 months to 7 years. The factors that cause patients to smoke include the addicting potential of nicotine, conditional response to stimuli surrounding smoking, psychosocial problems such as depression, poor education, and low income, and forceful advertising campaigns. Because the causes that drive the patient to smoke are multifactorial, the solutions for smoking cessation should also involve multiple interventions. Elements of successful smoking cessation programs are summarized in Table 5.

1. Physician or health care worker should initiate quitting.
   Explain risks of cigarette smoking.
   Offer strong admonition to quit; encourage a quit date; offer referral for self-help or group program.
2. Physician or health care worker may arrange telephone follow-up.
   Call 3 to 5 days after quit date. Review progress. Counsel regarding quitting and recruitment of support individual. Call 1 to 2 weeks after quit date.
   Repeat above as needed.
3. Physician or health care worker should arrange follow-up. Next regular visit should be <2 months after initiating quitting. May assess the progress with CO and expired air and/or continine in urine, blood, or saliva. If abstinent, should review and reward success. Continue follow-up at increasing intervals for 12 months postquitting.
4. If not abstinent, physician or health care worker should review and emphasize elements of success. Identify circumstances of failure. The physician usually offers nicotine replacement to control the withdrawal symptoms; infrequently, other pharmacologic therapy can be considered such as clonidine or buspirone.

TABLE 5. *Protocol for smoking cessation*

The clinician should always express strong interest in smoking cessation, for a physician's advice to quit smoking discriminates successful from unsuccessful results. A strong social support system, including professionals, family, and friends, is associated with cessation and long-term abstinence. The smoker should avoid circumstances likely to prompt relapse, including coping with personal and interpersonal stress. It is helpful for the physician to plan a quit date, because setting a quit date to stop “cold turkey” usually holds an advantage over gradual withdrawal. It may be helpful to make a telephone call to the patient at follow-up intervals to encourage cessation of smoking. This call may be made by the physician or a health care worker. Group smoking cessation clinics are offered by many hospitals and in may work sites as well as by voluntary agencies. They include programs such as the American Lung Association through its Freedom from Smoking clinics. Such programs may have an important role in the support of patients who attempt to quit smoking because they effectively integrate behavioral therapy, counseling, and adjunctive pharmacologic treatment.

Nicotine is the ingredient in cigarettes that is primarily responsible for the addiction of smoking. With each cigarette smoked, between 1 and 2 mg of nicotine is delivered to the lungs. Because of rapid absorption into the blood and a half-life of 2 hr, regular daytime smoking can cause nicotine accumulation for an entire 24-hr period. Nicotine is metabolized by the liver. Cotinine, a primary metabolite of nicotine, has a longer half-life and can be searched for in the urine to detect those patients who continue to smoke. Withdrawal from cigarettes causes anxiety, irritability, difficulty concentrating, anger, fatigue, drowsiness, depression, and sleep disruption, especially during the first week of cessation. In a dose-dependent relationship, nicotine replacement following cessation reduces withdrawal symptoms and enhances abstinence. Highly dependent nicotine smokers can be identified as those who smoke over one pack of cigarettes per day and who require their first cigarette within 30 min of arising and find it difficult to refrain from smoking in places where it is forbidden. Physical dependence can also be assessed by a formal questionnaire such as the Fagerstrom tolerance questionnaire. Nicotine polacrilex gum (2 mg per piece) is effective when compared to placebo, especially in self-referred smokers who are highly addicted to cigarettes. Transdermal nicotine patches are more readily available and may be prescribed for the patient who failed smoking cessation efforts in the past or whose smoking cessation has been troubled by withdrawal symptoms. Short-term success rates have varied widely (between 18% and 77%), but in general nicotine patches are about two times as effective as placebo. Long-term success rates (6 months and longer) are considerably lower (22% to 42%) but are consistently better than those obtained with a placebo patch (2% to 26%).

Adjuvant programs such as individual counseling and group therapy produce a higher success rate when added to pharmacologic intervention. The smoking status (abstinence or continued smoking) during the first 2 weeks of nicotine patch therapy can serve as a predictor of smoking cessation because smoking during this period is a powerful predictor of failure at the end of a 6-month trial. Patients who fail during the first 2 weeks of therapy should be offered more intense pharmacologic or adjuvant therapy. The ideal time of therapy for each dose has not been established. Recently, it has been recommended that nicotine patch therapy beyond 6 to 8 weeks may not be necessary. Although nicotine patches are well tolerated, mild erythema or other local skin reactions may be seen in up to 50% of patients; however, they can be minimized by rotating the patch to different sites on the skin.

Clonidine, an a_2-adrenergic agonist, may enhance abstinence in the short term, but its enduring effects have not been documented. The anxiolytic agent buspirone reduced withdrawal symptoms and may show some benefit on abstinence. Hypnosis may be an effective adjunct but is of little value when offered as a single-session cure. Acupuncture should not be done, as there is little evidence that it contributes to smoking cessation beyond its placebo effect.

PHARMACOLOGIC THERAPY

The pharmacologic therapy of COPD should be organized according to the severity of the disease and the tolerance of the patient for specific drugs. In the outpatient setting, a stepwise approach (Table 6 and Fig. 5), as has been developed for asthma and systemic hypertension, may be helpful. The most common drugs and dosages that are in current use, and the precautions to be taken when indicated are listed in Table 6. There is no current evidence that the regular use of any of these drugs alters the progression of COPD. Nevertheless, they alleviate symptoms, improve exercise tolerance, and improve quality of life, all worthwhile goals in COPD. It is important to remember that most COPD patients are older and thus particularly susceptible to the side effect of some of these medications and that dose adjustments must be made according to each individual circumstance.

TABLE 6. *Pharmacologic step care of COPD*

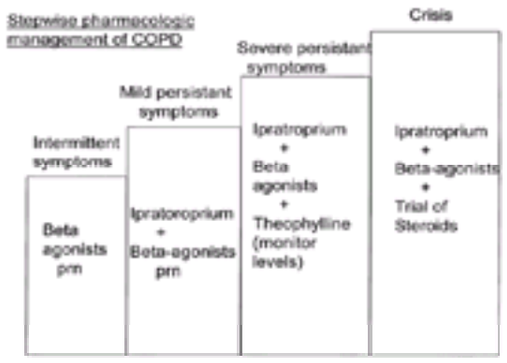

FIG. 5. Stepwise pharmacologic management of patients with COPD.

Bronchodilators

The bronchodilators used in COPD are similar to those used in asthma, but some differences are noteworthy. The b-agonists produce less bronchodilation in COPD, and in some patients the spirometric changes may be insignificant, although symptomatic benefit may be experienced, perhaps through other mechanisms such as decreased dynamic hyperinflation. However, the older age of patients with COPD may result in less tolerance for sympathomimetic-induced tremor, nervousness, and cardiac side effects. Likewise, many older COPD patients cannot effectively activate metered dose inhalers (MDI), and health providers should recognize this limitation and work with the patient to achieve mastery of the MDI. If this is not possible, use of a spacer to facilitate inhalation of the medication will help achieve the desired results. Mucosal deposition in the mouth will result in local side effects (i.e., thrush with inhaled steroids) or general absorption and its consequences (i.e., tremor after b-agonists).

b-Agonists

In patients with intermittent symptoms, it is reasonable to initiate drug therapy with an MDI of a b-agonist as needed for relief of symptoms. Albuterol, pirbuterol, metaproterenol, terbutaline, or isoetharine (each of which is preferable to the less-selective drugs epinephrine, isoproterenol, and ephedrine) should be taken up to a maximum of three or four times a day or as prophylaxis before exercise. The rapid onset of action of b-agonist aerosols may lead to dyspneic patients favoring them for regular use. b-Agonist therapy decreases dyspnea and improves exercise tolerance in COPD. The potential for arrhythmias necessitates careful dosing in patients with probable or known cardiac disease, although serious cardiac complications are rare with conventional doses. In more advanced disease, it may be reasonable to use slow-release oral albuterol, but the value and acceptability of such formulations has not been established. Similarly, the new, long-acting aerosol drug salmeterol has been shown to prevent nocturnal bronchospasm. These agents may improve compliance, which can result in an improved outcome in selected patients.

