There is increasing evidence that sleep apnea has a familial component. Symptoms relating to apnea are present with two to six times greater frequency in family members of affected patients than in a control population. Sleep apneic activity itself is present more often in first-degree relatives of patients than in age-, sex-, and socioeconomic-matched control families. These family studies also suggest that the frequency of sleep apnea is underestimated in the community and that the symptomatic sequelae of multiple apneas are quite variable. Furthermore, this effect is not sufficient to recommend screening of asymptomatic family members.

CLINICAL FEATURES OF SLEEP APNEA

Patients will often have five or more of the traits listed in Table 1. Signs and symptoms in a particular patient may be associated with central, obstructive, or mixed apneas during sleep.

Historical data	Clinical signs
Altered sleep; snoring, thrashing	Cardiac arrhythmias
Excessive daytime sleepiness	Systemic hypertension
Dyspnea, especially on exercise	Edema
Morning headaches	Polycythemia
Insomnia	Pulmonary hypertension
Fatigue	Reduced sleep latency by EEG
Intellectual deterioration	
Personality changes	
Hallucinations, automatic behavior	Reddened uvula; pharyngeal crowding
Family history of sleep apnea	

TABLE 1. *Clinical problems associated with sleep-disordered breathing*

Patients with obstructive sleep apnea may be obese and physically resemble patients described as suffering with pickwickian syndrome, exhibiting obesity, cardiopulmonary failure, polycythemia, and hypersomnolence. Yet nearly half of patients with the sleep apnea syndrome are not obese, and the suspicion that the syndrome is present should not be limited to the fat patient or to those with characteristics previously called the pickwickian syndrome.

Restless sleep and observed apneas are sensitive and specific indications of the recurrent apneas. Sleep complaints include either excessive daytime sleepiness or insomnia. Both are related to the number and type of nocturnal arousals. It is said that patients with insomnia generally have fewer and shorter, primarily central, apneas with little hypoxemia, whereas patients with excessive daytime sleepiness have more and longer, primarily mixed and obstructive, apneas with greater hypoxemia.

Bradyarrhythmias during sleep are found in patients with sleep apnea, and cardiac monitoring in the course of workup for heart disease can be a clue to the presence of apneas during sleep. An example of bradyarrhythmia during sleep apnea is shown in Fig. 2. During obstructive apneas, the depressive effects of the carotid body on heart rate predominate, while quickening of heart rate occurs when ventilation occurs. Patients with sleep apnea who exhibit bradycardia during sleep may have normal findings on His bundle studies and otherwise normal cardiac function during wakefulness. Other cardiac arrhythmias include ventricular ectopy and escape rhythms, but in addition, reflexes elicited by forceful respiratory efforts against a closed airway and the resulting swings in pleural pressure probably have significant effects on circulatory function. Arrhythmias in patients with sleep apnea disappear when the apneas are relieved. Holter monitoring is not sensitive or specific enough for use in screening.

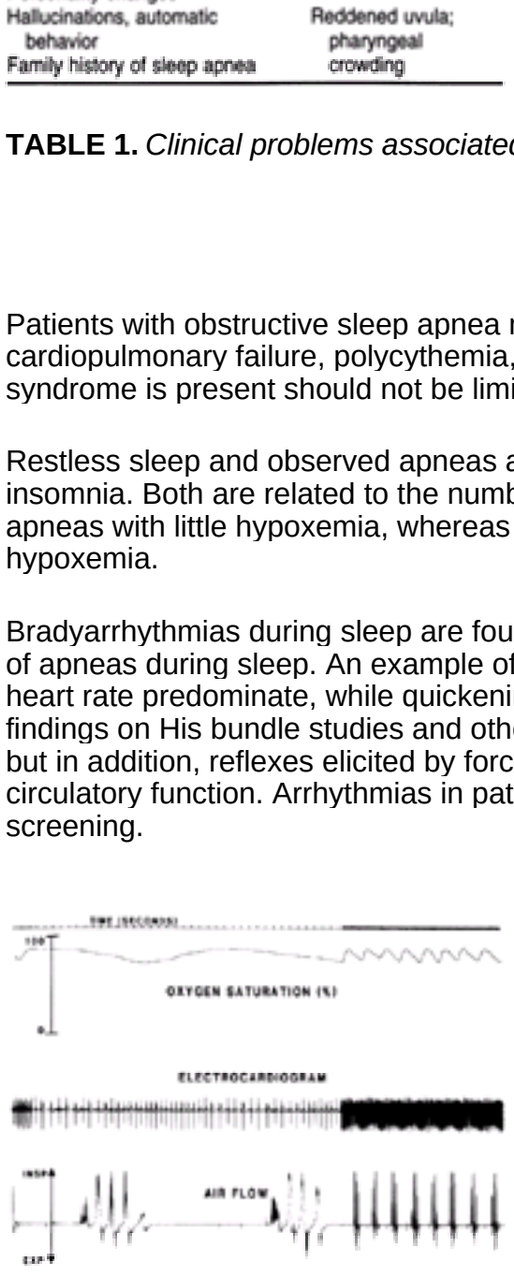

FIG. 2. Shown is the relationship between oxygen saturation, heart rate (indicated by an ECG rhythm strip), and ventilation (measured from a face mask). Cyclic changes in heart rate found on Holter monitoring of a patient can indicate the presence of apneas during sleep. INSP = inspiration; EXP = expiration.

Often it is the family members, rather than the patient, who first recognize the sleep disturbance, e.g., periods of absent breathing, loud snoring, or thrashing movements during sleep. The symptoms of sleepiness develop over many years. These are the most common constellation of presenting symptoms. Patients occasionally present with complaints of fatigue or decreased alertness or with apparently unexplained polycythemia. Sleep apnea is part of the differential diagnosis of

sexual dysfunction, personality changes, and morning headache.

Routine laboratory examinations are not helpful screening tools. Likewise, pulmonary function tests also may reveal no abnormality except those caused by associated obesity (somewhat diminished lung capacities, with greater reduction in the expiratory reserve volume). Although patients with lung diseases also may have the sleep apnea syndrome, there is no evidence that sleep apnea occurs more frequently in patients with pulmonary impairment.

The sleep apnea syndrome should be considered in patients with hypercapnia that is disproportionate to abnormalities in mechanical function of the lungs. Hypercapnia rarely occurs with obstructive lung disease unless forced expiratory volume in 1 sec (FEV_1) is reduced to less than 50% of the predicted value. Carbon dioxide elevation occurs in patients with asthma and fibrotic pulmonary disease only with even more severe reduction in the FEV_1. Patients with unexplained right-sided heart failure or pulmonary hypertension likewise should be questioned for the presence of sleep-disordered breathing. Finally, some patients with the sleep apnea syndrome may be mistakenly treated for primary heart disease because cardiac arrhythmias have been detected during sleep but respiratory disturbances have not.

LABORATORY DIAGNOSTIC SLEEP STUDIES

A definitive diagnosis can be made by polysomnography, in which continuous measurements of several physiological variables are made to assess sleep stages, breathing, and gas exchange. Figure 3 shows the elements of sleep and breathing that can be monitored in patients.

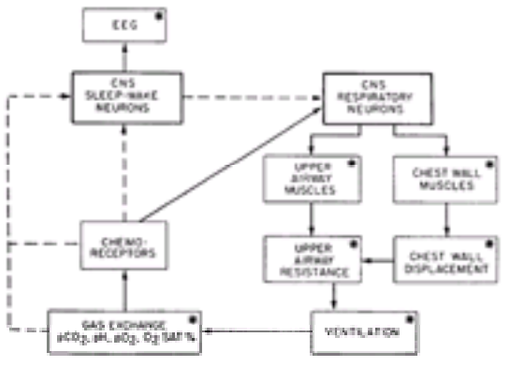

FIG. 3. This schematic diagram shows the general relationships between the respiratory system (CNS respiratory neurons, upper airway and chest-wall muscles, ventilation, chemoreceptors, etc.). And the CNS sleep-wake process. The boxes designated by the asterisks indicate the respiratory variables and the electroencephalogram (EEG) that can be measured in human subjects and are used in the diagnosis and assessment of treatment in patients with sleep apnea. Note that the basic mechanisms in respiration or sleep can be measured only indirectly. (Reproduced from KP Strohl et al. Physiologic basis for therapy of sleep apnea. *Am Rev Respir Dis* 134:791, 1986.)

Sleep staging requires monitoring of the electroencephalogram (EEG) (usually with two or three leads), the chin electromyogram (activity decreases in REM), and the electrooculogram (EOG) to detect REM. It is also useful to record the electrocardiogram (ECG) to see if arrhythmias occur with the apneic episodes.

To distinguish central from obstructive apneas, both respiratory efforts and some index of airflow must be measured.

Noninvasive oximeters that spectrophotometrically and continuously measure the level of oxygenated hemoglobin are ideal for use in sleep studies. These instruments are reliable and accurate for trending of oxygen saturations from 70% to 99%. Issues concerning artifact, sampling time, averaging routines, and sensor placement must be considered in their use and interpretation.

Gas exchange can be assessed by sampling from indwelling arterial catheters. However, intermittent sampling may miss the rapid falls in oxygen tension and saturation that occur during apneas. P_{CO_2} can be sampled by transcutaneous methods and can provide a reasonable alternative for assessment of alveolar ventilation. P_{O_2} can be assessed transcutaneously using electrodes applied to the skin, which is heated to increase blood flow; these electrodes probably have too long a response time to be useful in sleep apnea.

NONPOLYSOMNOGRAPHIC MONITORING TECHNIQUES

Because of the expense and time commitment involved in performing polysomnography, there have been three approaches to reduce the cost or performance of this diagnostic procedure. First, questionnaires have been proposed that could serve to screen individuals, thereby improving the prediagnostic probability and reducing the number of subjects who need polysomnography. Second, equipment has been developed to allow performance of a study equivalent to polysomnography in the home setting. In some instances, a van brings equipment and a technician to the patient. Third, simplified monitoring of selected, crucial variables could be used to assess therapeutic efficacy. In this instance, monitoring devices are carried around by the patient, as is done in Holter monitoring.

For the last purpose, a number of approaches have been suggested. Some include use of tracheal sound recordings, monitoring of position, and oximetry. No single channel of data alone can be used to detect apneas and hypopneas associated with desaturations, but the predictive value with respect to apneas is improved by experienced interpretation of a combination of measures. However, the added value of these abbreviated studies compared to the determination of probability by history and physical is low. Indeed, the absence of abnormalities in such tests does not prove that the patient is free of sleep apnea, that the amount and quality of sleep are adequate, or that other sleep disorders that can produce similar symptoms are not present.

Screening studies that combine continuous measurement of arterial oxygen saturation, airflow sounds, and/or ventilatory effort may be adequate for the follow-up of treatment for sleep apnea if cyclic saturation, breathing, and effort abnormalities were previously detected and then abolished by the application of nasal continuous positive airway pressure (CPAP).

Several approaches to unattended simultaneous monitoring of several variables have been developed recently, using both digital and analog recording techniques. Such devices are being continuously upgraded, as is the detection of respiratory events. Many devices employ signals from the chest and abdomen to detect apneas and hypopneas. In some instances, tidal volume changes can be estimated from the phase relationship between the rib cage and abdomen motion. Simultaneous with the respiratory measurements, recordings are made of other important variables, for example, ear oximetry, heart rate determined by the R-R interval of the ECG, tibialis electromyogram, and body movement with an activity monitor strapped to subject's wrist. The latter is used in an attempt to estimate sleep time.

At the present stage of development, the number of apneas detected by these instruments shows a good correlation with those detected by simultaneous polysomnography. Thus, in general, the instruments correctly identify persons who have sleep apnea. However, the devices are not as proficient in classifying apneas as being obstructive or central. In particular, with current digital systems, central apneas are frequently misclassified as obstructive or mixed. Improvements to obviate these and other problems will be made because the costs of center-based polysomnography limit access to diagnosis and management.

INTERPRETATION OF POLYSOMNOGRAPHIC MEASUREMENTS

Sleep apnea is often considered to be present if there are at least 30 apneas or hypopneas (each more than 10 sec) occurring in both non-REM (NREM) and REM sleep in a sleep recording lasting 6 hours. This is a very difficult number to defend as a classification of disease. There are reports of people who have more than 200 apneas per night yet are relatively asymptomatic, and many otherwise normal, healthy aging subjects would be classified as having sleep apnea syndrome based on currently used criteria, which depend on numbers of apneas. Definitive prospective longitudinal data on the risks associated with only the number of respiratory events during sleep are currently being collected. Retrospective studies suggest mortality increases as the apneic index (number of apneas per hour of sleep) increases. Controversy on the predictive value of polysomnography still exists. Treatment effect is still part of the disease definition.

Levels of oxygen saturation during wakefulness and sleep could be clinically more important than the number of abnormal respiratory events, however defined. With continuous monitoring of oxygen saturation, the fraction of the sleep period spent at each level of oxygen saturation can be determined to quantify hypoxemic exposure (Fig. 4). Minimum levels of oxygen saturation are important because severe hypoxia can trigger cardiac arrhythmias, but mean levels may be even more important. Recently, methods of quantitatively describing the profile of oxygen saturation throughout sleep and wakefulness have been developed and should prove valuable in

diagnosis and in evaluating the effects of treatment.

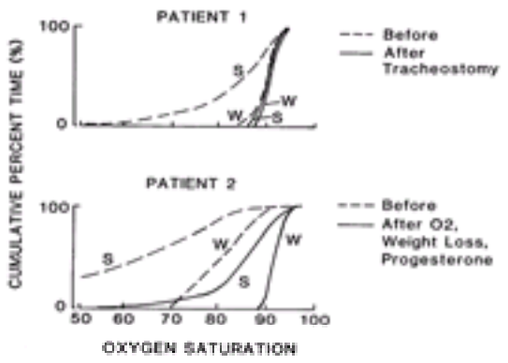

FIG. 4. The effect of treatment on oxygen saturation over time in two patients, one treated with tracheostomy and one with oxygen, progesterone, and associated weight loss. Studies in both patients were performed on room air. Treatment in both cases reversed hypersomnolence, and increased hematocrit, pedal edema, and signs of right-sided heart failure. S = sleep; W = wakefulness.

Some sleep investigators believe that sleep studies should be performed on at least two nights, because it has been shown that the distribution of sleep stages may be altered by unfamiliar surroundings. In patients with lung disease, however, ventilatory changes within a given sleep stage usually can be accurately assessed during a single night's examination. Because all-night studies are costly, attempts have been made to diagnose sleep apnea and its severity with shorter examinations of sleep. The specificity and sensitivity of such studies may improve as our ability to distinguish those patients most likely to benefit from noninvasive or rapid treatment of sleep apnea from those requiring more detailed assessment for other sleep disorders.

It is proposed that any diagnostic study for sleep apnea should include periods of both NREM and REM sleep for the reason that it is during REM sleep that severe changes in respiration often occur. Although this approach is reasonable, correlation of sleep events with clinical symptoms is currently imprecise, and furthermore, the relative importance of abnormal respiration occurring in REM and NREM sleep is unknown.

Figure 5) typifies the spectrum of disease from a personal perspective. Those with severe disease could be defined as individuals who have active daytime sleepiness interfering with normal daily activities and associated with signs of cardiopulmonary failure, polycythemia, and cor pulmonale. Such an individual would now be easily recognized as having a treatable disease. Once the apneic episodes during sleep are eliminated, excessive daytime sleepiness would resolve, and signs of hypoxic stress, such as polycythemia and cor pulmonale, would resolve or not progress. Noted is a correlation among the number of arousals, the number of respiratory events during sleep, and sleepiness as measured by multiple sleep latency testing. Patients fall asleep during the day, in a sitting posture, and are at extreme risk for accidental injury. Clinical studies have shown that reversal of sleep-related hypoxemia can improve sleepiness, hypertension, and abnormalities associated with hypoxemia, such as reversal of the polycythemic state and resolution of edematous states associated with cor pulmonale. The category of severe disease includes patients with more than 30 apneas per hour of sleep and hypoxemia that exceeds lower thresholds of 85% saturation for at least 15% of the time during sleep.

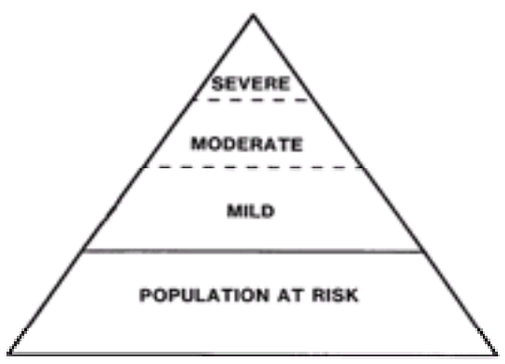

FIG. 5. Degrees of pathophysiology that exist in sleep apnea syndrome. Although this figure illustrates the spectrum of disease, it should be considered a hypothesis. For instance, the population at risk is presumed to be those who snore heavily, somewhere in the vicinity of 50 percent of males and 30 percent of females. Also, the natural progression of the disease is not known.

A second category would be that of moderate disease. This zone would include daytime sleepiness of which the patient is aware and takes steps to avoid falling asleep at times that might be inappropriate. One example might be the patient who often takes a nap in the middle of the day or avoids driving for fear of falling asleep. These individuals are less disabled by their daytime sleepiness than those with severe disease and often are able to continue their daily activities, but at reduced levels. These individuals do not often have daytime signs and symptoms of cor pulmonale; however, they often have hypertension. Detailed studies of pulmonary vascular resistance or of cognitive studies in these individuals have not been performed; however, this group appears to have an increased incidence of motor vehicle violations or accidents. Generally in these patients the apneic/hypopneic index is between 15 and 30, but positionally induced or positionally altered apneic indices could be common, and a high hypopneic index may be present. Sleep fragmentation is observed, but the progression of sleep stages is apparent. This category is distinguished from severe disease by the absence of disabling sleepiness, of cor pulmonale, and of hypercapnic respiratory failure.

A third category is that of mild disease. In these individuals, there is sleepiness that is manifested by a regular tendency to fall asleep under circumstances of inactivity such as reading the newspaper, going to movies, or watching television shows. This “passive” sleepiness may not be recognized by the patient, and the patient does not take steps to avoid activities that might make him or her sleepy. Indeed, sleepiness may be recognized only by family members and be noticed only in retrospect after direct treatment of apnea or of improvement by weight loss or alcohol abstinence. Respiratory disturbance indices in these individuals are generally in the range of 5 to 15 per hour. There may be no signs of hypoxic stress, and oxygen saturation levels during sleep are generally confined to less than 90% for only 5% of the time. Sleep stages and stretches of stage III and IV sleep are preserved. These individuals are distinguished from those with moderate disease to the extent that their sleepiness does not intrude on daily activity or behavior and by the absence of problems ascribed to hypoxic stress.

The substrate for development of disease related to sleep apnea is considered to be those individuals who snore on a regular basis and do not have observed apneas. People with simple snoring generally are not sleepy, although perhaps more susceptible to behavioral influences and morbidity from alcohol or sedatives than individuals who do not snore at all. This group would comprise half of the male and a third of the female population. Respiratory disturbance indices are usually low, and a positional component to snoring and apnea may be present. Aspects of the association between snoring and other common diseases and the distinction between heavy snoring and mild snoring have been reviewed in other sections of this chapter. The major epidemiologic associations with hypertension, cardiovascular disease, myocardial infarction, and stroke possibly include these individuals as well as those with mild or moderate disease severity.

It is clear that in the case of the excessively sleepy individual with cor pulmonale, carbon dioxide retention, and polycythemia, elimination of apneas during sleep by tracheostomy or by nasal CPAP is desirable, leads to clinical remission, and, as indicated by retrospective studies, reduces mortality. The same studies suggest that elimination of apneas in those with moderate disease can reduce mortality; perhaps more importantly, therapy will improve symptoms of sleepiness to the extent that there may be less morbidity from complications such as automobile or industrial accidents.

It is not clear what to do for patients with mild disease or those who snore heavily. The natural history is unclear, and therapy is not well developed. However, this is a large population, and untried and unproved therapies abound. These include antisnoring pillows, devices that attach to the glasses that keep one alert, dental prostheses, external nasal dilators, nasal decogestants, and steroid sprays. Some may have merit. However, prospective randomized trials are needed to assess beneficial effect not only in terms of patient and/or bed partner satisfaction but also in terms of physiological and objective criteria that may relate to morbidity and mortality.

The diagram shown in Fig. 5 really relates to that individual with uncomplicated obstructive sleep apnea, that is, the individual who does not have other concomitant

illness. It is known that sleep apnea can complicate other diseases, as outlined in other chapters; hence, distinguishing the effects of sleep apnea from other sorts of diseases that promote sleepiness and/or hypoxic complications is one major task of the clinician.

STUDIES DURING WAKEFULNESS

The patient with sleep-disordered breathing should undergo a complete clinical examination specifically looking for the presence of cardiovascular, respiratory, or metabolic disturbances that may predispose the patient to or cause repetitive apneas during sleep. Drug addiction or depression may masquerade as sleep apnea, especially in the elderly subject in whom a number of apneas during sleep may be considered “normal.” In addition, some patients with sleep apnea (approximately 10%) may have concomitant narcolepsy, as suggested by family history, and/or evidence for cataplexy or periodic limb movements or restless legs. A careful history is the key to recognizing these diseases. Certain diagnostic tests, such as arterial blood gases, thyroid function testing, pulmonary function tests, the ECG, echocardiogram, and chest roentgenogram, are electively indicated if signs of hypoxic exposure are present.

If the predominant pattern of apnea during sleep consists of repetitive obstructive or mixed apneas, a more detailed physical examination is indicated to determine the presence of anatomic or pathologic narrowing of the upper airway. Physical examination will exclude pathologic processes. In the patient without upper airway or respiratory complaints, the flow–volume loop is unhelpful. A pattern consistent with variable extrathoracic obstruction, that is, a decreased inspiratory flow relative to expiratory flow at 50% of vital capacity, has been described in sleep apnea but is not predictive of the illness nor by itself helpful in directing therapy.

Specialized assessment of upper airway structure or function can be performed in the patient without obvious anatomic or pathologic narrowing of the pharynx but cannot be recommended in routine testing of patients. Computed tomography has shown nasopharyngeal and pharyngeal narrowing in obese patients; of interest, this narrowing does not appear to be caused by fat deposition. Measurements of the bony structures and alignment of the jaw to the head and neck (cephalometrics) have revealed individual and familial traits of a relatively shortened mandible; the degree of such trait correlates with the development of sleep apnea. Electromyography of upper airway muscles has shown a correlation between a decrease in muscle activation and the onset of apnea, yet this finding is universal in patients. The usefulness of nasoendoscopy during wakefulness and sleep is currently being explored as a way of selecting patients for surgical therapy directed at enlarging the airway. Preliminary studies suggest that those patients who exhibit the tendency to obstruct at the level of the nasopharynx, as opposed to the oropharynx, have a greater likelihood of success with uvulopalatopharyngoplasty. Acoustic imaging of the extrathoracic airway has shown that patients with sleep apnea have a smaller and more compliant pharyngeal airway than age- and weight-matched controls. Although all these special studies have given insight into potential mechanisms causing sleep apnea, none has shown sufficient specificity or reliability to dictate one or another therapeutic approach.