Anticholinergic Agents

Once the patient suffers from persistent symptoms, regular use of ipratropium MDI is recommended. The drug has a slower onset and longer action than b_2-agonists such as albuterol and thus is less suitable for as-needed use. The appropriate dosage is two to four puffs three or four times a day, but some patients require and tolerate larger dosages. It has been shown that ipratropium is effective in increasing exercise tolerance and decreasing dyspnea. A recent multicenter controlled trial of therapy with ipratropium bromide documented a significant bronchodilator effect, but there was no alteration in the rate of decline in lung function in the patients receiving the medication. As is true for b-agonists, there is no substantial evidence to suggest that regular use of anticholinergic therapy, with or without a b_2-agonist, leads to a worsening of spirometry or to exacerbation of premature death in COPD. Thus, it is appropriate to use regular therapy with ipratropium and to add a b_2-agonist as often as needed for up to four treatments a day.

Theophylline

This currently represents a third-line agent in the therapy of COPD. The potential for toxicity has led to a decline in its popularity. It is of particular value for less compliant or less capable patients who cannot use aerosol therapy optimally because they can readily take theophylline once or twice a day. Theophylline has been shown to improve the function of the respiratory muscles, to stimulate the respiratory center, to enhance activities of daily living, and to decrease dyspnea. It also improves cardiac output, reduces pulmonary vascular resistance, and improves the perfusion of ischemic myocardial muscle. Recent evidence suggests an antiinflammatory role for this drug, thereby expanding its potential indications. It follows that there are several advantages to theophylline therapy in patients with cardiac disease or cor pulmonale, but its use should be carefully followed, and intermittent serum levels should be used. The previously recommended therapeutic serum levels of 15 to 20 mg/dl are too close to the toxic range and are frequently associated with side effects. Therefore, a lower target range of 9 to 14 mg/dl is safer and still therapeutic in nature. The regular use of theophylline has not been shown to have a detrimental effect on the course of COPD. Combination of theophylline, albuterol, and ipratropium can result in maximum benefit in stable COPD.

Antiinflammatory Therapy

In contrast to their value in asthma management, antiinflammatory drugs have not been documented to have a significant role in the routine treatment of COPD. Cromolyn and nedocromil have not been established as useful agents, although they could possibly be helpful if the patient has associated respiratory tract allergy. Corticosteroids may merit more careful evaluation in individual patients on adequate bronchodilator therapy who fail to improve. In outpatients, exacerbations may necessitate a course of oral steroids, but it is important to wean patients quickly because the older COPD population is susceptible to complications such as skin damage, cataracts, diabetes, osteoporosis, and secondary infection. These risks do not accompany standard doses of steroid aerosols, which may cause thrush, but pose a negligible risk for causing pulmonary infection. Most studies suggest that only 10% to 30% of patients with COPD improve if given chronic oral steroid therapy. The dangers of steroids require careful documentation of the effectiveness of such therapy before a patient is put on prolonged daily or alternate-day dosing. The latter regimen may be safer, but its effectiveness has not been adequately evaluated in COPD. Based on preliminary results, two large multicenter trials are being conducted to evaluate the role of inhaled corticosteroids in preventing or slowing the progressive course of patients with symptomatic COPD. Until the results are analyzed, the concurrent use of inhaled steroids with albuterol and ipratropium has to be evaluated on an individual basis.

Mucokinetic Agents

The only controlled study in the United States suggesting a value for these drugs in the chronic management of bronchitis was a multicenter evaluation of organic iodide. This study demonstrated symptomatic benefits. The values of other agents, including water, have not been clearly demonstrated, although some agents (such as oral acetylcysteine) are favored in Europe for their antioxidant effects in addition to their mucokinetic properties. Genetically engineered ribonuclease may prove to be useful in cystic fibrosis but seems to be of little practical value in COPD.

Antibiotics

They are of unproven value in the prevention or treatment of exacerbations of COPD unless there is evidence of infection, such as fever, leukocytosis, and a change in the chest radiograph. If recurrent infections occur, particularly in winter, continuous or intermittent prolonged courses of antibiotics may be useful. When an acute bacterial infection is believed to be present, antibiotic therapy may be justified, but the decision is usually made clinically because culture of sputum is not cost-effective. In prescribing treatment, fiscal concerns should be a consideration, because older less costly agents are often effective, e.g., tetracycline, doxycycline, amoxicillin, erythromycin, trimethoprim–sulfamethoxazole, or cefaclor. The major bacteria to be considered are *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis.* The antibiotic choice will depend on local experience supported by sputum culture and sensitivities if the patient is moderately ill or needs to be admitted to hospital.

a_1-Antitrypsin

Although replacement with this enzyme may be indicated in nonsmoking, younger patients with genetically determined emphysema, in practice such therapy is difficult to initiate. There is evidence that the administration of a_1-antitrypsin is relatively safe, but the appropriate selection of the candidate for such therapy is not clear. Patients with very severe and crippling COPD, or those with good lung function, are not good candidates for therapy. Likewise, deficient nonsmoker patients are at low risk to develop airflow obstruction. Therefore, the most likely candidates for replacement therapy would be smoking patients with mild COPD. The cost of therapy is

such that its use is debatable because its safety and long-term effects remain unknown.

Respiratory Stimulants

These drugs are currently not favored, although they are used in some countries. Psychoactive drugs are often sought by older patients to treat depression, anxiety, insomnia, or pain. In general, these agents can be given with appropriate care and with particular awareness of their depressant effect on the respiratory center. Benzodiazepines do not have a marked effect on respiration in mild or moderate COPD but can be suppressive in severe disease, particularly during sleep. The safer hypnotics for use in insomnia include sedating antihistamines and chloral hydrate. Antidepressants may also have the advantage of improving sleep. Concomitant use of cardiovascular drugs may be needed in severe COPD and cor pulmonale, e.g., diuretics, angiotensin-converting enzyme inhibitors, or calcium channel blockers. Digoxin is occasionally useful, but b-adrenergic blockers are generally contraindicated. These drugs must be used cautiously to avoid dehydration, hypotension, myocardial ischemia, and arrhythmias. Because most patients requiring such therapy are elderly or have impaired drug clearance, all potential side effects must be carefully sought and responded to by modifying the drug regimen.

Vaccination

Ideally, infectious complications of the respiratory tract should be prevented in patients with COPD by using effective vaccines. Although the currently available vaccines are not totally effective and are not utilized widely, there is evidence that COPD patients benefit from their use, and thus, routine prophylaxis with pneumococcal and influenza vaccines is recommended.