Multiple sleep latency testing consists of repetitive, bi-hourly observations of the time to sleep onset and REM. Healthy subjects will generally be unable to reproducibly initiate sleep or exhibit REM sleep at hourly intervals during periods of usual wakefulness. Patients with sleep apnea or narcolepsy will fall asleep and even exhibit REMs within 10 min of each hourly trial. This test is useful in the laboratory documentation of excessive daytime sleepiness, but its specificity and ability to predict daytime performance in the workplace have not been systematically demonstrated.

NATURAL HISTORY OF SLEEP APNEA

The natural history of the sleep apnea syndrome is largely unknown. Although there appear to be clinical categories of disease such as mild, moderate, and severe (see Interpretation of Polysomnographic Studies and Fig. 4), there is little evidence that progression from health to severe disease occurs according to these categories. There are few longitudinal studies in untreated patients with sleep apnea syndromes; those available have one or two subjects studied 4 to 8 years apart and show little change in the quantitative determination of breathing patterns during sleep. If this is the case, the disease progression is either slower than this time interval or sporadic.

It is proposed that snoring in early life leads to the insidious development of hypersomnolence and cardiovascular disease in patients with obstructive sleep apnea. In support of these suggestions are the findings that a history of heavy snoring is reported in more than 70% of adult patients with obstructive sleep apnea syndrome. Patients and family members often report minor symptoms of hypersomnolence occurring 10 to 20 years before diagnosis. Most clinical reports have emphasized the recognition of sleep apnea syndrome in the middle-aged man, and little is known about the natural history of these disorders in women, in the elderly, or in children. However, it is likely that in all groups, symptoms will increase abruptly with the appearance of increased hypoxemia and cardiopulmonary complications.

Death and sleep apnea are associated, but the nature of the association and extent of causality have not been satisfactorily explained. Early reports of patients with the pickwickian syndrome noted a high in-hospital mortality from cardiorespiratory failure, pulmonary embolus, and renal failure. Death has been reported to result from sedative drug use, particularly preoperative medications. However, it is the impression of some that automobile accidents related to excessive daytime sleepiness may have a greater impact on morbidity and mortality than cardiovascular complications or other nonaccidental sudden death.

PATHOPHYSIOLOGY

In most patients a variety of functional and anatomic factors can interact and produce repetitive apneas during sleep. These include sleep state, changes in respiratory control or mechanics with sleep, body habitus, body position, circulation time and cardiac output, and hereditary factors of respiratory control and upper airway morphology. Certain diseases of the cardiovascular and respiratory system are associated with respiratory disturbances during sleep, but in these instances, it is the disease rather than sleep-disordered breathing that dominates the clinical picture.

NEUROPHYSIOLOGY

The rhythmic cycle of a breath depends on interactions between groups of neurons located in the medulla: a dorsal group located in the vicinity of the nucleus tractus solitarius and a ventral group consisting of neurons in the nucleus retro- and paraambigualis, the nucleus retrofacialis, and nucleus ambigualis (NA). Efferent activity of the cranial nerves that supply upper airway muscles is adjusted by NA activity and the neural discharge to the chest-wall muscles by dorsal medullary nuclei. The activity of these medullary groups of respiratory neurons can be altered by descending pathways from pontine and suprapontine areas and can be affected by the sleep–wake cycle, in particular the waxing and waning of the meadian raphe, or reticular activating system.

It is difficult to produce apnea by hyperventilation in awake humans, but in anesthetized and sleeping animals and humans there seems to be some threshold level of carbon dioxide that is required to initiate breathing. This threshold level of P_{CO_2} is decreased by hypoxia in certain subjects, possibly by excitation caused by miscellaneous nonchemical stimuli.

The respiratory controller will influence the activity of the upper airway as well as the muscles of the chest wall. The electric activity of upper airway muscles often seems to be entrained to the respiratory rhythm, and phasic increases and decreases in the activity of many upper airway muscles can be discerned. The amplitude of these phasic changes can be altered by the same chemical stimuli (carbon dioxide and hypoxia) that affect diaphragm and intercostal muscle activity. Sleep may depress the sensitivity of upper airway muscles to chemical stimulation even more than the diaphragm.

The cardinal feature of sleep apnea syndrome in adults is the presence of recurrent apneas during sleep. Apneas may be central, obstructive, or mixed but are repetitively present. Theoretically, the causes of an apneic event include reduced excitatory stimulation, active suppression of breathing from inhibitory reflexes arising from the cardiovascular system, the lungs, and the chest wall or via other somatic and visceral afferents; and loss of reflexes that normally ensure the maintenance of ventilation and do not depend on chemical drive.

Two other explanations for repetitive apneas during sleep are (1) that sleep apnea patients have more pronounced ventilatory oscillations during wakefulness and sleep, and (2) that these oscillations have the same amplitude as in normal individuals, but nonspecific excitatory stimuli contribute to a larger extent to sleep apnea patients' total respiratory drive. Apnea occurs rather than just swings in ventilation during sleep because sleep, in addition to reducing the respiratory stimulatory effects of hypoxia and hypercapnia, also depresses metabolic rate and the overall level of respiratory excitatory input.

An alternative idea is that recurrent apneas result from instability in the feedback control of breathing, which causes ventilation to cycle rather than maintain a constant level. Instability of feedback control or a spontaneous oscillatory phenomenon could cause central, obstructive, or mixed apneas if, in response to the cyclic changes in drive, the mechanical outputs of chest-wall muscles and upper airway muscles are not identical either in phase or in amplitude.

MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

Significant changes occur in chest-wall and lung mechanics during sleep and can affect ventilation and later the efficiency of gas exchange, and upper airway resistance increases during sleep. For instance, in NREM sleep the ratio of rib cage to abdominal displacement is greater than during wakefulness, whereas in REM sleep it is less. These changes in movement may affect the distribution of ventilation in the lungs, increasing ventilation–perfusion mismatching, and so contribute to

hypoxia, necessitating changes in respiratory output and possibly initiating an unstable breathing pattern.

Negative pressures produced by the chest-wall muscles during inspiration tend to collapse the semirigid structure of the tissues forming the neck and pharynx. The degree of upper airway rigidity can depend on the long structures supporting the airway, on the soft tissue features of the upper airway, and on the level of activity in upper airway muscles. Studies suggest that the mechanical features of small airstream size and collapsible airway wall are essential in the pathogenesis of obstructive apneas. Furthermore, the spectrum of disease could relate to graded differences in these mechanical properties.

OBESITY

Several factors could predispose the obese patient to apneas during sleep. Hypoxemia occurs in the supine posture as a result of decreased functional residual capacity. Patients with obesity can show a decreased ability to respond with increased respiratory muscle output to added loading of the respiratory system. Another factor could be narrowing of the upper airway. Yet the fact remains that many obese people do not have sleep apnea or a history of snoring; neither can it be shown that sleep apneas cause obesity. Thus, the association between obesity and sleep apnea is quite indirect.

HEREDITY

Sleep apnea syndrome has been shown to exhibit familial clustering, and if snoring is considered as a variant of sleep apnea, the familial incidence of snoring and sleep apnea is quite striking. There is some evidence from cephalometric measurements that the arrangement of the jaw to the head and neck is familially determined. Conceivably, individuals with a certain structural framework would be predisposed to apneas. It is also known that there are familial traits in hypercapnic and hypoxic sensitivity; these could relate to the tendency to breathe periodically during sleep. It is not known if there is a familial trait involving the respiratory coordination of muscles of the chest wall and upper airway. In addition, obesity and alcoholism can be family traits and, to the extent that these factors are causally related to apneas, are bases for familial clustering of sleep apnea. However, this association is not strong enough for routine assessment of asymptomatic family members.

RESPIRATORY DEPRESSANTS: EXOGENOUS OR ENDOGENOUS

Patients with unrecognized sleep apnea may already be given hypnotic medications on the basis of their sleep complaint. However, studies using flurazepam on breathing during sleep have produced conflicting results on whether or not these agents produce apneas in healthy subjects. No study has shown that these drugs produce a syndrome of sleep apnea with associated daytime symptoms, yet it is best to avoid prescribing these medications to patients with sleep apnea.

On the other hand, in physiologic studies, alcohol has consistently been shown to promote apnea and, in particular, obstructive apneas during sleep in asymptomatic subjects and in patients. In one study it was shown that the number of episodes of respiratory disturbance during sleep doubled and that the effect of alcohol ingestion may even persist to the subsequent night's sleep. The mechanism by which alcohol promotes apneas may be through a relatively selective reduction in the respiratory output to the genioglossus muscle. What role alcohol has in the development of sleep apnea syndrome is unclear, but patients can benefit from abstinence from alcohol as a therapeutic intervention.

Do endogenous substances produce this syndrome? Naloxone has been given to patients with sleep apnea on the basis of speculation that opiate-like substances produce the problem, yet opiate receptor blockade does not affect apneas during sleep. There are sleep-promoting substances, but their role in sleep apnea has not been defined.

TREATMENT OF SLEEP APNEA: GENERAL MEASURES

Therapy is directed at sleep fragmentation and hypoxic exposure. Simple measures may be efficacious in many patients with sleep apnea. Initially, there should be a review of the patient for the presence of anatomic or medical conditions that, if reversed, would ameliorate or eliminate breathing disturbances during sleep. Because respiratory depressants seem to increase the appearance of respiratory disturbances during sleep, perhaps by elevating the P_{CO_2} threshold, withdrawal of respiratory depressants such as major tranquilizers, antihistamine, or alcohol is indicated. There are prophylactic measures on which to advise the patient. Preoperative sedation has been reported to be accompanied by some risk of lethal respiratory disturbances, so the patient should be advised to inform the anesthesiologist of his or her diagnosis before any elective surgical procedure. In addition, the excessively sleepy patient should not operate a motor vehicle or engage in activities during which sleep attacks would be hazardous. The risk of serious injury or death from accidents is possibly greater than that of the disease itself.

Metabolic diseases such as hypothyroidism may be associated with sleep apnea syndrome. Treatment with replacement hormones reverses the sleep apnea and clinical symptoms. Patients with sleep apnea and heart or respiratory disease, such as congestive heart failure or asthma, should be placed on maximal therapy for the concomitant disease. Of interest, treatment of hypertension will decrease apneic activity somewhat. Decreased circulation time and/or increased oxygenation may reduce the tendency for periodic behavior during sleep and decrease the incidence or severity of respiratory disturbances during sleep. Consequently, therapy is indicated for renal failure or congestive heart failure. In the patient with recent stroke or cerebrovascular disease, time may be all that is needed before respiratory stability will be restored. Treatment should be tailored to the individual patient and to the degree to which he or she is disabled by the breathing disturbances during sleep.

SURGICAL PROCEDURES

Tracheostomy

Tracheostomy bypasses the site of obstruction during sleep and is the most effective therapeutic maneuver for obstructive apnea. The procedure of choice is a semipermanent tracheal stoma, using skin flaps leading down to the edges of the tracheal fenestration. However, the tracheostomy may be technically difficult because of morphologic features such as obesity, a short neck, or a short mandible. Problems with stomal infection and granulation tissue often occur, and it may take a year or more before the tracheal site is well healed.

Tracheostomy is often not well tolerated because it can interfere with speech, exercise, and social interactions. Chronic cough, irritation from cold dry air, and positional pain or dyspnea are also common complaints. In some patients, revision of the tracheal stoma or custom-fit tracheostomy tubes are needed. Considerable education and counseling are advised both before and after the operation.

Plastic Procedures

Surgical correction of pathologic narrowing of the upper airway caused by enlarged tonsils, nasal polyps, macroglossia, or micrognathia is reported to improve signs and symptoms of sleep apnea. In prospective studies in which tonsillectomy has been performed for sleep apnea, it has been shown that obstructive apneas may persist, but their frequency is greatly diminished.

There are case reports to suggest that surgical intervention for a deviated nasal septum or for redundant nasal mucosa will reduce the symptoms and signs of sleep apnea. The rationale for these procedures lies in the association between increased nasal resistance and inspiratory pharyngeal occlusion. It should be noted that surgical manipulation of the posterior nasal cavity at the level of the velopharyngeal sphincter may in fact result in airway narrowing and precipitate the development of sleep apnea.

Extensive excision of soft tissue in the oropharynx, termed uvulopalatopharyngoplasty, may improve pharyngeal function during sleep. The procedure involves a submucosal resection of redundant tissue from the tonsillar pillars to the arytenoepiglottic folds. The indications for the procedure are the same as for a tracheostomy. In the series of patients reported in the literature, the success rate was approximately 60%, but success varied considerably from center to center. Most patients report symptomatic improvement; however, objective improvement of a reduction in the number or magnitude of respiratory disturbances during sleep is often absent. Patients with massive obesity or with anatomic narrowing of the airway may not show success with uvulopalatopharyngoplasty, whereas patients who snore but do not have frank obstructive apneas may do well. Potential complications of the procedure include speech and swallowing difficulties, in particular regurgitation of food. Some patients may have an increased number of respiratory disturbances during sleep after the procedure, but their recognition is obscured because snoring is absent. These “silent obstructions” may be as severe as apneas before surgical intervention.

Recently, new surgical procedures directed at increasing the size of the hypopharynx have been developed. Expansion hyoidplasty is a procedure directed at moving the hyoid arch forward by placing a prosthetic device in the hyoid arch. Other procedures include mandibular advancement, mandibular osteotomy, sectioning the hyoid, attaching the hyoid to thyroid cartilage, and midline glossectomy. With all these procedures, success in large series of patients remains to be determined.

MEDICAL TREATMENT

Nasal Sprays

There are case reports of successful treatment of obstructive apneas during sleep using nasal vasoconstrictive sprays. Apneas and arousals during sleep are more frequent when the nasal passage is occluded than when it is unoccluded. It is probable that an increase in baseline nasal resistance increases negative pharyngeal pressure on inspiration, thus magnifying the collapsing forces on oropharyngeal soft-tissue structures and promoting pharyngeal obstruction. Consequently, a trial of nasal (vasoconstrictive and antiinflammatory) decongestants is warranted in the patient in whom nasal obstruction is present.

Weight Loss

Even a 5% to 10% decrease in body weight can be accompanied by clinical and objective remission of sleep apnea syndrome in obese subjects. Few investigators, however, are enthusiastic about the long-term efficacy of dietary strategies, perhaps because adherence to dietary restrictions is difficult in the hypersomnolent patient.

Studies have documented that major surgical intervention (ileal bypass or gastric partitioning) for weight loss in obesity can reduce the number and severity of apneas and alleviate signs and symptoms of sleep apnea syndrome. It is interesting that with surgical treatment, large amounts of weight loss, on the order of 150 to 200 lb, was needed before a beneficial effect of weight loss can be demonstrated. Better treatments for obesity would have an immediate and major impact on the management and prevention of sleep apnea.

Oxygen Therapy

Studies of oxygen therapy in sleep apnea show inconsistent results. Certainly, in the patient with resting hypoxemia and cor pulmonale, 24-hr oxygen therapy can improve symptoms and cardiovascular performance, alleviating heart failure. Oxygen therapy appears to be effective in reducing or eliminating central apneas and hypopneic events. This relatively selective effect on central apneas occurs with oxygen therapy in patients who also have obstructive apneas. However, a beneficial effect of oxygen on upper airway obstruction during sleep cannot be found in every patient. Indeed, in some patients with obstructive sleep apnea syndrome, oxygen administration provokes respiratory acidosis. At the present time, one cannot predict which patient will respond to oxygen therapy.

Drug Therapy

General

Various drugs have been used in an attempt to specifically stimulate upper airway muscles in order to prevent obstructive apneas or to increase respiratory neural drive in general in order to alleviate central apneas or increase both upper airway and chest-wall muscle activation. Although this kind of therapy would seem optimal, it has had the least success and surprisingly has generated little interest in organized research. The efficacy of most proposed medical therapies has not been demonstrated. However, certain classes of medications have been used with some success.

Respiratory Stimulants

Good results have been reported in clinical demonstrations with acetazolamide and progesterone in patients with central apneas during sleep. Studies have shown that respiratory rhythmogenesis may be restored to some degree, thereby eliminating a need for other therapeutic measures. Patients who present with primarily central apneas during sleep are, however, in the minority of adult patients with sleep apnea syndromes. As a consequence, few large series have employed adequate clinical drug trials.

Agents with a progesterone-like activity have been tried in obstructive sleep apnea because of their apparent effectiveness in improving daytime sleepiness, cor pulmonale, and polycythemia in patients presenting with obesity, hypoventilation syndromes, and chronic mountain sickness. It is still unclear how progesterone specifically stimulates breathing. The two clinical demonstrations of progesterone usefulness in sleep apnea have suggested that if patients are considered as a group, progesterone has little effect on obstructive sleep apnea. Yet each study has shown that certain patients may respond with a reduction in obstructive apneas and an amelioration of symptoms. This subclass of patients appears to be those who present with hypercapnic respiratory failure. Both studies, however, lacked adequate control trials and were not intended to be adequate clinical trials of efficacy.

There are reports of the use of nicotine, acting both as a central and as a peripheral respiratory stimulant, in the management of obstructive apneas during sleep. Although effective, nicotine has a very short half-life, and it is probably not a clinically practical drug. Drugs directed solely at stimulation of the carotid body have met with only partial success. These drugs include the dopamine-blocking agent prochlorperazine and the orally administered almitrine. A third medication, strychnine, a glycine antagonist, reduces the threshold for activation of the motor neuron and has been tried in selected patients with obstructive sleep apnea. This report suggested that the beneficial effects of strychnine were produced by elevating tonic activity in upper airway muscles rather than by altering their respiratory-related activation. In summary, respiratory stimulants appear to be more efficacious in patients with primarily central apneas, and use in patients with obstructive sleep apnea may be restricted to those with hypercapnic respiratory failure. A most likely candidate for a trial of progesterone, for instance, would be a patient who presents with obesity hypoventilation syndrome, in whom the drug might be given solely on the basis of daytime signs of polycythemia and cardiopulmonary failure.

Antidepressants

The tricyclic medications protriptyline and clomipramine have been used in the therapy of obstructive sleep apnea. The rationale for their use is that they suppress REM sleep, a sleep stage in which apneas occur frequently and the stage of sleep in which there is often intermittent inhibition of chronic activity in postural muscles, including those of the upper airway. Several uncontrolled trials with protriptyline have suggested that it may have some use in diminishing the number of apneas or in improving oxygenation. The one double-blind trial in the literature found that both 2-week and 6-month administrations were associated with a mild reduction in daytime sleepiness and an unexplained increase in oxygenation associated with a diminished time in REM sleep. Side effects of the drug include drying of the mouth, urine retention, and increased cardiac arrhythmias, including ventricular arrhythmias, and these may limit its use.

More recently, more specific agents, such as the serotonin receptor antagonist fluoxetine, have been shown to reduce apneic activity. The precise role of these agents in the management of sleep apnea remains to be determined.

Hypnotic Drugs

Although it may seem odd to suggest that sleep-apneic patients be given a drug that promotes sleep, the argument could be made that these agents might increase the tendency for sleep and could, at least theoretically, reduce arousals and sleep fragmentation. It is known that apneas infrequently occur at deep stages of sleep (stages III to IV) and that in healthy subjects apneas appear only in early sleep stages I or II or in the transition between light and deep sleep. There is one report that found that the sleep-promoting substance L-tryptophan can decrease the number of obstructive, but not central, apneas during sleep. A mechanism of action of this drug was presumed to depend on central neural serotonergic transmitters and was related to its ability to promote sleep. There are no large clinical trials of this medication.

Other Agents

A variety of other agents have been tried without success. Bromocriptine, theophylline, and naloxone are three that have been tried in a small number of patients with sleep apnea and have not shown immediate success; therefore, they cannot be recommended even for clinical trials.

The enthusiasm for medical therapy is thus quite moderate at this particular time. It is hoped that with greater understanding of the neurophysiological basis of respiration in sleep, newer pharmacologic agents can be developed. It should be noted that perhaps one of the reasons for the mixed success of respiratory stimulant drugs in the treatment of apneas in general could be their relative unselectiveness in stimulating muscles. For instance, an increase in chest-wall muscle activity without a corresponding increase in upper airway muscle activity might actually worsen obstructive apneas. Indeed, in some of the clinical trials with progesterone, this actually may have occurred.

MECHANICAL DEVICES

Neural Stimulation

Electric pacing of the phrenic nerve can achieve adequate ventilation in the absence of spontaneous respiration in the patients with cervical injuries. Phrenic nerve pacing at the level of the thoracic inlet also has been successfully attempted in treating patients with only central sleep apnea. Yet stimulation of the diaphragm without upper airway muscle activation may lead to inward collapse of the upper airway and chest wall, producing upper airway obstruction and hypoventilation. Hence, a tracheostomy is necessary when the phrenic nerves are paced. Problems inherent with phrenic pacing result from the direct damage to the phrenic nerve occurring with operative handling or with postoperative infection or inflammation around the electrode. Experience and careful surgical technique will minimize these complications. Pacing with electrodes placed directly in the muscle may achieve equal or greater respiratory output in the diaphragm than phrenic pacing.

Ventilatory support also can be achieved by placing the patient with central apneas on mechanical ventilation during sleep. A ventilator attached to a tracheostomy is tolerated well by both children and adults. Other measures such as rocking beds, the iron lung, or a cuirass can effectively accomplish adequate gas exchange in patients with central apneas. However, the creation of negative pressures in the chest by an iron lung or cuirass may cause upper airway obstruction by a mechanism identical to that occurring with phrenic nerve pacing. Pacing can be applied to treat obstructive apneas. Initial reports suggested that transdermal pacing of the protrusor muscles of the tongue could shorten obstructive apneas. Devices were constructed that identified an apnea from the absence of oronasal flow and delivered electric stimulation to electrodes placed under the chin. A second generation of electric stimulators is being developed, one of which uses an implanted electrode on the hypoglossal nerve. It will be some time before a role for these devices in the routine care of patients is established.

Dental Devices

Intraoral appliances are gaining wider acceptance in the treatment of obstructive apneas. Some devices are designed to tug the tongue forward; others to protrude the mandible or, at the very least, prevent the mandible from retruding with sleep. There are anecdotal reports and reports of collections of patients that attest to the potential usefulness of oral appliances. At the present time there is an ongoing randomized trial comparing an oral device to nasal CPAP (see below) in the treatment of mild to moderate obstructive sleep apnea.

Experience with this therapy is limited; however, common sense suggests that it may be an attractive alternative if CPAP is not tolerated. Certainly, there must be close cooperation between dental and medical professionals when this therapy is chosen; however, indications and cost-effectiveness are not developed at present to the degree that this form of treatment can be considered routine medical practice.

Nasal CPAP

Continuous positive pressure applied to the nose (nasal CPAP) may eliminate obstructive apneas during sleep in adult patients with sleep apnea syndrome. Nasal CPAP seems to act as a pneumatic splint, preventing airway collapse.

Nasal CPAP is effective in the long-term treatment of obstructive sleep apnea and in the prevention of snoring. The effect is dependent on the level of positive pressure applied to the upper airway, and the optimal levels of pressure differ among patients. In general, though, at lower levels of pressure (3 to 6 cm H_2O), apneas are eliminated, but episodes of partial upper airway obstruction (snoring) persist. At higher levels of pressure (5 to 15 cm H_2O), regular breathing tends to be restored. An example of the effect of nasal CPAP in eliminating apneas is shown in Fig. 6. The effect of different levels of nasal CPAP on oxygenation over time is shown in Fig. 7. Most reports suggest that positive pressures must be present over the entire respiratory cycle for nasal CPAP to be effective.

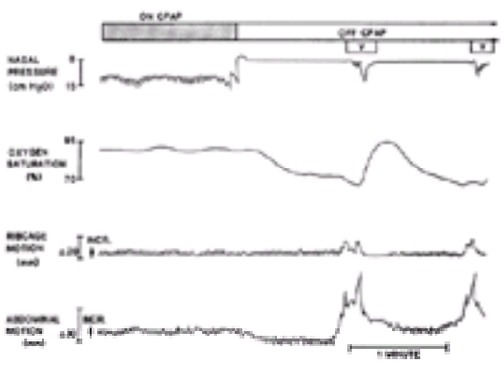

FIG. 6. The effects of approximately 14 cm H_2O positive pressure applied to the nose (nasal CPAP) on oxygen saturation and rib cage and abdominal motion during sleep. On CPAP, oxygen saturation was stable and approximately 90 percent. Respiratory efforts by the rib cage and abdomen were regular. When CPAP was abruptly discontinued, episodic upper airway obstruction interrupted by periods of ventilation (V) occurred, accompanied by hypoxemia. The patient is in REM sleep.

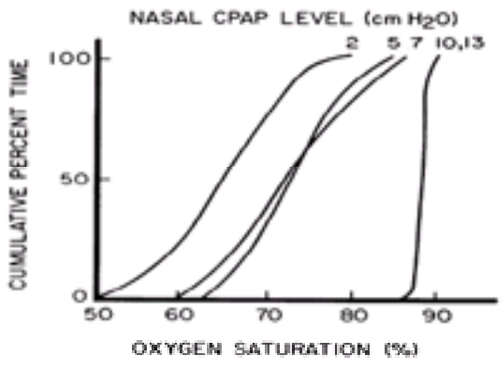

FIG. 7. The changes in oxygen saturation over time in one patient in different levels of nasal CPAP during a single study. Levels of 2 and 5 or 7 cm H_2O were accompanied by repetitive obstructive apneas and partial upper airway obstruction, respectively. At 10 or 13 cm H_2O, apneas and upper airway obstruction were eliminated.

Some patients can use their device every second or third night and remain free of apnea on the intervening nights. Symptoms always recur if CPAP is completely withdrawn, but this may take several days and occurs gradually, so that short interruptions of therapy for surgery or acute medical illnesses are usually well tolerated. Late failures of nasal CPAP occur occasionally. Some are caused by poor application of the mask, so that pressure is lost; some result from too low a pressure being initially prescribed; and some are caused by an increase in the pressure required to prevent apnea. Factors such as alcohol use, hypothyroidism, and obesity may worsen airway stability.

Bilevel ventilation for obstructive apneas is the application of an inspiratory assist over and above the expiratory pressure required to keep the pharyngeal airway open. The medical indications for this approach appear to include the concomitant finding of chronic hypoventilation in addition to obstructive apnea. Titration and chronic use of bilevel ventilation are facilitated by the common patient perception that the inspiratory assist is more comfortable, perhaps because with bilevel pressure, pressures in expiration are generally lower than those with CPAP. There are no direct comparisons of these interventions despite reports that application of CPAP alone over time improves alveolar ventilation. Clinical trials will be needed to determine the balance between patient comfort and medical necessity.

Absolute contraindications to nasal CPAP therapy are complete nasal obstruction and a communicating fracture of the base of the skull. Patients generally accept CPAP therapy fairly well, but in most large series there are some patients (30% or so) who do not. Side effects of therapy include feelings of suffocation, nasal drying or rhinitis, ear pain, and conjunctivitis. Inner ear and eye problems are said to resolve spontaneously and do not recur with continued CPAP therapy. Pulmonary

function does not deteriorate with nasal CPAP, and in patients with lung disease there have been no adverse effects.

PSYCHOSOCIAL FACTORS IN TREATMENT

Sleep apnea has a profound effect on the personal and family life of the patient because excessive sleepiness compromises the patient's ability to solve problems at work or at home or to perform even simple tasks. Family members may suffer injury from automobile accidents caused by the patient falling asleep at the wheel. In some instances, chronic delinquency may result from absent parental authority. Patients who are excessively sleepy limit social activities out of embarrassment. These and other family conflicts may result in personal and financial losses before a diagnosis is sought or made.

Treatment of the respiratory disturbance during sleep also entails psychological and social adjustments. Tracheostomy may change a patient's body image. Fears of inviting social ridicule or limitations in sexual activity are frequently present in patients facing the possibility of a tracheostomy. If the patient and family feel reasonably informed of therapeutic alternatives, they will be better able to cope with a tracheostomy. Supervised meetings of the patient and family with other patients and their families who have faced the same problem may be of help in this process.

Also, after effective treatment, changes in family dynamics may occur as the patient becomes a more active person. The health team can be helpful in assessing how both the patient and the family are adapting to treatment. Furthermore, employer education is often necessary before the patient can return fully to work.

NEED FOR RESEARCH

Sleep apnea is no longer a rare disease, and those with sleep apnea have a chronic illness, much like asthma or diabetes. The incidence of those meeting minimal criteria for clinical illness is 2% to 5%; yet many, perhaps one in 20, are unrecognized. Several efforts are under way to determine whether the lack of recognition results from ignorance of the medical profession or lack of impact of sleep apnea on human health, or both. Research defining the relationship of sleep apnea to cardiovascular risk is perhaps a high priority. One problem is that studies of sleep apnea have been either clinic-based or cross-sectional, and little information is available regarding the natural history of sleep apnea or symptoms attributable to sleep apnea. This information is crucial in areas of both treatment and prevention. Compared to information on the adult male, little is known of the prevalence in women or children.

Formal approaches to decision making in the management of sleep apnea are needed. Professional societies are beginning to see the need for standardized assessment; such criteria would provide a uniform method for recruitment of patients into clinical trials. There are few studies of the impact of sleep apnea from a patient's point of view. Indeed, for some patients with mild to moderate illness, the problems of current therapy are not worth the perceived benefit; recognizing this may prevent unwanted and perhaps unnecessary therapeutic adventures. Furthermore, there has been little formal assessment of ways to improve treatment acceptance and in the manner in which the patient and his or her physician decide on what treatment to use. Finally, primary care physicians will need to be involved in the design of recognition and treatment strategies.

Another new consideration is how sleep apnea might affect utilization of health care resources and costs to society. The Report of the National Commission on Sleep Disorders estimated that between 7 and 18 million people in the United States may meet minimal criteria for OSA, using a definition of an AHI > 5; 1.8 to 4 million people have higher levels (AHI > 15). Cost estimates related to diagnosis and treatment in 1991 are between $3 million (for the most severely affected) and $40 billion (for subjects with only heavy snoring and low levels of apnea), so there is an immediate need to establish thresholds for treatment. If current cardiovascular risks for OSA are correct, untreated OSA may contribute to 38,000 excess deaths per annum, and that $3 million to $2 billion of the health care costs associated with the treatment of vascular diseases may be attributable to untreated illness.

Behavioral and performance deficits associated with OSA could carry hidden costs from morbidity and mortality for motor vehicle crashes and industrial accidents; reports utilizing a variety of indirect sources and assumptions estimated an indirect cost in the billions of dollars. Obstructive sleep apnea is the most common medical cause for sleepiness, suggesting that it may play a significant role in these accidents of sleepiness or inattention. There must be increased educational efforts about the importance of adequate sleep and the perils of sleepiness to permit greater recognition of disorders of sleep by the medical community.

VARIANT PRESENTATIONS OF SLEEP-DISORDERED BREATHING/UPPER AIRWAY DISEASE

Patients with disease of the nose, larynx, and pharynx present with two major classes of sleep problems, sleep apnea and aspiration. Aspiration of secretions may occur because of excessive production of mucus, as exemplified by chronic allergic rhinitis, or because of inadequate neuromuscular tone, as in bilateral recurrent laryngeal nerve paralysis. In both instances, there occur frequent arousals from sleep associated with cough and/or a choking sensation. In sleep, and, in particular, in REM sleep, the cough response is less than during wakefulness. As a result, greater amounts of secretions are tolerated before a cough ensues. After awakening, this larger amount of material may precipitate paroxysmal cough. It is important to recognize that in these cases the disturbed sleep and what might sound like apnea result from problems with secretions or aspiration. Treatment with hypnotic medications may be particularly harmful because greater amounts of secretions may be tolerated before arousal from sleep, increasing the likelihood of aspiration injury to the lungs. In the patient with allergic rhinitis, nasal decongestants given before bedtime may be helpful. In the patient with neuromuscular impairment, elevation of the bed may diminish the tendency to aspirate pharyngeal contents.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients with chronic obstructive pulmonary disease (COPD) may present with a variety of sleep problems. Nocturnal cough can be related to bronchitis. Insomnia may be the consequence of therapy with drugs such as aminophylline. Hypoxemia during sleep may occur as a consequence of mechanical impairment of the airways already present during wakefulness but exacerbated by the normal changes in gas exchange during sleep. There seems to be an association between the occurrence of hypoxemia only during sleep and the development of cor pulmonale in the patient with moderately severe COPD. Recognition of these individuals occurs when it is noticed that features of hypoxemia and hypercapnia are not associated with a severe mechanical defect on pulmonary function testing. Certainly other diagnostic entities such as recurrent pulmonary emboli or chest-wall muscle weakness also should be explored. Hypoventilation will occur during sleep not only because of sleep apnea but also because of changes in ventilation–perfusion matching and a decrease in respiratory drive, especially during REM sleep. If the problem is sleep apnea, there is usually historical evidence for snoring and restless sleep, and the patient should be treated appropriately (see above). If apneas are not the problem, treatment with supplemental oxygen only during sleep may be indicated.

ASTHMA

The most common sleep problem associated with asthma is cough. Cough and arousals from sleep with cough may be the presenting complaints of the patient with asthma and increased airway reactivity. Cough may result from changes in airway smooth-muscle tone during sleep and of bronchoconstriction during REM sleep. There is some indication that gastroesophageal reflux may precipitate bronchoconstriction; however, patients with reflux are usually symptomatic during wakefulness as well as sleep. Cough occurring in the patient with uncomplicated asthma may indicate inadequate therapeutic effect of medication throughout the night or exacerbation of airway disease.

A related clinical problem is that of “morning dipping,” which refers to the fall in lung function that occurs in the early morning hours. Morning dipping has been reported in severe asthmatic attacks and has been held somewhat responsible for deaths from asthma. Morning dipping represents an extreme form of diurnal variation in lung function present in most patients with airway reactivity. Reports describing morning dipping emphasize that lung function measured some hours later during the day may be normal, whereas values during the night may show moderately severe airway obstruction. Symptoms suggestive of morning dipping are an indication that additional treatment is needed. If nocturnal symptoms are persistently bothersome, instruction of the patient in the use of a peak-flow measurement device and in the frequent recording of values of peak flow at night may be helpful in identifying changes in lung function throughout the day and in monitoring the effectiveness of medications over the course of a night's sleep.

NEUROMUSCULAR DISORDERS

Respiratory disturbances caused by obstructive apneas during sleep may occur because upper airway muscles such as the genioglossus are affected by the underlying disease process. Inadequate respiratory activation of upper airway muscles makes the upper airway vulnerable to collapse during inspiratory efforts by the muscles of the chest wall. Indeed, respiratory failure in the patient with neuromuscular disease may be related to upper airway muscle disease and not have as dire prognostic consequences as primary involvement of the chest-wall muscles such as the diaphragm.

Disturbances of sleep and respiration during sleep may be the first indication of involvement of the respiratory system in the patient with neuromuscular disease. Occasionally, sleep fragmentation and the effects of sleep deprivation dominate the clinical presentation of the patient with neuromuscular disease. After treatment for sleep-disordered breathing, the clinical manifestations of the primary neuromuscular disorder may not appear so severe.

KYPHOSCOLIOSIS

Severe kyphoscoliosis is associated with restrictive lung disease and cor pulmonale; however, recently it has been shown that treatment of hypercapnic respiratory failure by tracheostomy with or without positive-pressure ventilator support during sleep can reverse cor pulmonale and improve the appearance of the chest roentgenogram.

INTERSTITIAL DISEASES

Restrictive lung disease also can be associated with respiratory disturbances during sleep because of cough or hypoxemia. Patients also may have a concomitant sleep apnea. Sleep hypoxemia may be a factor in the development of pulmonary hypertension. Treatment of sleep hypoxemia is directed at apneas, or if apneas are not present, a trial of oxygen therapy may be indicated.

A restrictive defect on pulmonary function testing and interstitial fibrosis on the chest roentgenogram can reflect a history of chronic aspiration. There are ongoing investigations on aspiration during sleep and its acute and chronic effect on lung function. During sleep, the tone of the gastroesophageal junction relaxes, allowing stomach contents to regurgitate to the level of the pharynx. In patients in whom such a phenomenon is suspected, it may be useful to measure pH levels in the pharynx and esophagus during sleep in order to document gastroesophageal reflux during sleep as a potential cause for aspiration pneumonitis.

CHAPTER

45 Adaptation and Maladaptation to High Altitude

Robert B. Schoene

R.B. Schoene: Department of Medicine, Division of Respiratory Diseases, University of Washington Harborview Medical Center, Seattle, Washington 98104.

INTRODUCTION

Oxygen delivery to the tissues depends on an adequate supply of oxygen at each step of the oxygen transport chain from the inspired air to the mitochondria. The inspired partial pressure of oxygen is approximately 21% of the atmospheric pressure, which decreases predictably at altitudes above sea level (Table 1). Humans at high altitude, therefore, must overcome the disadvantage of ambient hypoxia by making a number of adaptations to optimize the availability of oxygen to the tissues.

Altitude		Barometric pressure (mm Hg)	Inspired P_{O_2} (mm Hg)
Meters	Feet		
0	0	760.0	159.1
1000	3,280	674.4	141.2
2000	6,560	596.3	124.9
3000	9,840	525.8	110.1
4000	13,120	462.8	96.9
5000	16,400	405.0	84.8
6000	19,680	354.0	79.1
8000	26,240	267.8	56.1
8848	29,028	253.0	43.1

[a] Values except 8848 are taken for midlatitude (45°N). There is greater variation at higher latitudes. Modified from Altman PL, Dittmer DS, eds., *Respiration and Circulation*. Bethesda, MD: Federation of American Societies for Experimental Biology, 1971; 12–13.

TABLE 1. *U.S. standard atmosphere: Altitude, barometric pressure, and inspired partialpressure of oxygen*[a]

For the sojourner, easy access to high altitude for work or recreation requires that the body must undergo rapid changes to overcome the disadvantage of hypoxia; for the nearly 30 million people who live at a high altitude in Asia, Africa, and North and South America, their bodies have had generations to adapt to the hypoxic stress. A large majority of travelers and high-altitude dwellers are successful in overcoming this stress, but some do not adapt well and suffer from acute and chronic altitude illness. This chapter, therefore, first reviews what is known about both acute and chronic adaptation to high altitude and then reviews the illnesses that occur when the body maladapts.

ADAPTATION

Abrupt exposure to high altitude (more than 3000 m) can result in illness and even death. This lesson was tragically learned in 1875 when two of three scientists died while exploring altitudes of over 8000 m in their hot-air balloon, the Zenith. Gradual ascent to these same heights, on the other hand, permits a number of physiological adaptations to take place that allow some exceptional humans to function quite well. Populations have lived for centuries as high as 5000 m, and brief forays above 8000 m, where the atmospheric pressure is a third that at sea level, are well documented and are a tribute to the resiliency of human physiology.

In order to optimize oxygen delivery, important compensations take place at each step of the oxygen cascade, which has a number of components: ventilation, matching of ventilation with blood flow, diffusion of oxygen from the air to the blood, circulation of the blood, diffusion of oxygen from the red blood cell to the tissue, and oxidative metabolism in the cell. The first portion of this chapter reviews each of these steps, beginning with the lung.

Pulmonary Adaptation

Ventilation

Acute Ventilatory Response

An increase in alveolar ventilation occurs immediately on ascent to a high altitude. The partial pressures of oxygen and carbon dioxide in the alveolus reflect the degree of hyperventilation that attempts to preserve oxygen partial pressure. For instance, at an extreme altitude (summit of Mt. Everest, 8848 m, 253 mmHg), alveolar ventilation in a climber increases to maintain an alveolar partial pressure of oxygen of about 32 mmHg and of carbon dioxide of about 8 to 10 mmHg. Lower altitudes have a proportionately lower degree of ventilation.

The increase in ventilation is a result of a complex interaction of physiological events, mediated largely by the hypoxic stimulus to the carotid body. The course of the ventilatory response is what constitutes ventilatory acclimatization. There is individual variation in this response, but essentially the pattern of any given level of high altitude is one of an abrupt increase in ventilation followed by a more gradual increase over the next 10 to 14 days to a plateau (Fig. 1). The carotid body plays a primary role in this acute ventilatory response, which may be blunted in part by the resulting alkalosis. The classic explanation for the subsequent ventilatory events goes as follows: Excretion of bicarbonate by the kidneys over days in compensation for the respiratory alkalosis partially restores the acid–base status, resulting in further respiratory stimulation.

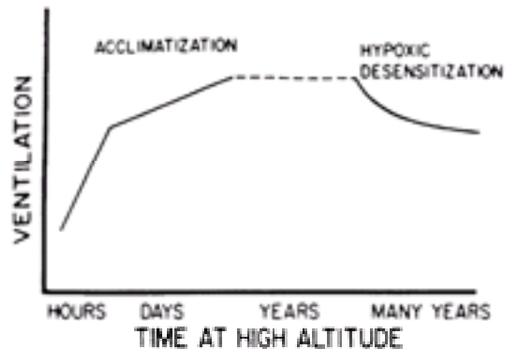

FIG. 1. The time course of ventilatory adaptation to high-altitude exposure. (From Weil JV. Ventilatory control at high altitude. In *Handbook of Physiology: The Respiratory System, Vol 2, Control of Breathing, Part 2.* Bethesda, MD: American Physiological Society, 1986.)

An arterial alkalemia is still present, however, and Severinghaus and colleagues presented data showing a cerebrospinal fluid (CSF) acidosis, which they claimed was the central stimulus for ventilation. Subsequent investigators at altitudes from 3000 to 4000 m documented that in humans and animals, both blood and CSF alkalosis developed in parallel during acclimatization. Additionally, a lower but persistent hyperventilation continued on descent. In light of the loss of hypoxic stimulus on descent and the blood and CSF alkalosis, a further explanation was sought.

The CSF may not reflect the actual milieu around the chemosensors. Data from brain interstitial and intercellular fluid in animals show an acidosis during hypoxic exposure, which may account for stimulation of ventilation. Recent data may shed light on the ongoing respiratory stimulation in the face of blood and CSF alkalosis. Ventilation is stimulated by hypoxia, leading to a degree of hypocapnia that is proportional to the magnitude of ventilation. Hypocapnia decreases cerebral blood flow, which, in addition to a leftward shift of the oxygen–hemoglobin dissociation curve by the respiratory alkalemia, may result in a decreased delivery of oxygen to the brain and subsequent anaerobic metabolism and tissue acidosis. A study in humans that used nuclear magnetic resonance (NMR) spectroscopy before and after a 7-day exposure to a simulated 4300-m altitude in a hypobaric chamber, however, failed to document brain tissue acidosis.

A further increase in ventilation is inhibited by a central suppression of ventilation. After 15 to 25 min of acute hypoxic exposure, ventilation decreases 25% to 30%, which is thought to be secondary to the action of neurotransmitters and a decrease in the metabolic rate in the brain, even though ventilation is elevated to a greater degree than the decrease in the metabolic rate alone would dictate. Acutely, however, true depression of ventilation with hypoxia does not occur when the partial pressure of arterial oxygen falls below 20 mmHg. A full understanding of the ventilatory adaptation to altitude is clearly lacking. A further stay at a high altitude for the sojourner results in an improvement in arterial oxygen saturation secondary to a gradual increase in ventilation over a fortnight or so. At extreme altitude, ventilatory adaptation may take weeks or months or may never be complete. The mechanism of this subsequent adaptation is not understood, but an increased sensitivity of the carotid body has been observed in humans and animals and must play an important role in the progressive hyperventilation. Carbon dioxide sensitivity, which is mediated primarily in the central chemosensors, has also been shown to increase with time at a high altitude and may, therefore, interact with input from the carotid body to effect an increase in ventilation.

On descent, even after the hypoxic stimulus has been removed, ventilation is greater for at least a couple of days than it was before the ascent. This phenomenon may be secondary to the rise in carbon dioxide that occurs as the hypoxic stimulus is removed.

Chronic Ventilatory Response

Alveolar ventilation and hypoxic chemosensitivity decrease in most lifelong residents of high-altitude regions (see Fig. 1). This decrease in hypoxic drive occurs in spite of a hypertrophy of the carotid bodies and is proportional to both the altitude and the duration of habitation. Because the mechanics of breathing entail a metabolic cost, it is conceivable that well-adapted high-altitude natives have invoked other mechanisms to improve oxygen transport to the mitochondrion while minimizing the metabolic cost with lower alveolar ventilation. The relative hypoventilation of the high-altitude native compared to sojourners may predispose some populations to chronic mountain sickness (CMS), which involves excessive hypoxemia and hypoventilation, pulmonary hypertension, polycythemia, and decreased cerebral function (see Chronic Mountain Sickness). Natives of the Tibetan and Nepalese Himalayas, in whom CMS is very rare, are reported to have less blunted alveolar ventilation and hypoxic chemosensitivity than other high-altitude dwellers, especially those in the Andes of South America, where CMS is much more common, but this issue is not fully resolved. This intriguing difference suggests an evolutionary influence wherein the Tibetans who have lived at a high altitude much longer than the South Americans have physiological characteristics that have led to more successful tolerance of high altitude. A genetic factor is also theoretically possible.

Functional and Structural Changes

Lung mechanics are affected at least transiently on ascent to a high altitude. Increased blood flow and central blood volume and a possible increase in interstitial fluid may lead to a decreased vital capacity, an increased residual volume, and decreased lung compliance. This explanation remains speculative. More recent observations in a high-altitude chamber during a 40-day simulated ascent of Mt. Everest showed that vital capacity began to decrease at 4572 m (P_B 429 torr) and was down 14% on the summit (P_B 250 torr). Increased lung water, which usually resolves on acclimatization, also has been noted. High-altitude dwellers in South America, on the other hand, have large chests on physical examination, accompanied by larger vital capacities, in comparison to low-altitude dwellers. These volumes remain increased in natives who descend to lower altitudes. The younger the age that the subjects begin living at a high altitude, the more pronounced is this characteristic. Similar augmentation of lung growth has been induced in rats exposed to hypobaric hypoxia.