MANAGEMENT OF ACUTE EXACERBATION

In the case of an acute exacerbation, the pharmacologic therapy is initiated with the same therapeutic agents available for chronic management. As described later in this chapter, care must be taken to rule out heart failure, myocardial infarction, arrhythmias, and pulmonary embolism, all of which may present with clinical signs and symptoms similar to exacerbation of COPD.

The most important components of therapy for acute exacerbation of COPD are anticholinergic and b-agonist aerosols. Ipratropium may be administered via a metered dose inhaler (MDI), sometimes with a spacer if the administration is erratic, or as an inhalant solution by nebulization. Although the upper limit of dosage has not been established, the drug is safe, and higher dosages than usual can be given to a poorly responsive patient. However, the prolonged half-life means that repeat doses should not be given more often than every 4 to 8 hr. b_2-Agonists should also be administered using the same inhaled techniques. These drugs have a reduced functional half-life in exacerbations of COPD and thus may be given every 30 to 60 min if tolerated. The safety and value of continuous nebulization have not been established, but in selected cases it may be worth a trial. Subcutaneous or intramuscular dosing are recommended only if aerosol use is not feasible; intravenous administration is not an acceptable practice. Careful administration of theophylline may be useful; the drug can be given as intravenous aminophylline in a severe exacerbation. Serum levels are needed as a guide to avoid toxicity, and in most patients a serum level of 8 to 12 mg/ml is appropriate. When the patient improves, oral long-acting theophylline can be substituted, using 80% of the daily dose of aminophylline.

Combination therapy is often needed, and systemic corticosteroids may then be added to the regimen. Corticosteroids can be very effective in a patient who demonstrates inadequate responsiveness to b-agonist or ipatroprium therapy. It is important to avoid prolonged or high-dose therapy in those patients who show little improvement, because older patients are susceptible to severe complications such as psychosis, fluid retention, and a vascular necrosis of bones. Rapid weaning must be accomplished as soon as possible.

Antibiotics such as amoxicillin, trimethoprim–sulfamethoxazole, doxycycline, or erythromycin have been helpful in exacerbations of COPD. Mucokinetic agents, such as iodides, given systemically have not been shown to be effective in exacerbations of COPD, although some patients report subjective improvement when given these agents.

HOME OXYGEN THERAPY

Therapeutic oxygen has been used systematically since Barach and then Petty et al. recognized the association between hypoxemia and right heart failure and appreciated the benefit of continuous oxygen delivery to patients with severe COPD. Since them, much has been learned about the effects of oxygen and hypoxemia, and progress has been made in the area of mechanical oxygen delivery devices.

The results of the Nocturnal Oxygen Therapy Trial (NOTT) and Medical Research Council (MRC) studies have established that continuous home oxygen improves survival in hypoxemic COPD and that survival is related to the number of hours of supplemental oxygen per day. Other beneficial effects of long-term oxygen include reduction in polycythemia, perhaps related more to lowered carboxyhemoglobin levels than to improved arterial saturation, reduction in pulmonary artery pressures, dyspnea, and rapid-eye-movement-related hypoxemia during sleep. Oxygen also improves sleep and may reduce nocturnal arrhythmias. Importantly, oxygen can also improve neuropsychiatric testing and exercise tolerance. This has been attributed to central mechanisms causing reduced minute ventilation at the same workload, thereby delaying the time until ventilatory limitation is reached; improved arterial oxygenation, enabling greater oxygen delivery and reversal of hypoxemia-induced bronchoconstriction; and the effect of oxygen on respiratory muscle recruitment.

Prescribing Home Oxygen

Patients are evaluated for long-term oxygen treatment (LTOT) by measuring the P_aO_2. It is therefore recommended that measurement of P_aO_2, not pulse oximetry (S_aO_2), be the clinical standard for initiating LTOT, particularly during rest. Oximetry S_aO_2 may be used to adjust oxygen flow settings over time. If hypercapnia or acidosis is suspected, an arterial blood gas measurement (ABG) must be performed. Some COPD patients who were not hypoxemic before the events leading to their exacerbation will eventually recover to the point that they will no longer need oxygen. It is therefore recommended that the need for long-term oxygen be reassessed in 30 to 90 days, when the patient is clinically stable and receiving adequate medical management. Oxygen therapy can be discontinued if the patient does not meet blood gas criteria. To prescribe long-term oxygen therapy, a certificate of medical necessity (HCFA form 484) must be completed. The HCFA form 484 evolved in an attempt to insure that the physician, not the home medical equipment (HME) supplier, was in charge of decisions concerning therapy. The HCFA requires the physician or an employee of the physician, rather than the HME supplier, to complete form 484.

Like any drug, oxygen has potential deleterious effects that may be particularly relevant to older patients. The hazardous effects of oxygen therapy can be considered under three broad headings. First, there are physical risks such as fire hazard or tank explosion, trauma from catheters or masks, and drying of mucous membranes as a result of high flow rates and inadequate humidification. Second, there are functional effects related to increased carbon dioxide retention and absorptive atelectasis. Elevated PCO_2 in response to supplemental oxygen is a well-recognized complication in a minority of patients. The mechanism has traditionally been ascribed to reductions in hypoxic ventilatory drive. However, in many patients the decrease in minute ventilation is minimal. The most consistent finding is a worsening of the pulmonary ventilation-to-perfusion distribution with an increase in the dead-space-to-tidal-volume ratio. This presumably results from oxygen blockage of local hypoxic vasoconstriction, thereby increasing perfusion of poorly ventilated areas. Third, although possible, cytotoxic and atelectatic effects have not clearly been demonstrated with the low flow rates (1 to 5 L/min, F_IO_2 24% to 36%) typically used for chronic home oxygen therapy in COPD.

Oxygen Delivery Systems

Long-term home oxygen is available from three different delivery systems: oxygen concentrators, liquid systems, and compressed gas. Each system has advantages and disadvantages, and the correct system for each patient depends on patient limitations and clinical application. Oxygen systems were recently compared on the basis of weight, cost, portability, ease of refilling, and availability. The former three factors may be of particular importance in elderly, often debilitated patients. Compressed gas is stored in variably sized steel or aluminum cylinders that weigh 200, 16, 9, and 4 lb and last 2.4 days, 5.2 hr, 2 hr, and 1.2 hr at 2 L/min flow. The advantages of compressed gas oxygen are its low price, availability, and capacity to be stored for long periods. Disadvantages are its weight (with the large cylinders), short oxygen supply time (with the smaller cylinders), potential hazard of a torpedo-like effect if the valve becomes suddenly disconnected from a compressed gas cylinder, and inferior transfilability. Liquid oxygen is stored at very low temperatures that reduce the volume to less than 1% of the room-temperature equivalent. Portable containers weigh up to 10 lb and last 4 to 8 hr at 2 L/min flow. A wheel-mounted, 140-lb stationary unit is also available that can last up to 7 days at 1 L/min. Advantages of this system are its relative portability and ease of transfilability. Disadvantages are its higher cost and requirements for intermittent pressure venting, resulting in oxygen consumption even when the system is not being used. Oxygen concentrators are electric devices that extract oxygen by passing air through a molecular sieve. The oxygen is delivered to the patient, and the nitrogen is returned to the atmosphere. The devices weigh about 35 lb and are not very portable. They are typically used in a stationary capacity such as in the car or a room, and liquid or gas is used to provide portability. The major advantage of the oxygen concentrator is its relative cost effectiveness; the disadvantages are its need for a power source, regular servicing, and relative lack of portability.