Gas Exchange

The increased ventilation on ascent to a high altitude results in an increased alveolar partial pressure of oxygen, but the arterial oxygen content depends on the transfer of oxygen from the alveolus to the capillary and red blood cells. This step requires matching of ventilation ($\dot{V}_A$) to perfusion ($\dot{Q}$) and the diffusion of oxygen to hemoglobin in the red blood cell.

The increase in ventilation is matched in part by an increase in cardiac output and pulmonary blood flow. Alveolar hypoxia leads to pulmonary vasoconstriction, which at rest improves the $\dot{V}_A/\dot{Q}$ match primarily by increasing blood flow to the underperfused portions of the lung, which are usually areas of high $\dot{V}_A/\dot{Q}$. This redistribution of blood flow results in greater homogeneity of $\dot{V}_A/\dot{Q}$.

The next step in gas exchange relies on diffusion of oxygen to the blood. This transfer depends on a pressure gradient for oxygen from the alveolus to the capillary, diffusion capacity of the alveolar–capillary interface (D_M), capillary blood volume (V_C), and the surface area for gas exchange. A true diffusion limitation for oxygen transfer exists at high altitudes. This phenomenon occurs for several reasons. With increasing altitude, the lower alveolar partial pressure of oxygen results in a lower alveolar–capillary oxygen pressure gradient. Full equilibration of oxygen to the blood is also dependent on the transit time of the red blood cell across the pulmonary capillary, usually requiring at sea level about 0.25 sec, one-third of the estimated 0.75-sec normal transit time. At high altitude, this estimated resting pulmonary transit time may not allow enough time for full equilibration. This problem is accentuated during exercise, when an increased cardiac output shortens transit time. For example, the circumstances at the summit of Mt. Everest, where the barometric pressure is about 250 mmHg, are expressed by a model for this diffusion limitation with given values for hemoglobin concentration, oxygen face area consumption ($\dot{V}_{O_2}$), diffusion capacity (D_M), acid–base status, and capillary transit time as shown in Fig. 2.

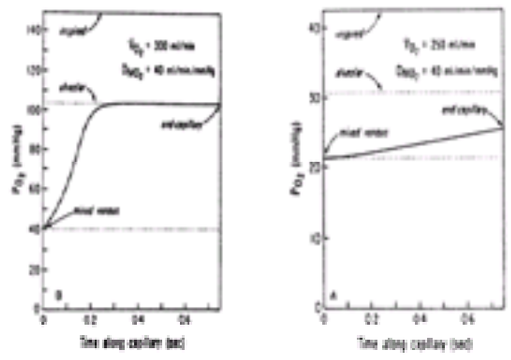

FIG. 2. Comparison of the calculated time course of partial pressure of oxygen in the pulmonary capillary of a climber at rest at sea level **(left)** (P_B = 760 mm Hg) and the summit of Mt. Everest **(right)** (P_B = 250 mm Hg). Adequate time for equilibration is available at sea level, whereas at 8848 m full equilibration is not possible. P_B, barometric pressure; $\dot{V}O_2$, oxygen consumption; D_MO_2, diffusion capacity of oxygen at the alveolar–capillary interface. (From West JB, Wagner PD. Predicted gas exchange on the summit of Mt. Everest. *Respir Physiol* 1980;42:1.)

An important factor in this process at extreme altitude may be relatively high oxygen–hemoglobin affinity secondary to respiratory alkalosis found in some high-altitude animals and in climbers at extreme altitudes. The diffusion capacity of the lung (D_L) may be more optimal in high-altitude natives secondary to either an increased capillary surface area (D_M) or pulmonary blood volume (V_C), which may compensate for the slightly lower level of ventilation at rest and during exercise.

Cardiovascular Adaptation

Cardiac Response

The cardiac response to high altitude also counteracts the stress of hypoxia and optimizes oxygen transport. To maintain a viable oxygen consumption in light of a decreased arterial oxygen content at a high altitude, heart rate increases, which results in a greater cardiac output. An accompanying elevation of catecholamines suggests that they mediate the increase in chronotropic effect on the heart. Subsequently, over the next few days, resting heart rate decreases as other compensatory mechanisms are invoked. Stroke volume decreases secondary to either a lower plasma volume or an increased pulmonary vascular resistance.

During exercise at high altitudes, the relationship between cardiac output and work is maintained, but both maximal work rates and cardiac output achieved at sea level are not reached at high altitudes. Both stroke volume and maximal heart rate are lower at high altitudes. There may be an impairment of stroke volume secondary to increased pulmonary vascular resistance, a decrease in left ventricular volumes secondary to right-to-left septal deviation from pulmonary hypertension, a decrease in myocardial contractility, or general constriction from the pericardium. The lower maximal heart rate is more marked in sojourners; may be secondary to hypervagal tone, hypoxic myocardial depression, or dysfunction of electrical conduction; and may be a major factor in the decrease in maximal exercise at high altitude. There are, however, few data in sojourners to support these possibilities, and it is now generally thought that the cardiac response is appropriate for the amount of work that is being done, which is limited by other factors. Studies in a few high-altitude natives suggest that they may not have a limitation to maximal heart rate at high levels of exercise, but further work is needed to elucidate this question.

Acute exposure to high altitudes results in an increase in systemic blood pressure and systemic vascular resistance both at rest and during exercise, whereas the dweller at a high altitude may actually develop a lower systemic blood pressure, perhaps secondary to microcirculatory vasodilation.

Pulmonary Vascular Response

Pulmonary artery pressure and pulmonary vascular resistance increase acutely at high altitudes, and this is secondary to the hypoxic pulmonary vascular response (HPVR). This initially results in improved $\dot{V}_A/\dot{Q}$ matching but may progress to $\dot{V}_A/\dot{Q}$ heterogeneity and possible interstitial edema.

The HPVR does not become marked until an alveolar partial pressure of oxygen (PO_2) of 60 mmHg or less is reached, and as with the ventilatory response to hypoxia, there is individual and interspecies variation of HPVR. Prolonged exposure to hypoxia may lead to pulmonary hypertension. Sojourners may have a more reactive HPVR than high-altitude natives. Smooth muscle hypertrophy occurs at the pulmonary arteriolar level and may be the mechanism of HPVR. Fibrosis of the intima, which may not be reversible, was found in high-altitude dwellers, suggesting a more fixed pulmonary vascular resistance. There is evidence that some high-altitude natives who have adapted well to the high altitude may have normal pulmonary artery pressures and no hypertrophy of the smooth muscle of the pulmonary arterioles.

Hematologic Adaptations

The purpose of optimizing $\dot{V}_A/\dot{Q}$ matching is to make oxygen available to hemoglobin in the red blood cell, which then carries oxygen in the vascular compartment to tissues where it is consumed. At high altitudes, two major adaptations of the carrier mechanism take place to facilitate delivery: (1) The number of red blood cells is increased by the process of erythropoiesis, and (2) the configuration of the hemoglobin molecule changes to alter the affinity of hemoglobin for oxygen in order to optimize the loading and unloading of oxygen.

Erythropoiesis

The decrease in arterial oxygen partial pressure and subsequently in oxygen content that occurs with progressive hypobaria at high altitude is counterbalanced in part by an increase in hemoglobin concentration and subsequent oxygen-carrying capacity. The rise over the first day or so is secondary to hemoconcentration from a diuresis, whereas the continued rise over the ensuing 2 to 3 weeks is a result of increased red blood cell production, which is stimulated by a humoral substance secreted in the kidney cell, erythropoietin. Erythropoietin levels increase rapidly according to the hypoxic stimulus and then decline a bit in the face of a continued rise in hemoglobin. Erythropoiesis stops abruptly on descent, and hemoglobin concentrations return to sea-level values in approximately 3 weeks.

A striking feature of the erythropoietic response is the variability between individuals and between different highland populations, which may reflect less-than-optimal adaptations to comparable hypoxic stress. For instance, in the Himalayas at 3600 m, hemoglobin levels of 16.1 ± 1.2 g/dl have been documented, whereas in the Andes at the same altitude, the values are 18.2 to 19.0 g/dl. Although the increase in hemoglobin concentration augments arterial oxygen content, an actual decrease in oxygen delivery may ensue if hyperviscosity of the blood limits perfusion to the microvasculature of the exercising muscle. Climbers on Mt. Everest undergoing isovolemic phlebotomy to decrease their hematocrits from 60% to 50% had an increase in psychometric function while not experiencing a decrease in aerobic capacity. Hemodilution in high-altitude natives of the Andes, achieved by decreasing the hematocrit 20%, resulted in an improved exercise performance. Excessive polycythemia in the highland dweller is discussed later.

Oxygen–Hemoglobin Affinity

The role of oxygen–hemoglobin affinity in oxygen delivery is not fully understood. Conditions of stress, such as fever and acidemia, are associated with a rightward shift of the oxygen–hemoglobin dissociation curve, or low oxygen and hemoglobin affinity, presumably to facilitate the unloading of oxygen to the tissues, whereas conditions such as hypothermia and alkalosis have opposite effects. At sea level, where there is an excess of oxygen in healthy individuals, shifts in the oxygen–hemoglobin curve make little difference in oxygen delivery, but at a high altitude, shifts in the curve may have a significant effect.

On acute ascent to a high altitude, hypoxia and the resultant hypocapnic alkalosis stimulate production of 2,3-diphosphoglycerate (2,3-DPG) within the red blood cell, which shifts the curve to the right. At the tissue level, production of carbon dioxide and hydrogen ions also improves the unloading of oxygen from hemoglobin, the Bohr effect. This shift was thought to be an advantage to acute high-altitude adaptation, but in subjects at 4300 m who had the curve shifted experimentally to the right, performance was not improved. Andean high-altitude natives both with and without evidence of polycythemia and pulmonary hypertension also were found to have right-shifted curves.

At moderate altitude, the rightward shifts may be an advantage, but the ease of unloading oxygen must be weighed against the potential disadvantage at higher

altitudes of loading oxygen onto hemoglobin at the pulmonary capillary level. A leftward shift would theoretically convey an advantage to loading oxygen at altitudes where the partial pressure of the inspired oxygen is so low that the diffusion gradient from air to blood is also very low. High-altitude animals and birds, such as the bar-headed goose, that migrate over the Himalayas have left-shifted curves, presumably from the marked hypocapnic alkalosis. Other experimental animal models bear out the advantage of a leftward shift during acute exposure. An optimal model may exist in the llamas and alpacas of the Andes, who have a left-shifted curve at the lung level and a right-shifted curve at the peripheral tissues.

Humans, on the other hand, have not lived long enough at high altitudes to evolve a characteristic hemoglobin that would be most suitable for high-altitude survival. A number of workers have found a modest leftward shift of the curve in humans living at high altitudes. Increased levels of 2,3-DPG have been found in these humans, but a leftward shift of the oxygen–hemoglobin curve was found probably because of the countereffect of the respiratory alkalosis. A group of climbers after 2 months at 6300 m or higher on Mt. Everest was found to have respiratory alkalosis, a modest polycythemic response (mean hematocrit of 54.4 ± 4.01%), and a persistently left-shifted curve despite an increased level of 2,3-DPG (Fig. 3). The advantages of a left-shifted curve at extreme altitudes, therefore, are at least suggested by the preceding data, but further work is necessary to elucidate the underlying mechanisms.

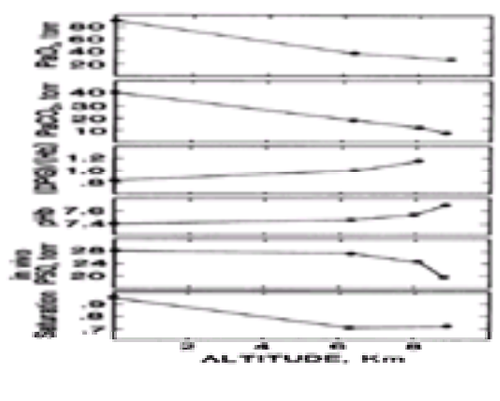

FIG. 3. Effect of altitude on oxygen–hemoglobin affinity. P_{50}, oxygen half-saturation pressure of hemoglobin; DPG, diphosphoglycerate. (From Winslow RM. Red cell function at extreme altitude. In West JB, Lahiri S, eds. *High Altitude and Man.* Bethesda, MD: American Physiological Society, 1984;59–72.)

Tissue Alterations

The final stages of oxygen delivery involve the diffusion of oxygen from the blood across the muscle capillary and muscle cell membrane to the cytoplasm and ultimately to the mitochondrion, where oxidative phosphorylation takes place. This process depends on a critical pressure gradient and radial distance for diffusion of oxygen from the blood to the cell. The critical pressure gradient is probably about 10 to 12 mm Hg, and certain adaptations that may optimize cellular transport and metabolism of oxygen take place.

Morphologic Changes

The purpose of structural changes is presumably to decrease the distance for diffusion of oxygen from the blood to the mitochondrion. Formation of new capillaries and a recruitment of preexisting capillaries in response to a hypoxic stimulus are strategies that can achieve that goal. Experimental animals exposed to hypoxia and guinea pigs native to high altitudes had an increased capillary density in the lung. Quantification of this response is difficult because muscle cell atrophy also occurs during prolonged (weeks, months) stays at high altitudes. In mice exposed to high altitude and exercise, capillary tortuosity and density were thought not to change when muscle fiber size and contractile state were considered.

The adaptation of the mitochondria to hypoxia is not well defined. Mitochondria have been found to be increased as well as unchanged or decreased at high altitudes. Human studies at very high altitudes, on the other hand, have shown a decrease in mitochondrial concentration. Whatever the final verdict, theoretically, an increase in both capillary and mitochondrial density would result in a facilitation of oxygen transport by decreasing the diffusion distance for oxygen from the blood to the mitochondria.

Biochemical Adaptations

Several biochemical mechanisms occur and improve oxygen metabolism. Myoglobin, an intracellular protein that binds oxygen at a very low tissue partial pressure of oxygen, facilitates diffusion of oxygen to muscle mitochondria and is increased in animals exposed to and native to hypoxia. The enzymes of oxidative metabolism also upgrade their function in response to exposure to and living at high altitudes. Succinic and lactate dehydrogenase, part of the glycolytic pathway, increase at high altitudes, but the changes in these studies were not consistent and depended on the degree of exposure, the tissue involved, and the stress itself. In human studies, the results suggest that fatty acid metabolism, which contributes to exercise endurance, is enhanced while glycolytic metabolism, which is responsible for high levels of aerobic work, is decreased. Further work is necessary to clarify this area of cellular adaptation to hypoxia.

Central Nervous System

The brain is the organ most sensitive to hypoxic stress. The historic flight of the Zenith in 1875, a hot-air balloon that carried three Italian scientists to over 8000 m, during which two of the scientists died, is a testament to the catastrophic effects of acute severe hypoxia on the brain. Less vivid but impressive examples of the effect of hypoxia on the brain are found throughout the medical and mountaineering literature.

The brain's defenses to the stress of hypoxia are both acute and chronic. The initial decrease in cerebral blood flow that occurs with hypocapnia secondary to hypoxia secondary to the respiratory alkalosis is outweighed by the increase in cerebral blood flow from the hypoxic stimulus. Blood flow increased 33% after 12 hr at 3800 m and decreased as respiratory adaptation continued but still was 13% greater than control values after 5 days. The net result is that oxygen supply to the brain is probably well preserved despite profound hypoxemia. Tibetans, a well-adapted high-altitude population, maintain cerebral blood flow during exercise better than sojourners.

In spite of augmented blood flow, varying degrees of cerebral dysfunction occur, depending on the acuity, duration, and degree of hypoxic stress. The higher one goes, the more that motor, sensory, and complex cognitive abilities are affected. Learning is impaired at 3000 m, and at 6000 m sensation, perception, and motor skills are diminished.

Acute elevation to 3500 m results in cortical depression of the electroencephalographic (EEG) pattern that is not apparent in inhabitants of that altitude. Correlation of the changes in the EEG with the symptoms of acute mountain sickness (AMS) at 4300 m was noted.

Several studies have addressed the question of prolonged or permanent effects of hypoxic exposure on central nervous system function. Some investigators found no residual psychometric deficits in climbers who had been above 5100 m in the Himalayas, but two other studies of individuals who had been at a high altitude for 10 months found residual motor incoordination and impaired speech, which resolved within a year. There was individual variation in these findings, which was also documented in a study of Polish alpinists who had climbed to 5500 m. All had some impairment noted by psychological testing, and 11 of 30 had EEG abnormalities. A later study showed transient deficits in learning, memory, and verbal expression in two groups of individuals, one of which had been on an expedition to Mt. Everest while the other had been exposed to a simulated similar altitude for 40 days in a hypobaric chamber. Fine-motor skills remained abnormal for up to 1 year in many. Unexpectedly, individuals with a high ventilatory response to hypoxia who are better oxygenated and who usually perform better physically had the greatest deficits. The authors speculated that those who hyperventilated more had greater hypocapnic cerebral vasoconstriction and thus lower oxygen delivery to the brain.

Sleep

Periodic breathing, which was described as far back as 1886, occurs during early exposure to high altitudes but decreases as acclimatization ensues. The degree of periodic breathing varies among individuals and may be a function of individual hypoxic chemosensitivity. Findings in both sojourners and high-altitude natives during sleep, when cortical input is minimized, suggest that individuals with high hypoxic chemosensitivity have ventilatory overshoot, resulting in hypocapnic alkalosis, suppression of ventilation, and periodicity of respiration. These oscillations persist throughout sleep and can result in profound arterial oxygen desaturation during the

hypopneic and apneic phases. The resulting hypoxemia may contribute to some of the aspects of altitude illness.

Carbonic anhydrase inhibitors eradicate periodic breathing, which may be a result of drug-induced tissue acidosis and subsequent ventilatory stimulation. Discussion of their therapeutic efficacy follows in the section on altitude illness.

Exercise

Although a number of observations of the effect of hypoxia on oxygen transport during exercise have been made, an understanding of exercise limitation at high altitudes remains elusive. One thing is certain: oxygen consumption and, subsequently, exercise performance predictably decrease with ascent to high altitudes (Fig. 4).

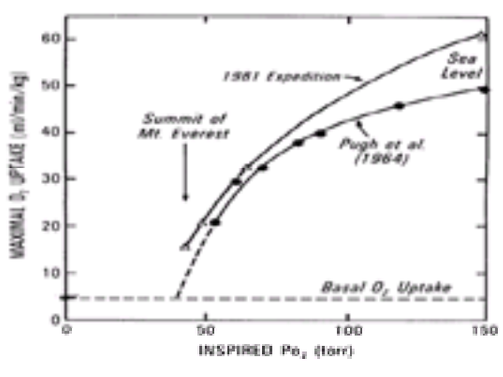

FIG. 4. Maximal oxygen consumption ($\dot{V}O_{2max}$) against inspired partial pressure of oxygen. There is a predictable decrease in $\dot{V}O_{2max}$ at higher altitudes. The more recent data demonstrate that a low amount of work is possible on the summit of Mt. Everest. (From West JB, et al. Maximal exercise at extreme altitudes on Mount Everest. *J Appl Physiol* 1983;55:688.)

Ventilation

The increased metabolic rate of exercise and hypoxia of high altitude interact synergistically to augment exercise hyperpnea. The increase in exercise ventilation is proportional to the degree of hypoxia (Fig. 5). The degree of exercise hyperpnea is also influenced by the individual's hypoxic ventilatory response, measured at sea level or a high altitude, and extraordinary levels of exercise ventilation may be augmented by the lower gas density. The study on Mt. Everest demonstrated that climbers with higher hypoxic chemosensitivity had greater exercise ventilation, less arterial oxygen desaturation, and better climbing performance. These data supported studies suggesting that climbers to extreme altitudes (higher than 7500 m) benefited from a brisk high ventilatory response. It is, therefore, the ventilatory response at high altitudes that is primarily responsible for the preservation of alveolar and arterial oxygen partial pressure. On the other hand, in the high-altitude dweller, a lower exercise ventilation is accompanied by a lower alveolar–arterial gradient, suggesting a genetic or adaptive increase in diffusion capacity of the lungs for oxygen that results in improved oxygen transport from the air to the blood.

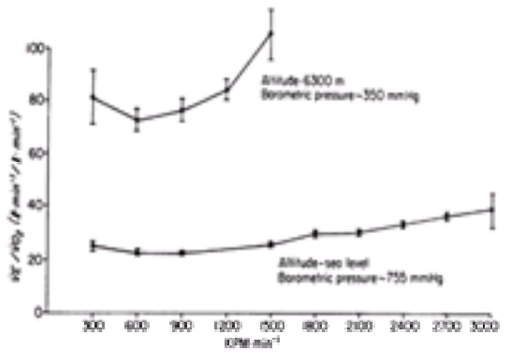

FIG. 5. The ventilatory equivalent ($\dot{V}_E/\dot{V}O_2$) for given workloads in a group of climbers at sea level *(lower line)* an at 6300 m *(upper line).* The data demonstrate the stimulation of ventilation by hypoxia. (From Schoene RB. Hypoxic ventilatory response and exercise ventilation at sea level and high altitude. In West JB, Lahiri S, eds. *Man at High Altitude.* Bethesda, MD: American Physiological Society, 1984; 19–30.)

Gas Exchange

Arterial oxygen saturation in sojourners decreases with exercise at high altitude. This desaturation is largely secondary to a diffusion limitation for oxygen from the air to the blood, but some $\dot{V}/\dot{Q}$ heterogeneity contributes to this phenomenon. This $\dot{V}/\dot{Q}$ heterogeneity may be secondary to interstitial lung water, whereas the diffusion limitation is a result of a decreased driving pressure of oxygen from air to blood compounded by a decrease in transit time of blood across the alveolar–capillary membrane.

Cardiac Response

At submaximal work loads during acute exposure, cardiac output is moderately higher than at sea level, but after prolonged exposure, heart rate and cardiac output are matched for comparable sea-level work loads. On acute high-altitude exposure, maximum cardiac output is the same as at sea level, but it decreases 20% to 30% after 2 months above 4300 m. This decrease is a result of a decrease in both maximum heart rate and stroke volume. The decrease in maximum heart rate is more pronounced in sojourners than high-altitude natives. On the other hand, cardiac output remains appropriate for oxygen consumption, and myocardial contractility, as measured by echocardiography, is preserved even at extreme altitudes. Although pulmonary artery pressures are very high during exercise at extreme altitudes, the increase in pulmonary vascular resistance is not a limiting factor.

Hematologic Changes

A modest increase in hemoglobin secondary to the erythropoietic response may improve oxygen transport, but polycythemia and its accompanying hyperviscosity may result in a decrease in microperfusion of the muscle tissue and a subsequent decrease in oxygen extraction. A study on Mt. Everest showed that isovolemic hemodilution of mountaineers from hematocrits of 60% to the low 50% range did not decrease maximum exercise capabilities. In fact, data from Himalayan highlanders suggest that the optimal hematocrit may be somewhat lower than previously thought.

Tissue

Muscle tissue undergoes some morphologic and chemical changes, the net result of which is that oxidative capacities are reduced. For instance, in climbers returning from 2 months at an extreme altitude, muscle mass decreased, capillary density was unchanged, mitochondrial density increased, and muscle succinic dehydrogenase (a marker for aerobic metabolism) decreased—all of which resulted in impaired aerobic functioning. It is not clear from other studies what effect a decrease in muscle fiber size has on the relationship of capillary and mitochondrial density and subsequent oxygen extraction.

In summary, exercise at modest altitude results in a number of cardiopulmonary changes that optimize gas exchange, while the blood and peripheral vasculature also undergo certain changes that may improve oxygen transport. At extreme altitude, on the other hand, the tissue adaptations may impose limitations on both submaximal

and maximal exercise.

Athletic Performance and Training at High Altitudes

Much of the work on athletic performance at high altitudes was done during the Mexico City Olympic middle-distance running events (at 2270-m elevation). Times were about 8% slower on arrival and approached but did not reach previous best sea-level performances. These findings correlated with measurements of maximum oxygen consumption. Performances in short-distance events (less than 2 min) are not impaired and in fact may be better than at sea level because of decreased air resistance. On the other hand, for prolonged work activities, endurance is improved by training and living at high altitude.

There is controversy over the benefits of training for athletic events at moderate altitudes. After the success in the Mexico City Olympics of the Africans who lived at an altitude of approximately 2000 m, it became quite fashionable for middle- and long-distance athletes to live and train at these altitudes. The results of studies to document this presumed benefit were mixed. The benefits of living at these altitudes (e.g., increased level of hemoglobin) may be outweighed by the fact that training schedules cannot be as intense. A recent study tried to address this controversy by studying four groups of athletes: individuals living and training at a low altitude, ones living and training at a high altitude (3000 m), those living at a high altitude and training at a low altitude, and a final group living at a low altitude and training at a high altitude. The results were not striking but suggested that those who lived at a high altitude and trained at a low altitude had a slight edge over the others. These findings may be explained by the slight elevation in hemoglobin.

MALADAPTATION

Overview

Modern travel and recreation permit rapid ascent to high altitudes, which is the major cause of acute mountain illnesses. On the other hand, millions of people reside at altitudes above 2500 m, and a certain percentage of those individuals develop chronic altitude disorders. In both of these groups, mounting evidence suggests that failure of the body to respond to hypoxic stress with an adequate ventilatory response results in greater hypoxemia, pulmonary hypertension, increased intracranial pressure, fluid retention, and erythropoietic response, all of which may lead to clinical illnesses at high altitudes. Hypoventilation, therefore, may be one of the crucial factors underlying all altitude illnesses. With the previous notes on formal adaptation as a guide, it therefore is the purpose of this section to deal with both acute and chronic mountain sicknesses.

Illnesses of Sojourners to High Altitudes

As was so tragically demonstrated by 19th-century balloonists, acute ascent above 8000 m can lead to death, whereas, as has been repeatedly achieved in the 20th century, climbers can gradually ascend to these altitudes and live and work for short periods of time quite effectively. Failure of the body to adapt to the hypoxic stress leads to acute mountain illnesses that can be fatal. These disorders are classified as AMS, high-altitude pulmonary edema (HAPE), and high-altitude cerebral edema (HACE). Although there is a great deal of individual variability and overlap in these disorders, this section deals with them separately.

Acute Mountain Sickness

Clinical Picture

Historically, AMS was described many centuries ago, and one consistently described symptom is headache. The headache usually begins shortly after ascent, is more severe in the morning, and is usually treatable with mild analgesics. Other symptoms can include anorexia, lassitude, insomnia, nausea, and vomiting, and some subjects show signs of fluid retention. Sojourners with AMS may be tachycardic and tachypneic but are not febrile. All these signs and symptoms usually abate over several days as acclimatization ensues and rarely requires more than rest, hydration, and mild analgesics. The severity and duration of AMS are a function of the altitude and the rapidity of ascent. For instance, on Mt. Rainier (4400 m), nearly two-thirds of climbers who routinely ascend from sea level over 1 to 3 days develop AMS, and in Summit County, Colorado (2880 m), 25% of travelers from low altitude have AMS. In both of these cases, the symptoms usually resolve in 1 to 3 days without sequelae. However, AMS can progress to HAPE and/or HACE, which can be life-threatening.

In many subjects with AMS, hypoventilation, gas-exchange abnormalities, and pulmonary mechanical dysfunction occur. Fluid retention, weight gain, proteinuria, and increased CSF pressure and brain swelling also have been documented. Individuals who are susceptible to AMS have an exaggerated aldosterone and antidiuretic hormone (ADH) response on ascent that is different from well-acclimatizing individuals who have low ADH and a diuresis. A shift of fluid from the extracellular space to the interstitial and intracellular compartments occurs normally during the initial few days at high altitude, but it may be accentuated and prolonged in persons with hypoventilation and AMS. Fluid shifts also may explain the pulmonary dysfunctions of relative hypoxemia and mechanical dysfunction, which may be precursors of overt HAPE. Evidence that dexamethasone, a medication commonly used for the treatment of many forms of edema, is effective in preventing and treating AMS supports the concept that extravascular fluid extravasation plays a role in altitude illnesses.

Why do some individuals get AMS and others not? Although the answer is not known, mounting evidence suggests that individuals with a blunted hypoxic ventilatory response are more predisposed to AMS and fluid retention. It is probably safe to say that the individual who does not mount a sufficient ventilatory response is more hypoxemic and susceptible to the ill effects and will, therefore, be predisposed to all forms of altitude illness, the first of which is AMS.

Treatment

Successful management of AMS involves recognition and appropriate treatment. If the awareness of and suspicion for AMS are keen enough, then AMS usually will not progress and can be treated with conservative measures, such as rest and mild analgesics (aspirin, acetaminophen, codeine, prochlorperazine). Sedatives, narcotics, and alcohol should be avoided because they may suppress ventilation and mask worsening symptoms. If the subject seems more ill with worsening headache or any other clear neurologic signs, especially ataxia, then this situation should be considered serious, and the patient should descend as quickly as possible. Even a few hundred meters may be helpful. If conditions do not permit descent, then oxygen, if available, is a good temporizing measure.

Few medications have been found to be helpful in either the prevention or the treatment of AMS. Acetazolamide, a carbonic anhydrase inhibitor, is effective in preventing and treating AMS, although its mechanism of action is unknown. Acetazolamide eradicates periodic breathing and arterial oxygen desaturation during sleep at high altitudes, which may improve overall oxygen delivery. The drug also stimulates ventilation at rest and during exercise; induces a renal excretion of bicarbonate, which may facilitate acclimatization; and lowers CSF pressure by decreasing CSF formation. Which of these effects is responsible for the drug's efficacy is not known, but it is effective and safe. Its side effects are minimal and include peripheral, self-limited paresthesias and mild gastrointestinal upset. The present recommendations are that sojourners who frequently get AMS should take acetazolamide (125 mg p.o. b.i.d.) on ascent to minimize the chances of illness; otherwise, those who go high quickly should begin therapy only after the first signs of illness. Individuals who are allergic to sulfa drugs should not take acetazolamide.

Dexamethasone has been shown to be effective in treating and preventing AMS and should be used in situations where treatment is imperative to aid a sojourner's descent. Because there are no data to suggest that the drug facilitates acclimatization, a person who stops taking the drug while still at a high altitude may suffer a rebound of altitude illness. Individuals progressing to more severe signs suggestive of cerebral edema should use dexamethasone immediately.

Recently, a portable hyperbaric chamber has been used for treatment of altitude illnesses in the field. This equipment is lightweight and is effective in treating illness. This manually operated chamber can lower the altitude by 1500 m with a pressure of 2 psi, which, after several hours, is enough to improve symptoms such that a victim can descend under his or her own power. In remote areas, the hyperbaric bag provides an excellent, reusable alternative to oxygen. Whether it is more effective than oxygen alone has not been established.

The best treatment is prevention, and slow, gradual ascent is still the best preventive measure. Maintenance of fluids to ensure a normal urine output and adequate calories in carbohydrates are time-honored tactics. A number of other drugs (morphine, furosemide, spironolactone, phenytoin) have been used, but none is effective, and most have potentially deleterious side effects.

High-Altitude Pulmonary Edema

Clinical Picture

High-altitude pulmonary edema (HAPE) was thought for many years to be pneumonia or heart failure at a high altitude. It was not until the 1960s that HAPE was described as a noncardiogenic form of pulmonary edema. The syndrome affects healthy sojourners of all ages, usually within several days of ascent above 3000 m, although it can occur later and at lower altitudes. It also is more common at higher altitudes with quick ascent. Symptoms and signs of AMS may precede those of

HAPE, and often HAPE and HACE occur simultaneously with varying degrees of each. Dyspnea on exertion, fatigue, and dry cough are early symptoms, with cyanosis, tachypnea, and tachycardia as accompanying signs. Crackles are universally present, although pink frothy sputum is present only in severe cases. Many victims have a low-grade fever, and all will have fluffy infiltrates without cardiomegaly on chest radiograph (Fig. 6). If symptoms are recognized early enough, while the patient is still ambulatory, descent is very effective as a treatment. Most patients recover fully, and many have been able to reascend to very high altitude within a fortnight. This observation is important, as it implies that the lung architecture is preserved.

FIG. 6. Chest x-ray film from a victim of high-altitude pulmonary edema with bilateral infiltrates and normal cardiac silhouette. (Hackett PH. *personal communication,* 1987.)

High-altitude pulmonary edema may be an extension of the normal process of accumulation of lung water that occurs on acute ascent to altitude. Additionally, many asymptomatic individuals have crackles on chest auscultation that resolve with further acclimatization. These findings suggest either that those who go on to develop HAPE are not able to compensate for the normal fluid accumulation or that their fluid shift is overwhelming.

Pathophysiology

Both autopsy and bronchoalveolar lavage (BAL) data demonstrate that HAPE is a high-protein/high-permeability leak (Fig. 7). Over 20 autopsies demonstrated a proteinaceous alveolar exudate with hyaline membrane formation. Neutrophils were present, and capillary and arteriolar thrombi and fibrin deposition were found. These data are from those individuals who did not survive and thus are not representative of the early pathophysiological process.

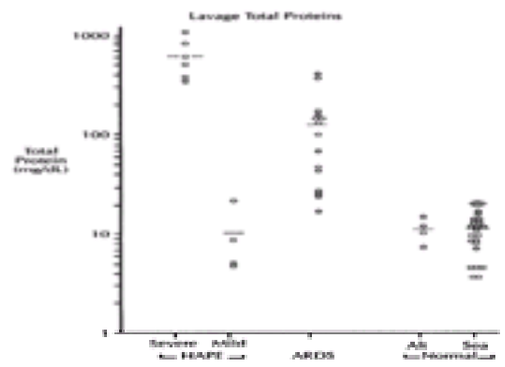

FIG. 7. Protein concentration in bronchoalveolar lavage fluid in patients with **(left to right)** high-altitude pulmonary edema (HAPE), acute mountain sickness with mild arterial oxygen saturation, adult respiratory distress syndrome (ARDS), and two control populations. (From Schoene RB, et al. The lung at high altitude: Bronchoalveolar lavage in acute mountain sickness and pulmonary edema. *J Appl Physiol* 1988;64:2605.)

Bronchoalveolar lavage at 4400 m on Mt. McKinley characterized the cellular and biochemical responses in subjects with HAPE. The protein content was higher than that of patients with adult respiratory distress syndrome (ARDS), and the fluid also was very cellular, but unlike the fluid found in ARDS, which contains primarily neutrophils, BAL fluid from subjects with HAPE consisted largely of alveolar macrophages. Additionally, there was evidence of inflammation with complement activation and leukotriene B_4 production, but inhibition of neutrophil chemotaxis was present, suggesting a mechanism protecting against parenchymal destruction. Thromboxane B_2 also was present, suggesting a vasoactive process. These findings provide important insight into the underlying mechanism of HAPE, although the picture is not complete.

Other physiological observations may provide further understanding of this high-permeability lung leak. A number of subjects with HAPE have a blunted ventilatory response to hypoxia that presumably leads to a more profound degree of hypoxemia, especially during sleep, and subsequent higher pulmonary artery pressures mediated by the HPVR. In addition, studies have shown that subjects with HAPE had very elevated pulmonary artery pressures. Decreasing these pressures with nitric oxide, which vasodilates the pulmonary vasculature, improves gas exchange in victims of HAPE. In a number of patients with HAPE, congenital absence of a pulmonary artery has also been demonstrated. These findings suggest that the pulmonary vascular endothelium undergoes extraordinary stress from an increased cardiac output during exercise at high altitudes, which is being directed through an either globally or patchily vasoconstricted and compromised pulmonary vascular bed. An animal model for capillary stress and failure has been described. Could high shear forces lead to a mechanical stretching of endothelial pores and subsequent permeability leak, or are other biochemical mechanisms responsible? Clearly, high intravascular pressures play a role in the development of HAPE but are not the entire story.

The BAL data showed that biochemical mediators are present. These findings suggest that stress on the endothelium may lead to release of inflammatory mediators, which may affect permeability. It would seem reasonable, therefore, not to classify pulmonary edema as caused by either pure increased permeability or pure increased hydrostatic pressure. This arbitrary division has led to some misunderstanding of some clinical illnesses, which may have a number of contributory factors. It is conceivable that the pathophysiologic process in HAPE begins with high hydrostatic forces, which may lead to leak of protein into the interstitial and alveolar spaces and/or to release of biochemical mediators that affect pulmonary vascular integrity. This latter scenario suggests mechanisms that would violate the traditional separation of causes of lung leak but that may be more realistic.

Treatment

The guidelines for field treatment that have been outlined for AMS are applicable to HAPE, except that it is important to emphasize that HAPE can be fatal. Early recognition is essential to avoid catastrophe. Descent, especially from remote areas where medical help is not available, is still the most important step, and avoidance of any medications that may suppress ventilation, especially sleeping pills, is mandatory. Oxygen, if available, is very effective, but it should be regarded only as a temporizing measure. However, if mild to moderate cases of HAPE are seen in areas where medical help is available, and if the patient's S_aO_2 can be increased to ^{3}90% on low-flow oxygen, then he or she can remain at altitude on oxygen under the overnight observation of family or friends and be seen in follow-up. This approach is reasonable, especially in recreational areas where evacuation is an expensive and logistically unnecessary overreaction. Because HAPE and HACE often occur together to varying degrees, the victim may be more or less incapacitated, and rescue units should have oxygen and/or a portable hyperbaric bag available, as these improve oxygenation and decrease pulmonary artery pressure. Victims usually improve enough within 12 to 24 hr of descent to safer altitudes. Recent studies have shown end-positive airway pressure (EPAP) masks to be effective in improving oxygenation, and these may be useful until the victim can descend or be evacuated.

A number of medications have been used, but no data are available to validate their efficacy. The low incidence of HAPE and the lack of an animal model make a drug trial very difficult. Acetazolamide is certainly safe and may be effective in preventing or treating HAPE, but no studies have been done to prove this point. Potent diuretics are potentially dangerous. Morphine sulfate may improve symptoms, but it suppresses ventilation. Drugs that decrease pulmonary artery pressures have been shown to be efficacious. In a field study in the Alps, Bartsch and colleagues pretreated HAPE-susceptible climbers with nifedipine and placebo. There was a decrease in pulmonary artery pressure and no HAPE occurred in the nifedipine group. Therefore, in HAPE-susceptible individuals who return to high altitude, prophylactic

treatment with nifedipine XL, 30 mg p.o. q.d. or b.i.d., is appropriate.

High-Altitude Cerebral Edema

Because the symptoms of AMS are similar yet milder than those of HACE, it is reasonable to assume that HACE is merely an extension of AMS. High-altitude cerebral edema usually, but not always, follows AMS and is marked by severe headache and papilledema with deterioration of mental status in the presence of objective neurologic signs, especially ataxia. This usually is seen after a recent ascent. The symptoms may rapidly progress to coma and death. Usually HACE occurs at higher altitudes (higher than 4000 m) and is less common than HAPE (approximately 1%). If a severe headache cannot be relieved by analgesics, then HACE should be suspected, especially if other neurologic signs or symptoms develop. Both HAPE and HACE often occur simultaneously with differing degrees of severity.

Autopsies have shown gross cerebral edema with herniation and small petechial hemorrhages in seven of eight HACE victims. The underlying pathophysiological mechanism is unclear, but it probably involves high cerebral vascular pressures with filtration of plasma proteins and water into the interstitial spaces.

Recognition is absolutely essential because HACE, more than any other altitude illness, can progress rapidly to death. Recovery occurs with descent, although oxygen and dexamethasone (10 mg i.m. or 8 mg p.o. immediately and 4 mg p.o. q6h until symptoms resolve) may give symptomatic relief until descent can be achieved. Hyperbaric therapy may also be helpful but should never delay descent if the patient is ambulatory or transportable.

Ophthalmologic Syndromes

A number of ophthalmologic changes have been noted at high altitudes. As the window of the brain, the retina may offer some interesting insight into the effect of altitude on the brain. Retinal hemorrhages are common (more than 50%) in sojourners above 4500 m and were recently observed in all eight subjects who underwent a 40-day simulated ascent of Mt. Everest. Rarely are visual changes encountered, and the hemorrhages resolve within a fortnight and deserve no treatment *per se.* Other funduscopic changes include papilledema, vitreous hemorrhages, and vascular tortuosity and engorgement. The hemorrhages are similar to those found in necropsies of the brain at high altitude, and one can only speculate if these are concomitant processes in the eye and brain.

Visual changes, including visual blurring and intermittent blindness, also occur. This latter phenomenon is probably cortical in origin secondary to global hypoxia and/or decreased perfusion secondary to hypocapnic vasospasm. Visual field impairment also has been described and is vascular in origin.

Illnesses of High-Altitude Residents

Subacute Mountain Sickness

Recently, a syndrome has been found in Indian soldiers who lived for longer than 3 months at an altitude of 5800 m. It is characterized by fluid retention, cor pulmonale, polycythemia, and left ventricular dysfunction. The mortality rate was high in these individuals unless they moved to a low altitude. An infantile counterpart has been observed in Han Chinese infants who have moved to Lhasa, Tibet. Investigators are presently trying to understand the underlying mechanisms of this newly described entity.

Chronic Mountain Sickness

Human habitation at high altitudes is limited both by prolonged hypoxic stress and by the harsh nature of the environment. Nevertheless, millions of people live between 3000 and 5000 m. Some environments might permit living at higher altitudes, but anecdotally, civilizations have settled below 5000 m, suggesting that chronic deterioration occurs above this altitude such that populations tend not to thrive.

Some insight into this phenomenon can be gained by observing some individuals in populations residing at high altitudes who develop deleterious manifestations of chronic hypoxic stress—polycythemia, pulmonary hypertension, mental slowing, and cor pulmonale. This disease is termed *chronic mountain sickness* (CMS) and was first described by Monge in 1928, who noted the sickness in high-altitude natives of the South American Andes. Interestingly, although CMS has been observed in all mountain ranges, some populations, especially inhabitants of the Tibetan plateau and women, do not seem very susceptible to CMS. Populations of lowland natives who move to high altitudes develop CMS over the ensuing years. An interesting study on the Tibetan plateau showed a 13% incidence of CMS in relocated Chinese men, a 1.6% incidence in Chinese women, and a 1% incidence in Tibetan men. One could speculate that the Tibetans, who have lived at high altitudes for over 250,000 years, have evolved more successful mechanisms to improve oxygen transport and cope with the hypoxic stress than have Andean natives, who have lived at high altitudes for less than 30,000 years.

Clinical Picture

Andean villages have many individuals suffering from CMS. The plethoric, sometimes obese male with both mental and physical torpor is classic. Neurologic findings include mental dullness, lethargy, and poor memory. The subjects have polycythemia and cyanosis and resemble in many respects the sea-level dweller with cor pulmonale, polycythemia, and sleep disorders with marked nocturnal oxygen desaturation. There may be underlying lung disease as well.

Most of the clinical manifestations can be attributed to hypoventilation, which is associated with a blunted hypoxic chemosensitivity and subsequent relatively greater hypoxemia. Worse pulmonary hypertension may lead to right-sided heart failure and cor pulmonale. A high-frequency, low-tidal-volume pattern of ventilation may contribute to a low $\dot{V}/\dot{Q}$ ratio, contributing further to the hypoxemia. An increase in red cell mass relative to plasma volume results in a true hyperviscous polycythemia. Hematocrit levels as high as 80% have been described. Hypoventilation, therefore, may be one of the key factors that allows CMS to develop. Other underlying problems, such as lung disease and an inordinate erythropoietic response, may contribute to the development of CMS.

Treatment

The mainstay of treatment is improvement of arterial oxygenation, which should decrease the polycythemia, improve pulmonary hypertension, and improve cerebral function. If possible, the individual should move to a lower altitude and stop cigarette smoking. Often a relocation is not logistically or culturally possible, and most victims of CMS languish away in remote high-altitude villages. On the other hand, some therapeutic interventions are beneficial. Phlebotomy improves cor pulmonale and increases cardiac output and oxygen transport, but the erythropoiesis eventually returns. Low-flow oxygen, especially at night, is also helpful but not always logistically feasible. Medications that stimulate ventilation and result in a marked improvement in nocturnal oxygen saturation are also beneficial. Acetazolamide is particularly effective, as is medroxyprogesterone acetate, although to a lesser degree. Other respiratory stimulants have not been tried.

Reentry Pulmonary Edema

Long-time residents at high altitudes may be more susceptible to high-altitude pulmonary edema if they descend to a low altitude and reascend. Young people (children and teenagers) may be more susceptible, especially if descent and ascent are rapid. Cases have been reported from South America (6.4% incidence) and Leadville, Colorado, but none from Asia. The reasons for this difference are not clear, but it may be secondary to the logistic imposition of a slower ascent in the Himalayas or to the overall better adaptive capabilities of the Tibetan descendants. The cause of reentry HAPE is not known, but it may be secondary to a hypermuscularization and subsequent hyperreactivity of the pulmonary vasculature to hypoxia on reascent.

CHAPTER

46 Near-Drowning and Diving Accidents*

Thomas A. Dillard · Kurt W. Grathwohl

K.W. Grathwohl: Medical Corps, U.S. Army, Pulmonary and Critical Care Medicine, Madigan Army Medical Center, Tacoma, Washington 98431.

INTRODUCTION

Near-drowning and diving accidents have a special importance for pulmonologists and intensivists. These aquatic injuries often cause acute respiratory distress syndrome and other respiratory complications, which usually respond to careful management. The treatment of near-drowning may require the full spectrum of pulmonary and critical care medicine.

Diving accidents may also require specialized intervention such as surface decompression in a hyperbaric chamber. Because of the millions of recreational diving enthusiasts in the United States, pulmonary and critical care providers should maintain familiarity with medical management of diving accidents. Emergency medical services at virtually any location may refer divers with acute injuries for further care.

This chapter considers clinical aspects of near-drowning and diving accidents from the point of view of pulmonologists and intensivists. The chapter begins with a presentation of definitions and incidence of these entities. Near-drowning is considered using a problem oriented, organ systems approach to manifestations and treatment, followed by a similar review of diving accidents. A brief consideration of fitness for diving follows thereafter.