Administration Devices

Oxygen is typically administered with continuous flow by nasal cannula; however, because alveolar delivery occurs during a small portion of a spontaneous respiratory cycle (approximately the first one-sixth), the rest of the cycle being used to fill dead space and for exhalation, the majority of continuously flowing oxygen is not used by the patient and is wasted into the atmosphere. To improve efficiency and increase patient mobility, several devices are available that focus on oxygen conservation and delivery during early inspiration. These devices include reservoir cannulas, demand-type systems, and transtracheal catheters.

Reservoir nasal cannulas and pendants store oxygen during expiration and deliver a 20-mL bolus during early inspiration. Because more alveolar oxygen is delivered, flows may be reduced proportionally. This has been shown to result in a 2:1 to 4:1 oxygen savings at rest and with exercise. Cosmetic considerations have traditionally limited patient acceptance of these devices.

Demand valve systems have an electronic sensor that delivers oxygen only during early inspiration or provides an additional pulse early in inspiration as an adjuvant to the continuous flow. By restricting or accentuating oxygen during inspiration, wasted delivery into dead space or during exhalation is minimized. This results in a 2:1 to 7:1 oxygen savings. The effect of mouth breathing on efficacy is not yet clear. Transtracheal oxygen (TTO) therapy employs a thin flexible catheter placed into the lower trachea for delivery of continuous (or pulsed) oxygen. Because oxygen is delivered directly into the trachea, dead space is reduced, and the upper trachea serves as a reservoir of undiluted oxygen. This provides a 2:1 to 3:1 oxygen savings over a nasal cannula. Other benefits of TTO include its relative inconspicuousness; lack of nasal, auricular, or facial skin irritation; stationary position with ambulation or during sleep; and its purported efficacy in providing adequate oxygenation where a nasal cannula cannot. Transtracheal oxygen therapy has also been reported to reduce minute volume and dyspnea and to improve exercise tolerance by mechanisms related solely to improvements in oxygenation. Thus, TTO appears to reduce dyspnea and improve exercise tolerance through mechanisms that include decreased dead space and decreased minute ventilation.

Complication rates tend to be lower in the larger series and higher in the smaller series. The most frequent complications are dislodged catheters (up to 33%, average 10%), subcutaneous emphysema (up to 10%, average 6.5%), stomal infection requiring antibiotics (up to 25%, average 6.5%), and the formation of symptomatic mucus balls at the tip of the catheter (up to 25%, average 10%). The latter complication may be potentially serious or even fatal. Other complications of TTO therapy include migration of the catheter into the mediastinum, broken catheter tips in the airways, pneumonia, hemoptysis, keloid formation, hoarseness, cardiac arrhythmias, and tracheal stricture. Overall, the TTO catheter offers several potential advantages over more conventional continuous oxygen administration devices, but it requires a motivated dexterous patient for routine care and daily cleaning, and it has a modest rate of usually minor, but potentially serious, complications.

HOSPITALIZATION AND DISCHARGE CRITERIA

Although acute exacerbations are difficult to define, and their pathogenesis is poorly understood, impaired lung function can lead to respiratory failure requiring intubation and mechanical ventilation. The purpose of acute treatment is to manage the patient's acute decompensation and comorbid conditions in order to prevent further deterioration and readmission. Table 7 lists the components of the history, physical examination, and laboratory evaluation that should be obtained during a moderate to severe acute exacerbation to assist the formulation of therapy and the decision for hospital admission.

History	Baseline respiratory status, sputum volume and characteristics, duration and progression of symptoms. Dyspnea severity, exercise limitations, sleep and eating difficulties, home care resources, home therapeutic regimen, symptoms of comorbid acute or chronic conditions.
Physical	Evidence of cor pulmonale, tachypnea, bronchospasm, pneumonia. Hemodynamic instability, altered mentation, respiratory muscle fatigue, excessive work of breathing; acute comorbid conditions.
Laboratory[a]	ABG, chest radiograph (PA, Lat), ECG, theophylline level (if outpatient theophylline used). Pulse oximetry monitoring, ECG monitoring. Post-ER treatment spirometry (if FEV_1, changes from baseline to be used as admission criteria), additional studies as clinically indicated.

[a] Abbreviations: FEV_1, forced expiratory volume in 1 sec; ECG, electrocardiogram; ER, emergency room; ABG, arterial blood gas; PA, posterior–anterior; Lat, lateral.

TABLE 7. *Emergency room evaluation of exacerbations of COPD*

Traditionally, the decision to admit derives from subjective interpretation of clinical features such as the severity of dyspnea, determination of respiratory failure, short-term response to emergency room therapy, degree of cor pulmonale, and the presence of complicating features such as severe bronchitis, pneumonia, or other comorbid conditions. This approach to decision making is less than ideal in that up to 28% of patients with an acute exacerbation of COPD discharged from an ER have recurrent symptoms within 14 days. Additionally, 17% of patients discharged after ER management of COPD will relapse and require hospitalization. Few clinical studies have investigated patient-specific objective clinical and laboratory features that identify patients with COPD who require hospitalization. General consensus supports the need for hospitalization in patients with severe acute hypoxemia or acute hypercarbia. Less extreme arterial blood gas abnormalities, however, do not assist decision analysis. The posttreatment FEV_1 as a percentage of predicted, combined with clinical assessment, identifies patients in need of admission. Asymptomatic patients with posttreatment FEV_1 less than 40% of predicted were successfully discharged from the ER; patients with a posttreatment FEV_1 less than 40% of predicted, accompanied by persistent respiratory symptoms, require admission.

Other factors that identify “high-risk” patients include a previous emergency room visit within 7 days, the number of doses of nebulized bronchodilators, use of home oxygen, previous relapse rate, administration of aminophylline, and the use of corticosteroids and antibiotics at the time of ER discharge.

The pharmacologic treatment of acute exacerbations is similar to that available for chronic management. Inhaled administration is preferred, although intravenous treatment may be reserved for certain drugs such as corticosteroids and theophylline. Once stable, the patient may be switched to oral and inhaled medications. Once the patient has improved, clinical assessment plans for modifying drug regimens, utilization of home oxygen, or potential benefits from pulmonary rehabilitation programs should be prepared. Duration of hospitalization in COPD depends at least partially on the existence of a multidisciplinary team that directs respiratory management.

Because of the complex management issues in caring for COPD patients with impending or frank respiratory failure, physician specialists with extensive experience in and knowledge of COPD should participate in the care of hospitalized patients who present with underlying severe disease or who require invasive or noninvasive modes of mechanical ventilation, develop hypoxemia unresponsive to F_IO_2 0.50 or new-onset hypercarbia, require steroids for more than 48 hr to maintain adequate respiratory function, undergo thoracoabdominal surgery, or require specialized techniques to manage copious airway secretions.

The indications for hospital admission are summarized in Table 8. Based on experts' consensus, they consider the severity of the underlying respiratory dysfunction, progression of symptoms, response to outpatient therapies, existence of comorbid conditions, necessity of surgical interventions that may affect pulmonary function, and the availability of adequate home care. The severity of respiratory dysfunction dictates the need for admission to an ICU (Table 9). Depending on the resources available within an institution, admission of patients with severe exacerbations of COPD to intermediate or special respiratory care units may be appropriate if personnel, skills, and equipment exist to identify and manage acute respiratory failure successfully. Limited data support the discharge criteria listed in Table 10.

1. The patient has an acute exacerbation of COPD characterized by increase dyspnea, cough, and sputum production with one or more of the following features:
   - Symptoms that do not adequately respond to outpatient management.
   - Inability of a previously mobile patient to walk between rooms.
   - Inability to eat or sleep because of dyspnea.
   - Family and/or physician assessment that the patient can not manage at home, and supplementary home care resources are not immediately available.
   - Presence of high-risk comorbid pulmonary (e.g., pneumonia) or nonpulmonary conditions.
   - Prolonged, progressive symptoms before emergency room visit.
   - Presence of worsening hypoxemia, new or worsening hypercarbia, or new or worsening cor pulmonale.
2. Acute respiratory failure characterized by severe respiratory distress, uncompensated hypercarbia, or severe hypoxemia.
3. New or worsening cor pulmonale unresponsive to outpatient management.
4. Plans for invasive surgical or diagnostic procedures requiring analgesics or sedatives that may worsen pulmonary function.
5. Comorbid conditions, such as severe steroid myopathy or acute vertebral compression fractures with severe pain, have worsened pulmonary function.

TABLE 8. *Indications for hospitalization in COPD*

A patient with severe dyspnea does not respond to initial Emergency Room therapy.
A patient demonstrates confusion, lethargy, or respiratory muscle fatigue characterized by paradoxic diaphragmatic motion.
Laboratory evidence demonstrates persistent/worsening hypoxemia despite supplemental oxygen or severe/ worsening respiratory acidosis (e.g., pH < 7.30).
A patient requires assisted mechanical ventilation by means of an endotracheal tube or noninvasive technique.

TABLE 9. *Indications for ICU admission of patients with acute exacerbations of COPD*

Inhaled β-agonist therapy is required no more frequently than every 4 hr.
Previously ambulatory patient is able to walk across the room.
The patient is able to sleep without frequent awakening by dyspnea.
Any component of reactive airway disease is under stable control.
The patient is stable off of parenteral therapy for 12 to 24 hr.
The patient or home caregiver is educated as to correct use of medications.
Arrangements for follow-up care and home care (e.g., visiting nurse, home oxygen delivery, meal provisions) are completed.

[a] Patients who do not yet fulfill criteria for discharge to home may be successfully managed at non-acute care placement sites for observation during the final resolution of symptoms.

TABLE 10. *Discharge criteria after treatment for acute exacerbations of COPD*[a]

ASSISTED VENTILATION

Progressive airflow obstruction may impair gas exchange to the degree that assisted ventilation will be required. In this clinical context, the therapeutic goals are to support the patient over the short term during the course of acute respiratory failure and to enhance gas exchange and functional status in patients with chronically impaired ventilation.

Assisted ventilation should be considered for patients with acute exacerbations of COPD when pharmacologic and other nonventilatory treatments fail to reverse clinically significant respiratory failure. Indications for initiating assisted ventilation during acute COPD exacerbations include signs of respiratory muscle fatigue, worsening respiratory acidosis, and/or deteriorating mental status. Although several investigators have reported success with negative-pressure ventilation, most studies advocate positive-pressure inflation for acute exacerbations of COPD.

Also, because negative-pressure ventilation may cause upper airway obstruction and arterial oxygen desaturation (when upper airway muscle activation is asynchronous with negative-pressure breaths), its role in managing patients with COPD has been questioned.

The goals of assisted positive-pressure ventilation in acute respiratory failure complicating COPD are (1) resting of ventilatory muscles and restoration of gas exchange to a stable baseline, (2) avoidance of complications associated with mechanical ventilation, and (3) facilitation of weaning and discontinuation of mechanical ventilation as soon as possible.

Major complications associated with assisted positive-pressure ventilation include risks of ventilator-associated pneumonia, pulmonary barotrauma, and laryngotracheal complications associated with intubation and/or tracheotomy. In addition to these general hazards, specific pitfalls in ventilating patients with COPD include overventilation, resulting in acute respiratory alkalemia, especially in patients with chronic hypercapnia; creation of auto-PEEP (or intrinsic PEEP), especially when expiratory time is inadequate; and initiation of complex pulmonary and cardiovascular interactions that result in systemic hypotension. Auto-PEEP has been reported to occur in up to 39% of mechanically ventilated patients, for which one must decrease the respiratory rate, increase inspiratory flow rates to avoid a disadvantageous inspiratory:expiratory (I:E) ratio, use a large-caliber endotracheal tube, and reduce the compressible volume in the ventilator circuit.

Modes of Ventilation

Invasive Ventilation

The three ventilatory modes most widely used for managing COPD patients are assist-control (AC), intermittent mandatory ventilation (IMV), and pressure-support (PS) ventilation. Because some (but not all) clinical reports indicate that PS ventilation provides increased patient comfort, promotes patient synchrony with the ventilator, and may accelerate weaning, it may be a particularly valuable mode of ventilatory support for stabilized patients with COPD and acute respiratory failure who maintain adequate ventilatory drive. No direct evidence exists, however, that patient outcome is improved with the use of PS compared to volume-cycled modes of mechanical ventilation in patients with COPD.

Noninvasive Ventilation

Translaryngeal intubation presents risks of nosocomial pneumonia, laryngotracheal injury, and bacterial sinusitis and also interferes with the patient's capacity for verbal communication. The advent of noninvasive positive-pressure-assisted ventilation modes offers an alternative to intubation in some patients with COPD and acute respiratory failure. Noninvasive positive-pressure ventilation for acute exacerbations of COPD has been examined in several studies, using both facial and nasal masks in conjunction with volume-cycled ventilation, bilevel positive-airway-pressure, and pressure-support modes. Although available studies suggest a significant success rate in patients with acute respiratory failure complicating COPD, the reported experience is still limited, and failure rates up to 40% have been reported in some studies. Primary use of noninvasive techniques for respiratory failure in patients with COPD should be reserved for centers with adequate expertise and supervision to allow safe implementation. Patient features that should discourage considering noninvasive ventilation for acute COPD exacerbations include hemodynamic instability, copious secretions, inability to defend the airway, poor cooperation with the technique, or impaired mental status.

Weaning from Mechanical Ventilation

Many COPD patients who undergo mechanical ventilation for acute bronchospasm, fluid overload, oversedation, or inadvertent hyperoxygenation may experience successful extubation without going through a period of weaning. Some patients with COPD intubated for respiratory failure require gradual weaning. Available techniques for weaning COPD patients from mechanical ventilation include assist-control ventilation with T-piece trials, IMV, and PS ventilation. Theoretical advantages exist to using IMV and PS modes because they provide partial support when the patient is connected to the ventilator and present less opportunity for barotrauma. Insufficient investigations exist to establish that weaning is accelerated or outcomes improved with any of the available weaning techniques.

ETHICAL ISSUES REGARDING INITIATING AND WITHDRAWING MECHANICAL VENTILATION

Because COPD affects patients at more advanced ages, frequently progresses, and may require highly expensive and prolonged life-saving medical technology, affected patients frequently present ethical dilemmas in their management and care. Deliberations in individual patients require a careful analysis of COPD survival statistics, quality of life, community health care resources, and economic aspects of care. Clinicians commonly attempt to determine the value of mechanical ventilation in individual patients with COPD by subjectively estimating the likelihood of survival after intubation. Unfortunately, subjective bedside assessment is extremely inaccurate to predict the survival of COPD patients. The predictive accuracy does not correlate with physicians' experience or level of training.