DEFINITIONS

Drowning consists of death from asphyxiation as a result of submersion in a fluid medium. Although aspiration occurs in the vast majority of cases, the definition of drowning does not inherently require significant aspiration of fluid into the lower respiratory tract. Mechanisms of drowning without aspiration are considered below.

Near-drowning consists of survival for a period of time despite illness or soft-tissue injuries resulting from submersion in a fluid medium. The definition usually implies anoxic injury or aspiration. Death may follow at a later time. For cases surviving less than 24 hrs, the distinction between drowning and near-drowning becomes somewhat arbitrary.

Immersion of the face without total body submersion can produce near-drowning in some circumstances. Minimal aspiration associated with momentary submersion and without sequelae constitutes the mildest form of near-drowning and differs little from any simple aspiration. Partial submersion without facial immersion or aspiration may not justify diagnosis of near-drowning.

Diving accidents defy a single definition and consist of several different complications in divers. These include decompression sickness, arterial gas embolism, nitrogen narcosis, oxygen-induced seizures, and other complications. Each can also cause drowning or near-drowning. These are addressed in the section on diving accidents.

INCIDENCE

National mortality statistics have reported 4000 to 5000 accidental drowning deaths per year in the United States during the 1990s. The reported mortality rate from accidental drowning has averaged 1.8 per 100,000 population during these years. This compares favorably with a mortality rate of 3.7 per 100,000 from accidental drowning during the mid-1970s.

Recent medical reviews have typically estimated a greater number of drownings, usually 7000 to 9000 victims per year in the United States and over 100,000 victims worldwide. The difference may reflect the fact that drowning often complicates other types of accidents such as motor vehicle and boating accidents. Statistical summaries that classify by primary accident alone would not reflect the role of drowning as a contributory cause of death.

Near-drowning exceeds drownings five- to tenfold based on emergency room visits and two- to sevenfold based on hospitalizations. Rough estimates place the number of people seeking medical attention for near-drowning at 50,000 or more every year. Submersions not resulting in medical encounters outnumber actual drownings by several hundredfold. Age distributions of drownings reveal two modal peaks: young children below 5 years of age and a broader peak between 14 and 24 years of age. The risk of drowning and near-drowning for boys and men exceeds that for girls and women by up to 4:1. By age and sex distributions, young adult and adolescent boys have the greatest risk. The tendency for risk-taking behavior in boys and the greater likelihood of intoxication in male adolescents and young adults contribute to this gender difference in incidence.

Diving accidents contribute to the annual toll of drowning victims. Fatalities among divers occur in approximately 100 cases per year. The most common causes of death among self-contained underwater breathing apparatus (SCUBA) divers consist of depletion of oxygen while submerged at depth, arterial gas embolism, and drowning. Nonfatal but serious diving accidents occur in approximately 750 cases per year.

NEAR-DROWNING

Pathogenesis

The most common sites of drownings in toddlers and preschool children by far are swimming pools. In adults, drowning also commonly occurs in ponds, lakes, and rivers used for recreational activities. Less frequent sites in adults include bathtubs, hot tubs, and other sites. In contrast, drowning in infants most often occurs in the bathtub. In these instances, child neglect or abuse should be considered.

Table 1 lists some common factors predisposing to near-drowning. Common denominators include loss of consciousness, neuromuscular weakness, poor judgment, lapses in safety, and unexpected events.

Category	Mechanisms	Examples
Intoxication	Impaired consciousness	Alcohol
	Impaired judgment	Illegal drugs
	Impaired coordination	Multiple drugs
Trauma	Closed head injury	Aquatic sports
	Spinal cord injury	Pool dives
		Auto accidents
Maladaptive response	Hypocapnic hypoxemia	Shallow water blackout
	Cardiac arrest	Sudden immersion syndrome
Medical conditions	Arrhythmias, syncope	Cardiac disease
	Seizures	Epilepsy
	Hypoglycemia	Diabetes mellitus
Hypothermia	Motor impairment	Prolonged immersion
	Arrhythmias	Frigid waters
	Loss of consciousness	
Diving accidents	Hypoxemia	Oxygen depletion
	Delirium	Nitrogen narcosis
	Seizures	Oxygen toxicity
	Neuromuscular impairment	Arterial gas embolism
	Carbon monoxide poisoning	Surface air contamination
Miscellaneous	Lack of supervision	Child drowning
	Exhaustion	Unexpected immersion
	Lack of flotation device	
	Wounds	Animal bite
	Entrapment	Bottom vegetation

TABLE 1. *Pathogenesis of near-drowning: Some common factors*

Intoxication contributes significantly to drowning in adults and adolescents. One-third to one-half of drownings in these age groups involve alcohol consumption. In addition to impairing judgment, coordination, and level of consciousness, alcohol predisposes to loss of body heat and development of hypothermia. Illegal and prescribed drugs also play a role in adult and adolescent drownings. Screening for intoxicants is appropriate in most cases of near-drowning.

Patients with closed head injury or cervical fracture typically make no attempt to surface after entry into a body of water because of unconsciousness or loss of motor function. Aquatic sports such as surfing, waterskiing, and pool diving produce hundreds of these injuries annually. Physicians should keep a low threshold for cervical immobilization and obtaining radiographic studies to exclude these injuries.

Maladaptive responses may be regarded as pathologic consequences of physiological processes or reflexes. Two maladaptive responses contribute to near-drowning episodes: shallow-water blackout and sudden immersion syndrome.

Shallow-Water Blackout

A swimmer who hyperventilates before a breath-hold swim delays the ventilatory response to rising carbon dioxide. Vigorous muscular activity while swimming underwater then depletes alveolar oxygen. This can cause hypoxemia sufficient to produce loss of consciousness, such as a P_aO_2 of 30 mmHg for 20 sec. Aspiration of water can then follow because of cessation of voluntary breath holding. Shallow-water blackout thus consists of the sequence of hyperventilation, breath holding, exercise, and loss of consciousness.

Sudden Immersion Syndrome

This phenomenon consists of a vagally mediated asystolic cardiac arrest caused by sudden immersion in very cold water. Ventricular fibrillation may supervene. Sudden immersion syndrome disrupts the circulation and thus consists of a maladaptive response. This differs from the diving reflex, which consists of bradycardia and peripheral vasoconstriction causing hypertension, reduced cardiac output, and central redistribution of the circulation.

The medical conditions listed in Table 1 have a high prevalence in the general population. Epileptic seizures contributed to drownings in 6% to 8% of cases in some series. Sudden cardiac death from ventricular fibrillation or tachycardia and syncope from valvular or muscular subaortic stenosis can present in the water as well as on land. Hypoglycemia most often occurs in diabetic patients using oral or injectable medications.

A variety of other factors predispose to near-drowning. Lack of supervision and lapses in safety cause most of the drownings and near-drownings in infants and preschool children. Lack of flotation devices, animal bites, and entrapments represent unexpected circumstances associated with near-drowning. Detailed analysis of these and many other factors exceeds the scope of this chapter.

Pathophysiology

Three mechanisms produce most of the pathologic changes associated with near-drowning: anoxia, aspiration, and hypothermia.

Anoxia

Hypoxemia constitutes the most critical pathophysiological event in near-drowning. The degree and duration of hypoxemia determine the extent of anoxic brain damage, which in turn directly affects outcome and prognosis. Other injuries can also cause death, but patients usually recover with medical support.

Many drownings begin with a period of panic associated with attempted breath holding. The victim struggles to reach the surface and may swallow large amounts of water. Oxygen becomes depleted, and carbon dioxide accumulates. The breath hold eventually ends with inspiratory efforts and aspiration of varying amounts of water. When hypoxemia reaches a critical level, the victim loses consciousness. Cardiac arrest eventually ensues. Anoxic brain injury results from profound hypoxemia and circulatory arrest.

Witnesses of near-drowning incidents may not report the pattern of struggling described above. Common explanations for the motionless drowning victim include hypothermia, shallow-water blackout, sudden immersion syndrome, closed head injury, and other causes of unconsciousness, impaired ventilatory drive, and neuromuscular weakness.

Hypoxemia remains the gravest concern even in near-drowning without struggling. Although hypoxemia develops more gradually in the absence of vigorous muscular activity, the factors inhibiting the struggle carry additional morbidity of their own.

Aspiration

Drowning occurs without significant aspiration in 10% of cases. “Dry” drowning and near-drowning events have been attributed to laryngospasm resulting from tracheal irritation by minimal aspirated fluid. Apnea or simultaneous cardiopulmonary arrest can also produce relatively dry lungs.

Aspiration of considerable fluid occurs in the vast majority of near-drowning cases. Entry of fluid into the lungs depends on the action of the respiratory muscles and stops with cessation of respirations. Table 2 presents a listing of common respiratory complications of near-drowning.

Pulmonary mechanics	Complication	Onset
Restriction[a]	Aspiration	Early
	Abdominal distention	Early
	ARDS	Delayed
	Pneumothorax	Either
Obstruction[b]	Foreign body	Early
	Bronchospasm	Early
	Laryngospasm	Early
Normal	Hypoventilation	Early
	Pneumonia	Delayed

[a] Decreased static compliance with increased airways resistance; increased peak inspiratory pressure with normal plateau pressure.
[b] Normal static compliance; increased airways resistance; increased peak inspiratory pressure with normal plateau pressure.

TABLE 2. *Respiratory complications of near-drowning*

Aspiration of water grossly contaminated with particulates may obstruct large airways, smaller bronchi, or respiratory bronchioles. Clinicians should consider sand or gravel aspiration in all cases of near-drowning in shallow waters. The Heimlich maneuver, however, should be reserved for cases with inability to ventilate at the rescue scene. Clinicians should note any history of application of the Heimlich maneuver, as this may indicate the possibility of additional particulates and may warrant observation for complications of abdominal thrusts.

Nationwide, near-drowning in fresh water occurs much more frequently than in sea water. The manifestations of hypertonic and hypotonic fluid aspiration differ in several respects. With both types of water, pulmonary edema occurs and adds to the ventilation–perfusion abnormality. Near-drowning in brackish, polluted, or waste water and industrial solutions represent less common problems. In general, aspiration of fresh, salt, brackish, or chlorinated waters has no significant effect on outcome.

Fresh water disappears relatively rapidly from the lower respiratory tract, a characteristic of hypotonic fluids. Investigators recovered little fresh water from the lower respiratory tract of experimental animals even with suctioning within 3 to 5 min after instillation in the trachea. Because of clearance of hypotonic fluid by the circulation, the space-occupying effects of fresh water near-drowning do not persist after rescue and restoration of ventilation.

Aspiration of fresh water alters surface tension in the alveoli by inactivating preexisting lung surfactant. Both chlorinated and nontreated fresh water have this property. Fresh water also may inhibit surfactant production by type II pneumocytes for a period of time. Lack of surfactant renders affected alveoli susceptible to atelectasis of varying degrees. This alters the distribution of ventilation and ventilation–perfusion ratios.

Osmotic pressure from seawater aspiration brings additional fluid from the plasma into the lungs. Seawater aspiration produces fluid-filled alveoli that persist much longer than freshwater aspiration (Fig. 1 and Fig. 2). Perfusion of fluid-filled lung units causes pulmonary venous admixture.

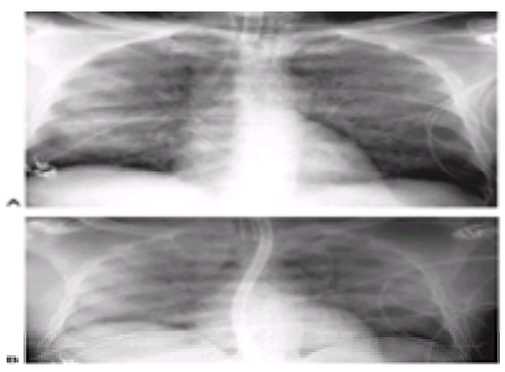

FIG. 1. Salt-water near-drowning. **(a)** Portable anteroposterior chest radiograph within 1 hr after presentation. Chest film shows extensive confluent perihilar density in the right and left lungs. Note sparing of subpleural areas at the periphery and at both bases. **(b)** Twelve hours later. Note progression of lung infiltrates throughout both lungs, air bronchograms, and reduced lung volumes despite gastric tube decompression.

FIG. 2. Freshwater near-drowning. **(a)** Portable anteroposterior chest radiograph within hours of presentation. Note less extensive infiltrates than in Fig. 1a in the right and left midlung zones as well as reduced lung volumes. **(b)** Ten hours later. Note improvement of infiltrates with some residual RLL density and further loss of lung volumes.

Clearance of seawater from the lungs takes longer than fresh water. The space-occupying effects of seawater aspiration thus pose greater problems for rescue ventilation. Aspiration of hypertonic fluid does not inactivate pulmonary surfactant to the same extent as hypotonic fluids. Injury to type II pneumocytes, however, can occur.

Aspiration of both contaminated water and gastric contents creates additional risks. These include the risk of pneumonia and chemical injury to the pulmonary epithelium.

Hypothermia

Hypothermia can be fatal on its own without immersion or aspiration. Lowered body temperature can complicate or precipitate near-drowning in virtually any outdoor setting.

Water conducts heat 32 times faster than air because of its greater heat capacity and mass density. Depending on water temperature, immersion can rapidly lower body temperature. Unprotected persons will experience a rapid decline in body temperature in water below 72°F (22°C).

Normal clothing provides little protection from immersion hypothermia following replacement of air with water between layers of clothing and between fibers of fabric. Obesity does convey protection from hypothermia because of insulation by adipose tissue. Obesity also conveys greater buoyancy during immersion.

Hypothermia causes drowning and near-drowning by degrading functional state. Table 3 displays signs and symptoms of falling core temperature. Neuromuscular impairment develops as core temperature falls from 93° to 90°F (34° to 32°C). Loss of consciousness occurs around 84°F (29°C) unless this occurs earlier from other causes. In adults, ventricular fibrillation occurs at core temperatures around 79° to 80°F (26° to 27°C). In the absence of anoxia, survival can occur at lower temperatures.

Core temperature		Signs and symptoms	Rewarming[a]
°F	°C		
95	35	Confusion, irrationality	PER
93	34	Sensory and motor impairment	PER
90	32	Hallucinations, dysrhythmias, gross motor impairment	PER
88	31	Loss of shivering, disoriented	ACR + AER
86	30	Muscle rigidity, anesthesia	ACR + AER
84	29	Loss of consciousness	ACR + AER
81	27	Ventricular fibrillation, asystole	ACR + AER or ECR

[a]Suggested rewarming for hypothermia with a perfusing rhythm and pulse. Abbreviations: PER, passive external rewarming, e.g., blankets; ACR, active core rewarming, e.g., gastric or peritoneal lavage, heated, humidified oxygen; AER, active external rewarming (thorax only initially), e.g., heating blankets or lamps; use only with ACR if at all because of the risk of paradoxic drop in temperature; ECR, extracorporeal rewarming, considered for other pulseless hypothermia (T < 32°C).

TABLE 3. *Hypothermia and near-drowning: Effects of a falling core temperature*

Profound hypothermia can occasionally impart a protective effect on victims immersed in extremely cold water. This appears most likely in waters below 38°F (3°C) and practically never above 50°F (10°C). Such cases usually involve children over age 3 years with profound core hypothermia. The sequence of hypothermia preceding submersion by some period may be critical in order for cerebral protection to precede the anoxic insult.

Reports have attested to survival in patients immersed in frigid waters for more than 30 min and, in at least one published case with an initial rectal temperature of 72°F (22°C), 66 min.

Table 3 shows rewarming strategies for patients with a perfusing rhythm and pulse. Active core rewarming should be instituted in patients presenting with a temperature below 90°F (32°C). In patients without a pulse, CPR should be continued until rewarming has been accomplished. Extracorporeal rewarming (ECR) constitutes an efficient means for active core rewarming in pulseless severe hypothermia. Correction of hypoxemia should precede attempts at rewarming. In patients with mild hypothermia (*T* > 90°F, 32°C) passive external rewarming will usually suffice.

In most cases a lowered body temperature carries a poor prognosis. Most immersions involve water temperatures warmer than 3° to 10°C and lack the sequence of presumed hypothermia preceding asphyxia. Rather, the immersion occurs simultaneously with asphyxia. Irreversible brain damage occurs before protective cooling can take place. Moreover, adults do not cool as rapidly as small children because of greater body mass and insulation. At all ages, the combination of near-drowning and hypothermia usually causes death in the vast majority of cases.

Manifestations of Near-Drowning

Pulmonary Complication

Death rarely results from pulmonary complications, and judicious management should lead to recovery. Table 2 lists common respiratory complications in near-drowning victims.

The first concern is to ensure an adequate airway. Aspiration of a foreign body should receive a high index of suspicion especially in patients requiring clearance of pharyngeal particulates at the rescue scene. Inspection of the lower airways by fiberoptic bronchoscopy may be required to exclude foreign bodies.

In the ventilated patient, a high peak-to-plateau pressure difference may indicate residual particulate matter obstructing the lower airways or bronchospasm. In the spontaneously breathing patient, inspiratory stridor or expiratory wheezing should suggest these possibilities.

Large volumes of swallowed water can accompany near drowning. The swallowed fluid will usually be regurgitated and aspirated along with gastric contents. Large volumes of swallowed water can also restrict ventilation before and after rescue through gastric distention. After securing the airway, clinicians should decompress the stomach routinely.

Both hypertonic and hypotonic aerosol inhalation can produce bronchospasm. Direct contact of the airways with seawater or fresh water similarly can cause increased airways resistance. A trial of aerosol bronchodilator inhalation with monitoring of lung mechanics before and after treatment can confirm and relieve this complication.

Aspiration represents the next concern and requires treatment to reverse hypoxemia. The propensity for rapid changes in either direction necessitates frequent monitoring of gas exchange. Near-drowning cases typically manifest severe reduction of P_aO_2/F_IO_2 ratio; however, this index has little bearing on the eventual outcome in near-drowning and should not be used for prognosis. A P_aO_2/F_IO_2 ratio below 300 justifies consideration of positive pressure in the form of CPAP or PEEP. Chest x-rays usually reveal one of four patterns: (1) bilateral perihilar density, (2) diffuse alveolar infiltrates, (3) multifocal densities, or (4) no significant infiltrate. Seawater near-drowning will generally cause greater infiltration than freshwater aspiration at the outset (Fig. 1 and Fig. 2). Up to 20% of near-drowning cases may have clear chest films initially. Worsening of infiltrates may occur in the first 48 hr, especially with seawater near-drowning.

Initial management of aspiration depends on the degree of hypoxemia and the extent of infiltrates. Because of the systemic hypoxic injury, an oxyhemoglobin saturation of 95% or greater represents a reasonable initial target in the first few hours. Overall improvement would justify acceptance of a lower saturation around 90% thereafter.

Diffuse bilateral infiltrates and severe hypoxemia warrant the application of PEEP up to 10 to 12 cm H_2O in the intubated patient. Cerebral edema may limit the application of positive pressure. An intermediate goal consists of reduction of F_IO_2 to 0.5 or lower to prevent hyperoxic injury. Further increments of PEEP justify heB Amodynamic monitoring. Mask CPAP represents an option for the alert, spontaneously breathing patient with diffuse infiltrates.

Hypoxemia in the absence of infiltrates warrants consideration of bronchospasm or atelectasis. As noted above, freshwater drowning predisposes to atelectasis. If bronchodilators fail to improve oxygenation, cautious application of PEEP or mask CPAP can be entertained in patients with hypoxemia with mild or no infiltrates.

Precautions with application of positive airway pressure include concern for hemodynamics. In patients with unilateral or focal infiltrates, clinicians should remain alert for paradoxical worsening of hypoxemia on application of positive pressure.

The potential for lung injury and the acute respiratory distress syndrome (ARDS) exists in all cases and occurs in about 40% of near-drownings. Both seawater and freshwater near-drowning can cause injury to bronchopulmonary lining cells. Gastric aspiration, chemical constituents, and biological materials in aspirated waters or endogenous toxins from systemic injury may contribute to secondary lung injury in specific cases. Multiple organ failure from systemic injury may accompany ARDS.

Patients with near-drowning who develop ARDS usually do so within 48 hr of hospitalization. Patients with seawater near-drowning may present with an ARDS picture from the outset, which may worsen over several days. The ARDS associated with near-drowning usually responds to medical management and generally does not determine outcome. Improvement of infiltrates usually begins by the fifth or sixth day.

Corticosteroid therapy has no role in the initial management of lung injury from near-drowning. Surfactant replacement therapy also has no proven role. Diuretics can hasten resolution of pulmonary edema in hemodynamically stable patients. Delayed resolution of infiltrates in near-drowning patients with ARDS warrants consideration of pulmonary infection or fibroproliferation. Detailed consideration of the treatment of ARDS can be found in Chapter 47.

Barotrauma may complicate near-drowning. Causes include diving accidents, intubation complications such as tracheal injury or right mainstem bronchus intubation and volume injury from mechanical ventilation of lungs with low compliance.

Pneumonia can occur for several reasons. These include contaminated waters, aspiration of mouth anaerobes or pharyngeal flora, and nosocomial infection via the endotracheal tube. Nonspecific fever and leukocytosis should be anticipated early in near-drowning, but persistent or new-onset fever, leukocytosis, and infiltrates should raise concern for complicating infection.

Prophylactic antibiotics have no proven benefit in most near-drownings; however, cultures of respiratory secretions should be obtained early as a baseline and repeated based on clinical course. Leukocytes in the respiratory secretions without isolation of bacteria may indicate anaerobic infection or nonspecific lung injury. Quantitative cultures of protected specimens may be required to confirm anaerobic infection.

Indications for bronchoscopy in near-drowning include suspicion of foreign body aspiration in the upper airway, lobar collapse, and need for protected or directed specimens to exclude anaerobic or other infections.

Neurologic Complications

Neurologic outcome outweighs all other considerations in near-drowning. Anoxic encephalopathy in near-drowning can result in brain death, persistent vegetative state,

spastic quadriplegia, aphasia, cortical blindness, and recurrent seizures in addition to other deficits.

Many studies have evaluated prognostic variables in near-drowning unassociated with frigid waters. A duration of submersion longer than 25 min and a duration of rescue CPR longer than 25 min by reliable history carry a poor prognosis. Irreversible brain injury can certainly occur within a shorter interval. Initial pupillary response does not reliably predict outcome. Ongoing need for inotropic agents indicates a poor prognosis. Patients with any level of eye opening, verbal responsiveness, and purposeful movement in response to stimuli (Glasgow Coma Scale ³ 7) in the emergency room usually have a full neurologic recovery. Coma persisting after emergency room management indicates an increased risk for poor outcome, but many exceptions occur. Thus, coma has limited prognostic value.

Initial cerebral protection studies of barbiturate-induced coma and controlled hypothermia in near-drowning suggested an improved outcome; however, subsequent studies did not confirm these results. These techniques cannot be recommended at the present time. Likewise, corticosteroids have no proven benefit.

The use of intracranial pressure (ICP) monitors in near-drowning cases also has declined in recent years. An ICP greater than 20 mmHg carries a poor prognosis. Lowering the elevated ICP below 20 mmHg and maintaining cerebral perfusion pressure ³50 mmHg does not improve poor neurologic outcome but may increase survival. A normal ICP initially does not assure favorable neurologic outcome. The ICP often rises by 48 to 72 hrs, reflecting edema from anoxic injury. Monitoring ICP deserves consideration in selected cases, but in most patients empirical therapy can be implemented without ICP monitoring.

Commonly accepted management of hypoxic cerebral injury consists of hyperventilation to a P_aCO_2 of 25 mm Hg to 30 mmHg, 30° elevation of the head (after exclusion of cervical injury), fluid restriction, and mannitol infusion of 0.25 to 0.5 mg/kg ideal body weight if blood pressure allows. Individual cases may require sedation, paralysis, or anticonvulsants.

Computed tomography of the head can be useful to exclude cranial trauma and to confirm cerebral edema (Fig. 3). Cranial trauma alters the clinical picture and may justify additional interventions. Diffuse cerebral edema implies global hypoxic injury (Fig. 3).

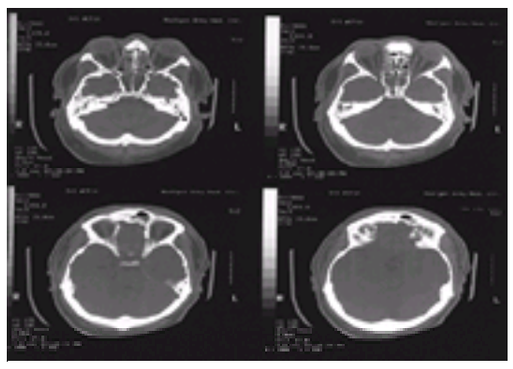

FIG. 3. Noncontrast cranial computed tomography of the patient with freshwater drowning. Note obliteration of the subarachnoid space and ventricles consistent with diffuse cerbral edema. Note also frontal and ethmoid sinus fluid density and air–fluid levels.

Computed tomography often reveals sinus opacification in near-drowning. Figure 3 reveals pansinus opacification in a case of salt-water near-drowning. Bland sinus fluid can become a source of fever later in the hospital course, particularly in the patient with nasally placed gastric tubes.

Acid–Base Disorders

Analysis of arterial blood samples generally does not occur before field resuscitation and transport to the emergency room. Severe acidemia would be expected before resuscitation because of the combination of respiratory and metabolic acidosis.

Initial arterial blood gas values obtained in the emergency room usually reflect therapeutic ventilatory support with metabolic acidosis and some degree of ventilatory compensation. Acid–base disturbances may include metabolic acidosis with incomplete respiratory compensation, combined metabolic and respiratory acidosis, or simple mild metabolic acidosis. Of note, acidosis has no particular prognostic value in near-drowning, even with pH well below 7.0.

Acid–base disorders may worsen after establishment of effective circulation. Reperfusion of ischemic tissue mobilizes lactic acid and increases carbon dioxide production. Subsequent arterial blood gases may reveal both worsening metabolic acidosis and higher P_aCO_2. Increased mechanical ventilation can compensate and should be attempted if high ventilator pressure can be avoided. Severe near-drowning injuries justify arterial catheters to monitor acid–base status and oxygenation.

Physicians may consider careful base augmentation therapy in the appropriate setting of adverse hemodynamics, maximum ventilatory support, and pH below 7.20. Unless acidosis persists, stable hemodynamics will gradually correct the disorder.

Mild cases of near-drowning may present with normal acid–base status or respiratory alkalosis. The degree of metabolic alkalosis depends on the degree of hypoxemia, anxiety, and other ventilatory stimuli.

Electrolyte Disturbances

Electrolyte disturbances occur commonly in near-drowning and may require medical management, particularly following salt-water near-drowning. In rare situations brackish waters like the Dead Sea can contribute to cardiac or systemic toxicity. Brackish waters can contain toxic amounts of divalent cations such as calcium and magnesium as well as sodium or potassium and cause specific toxicity.

Salt water consists of hypertonic concentrations of electrolytes: sodium 509 mEq/L, chloride 561 mEq/L, and potassium 11 mEq/L. Depending on the amount of salt water swallowed or aspirated, elevations of serum electrolytes can occur, resulting in hypernatremia, hyperchloremia, and hyperkalemia. Correction of hypernatremia should proceed gradually with frequent monitoring. Care should be take to avoid hyperglycemia, which may aggravate neuronal injury.

Freshwater near-drowning may lower serum sodium and chloride. These abnormalities seldom present a major clinical problem. Hypotonia in freshwater near-drowning usually responds to diuresis with normal saline replacement. Abnormalities of divalent cations may also accompany near-drowning.

Hemodynamic Complications

Near-drowning victims without hypothermia usually have normal or increased intravascular volumes and cardiac filling pressures initially. This results from swallowing and aspirating fluid. Empirical fluid administration should be avoided without hemodynamic monitoring for fear of worsening cerebral and pulmonary edema.

Later, fluid extravasation into the interstitial spaces may ensue because of systemic injury, an ominous development. Management of the patient in this situation becomes difficult because of multiple organ failure. Patients with hypothermia may present with volume contraction from diuresis.

Cardiac function can suffer from hypoxic injury initially but usually recovers with general support. Persistent need for inotropic agents has a poor prognosis. Cardiac enzymes can confirm myocardial injury. Virtually any arrhythmia can occur during resuscitation. Later, sinus tachycardia and other supraventricular arrhythmias prevail. Hypothermia can also produce characteristic ECG changes with prolongation of PR and QRS intervals, J-point elevation (Osborne waves), and cardiac dysrhythmias.

Systemic Complications

Near-drowning can produce abnormalities in other organ systems. Manifestations include renal insufficiency, coagulopathy, and hematologic abnormalities. Secondary pathophysiological processes contributing to these manifestations include disseminated intravascular coagulation, hemolysis, rhabdomyolysis, and systemic

inflammation.

Oxygen-carrying capacity remains largely intact in near-drowning. Near-normal values for red blood cell concentrations have been reported in several series. Freshwater hemolysis and salt water hemodilution do occur but have minor clinical effects on red cell mass in most cases.

Disseminated intravascular coagulation (DIC) may complicate freshwater near-drowning but not salt-water near-drowning. Bleeding diatheses, rather than thrombosis, result from DIC in most cases and may require fresh frozen plasma and platelet transfusion. Prolonged prothrombin and partial thromboplastin times and reduced platelet counts may signal the presence of DIC. Clinicians should routinely measure these values. D-dimer and fibrin split products will confirm DIC.

Near-drowning can cause acute renal failure from acute tubular necrosis. Mechanisms of injury may include hypoxemia, hemoglobinuria following hemolysis, myoglobinuria from rhabdomyolysis, or other endogenous toxin. Pigmenturia may be suspected from dark urine or, in less obvious cases, by a positive test for hemoglobin on dipstick without visible red blood cells on urinalysis. Red cell morphology or serum haptoglobin can suggest intravascular hemolysis. Urinary myoglobin and serum creatine phosphokinase (CPK) levels can confirm rhabdomyolysis with myoglobinuria. Alkalinizing the urine may merit consideration unless contraindications exist. Mild hypothermia can also affect renal tubular function and promote diuresis through nephrogenic diabetes insipidus.

Prognosis

Over 80% of patients hospitalized for near-drowning recover fully and return home. Approximately 10% of cases suffer permanent neurologic injury, and 10% die after admission. Occasional patients succumb from other complications despite neurologic recovery. No single variable can give 100% accuracy in prognosis. Coma in the first few hours cannot be relied on for individual prognosis but does indicate higher risk. Hypoxemia, acidosis, and electrolyte disturbances early in the course have no firm prognostic value. Prolonged submersion, prolonged CPR, and continuing need for inotropic support do indicate a poor prognosis.

Pulmonary injuries in near-drowning usually resolve with medical management, and neurologic injury dominates the picture for outcome. Pulmonary function testing after recovery generally reveals mild abnormalities mostly involving small airway function or bronchial airway hyperresponsiveness.

Summary

Near-drowning presents a spectrum from minimal aspiration to acute respiratory distress syndrome. Active management of pulmonary complications succeeds in most cases. Cerebral injury from anoxia is the most critical pathologic process and determines overall prognosis. Systemic organ injuries can occur, but these usually improve with medical support.

DIVING ACCIDENTS

Introduction

The term diving encompasses several techniques to safely submerge below the water surface (Table 4). These techniques include breath holding, SCUBA, surface-supplied, and saturation diving. Surface-supplied diving requires a high-pressure compressed-air conduit to a diving suit or mask. Saturation divers remain submerged for days to weeks and can enter and leave a submerged habitat.

Dive technique	Self-contained	Gas	Maximum working depth (fsw)[a]
Breath hold	Y	Air	100
SCUBA[b]			
Open system	Y	Air	130
Semiclosed	Y	32–60% O_2, N_2	150
Closed	Y	100% O_2	25
Surface-Supplied[c]			
Free flow	N	Air	200
Demand	N	16% O_2, He	300
Saturation[d]	N	O_2, He, N_2	1500

[a] Usual maximum working depth; fsw, feet of sea water.
[b] SCUBA, self-contained underwater breathing apparatus.
[c] Air supply tethered from the surface to the diver.
[d] Divers live under pressure in a deep diving chamber for days to weeks and work undersea.

TABLE 4. *Dive techniques and apparatus in common use*

In the last 20 years recreational diving has increased significantly in the United States, where diving enthusiasts number an estimated 3 to 5 million people. This rapid growth produces a steady influx of inexperienced divers. Diving accidents can occur even with adherence to accepted practices by both experienced and inexperienced divers.

Diving accidents result from environmental hazards, exposure to compressed gases, and changes of ambient pressures and volumes associated with both descent and ascent. Table 5 shows the pressure equivalents at common working depths. Because changes in pressure and volume affect the upper and lower respiratory tract, pulmonary physicians should be aware of the clinical syndromes that manifest as diving injuries. This section reviews breath-hold diving, gas-breathing disorders, descent injuries, ascent injuries, and fitness for diving.

Depth (fsw)[a]	PSIG[b]	PSIA[c]	ATA[d]	mm Hg	P_{N_2} (mm Hg)	P_{O_2} (mm Hg)
Sea level	0.0	14.7	1	760	600	160
33	14.7	29.4	2	1520	1200	320
66	29.4	44.1	3	2280	1800	480
99	44.1	58.8	4	3040	2400	640

[a] fsw, feet of sea water.
[b] PSIG, pounds per square inch gauge pressure.
[c] PSIA, pounds per square inch absolute pressure.
[d] ATA, absolute atmospheric pressure.

TABLE 5. *Pressure equivalents of various depths*

Breath-Hold Diving

Millions of people perform breath-hold dives for recreation in relatively shallow water for periods of less than 2 min. Some professional divers, such as the women divers of Japan and the pearl divers of the Tuamotu Archipelago, can dive to depths of 100 feet of seawater (fsw).

The most common medical problems associated with breath-hold diving consist of the upper respiratory tract descent injuries addressed below. Breath-hold divers often manifest the diving reflex and, occasionally, deep-water blackout, a maladaptive response.

The diving reflex accompanies breath-hold dives and immersion of the face in ice water. This reflex consists of apnea, peripheral vasoconstriction, and bradycardia, which raise systemic blood pressure and reduce cardiac output and O_2 consumption. The diving reflex may protect against hypothermia and permit increased bottom

time. Expression of the diving reflex varies considerably in humans. A variety of cardiac rhythms may accompany the diving reflex with no known significance.

Deep-water blackout results from the fall in P_aO_2 on ascent from a breath-hold dive. This maladaptive response has a similarity to shallow-water blackout (pg. 903) with the added dimension of ascent hypoxemia at the end of the dive. Dalton's law explains the pathophysiology of this phenomenon. According to Dalton's law, the partial pressure of a gas A (P_A) depends on barometric pressure and the fraction of gas A by volume: $P_A = P_B \times (\%A)$, where P_B equals barometric pressure and (%A) equals percentage of gas A by volume in the mixture.

At the beginning of the breath-hold dive, the partial pressures of oxygen, nitrogen, and carbon dioxide all increase as the barometric pressure increases with descent (Table 5). During breath-hold diving, alveolar oxygen tension tends to increase because of descent and to decrease as a result of oxygen consumption. At bottom, the P_aO_2 progressively falls because of oxygen consumption, but for a while the product of $P_B \times F_IO_2$ remains high enough to remain on bottom and suppress hypoxic drive to end the breath hold.

Breath-hold divers may hyperventilate before diving in order to lower initial P_aCO_2 and increase breath-hold time. This succeeds but also permits the P_aO_2 to decrease even lower before the urge to end breath hold. Ambient barometric pressure progressively falls as the diver ascends, and alveolar partial pressure of oxygen decreases proportionately. This can result in hypoxemic loss of consciousness and drowning. Most authorities recommend avoidance of hyperventilation before breath-hold swimming or diving.

Breath-hold divers do not normally experience pressure–volume injuries associated with ascent. Lung volumes decrease during descent in accordance with Boyle's law and can only reexpand to their original size.

Breathing Gas Disorders

Forms of diving other than breath holding utilize various combinations of inert gases and oxygen (Table 4). Some breathing gas disorders tend to occur during bottom time but can occasionally occur at other times. These include hypoxia, carbon monoxide poisoning, and carbon dioxide intoxication. Table 6 presents a differential diagnosis of loss of consciousness in divers. Some of these disorders are considered with descent or ascent injuries.

Cause	Usual time of occurrence after surfacing[a]	Phase of dive[a]	Comments
Breath-hold blackout	Before	Ascent	Without compressed air
Hypoxia	Before	Any	Equipment failure
Hypercapnia	Before	Bottom	Equipment failure
Oxygen toxicity (seizure)	Before	Bottom	
Carbon monoxide poisoning	<2 min	Ascent	Increased partial pressure of O_2 delays onset
Nitrogen narcosis	Before	Descent	May be sudden
Arterial gas embolism	<10 min	Ascent	>10 min unlikely
Decompression sickness	<6 hours	Ascent	LOC uncommon

[a]Exceptions may occur.

TABLE 6. *Differential diagnosis of loss of consciousness (LOC) in divers*

The most common cause of diving hypoxia consists of disconnection or depletion of the breathing gas supply. Another uncommon cause consists of a gas mixture with insufficient oxygen. Loss of consciousness because of lack of oxygen is the most common diving accident that results in death. Careful examination of the diving apparatus may reveal the cause of hypoxic loss of consciousness.

Carbon monoxide poisoning may result from contamination of a surface-supplied diver's air by exhaust from the air compressor or other engine entering the air intake system. Divers are usually protected during descent and at bottom by increased partial pressure of oxygen at depth. The symptoms of carbon monoxide poisoning therefore typically occur during ascent or at the surface. Divers may develop headache, nausea and vomiting, or more severe sequelae such as confusion, syncope, seizures, and loss of consciousness. Severe carbon monoxide poisoning should be treated with 100% oxygen initially, followed by recompression with hyperbaric oxygen. The diver's breathing gas should be tested for contamination.

Carbon dioxide intoxication results either from exposure to gases containing high concentrations or from retention as a result of inadequate ventilation by impaired equipment or respiratory function. With increasing levels of carbon dioxide, dyspnea and anxiety progress to impaired mental function and then loss of consciousness.

Merely surfacing will reverse mild to moderate hypoxemia and hypercapnia. In many cases a complete and reliable history may not be available. Divers with symptoms from any of these disorders at the surface should receive attention to airway, breathing, and circulation as well as 100% oxygen and consideration of recompression.

Injuries Associated with Descent

The remainder of the medical problems involving the respiratory tract can be divided into those that occur during descent or ascent. This division facilitates understanding the pathophysiology and clinical diagnosis of these entities.

Nitrogen Narcosis

Nitrogen narcosis occurs during descent to depths below 100 to 150 fsw with air breathing and becomes worse with increased depth. As mentioned earlier, according to Dalton's law, the partial pressures of all the breathed gases are increased. As the partial pressures of nitrogen and other inert gases increase, they penetrate the lipid layers of nerve cells and interfere with electrochemical transfer of signals at the synapses.

Narcosis or “rapture of the deep” may cause paresthesias, light-headedness, euphoria, overconfidence, and inability to reason. Mentation slows, resulting in memory and psychomotor impairment and even loss of consciousness (Table 6). Rapid recovery follows ascent to lesser depth. Experienced divers can develop tolerance, permitting air dives to 200 fsw.

High-Pressure Neurologic Syndrome

To overcome inert gas narcosis, divers use various mixtures of compressed gases. The most common mixture is 80% helium/20% oxygen (heliox). Helium has less lipid solubility and does not cause narcosis. With heliox, at depths greater than 500 fsw, divers can experience a different disorder with symptoms of extremity or body tremor, dizziness, nausea, vomiting, and seizure. The etiology is thought to be central nervous system hyperexcitation. The rate of descent correlates with the observation of this syndrome, and decreased rates of compression can negate the symptoms. Also, the addition of a small amount of nitrogen overcomes the features of high-pressure neurologic syndrome. Thus, trimix, the combination of helium, oxygen, and nitrogen, is used at extreme depths greater than 1000 fsw. Unfortunately some nitrogen narcosis can still occur.

Oxygen Toxicity

Recreational divers breathing compressed air seldom develop oxygen toxicity; however, some closed-circuit breathing systems use 100% O_2. The maximum depth of 100% O_2 systems is approximately 25 fsw. Divers who use mixed gases and saturation divers may become exposed to toxic levels of oxygen. Oxygen toxicity can also complicate recompression therapy. Studies of oxygen toxicities in animals and humans at increased atmospheric pressures have shown both pulmonary and central nervous system toxicities.

Pulmonary oxygen toxicity presumably results from the generation of oxygen free radicals. The resultant pulmonary pathology reveals diffuse alveolar damage and subsequent fibroproliferative changes. Divers with pulmonary oxygen toxicity may complain of substernal irritation or burning pain, cough, and dyspnea. The

appearance of symptoms is variable between individuals. Treatment consists of removal from hyperoxia and supportive care.

Divers may experience several signs and symptoms of central nervous system toxicity, which include constriction of vision, tinnitus, vertigo, facial twitching, tingling, syncope, and seizures. Seizures from oxygen toxicity are not dangerous by themselves, although in a diving environment they can precipitate a serious emergency. Oxygen toxicity should be avoided by proper attention to gas mixtures and pressure. Oxygen toxicity may be difficult to differentiate from other serious injuries. If more serious injury such as arterial gas embolism cannot be ruled out, the diver should be treated with recompression.

Upper Respiratory Tract Barotrauma

Injuries to the air-containing spaces of the auditory apparatus and paranasal sinuses are the most common conditions experienced by divers. Normally pressures in all the gas-containing spaces can be equalized to ambient pressure without resultant net change in volume. Failure to equalize pressure causes tissue injury.

Changes in pressure distort air-containing tissues until damage ensues. Boyle's law states that at constant temperature, the volume of a fixed mass of gas is inversely proportional to the pressure of the gas: $PV = K$, where P is absolute pressure, V is volume, and K is a constant. For example, if the pressure of gas is doubled, its volume is subsequently decreased by half.

Upper respiratory tract barotrauma includes external ear squeeze resulting from a tight-fitting wet suit hood, cerumen, otitis externa, or earplugs. Damage may include external ear canal hemorrhages and rupture of the tympanic membrane. Middle-ear squeeze occurs by failure of the eustachian tube to equalize pressure. The tympanic membrane may develop hemorrhage and rupture. Inner ear barotrauma can injure the round or oval window, causing perilymph fistula formation with hearing loss, tinnitus, and vertigo.

Paranasal sinus squeeze most frequently involves the frontal and maxillary sinuses as a result of obstruction of the ostia from mucus plugs, mucosal thickening, or infection. The mucosa hemorrhages, causing pain and epistaxis. Alternobaric vertigo can result from unilateral pressure differences between the middle and inner ear. This typically occurs during ascent but has been described on descent. Some divers may also experience unilateral facial paralysis from compression of air on the facial nerve as it courses near the middle ear.

Upper respiratory tract injuries usually respond to treatment with decongestants, antihistamines, and antibiotics for infection if present. Patients should refrain from diving until healing is complete. Bedrest, antiemetics, and occasionally surgery may be warranted for some of these complications.

Injuries Associated with Ascent

Pulmonary Pressure–Volume Injuries's

Boyle's law describes the pressure–volume effects of ascent and descent on air in the lungs. On ascent, the decreased pressure results in expanding volumes in the lungs. Overdistention of air spaces results in tissue injury. Normally divers continue to exhale throughout ascent, and this adequately vents excess alveolar volume. Mechanisms of pulmonary pressure/volume injury include any cause of breath holding during ascent or impedance to expiratory airflow. These causes include panic breath holding; buddy-breathing breath holding; laryngospasm, bronchospasm, or mucus plugging of the airways; pulmonary blebs and bullae; mucus impaction; coughing or forceful exhalation at low lung volume; uncontrolled ascent; and regulator malfunction.

Once the alveolus ruptures, gas escapes into the interstitial and perivascular spaces (Fig. 4). The air may be contained in the interstitium or dissect into the mediastinum, pericardium, subcutaneous tissue, retroperitoneum, or pleural space. With continued ascent, the volume of escaped gas can increase in size, causing further symptoms and signs. During ascent or within minutes of surface arrival, divers will complain of cough, chest pain, dyspnea, difficulty swallowing, hoarse voice, or hemoptysis. Table 7 presents a differential diagnosis of chest pain in the diver.

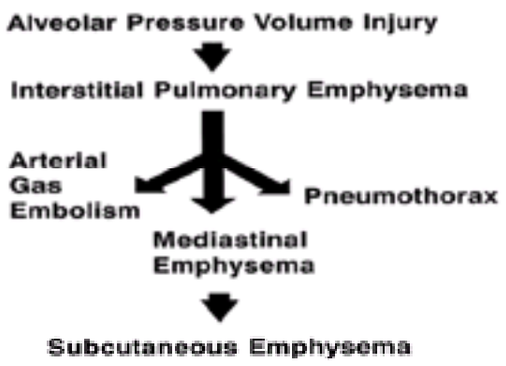

FIG. 4. Sequence of pressure–volume injury in the lung. Alveolar disruption leads to alveolar air entering the interstitial compartment of the lung. Further dissection of air proceeds along the path of least resistance. Entry of air into pulmonary veins leads to arterial gas embolism. Entry of air into the bronchovascular bundle produces mediastinal and subcutaneous emphysema. Exit of air from the interstitial space into the pleural space causes pneumothorax.

Cause	Phase of dive[a]	Comments
Pulmonary DCS[b]	Ascent	Usually accompanies other stigmata of DCS
Spinal cord DCS	Ascent	Back pain radiating to chest
Pulmonary O_2 toxicity	Bottom	Gradual onset; associated cough and dyspnea
Pneumomediastinum	Ascent	Subcutaneous crepitance
Pneumothorax	Ascent	May cause circulatory collapse
Myocardial ischemia	Any	Coronary artery disease
	Ascent	Arterial gas embolism
Hyperventilation syndrome	Any	Anxiety

[a]Exceptions may occur.
[b]DCS, decompression sickness.