No correlation exists, for instance, between short-term survival and admission arterial blood gas results, spirometric values, hematocrit, patient age, or number of previous admissions for exacerbations of COPD. Scoring systems such as the Simplified Acute Physiology Score are weak predictors of short-term outcome in patients with COPD and respiratory failure. Nonpulmonary comorbid conditions, such as gastrointestinal hemorrhage, pulmonary embolism, or coronary heart disease, present at the onset of respiratory decompensation contribute to poor patient outcome. Housebound patients with severe, end-stage lung disease and comorbid conditions, therefore, have a worse short-term prognosis than more active patients with less severe underlying pulmonary impairment during episodes of respiratory failure of similar severity. Close to 80% of patients with COPD who require mechanical ventilation for acute respiratory failure survive to hospital discharge. Patients followed from the onset of an episode of acute respiratory failure have a 2-year survival between 28% and 70%. In contrast to common belief, patients with COPD have the highest survival rate among patients with various causes of acute respiratory failure. Finally, the long-term prognosis of patients surviving mechanical ventilation is similar to that of patients with the same degree of underlying respiratory impairment who have not required mechanical ventilation.

It follows that patients with COPD complicated by acute respiratory failure requiring life-support measures do not have an overall grim prognosis. Consequently, no fundamental ethical dilemma exists in considering all patients with COPD for intubation and mechanical ventilation. However, patients who have poor baseline function, marginal nutritional status, severely restricted activity levels, and inexorable deterioration of their late-stage pulmonary dysfunction may elect to forgo intubation when, in their and their physician's judgment, it will only temporarily interrupt the terminal phases of the disease.

Physicians have an obligation to assist their patients with COPD in formulating advance directives before respiratory decompensation occurs. In counseling patients regarding the value of intubation and mechanical ventilation and considerations of forgoing life-support measures, the physician has the responsibility to ensure that (1) the patient has decision-making capacity; (2) the patient has been informed regarding his or her diagnosis and prognosis and of the risks, benefits, and consequences for the full range of available medical interventions including the option of no therapy; (3) the patient has received from the physician professional recommendations regarding the medical choices available, including the use of life-sustaining therapy, based on knowledge of both the medical situation and the values and goals of the patient.

Decisions regarding limitations of care are best made during stable periods before respiratory failure or other life-threatening conditions occur. Patients who choose to forgo life-support measures should be encouraged to outline their wishes as specifically as possible in an instrument of advance directive such as a living will. Patients with COPD should specifically define their health care preferences for several clinical situations likely to be encountered, such as intubation, mechanical ventilation, cardiopulmonary resuscitation, tracheotomy, and long-term life support with difficult weaning. The patient should be encouraged to share these preferences with a trusted family member, friend, or other person who can be designated as a surrogate decision maker through a durable power of attorney for health care.

Once these advance directives are properly established or the wishes of an informed patient with decision-making capacity are known, respect for patient autonomy requires physicians in charge of the patient's care to honor the patient's right to forgo medical intervention. This is considered distinct from participating in assisted suicide or active euthanasia. Physicians faced with a critically ill patient should determine, however, that requests to forgo care are reasonable under the clinical circumstances and derive from deep-seated values and appropriate responses to the severity of underlying disease rather than endogenous depression or temporary conditions of pain, fear, depression, or anxiety during episodes of acute respiratory failure. Physicians who have personal ethical or religious values that do not allow them to comply with a patient's well-conceived request to forgo support should transfer the patient's care to another physician who can honor the patient's directives.

It should be recognized that there is no ethical difference between withholding and withdrawing life-support measures in patients with acute respiratory failure. Ethical principles underlying the decision to withhold intubation and mechanical ventilation apply equally when patients or proxies request a discontinuance of care for patients with terminal disease or a progressive degenerative condition who have no hope for an acceptable and meaningful recovery. Patients electing to have ventilatory support withdrawn may request and receive adequate sedation and analgesia to extinguish all pain and suffering during the dying process even if such treatment accelerates their imminent death.

SURGICAL OPTIONS FOR EMPHYSEMA

In 1959, Otto Brantigan postulated that the tethering forces that tend to keep the intrathoracic airways open were lost in emphysema and that by resecting the most affected parts of the lungs in patients with the most severe form of the disease, the force could be partially restored. Indeed, he developed an operation to resect wedges of hyperinflated lungs. In spite of a significant morbidity and mortality (16%), 75% of his patients manifested clinical improvement for up to 5 years. Because of the lack of some of the technical material now available (pericardial strips) and the need for bilateral thoracotomy, the procedure was abandoned. Recently, Cooper et al. have reported the results of surgical resection of emphysematous lungs of patients with very severe COPD. Using the technique developed by Brantigan, but doing both lungs in the same sitting through a median sternotomy, they have reported a 1-year 45% increase in FEV_1, a 25% decrease in TLC, and a significant improvement in exercise performance.

Although the results are preliminary, several groups have shown improvement in lung function, dyspnea, and quality of life. It is difficult to delineate clearly the factors responsible for this improvement, but recent reports indicate a postoperative increase in lung elastic recoil as one likely explanation. The decrease in lung volume lengthens the diaphragm and other respiratory muscles, placing them in a better contractile position on the length–tension curve. This should result in less effort to produce the same ventilatory pressure. Perhaps this decreases respiratory drive and hence reverses some of the factor associated with dyspnea in these patients. More studies are needed to be able to recommend this procedure to most patients with emphysema. Little is known about the factors that help select the best candidates for surgery. More needs to be learned about the best surgical technique and the optimal timing of the surgery. Nevertheless, for a disease with few therapeutic choices when it is advanced, this revival of an old operation seems to offer a possible and reasonable alternative to lung transplant.

SLEEP AND COPD

Patients with COPD seen to have a higher prevalence of insomnia, excessive daytime sleepiness, and nightmares than the general population. This is not a result of the bronchodilators because studies with these agents have failed to demonstrate any adverse effects on sleep staging or sleep efficiency. Oxygen desaturation during sleep, especially in REM sleep, has long been recognized in patients with COPD. Clinical parameters that have been associated with the presence of nocturnal desaturation include daytime hypoxemia, blunted awake chemosensitivity, severe dysfunction on pulmonary function testing, and chronic CO_2 retention. None of these characteristics has been useful in predicting individual REM desaturators. The mechanisms leading to hypoxemia include ventilation, which is reduced in all stages of sleep, especially in REM sleep. It has also been postulated that it may be related to ventilation–perfusion imbalance, though this has been difficult to prove. REM-associated falls in S_aO_2 are associated with increases in pulmonary artery pressures. It is not clear whether isolated increases in pulmonary artery pressures during sleep can lead to sustained pulmonary hypertension. However, recent studies of COPD patients with nocturnal desaturation and daytime PO_2 levels over 60 mmHg have demonstrated higher daytime resting and exercise-induced pulmonary artery pressures in these patients than in a similar group of patients who did not desaturate at night.

Patients with COPD have increased premature ventricular contractions during sleep, and there is a tendency for these to decrease in frequency when these patients are given supplemental oxygen. The effect of nocturnal oxygen saturation on survival has recently been reported. Both the mean nocturnal S_aO_2 and the S_aO_2 nadir during sleep were significantly related to survival. However, neither measure improved the prediction of survival over measurements of vital capacity or awake S_aO_2. The measurement of nocturnal S_aO_2 during sleep therefore cannot be recommended in the routine clinical management of COPD patients. Several studies have demonstrated that COPD and OSA can coexist, but there is no evidence that this coexistence is more common than would be expected from the relative frequencies of these two conditions. The significance of the association seems to be that patients with both disease processes seem more likely to develop pulmonary hypertension and right-sided heart failure than do patients who have either condition alone. Full polysomnography, however, would be beneficial in those COPD patients with symptoms suggestive of coexistent OSA.

AIR TRAVEL

Commercial airline travel exposes passengers to hypobaric hypoxia because aircraft cabins are not routinely pressurized to sea level. In patients who have compensated COPD at sea level, lowering the partial pressure of oxygen in the aircraft cabin can produce severe hypoxemia. Physical exertion during the flight can increase the risk of an exacerbation of symptoms. It is unknown what proportion of patients who suffer cardiac events during air travel have COPD as a comorbid

condition. Aircraft are usually pressurized to between 5000 and 7000 feet (1500 to 2100 m). For the preflight evaluation of most patients, clinicians should consider 8000 feet (2438 m) of altitude above sea levels as a realistic “worst-case scenario.”

Preflight assessment can be accomplished by estimating the expected degree of hypoxemia at altitude, identifying comorbid disease conditions, and providing an oxygen prescription if necessary. Documentation of the recent clinical condition and laboratory tests, particularly if the patient is traveling abroad, and counseling are also desirable elements of the preflight patient care. The two means of estimating the degree of hypoxia at altitude are the hypoxia inhalation test (HIT) and the use of regression formulas. The HIT is not performed in many clinical laboratories in the United States. Regression equations offer the opportunity to compare a patient with a group of patients with similar clinical characteristics who have been previously studied during exposure to hypoxia. Although regression equations may provide a more physiological basis for the effects of high altitude than the HIT, the regression approach does not assess the individual's susceptibility to the development of symptoms or electrocardiographic changes during hypoxia. The A–a O_2 gradient generally has no advantages over regression equations. Currently it is recommended that the P_aO_2 during air travel be maintained above 50 mmHg. Although 2 to 3 L of oxygen by nasal cannula will replace the inspired oxygen lost at 8000 feet compared to sea level, lesser increments of oxygen will maintain the P_aO_2 above 50 mmHg in many patients, and a 1- to 2-L increment may be sufficient.

Patients with COPD receiving continuous oxygen at home will require supplementation during air flight. Such patients should receive greater oxygen supplementation during the flight than at sea level. Increments equivalent to 1 to 2 L of oxygen by nasal cannula during flight should suffice for most patients. Patients will also require additional oxygen supplementation if the elevation at the destination is significantly greater than at home. The Federal Aviation Administration requires a physician's statement of oxygen need in order for a patient to receive continuous oxygen during flight. There is no uniform airline request form, so each airline must be contacted by the patient to determine what is required. Because the airlines do not provide oxygen for ground use in the airline terminal, patients who require continuous oxygen should be advised to make plans for such locations. The American Lung Association provides patient education materials, including a booklet entitled *Airline Travel with Oxygen,* for individuals who travel with oxygen.

NUTRITION

As many as 25% of outpatients with COPD may be malnourished, and almost 50% of those patients admitted to the hospital have evidence of malnutrition. Sixty percent of critically ill COPD patients with acute respiratory failure are malnourished. The exact cause is not clear, but factors such as increased work of breathing, decreased food intake because of dyspnea, and secretion of cytokines such as tumor necrosis factor may combine to generate the malnutrition state. Malnutrition is associated with wasting of respiratory muscles, causing respiratory muscle weakness.

Assessment

The nutritional assessment of COPD patients includes body weight (loss in excess of 10% ideal body weight), but presence of edema limits the utility of body weight. Hepatic secretory proteins such as albumin, transferrin, retinol-binding protein, and prealbumin are markers of visceral protein stores and proposed as methods of nutritional assessment. Unfortunately, all are influenced by numerous factors in addition to the nutritional state. Anthropometry involves application of simple measurements of skin folds and circumferences to divide the body into compartments of fat, muscle tissue, and skeletal mass. This is used with limited success. Depression of cellular immunity is consistently associated with malnutrition, and nutritional repletion is associated with improved immunocompetence. The utility of skin testing is limited by multiple factors, which include technical application and interpretation of skin tests. Tests of muscle function are also used as markers of nutritional status. Unfortunately, no simple recommendation can be given regarding the “best” test for nutritional assessment. Utilization of any of these methods can be appropriate, providing the limitations are clearly understood.

Nutritional Support

Aggressive oral nutritional supplementation of COPD patients does result in improvement of respiratory strength, but it is laborious, time intensive, and often cannot be maintained by the patient. It has been suggested that COPD patients might benefit from a high-lipid, low-carbohydrate diet because of the reduced RQ when the latter substrates are fed. However, the clinical benefits of altering fat-to-carbohydrate ratios in COPD patients when calories supplied are appropriate remains unproven. Overfeeding should be avoided. Electrolyte disturbances are common in COPD patients and have potential for significant adverse outcomes. Hypophosphatemia, hyperkalemia, hypocalcemia, and hypomagnesemia are associated with decreased respiratory muscle function while repletion of these abnormalities results in improved function. Hypophosphatemia can develop as a consequence of refeeding. Although these complications apply to all patients receiving nutritional support, COPD patients may be at increased risk relative to decreased respiratory muscle function secondary to their prior lung disease. Monitoring electrolyte levels and providing supplemental electrolytes, especially phosphorus in malnourished patients, should be routine in COPD patients with respiratory failure. Patients with COPD should be instructed on good dietary habits. Their weight should approximate ideal body weight. If they are malnourished, attempts should be made to restore nutritional balance. Several smaller meals a day may help maintain caloric needs but avoid undue dyspnea. Forced nutrition or special diets are not recommended at the present time. The use of hormones to improve muscle functions remains experimental.

CONCLUSION

Over the years, our knowledge about COPD has increased significantly. Smoking cessation campaigns have resulted in a significant decrease in smoking prevalence in the United States. Similar efforts in the rest of the world should have the same impact. The consequence should be a drop in incidence of COPD in the years to come. The widespread application of long-term oxygen therapy for hypoxemic patients has resulted in increased survival. During this time we have expanded our drug therapy armamentarium and have used them to effectively improve dyspnea and quality of life. Recent studies have documented the benefits of pulmonary rehabilitation (Chapter 51). Noninvasive ventilation has offered new alternatives for the patient with acute failure. The revival of surgery for emphysema, although still experimental, may serve as an alternative to lung transplant for those patients with severe COPD who are still symptomatic on maximal medical therapy. With all these options, a nihilistic attitude toward these patients is not justified.

Long-term oxygen therapy can reverse the progression of pulmonary hypertension in patients with chronic obstructive pulmonary disease. *Am Rev Respir Dis* 1985;131:493–498. *Excellent study that will be difficult to repeat. The authors prospectively demonstrated that over 40 months, pulmonary artery pressure increased in COPD patients. After treatment with supplemental oxygen, not only did pressures stop increasing, but the value actually declined over the subsequent 2 years.*

Withholding and withdrawing life-sustaining therapy. *Am Rev Respir Dis* 1991;144:726–731. *Very important position paper that provides a guide to the issues related to severely ill patients requiring extraordinary support.*

Ziment I. Pharmacologic therapy of obstructive airway disease. Clin. Chest Med. 1990;11:461–486. *Good review article that places in perspective all the pharmacological agents available for the treatment of COPD.*

CHAPTER

44 Sleep Apnea Syndrome and Sleep-Disordered Breathing

Kingman P. Strohl

K. P. Strohl: Department of Medicine, Case Western Reserve University, Cleveland, Ohio 44110.

INTRODUCTION

Sleep-disordered breathing comprises a collection of syndromes characterized by breathing abnormalities during sleep, by intermittent disruptions in gas exchange, and by sleep interruption. According to cross-sectional studies, sleep apnea is common in the population, and 2% to 4% of the population could be candidates for treatment on the basis of excessive daytime sleepiness, cardiac arrhythmias, cognitive abnormalities, and/or behavioral abnormalities. In addition, there are epidemiologic data to suggest that snoring (partial upper airway obstruction during sleep) is associated with systemic hypertension and stroke and, possibly, myocardial infarction and premature sudden death. Finally, a positive association between sleep apnea and motor vehicle accidents exists. Clearly, sleep-disordered breathing has a medical and social impact on the community.

The purpose of this chapter is to describe the pathophysiology and clinical management issues for respiratory disorders of sleep.

DEFINITIONS USED IN DESCRIBING SLEEP-DISORDERED BREATHING

Sleep apnea syndrome is a disorder characterized by the association of apnea and/or hypoventilation during sleep with a constellation of symptoms and signs related to sleep fragmentation and hypoxic exposure. The syndrome will resolve when the sleep-induced respiratory disturbance is eliminated.

Three patterns of apnea, i.e., cessation of breathing, can be observed during sleep. These are schematically shown in Fig. 1. A central apnea occurs when both airflow and respiratory efforts are absent. Other terms used in the literature that are equivalent to central apnea are diaphragmatic or arrhythmic apnea. These terms imply that there is a cessation of respiratory effort. During an obstructive apnea, respiratory efforts persist, although airflow is absent at the nose and mouth. Other terms for obstructive apnea are upper airway and peripheral apnea. Obstructive and central apneas are not necessarily unrelated. Many adult patients exhibit apneas in which both central and obstructive patterns occur, which are termed mixed apneas. In a single apneic episode there may be a period in which no efforts occur, followed by the appearance of respiratory efforts, also without airflow. In addition, in the same night, patients may have central, mixed, and obstructive apneas.

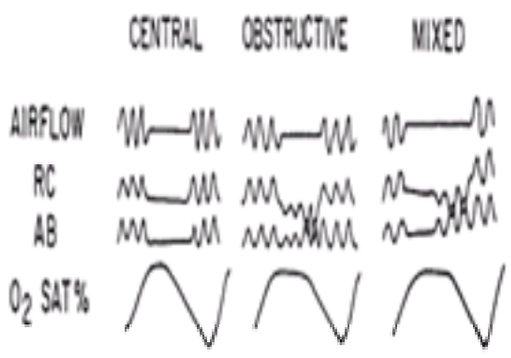

FIG. 1. Shown in diagrammatic form are the three patterns of apnea identified during sleep in human subjects. In each, airflow at the nose and mouth is absent, indicating apnea. In central apnea, respiratory efforts, indicated in this instance by rib cage (RC) and abdominal (AB) displacement, are absent. During an obstructive apnea, efforts by the chest-wall muscles are present throughout the entire episode of apnea. In mixed apneas, both central and obstructive patterns are present in the same apnea. Oxygen saturation (02 SAT %) will fall according to the general level of oxygen saturation and the length of the apnea. (Reproduced from KP Strohl et al. Physiologic basis for therapy of sleep apnea. *Am Rev Respir Dis* 134:791, 1986.)

Hypopneas or hypoventilation during sleep may arise by mechanisms similar to that producing apnea. Hypoventilation (hypopnea) leads to increased carbon dioxide and decreased oxygen levels in arterial blood and arousals from sleep; like apneas, hypopneas result from reduction in respiratory efforts or partial upper airway obstruction. Snoring is a form of partial airway obstruction. Although in most instances snoring is of mild severity, patients who snore heavily may present with symptomatic features of sleep apnea syndrome even if complete cessation of airflow (apnea) never occurs during sleep; moreover, these patients may exhibit abnormal sleep and cardiorespiratory changes as well.

There are certain summary measures used to describe respiratory disturbances during sleep. The *apnea–hypopnea index* (AHI) is the total number of apneas and hypopneas during sleep divided by the hours of sleep time. Values of AHI can be computed for the different stages of sleep. Another term used is the *respiratory*

disturbance index (RDI), which is equivalent to AHI. The term *desaturation index* (DI) refers to the number of times per hour that oxygen saturation falls by more than 4%. Finally, if formal sleep measures are performed, an *arousal index* (AI) is computed. The number or arousals per hour of sleep may not be equivalent to AHI or RDI because many (approximately 20%) apneas or hypopneas are not accompanied by arousals and/or other causes for arousals are present.

EPIDEMIOLOGY OF SLEEP-DISORDERED BREATHING

Subjects without clinical problems may exhibit obstructive or central apneas at sleep onset or during periods of rapid eye movement (REM) sleep. Apneic episodes are usually less than 10 to 15 sec in duration and are not repetitive. Occasionally, longer periods of apnea lasting up to 30 sec are seen in normal subjects, particularly during REM sleep. These episodes are not usually accompanied by arousal or sleep-state changes. Whether there are gender differences in the appearance of sleep apneas in healthy subjects is unclear. In healthy young subjects, some studies have shown that more boys than girls have frequent apneas during sleep, but others report little gender difference in the occurrence of apneas. Study differences may be confounded by small numbers of subjects, subject selection, and the effect of obesity. After the sixth decade, however, respiratory disturbances during sleep seem to increase in number and occur with equal frequency in men and women. Patients with a clinically important sleep apnea may be distinguished from normal by the existence of *repetitive* apneas greater than 10 sec in duration during stages I and II and REM sleep and by improvement in daytime symptoms and general performance with treatment of sleep-disordered breathing. Unfortunately, the number of respiratory disturbances *per se* is not a good indicator of disease, and symptoms of sleepiness are better predictors of treatment success, as experienced by the patient and by objective testing.

A recent epidemiologic study estimated that 9% of women and 27% of men in the U.S. population may have an AHI > 5, a number often quoted as a “threshold value” for normality; however, many people with an AHI > 5 have no symptoms or apparent illness. In a sample of 1500 factory workers, it was found that at least 2% had symptomatic sleep apnea. These studies also suggest that these subjects have higher accident rates and substantial disability. This prevalence rate of symptomatic people with AHI > 5 was confirmed in the U.S. population.

Snoring is believed to be a predisposing feature in the development of disease. Snoring increases markedly with age, so that approximately 45% of men and 30% of women 65 are said to snore. Hypertension is twice as common among persons who snore, even after age and obesity are taken into account.

Reports from sleep clinics suggest that sleep apnea should be considered in any patient referred for problems of initiating and maintaining sleep or excessive somnolence. The incidence of sleep apnea in patients presenting to sleep centers ranges from 7% to 33% and is increasing as there occurs greater recognition of sleep apnea and its sequella by primary care providers.