TABLE 7. *Differential diagnosis of chest pain in divers*

Physical findings depend on the form of injury but may include subcutaneous crepitance, shifted trachea, distended neck veins, and absent breath sounds. Large symptomatic pneumothorax or tension pneumothorax should be treated with chest tube placement. Recompression will also decrease the size of the pneumothorax. A chest tube can be placed before decompression. If a patient with a chest tube needs recompression, the chest tube should be clamped during recompression and placed on suction during decompression.

Arterial Gas Embolization

Arterial gas embolization (AGE) constitutes the most serious form of pulmonary pressure–volume trauma. Air that escapes into the interstitium and perivascular space can also enter the pulmonary capillaries and travel to the left heart. The circulation then distributes the air systemically, most notably to the coronary and cerebral arteries. The air emboli obstruct flow, increase capillary permeability, and cause edema of surrounding tissues, disseminated intravascular coagulation, and hemoconcentration. Systemic hypertension results in increased cerebral blood flow and intracranial pressure. The latter also increases by vasogenic edema. Injury may be limited to the brain, although cardiac function usually decreases, and arrhythmias or cardiac arrest may occur.

Arterial gas embolization presents within 10 min of surfacing in over 90% of cases. Patients may present with loss of consciousness or cardiac arrest. More commonly, patients present with a wide variety of neurologic events including obtundation, seizures, vertigo, visual disturbances, headache, and sensory and motor changes.

Other features of AGE include marbling of the skin, retinal vessel emboli, and pallor of the tongue.

Treatment of AGE includes attention to the airway, breathing, and circulation. The patients should receive 100% O_2 and emergent recompression therapy. Patients with severe neurologic findings or inability to protect the airway should be intubated and hyperventilated to decrease intracranial pressure. The endotracheal tube cuff should be inflated with saline, a noncompressible material, rather than air to prevent air leak during recompression treatment.

Intravenous access should be obtained, but fluids should be administered sparingly to avoid increased intracranial pressure unless the patient has signs of obvious clinical volume depletion. Medications can include vasopressors to support hypotension and benzodiazepines for sedation and to control seizures. Patients should assume the supine position, and transport should be arranged by ground if possible or by low-flying or pressurized aircraft. The use of steroids remains controversial.

Decompression Sickness

Decompression sickness (DCS) consists of a multisystem disorder that results from nitrogen bubble formation when ambient pressure decreases after surfacing. It can occur in divers well within no-decompression guidelines or who have carefully followed decompression tables.

This phenomenon occurs as a result of Henry's law: the amount of gas that dissolves in a liquid at constant temperature is directly proportional to the partial pressure of that gas. During descent, while the diver is breathing compressed air, the alveolar partial pressures of nitrogen, oxygen, and carbon dioxide increase. The increased partial pressure of nitrogen dissolves more nitrogen in body tissues.

The depth and amount of time spent on a dive and solubility of nitrogen determine the maximum amount of gas that can be dissolved in tissues. Perfusion and tissue bulk also determine the amount of nitrogen being dissolved. Nitrogen dissolves rapidly in muscle but less so in bone and fat. The same rules apply when nitrogen leaves tissues on ascent. As a diver ascends, the ambient partial pressure of nitrogen also decreases. If ascent occurs too rapidly, nitrogen will form bubbles in body tissues.

Decompression sickness can usually be avoided by adhering to “no decompression” diving tables: a specified maximum bottom time for each depth. Repetitive dives within 12 hr require shorter bottom times because of residual nitrogen accumulation. Recreational divers should limit diving time to prevent DCS without need for decompression stops. Decompression sickness can occur in divers well within no-decompression limits or in those who have carefully followed decompression tables.

Deeper air divers and those using other mixed inert gases must ascend to a predetermined safe depth and wait to allow gases to exit tissues without bubble formation. Several decompression stops may be needed.

The bubbles can occupy interstitial, lymphatic, or intravascular spaces. They cause mechanical obstruction and compression as well as stimulating endothelial damage and hematologic abnormalities. Decompression sickness has historically been categorized into type I (joints pain and pruritus, only) and type II (other organs including CNS, lung, and heart) to distinguish mild from severe forms.

The symptoms of decompression sickness can occur immediately or most commonly 10 min to 6 hr after decompression. Symptoms appear within 24 hr after surfacing in 95% of cases. The classic presentation includes the “pain only” form, which affects the upper extremities more than the lower. The pain ranges from minimal to severe, and it is usually aggravated with movement and relieved with direct pressure. The pain may last hours and often subsides spontaneously.

The skin may be affected by marbling, rashes, and pruritus. The areas affected may be large or localized. Pruritus can be relieved with pressure. Marbling may be a sign of systemic involvement and should be treated with recompression. The lymphatics can become obstructed, resulting in edema and pain. Recompression will typically relieve pain.

The central nervous system may be affected in various forms. Bubbles frequently migrate to the white matter of the spinal cord and cause hemorrhages and degeneration. Divers may complain of back pain, although most commonly they note distal lower extremity paresthesias that spread proximally. Motor weakness may develop, and the gait may become unsteady. Bladder function may become impaired, and paraplegia soon follows. The brain can be affected less frequently with various manifestations such as vertigo, seizure, loss of consciousness, visual disturbances, and hemiplegia. Cranial nerves and the inner ear can also be affected, producing deafness, tinnitus, and vertigo.

Bubbles can form in tissues and embolize to the pulmonary circulation of the lung and give rise to increased pulmonary artery pressures, pulmonary edema, and hypoxemia. These patients complain of substernal chest pain, dyspnea, and cough.

Early recognition of DCS usually ensures survival and complete resolution of symptoms. Patients can be permanently disabled if not treated appropriately. Some patients have been successfully treated days after the onset of symptoms. Because the signs and symptoms can be subtle and confused with other less serious injuries, health care providers should err on the side of recompression treatment.

Treatment of DCS is similar to that for arterial gas embolism and includes prompt recompression and 100% O_2. Additionally, DCS victims are typically hemoconcentrated and intravascularly volume depleted secondary to third-space movement of fluids through permeable capillaries. They often have volume contraction and should be vigorously fluid resuscitated with normal saline, although pulmonary edema should be avoided. Use of dextran is no longer recommended because of the risk of fluid overload, renal failure, and anaphylaxis. Antiplatelet drugs and anticoagulants have no proven benefits for postinjury treatment. The Divers Alert Network [phone (919) 684-8111] can give advice for medical emergencies involving divers.

Air Travel After Diving

Recreational divers will frequently travel to exotic areas to dive, and many travel by air after diving. Some divers develop symptoms of decompression sickness during the air travel. Most commercial aircraft are pressurized to 5000 to 8000 feet, and this results in decreased ambient pressure. Subsequently, nitrogen may come out of solution causing decompression sickness. One study found asymptomatic intracardiac air bubbles in subjects flying at simulated altitudes of 9000 m at 12 and 24 hr after no-decompression dives. No adequate studies have established firm guidelines for air travel after diving, but most experts advise waiting 12 hr after no-decompression dives and 24 hr after decompression stop dives or multiple dives.

Medical Evaluation for Diving Fitness

All divers should obtain a physical examination before starting SCUBA diving and annually thereafter. The evaluation should focus on the use of medications as well as the upper and lower respiratory tracts, cardiovascular system, and central nervous system. Medical clearance to return to diving should be obtained following virtually any acute illness. Table 8 lists absolute and relative contraindications for fitness to dive. Some relative contraindications can be treated and relieved. Some absolute contraindications can be evaluated on a case-by-case basis.

Absolute contraindications	Relative contraindications
Pregnancy	Monomeric tympanic membrane
Active middle ear infection	Cholesteatoma
Poststapedectomy	Ear atresia/stenosis
Meniere's disease	Chronic otitis externa
Tracheostomy	Sinus obstruction
Osteomyelitis	Migraine headaches
Dental caries	Prior thoracic surgery
Poorly controlled asthma	Mild asthma
Exercise-induced asthma	History of pneumothorax
Cold air bronchospasm	Hypertension
COPD	Herniated nucleus pulposa
Active pulmonary infections and diseases	Medications
Cavitary lung diseases	Unilateral sensorineural hearing loss
Seizure disorders	
Coronary artery disease	
Prior arterial gas embolism	
Decompression sickness	
Insulin-dependent diabetes mellitus	
Sickle cell trait or disease	
Esophageal diverticulae	
Active ruptured tympanic membrane	

TABLE 8. *Fitness for diving: Recommended restrictions for common medical conditions*

The pulmonary evaluation should identify preexisting and occult pulmonary diseases that may lead to overinflation and decompensation during diving. Mass screening of divers with chest x-ray and pulmonary function testing seems unwarranted; however, any history of smoking, cough, dyspnea, asthma, pneumothorax, pneumonia, or other pulmonary disease warrants further investigation before clearance.

If history or physical examination suggest pulmonary abnormalities, clinicians should obtain pulmonary function tests, provocative tests for asthma, and chest x-ray. These still may not identify all patients at risk for injury. Physicians should avoid “clearing” divers to dive in shallow water only. The greatest change in volumes occurs in the first 33 feet of a dive.

Conclusion

Diving accidents represent medical complications with interesting manifestations and pathophysiology. These result mostly from the toxic effects of breathing gases and the physical properties of gas volumes under compression or decompression. A careful history can narrow the differential diagnosis considerably. Clinicians should consider recompression therapy for divers with loss of consciousness.

CHAPTER

47 Acute Respiratory Failure

John J. Marini · Laurel A. Wright

J.J. Marini and L.A. Wright: St. Paul Ramsey Medical Center, University of Minnesota, St. Paul, Minnesota 55101.

INTRODUCTION

The respiratory system's primary purpose is to provide fresh gas from the environment to the alveolus, where the capillary blood can exchange oxygen for carbon dioxide across a thin gas-permeable membrane. Provision of oxygen is fundamental to sustaining aerobic metabolism, while carbon dioxide elimination, acting through the bicarbonate buffer system, helps maintain pH homeostasis.

Respiratory failure may be thought of as a problem in one or more of the steps necessary to sustain oxygen availability for mitochondrial energy production. Dysfunction of the respiratory system may occur in ventilation (the movement of gases between the environment and the lungs), in intrapulmonary gas exchange (the process in which mixed venous blood releases CO_2 and becomes oxygenated), in gas transport (the delivery of adequate quantities of oxygenated blood to the metabolizing tissue), or in tissue gas exchange (the extraction or utilization of O_2 and release of CO_2 by the peripheral tissues). The latter two steps in this process may fail independently of the performance of the lung or ventilatory pump.

This discussion examines one primary manifestation of acute respiratory insufficiency—oxygenation failure. The aim is to describe an approach to management that flows from an understanding of the underlying pathophysiology. Ventilatory failure, the second major manifestation of acute respiratory insufficiency, is discussed in Chapter 43 and Chapter 50.

OXYGENATION FAILURE

Definitions

Tissue O_2 delivery, also known as O_2 transport (DO_2), depends not only on the partial pressure of arterial oxygen (P_aO_2) but also on nonpulmonary factors—cardiac output (Q_T), hemoglobin (Hgb) concentration, and the ability of Hgb to take up and release O_2: $DO_2 = Q_T \times C_aO_2$, and $C_aO_2 = 1.36$ (Hgb) $S_aO_2 + 0.003$ (P_aO_2). Cardiogenic shock, anemia, and carbon monoxide poisoning provide clinical examples of O_2 transport failure. Laboratory abnormalities characteristic of such conditions are lactic acidosis and reduced O_2 content of mixed venous blood (even in the face of adequate arterial oxygen tension).

Failure of O_2 uptake refers to the inability of tissue to extract and utilize O_2 for aerobic metabolism. The clearest clinical examples of a derangement in this terminal phase of the oxygen transport chain are cyanide poisoning, in which cellular cytochromes (key enzymes in the electron transport process) are inhibited, and septic shock. During sepsis there is failure of an often generous cardiac output to distribute appropriately and/or an inability of the tissues themselves to make use of the O_2 available. Unlike transport insufficiency, failure of tissue uptake is distinguished by normal or high values for mixed venous oxygen tension, saturation, and content. Thus, some indices that are helpful in other forms of oxygenation failure, i.e., cardiac output, arterial O_2 tension, and mixed venous O_2 saturation (S_vO_2), may not reflect impaired tissue O_2 uptake; lactic acidosis may be the sole laboratory indicator. Therapy directed at failure of the O_2 transport and uptake mechanisms is discussed in detail elsewhere. The present discussion focuses on the problems that bear on the performance of the lung in oxygenating the arterial blood.

MECHANISMS OF ARTERIAL HYPOXEMIA

Six mechanisms may contribute to arterial oxygen desaturation (Table 1):

Low inspired F_IO_2
Hypoventilation
Impaired diffusion
V/Q mismatching
Shunt
Desaturated mixed venous blood[a]

[a] In the presence of other mechanisms for hypoxemia.

TABLE 1. *Mechanisms ofarterial hypoxemia*

1. Inhalation of a hypoxic gas mixture or severe reduction of barometric pressure.
2. Hypoventilation.
3. Impaired alveolar diffusion of oxygen.
4. Ventilation/perfusion *(V/Q)* mismatching.
5. Shunting of systemic venous blood to the systemic arterial circuit.6. Abnormal desaturation of systemic venous blood.

Low Inspired Oxygen Fraction

A decrease in the partial pressure of inhaled oxygen occurs in toxic fume inhalation, in fires that consume O_2 in combustion, and at high altitude because of reduced barometric pressure.

Hypoventilation

Hypoventilation causes the partial pressure of alveolar oxygen (P_AO_2) to fall when alveolar oxygen is not replenished quickly enough in the face of its ongoing removal by the blood. Although the arterial partial pressure of oxygen (P_aO_2) may fall much faster than P_aCO_2 rises during the initial phase of hypoventilation or apnea, the steady-state concentration of P_AO_2 is predicted by the alveolar gas equation:

$$P_AO_2 = P_IO_2 - P_aCO_2/R$$

In this equation, P_IO_2 is the partial pressure of inspired oxygen at the tracheal level (corrected for water vapor pressure at body temperature), and R is the respiratory exchange ratio, i.e., the ratio of CO_2 production to oxygen consumption at steady state. This value usually approximates 0.8. since normally the rate of oxygen consumed by the tissues exceeds that at which CO_2 is produced. Transiently, however, R can fall to very low values as oxygen is taken up faster than CO_2 is delivered to the alveolus. Such a mechanism explains posthyperventilation hypoxemia and hypoxemia that accompanies hemodialysis across membranes that remove CO_2.

Impaired Diffusion

Impaired oxygen diffusion prevents complete equilibration of alveolar gas with pulmonary capillary blood. Although this mechanism has uncertain clinical importance, many factors that adversely influence diffusion are encountered clinically: increased distance between alveolus and erythrocyte, decreased O_2 gradient for diffusion, and shortened transit time of the red cell through the capillary (high cardiac output with limited capillary reserve).

Ventilation/Perfusion Mismatching

Ventilation/perfusion *(V/Q)* mismatching is the most frequent contributor to clinically important O_2 desaturation. Lung units that are poorly ventilated in relation to perfusion cause desaturation; high-*V/Q* units contribute to physiological deadspace but not to hypoxemia. The relationship of O_2 content (C_aO_2) to P_aO_2, like that of P_aO_2 and hemoglobin saturation, is curvilinear. At normal barometric pressure, little additional O_2 can be loaded onto blood with already saturated Hgb, no matter how high the O_2 tension in the overventilated alveolus may rise. Because samples of blood exiting from different lung units mix gas contents (not partial pressures), overventilating some units in an attempt to compensate for others that are underventilated does not maintain P_aO_2 at a normal level. Hence, when equal volumes of blood from well-ventilated and poorly ventilated units mix, the blended sample will have an O_2 content halfway between them but a P_aO_2 disproportionately weighted toward that of the lower-*V/Q* unit. Even though total V_E and Q may be absolutely normal, regional *V/Q* mismatching will cause P_aO_2 to fall.

Supplemental O_2 will reverse hypoxemia when *V/Q* mismatching, hypoventilation, or diffusion impairment is the cause. (The P_AO_2 of even poorly ventilated units climbs high enough to achieve full saturation.) After a sufficient period of time has been spent breathing 100% O_2, only perfused units that are totally unventilated (shunt units) contribute to hypoxemia. However, when hypoxemia is caused by alveolar units with very low *V/Q* ratios, relatively concentrated O_2 mixtures must be given before a substantial change in the P_aO_2 is observed.

Shunting

The term *shunt* refers to the percentage of the total systemic venous blood flow that bypasses the gas-exchanging membrane and transfers venous blood unaltered to the systemic arterial system. Changes in F_IO_2—either upward or downward—have very little influence on P_aO_2 when the true shunt fraction, as measured on pure oxygen, exceeds 30% (Fig. 1). In contrast, venous admixture of similar magnitude is variably responsive to the extent that low-*V/Q* units account for the hypoxemia. Shunting can be intracardiac, as in cyanotic right-to-left congenital heart disease, opening of a patent foramen ovale because of right ventricular overload, or result from passage of blood through abnormal vascular channels within the lung, e.g., pulmonary arteriovenous communications. However, by far the most common cause of shunting is pulmonary disease characterized by totally unventilated lung units that cannot respond to oxygen therapy. After an extended exposure to an F_IO_2 of 1.0, all alveoli that remain open are filled with pure oxygen. Hence, the percentage of shunt can be calculated from the formula:

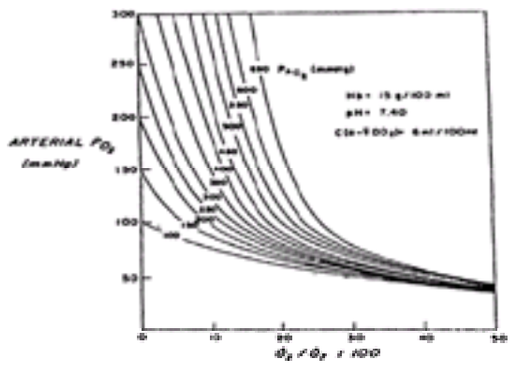

FIG. 1. Relationship of arterial oxygen tension (P_aO_2) to true shunt fraction (Q_S/Q_T) for a range of alveolar oxygen tensions (P_AO_2) that are achieved by varying fractions of inspired oxygen (F_IO_2) from room air to pure oxygen. Variations of F_IO_2 exert negligible effects on P_AO_2 when true shunt exceeds 30%. (Reprinted with permission from Pontoppidan et al. Acute respiratory failure in the adult. *N Engl J Med* 1972;287:743–752.)

$$Q_S/Q_T = [(C_cO_2 - C_aO_2)/(C_cO_2 - C_vO_2)] \times 100$$

In this equation, *C* denotes content, and the lower case subscripts *c, a,* and *v* denote end-capillary, arterial, and mixed venous blood, respectively. In making such calculations, end-capillary and calculated alveolar oxygen tensions are assumed equivalent. For a patient breathing pure O_2, shunt fractions <25% can be estimated rapidly by dividing the alveolar-to-arterial O_2 tension difference (»670 – P_aO_2) by 20, assuming also that the P_aCO_2 and C_vO_2 are normal. Note that some absorption atelectasis may occur in very low-*V/Q* areas when pure oxygen is breathed, adding to the measured shunt. In the clinical setting, however, the magnitude of this artifact is usually small.

At inspired oxygen fractions less than 1.0, true shunt cannot be estimated reliably by an analysis of oxygen contents, but venous admixture or physiological shunt can. (Note: many authors refer to a venous admixture from any cause as “shunt.”) Any degree of arterial O_2 desaturation can be considered as if it all originated from true shunt units. To calculate venous admixture, C_cO_2 in the shunt formula is estimated from the ideal alveolar PO_2 at that particular fraction of inspired oxygen (F_IO_2).

Many indices have been devised in an attempt to characterize the efficacy of oxygen exchange across the spectrum of F_IO_2. Although no index is completely successful, the P_aO_2/P_AO_2 ratio and the alveolar-to-arterial oxygen tension difference $D(A\text{-}a)O_2$ are often utilized. Both, however, are affected by changes in S_vO_2, even when the lung tissue itself retains normal ability to transfer oxygen to the blood. Another imprecise but commonly used indicator of gas exchange is the P_aO_2/F_IO_2 ratio (the “*P/F*” ratio). In healthy adults, this ratio normally exceeds 400, whatever the F_IO_2 may be. Hypoventilation and changes in the inspired O_2 concentration minimally alter these ratios in the absence of F_IO_2-related absorption atelectasis or cardiovascular adjustments. Whatever index is employed, it should be emphasized that the end-expiratory lung volume and mean alveolar pressures can exert a profound influence. For this reason, many centers utilize an oxygenation index that incorporates

the mean airway pressure when assessing the efficiency of transpulmonary O_2 transfer under conditions of controlled mechanical ventilation.

Abnormal Desaturation of Systemic Venous Blood

The admixture of abnormally desaturated venous blood is an important mechanism acting to lower P_aO_2 in patients with impaired pulmonary gas exchange and reduced cardiac output. C_vO_2, the product of Hgb concentration and S_vO_2, is influenced by cardiac output (Q), arterial oxygen saturation (S_aO_2), and oxygen consumption (VO_2):

$$S_vO_2 \approx S_aO_2 - [VO_2/(\text{Hgb} \times Q)]$$

It is clear from this equation that S_vO_2 is directly influenced by any imbalance between VO_2 and oxygen delivery. Thus, anemia uncompensated by an increase in cardiac output or a cardiac output too low for metabolic needs can cause both S_vO_2 and P_aO_2 to fall when the venous admixture percentage is abnormal.

Fluctuations in S_vO_2 exert a more profound influence on P_aO_2 when the shunt is fixed, as in *regional* lung diseases (e.g., atelectasis), than when the shunt varies with changing cardiac output, as it tends to do in diffuse lung injury (ARDS) (Fig. 2). Even when S_vO_2 is abnormally low, P_aO_2 will remain unaffected if all mixed venous blood gains access to well-oxygenated, well-ventilated alveoli. A marked decline in S_vO_2 without arterial hypoxemia occurs routinely during heavy exercise in healthy subjects. Thus, abnormal *V/Q* matching or shunt is necessary for venous desaturation to be a contributing mechanism in hypoxemia.

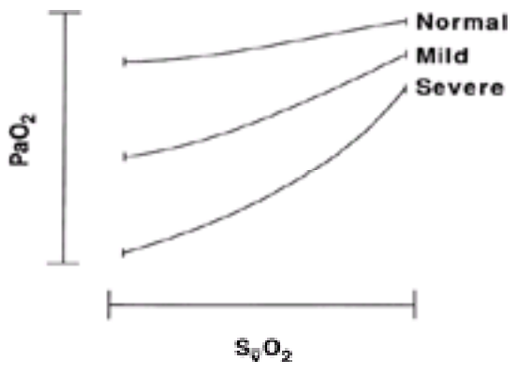

FIG. 2. Influence of mixed venous oxygen saturation (S_vO_2) on P_aO_2 in patients with mild and severe lung disease. Variations in S_vO_2 related to an oxygen consumption/delivery imbalance have minimal effects on P_aO_2 in normal subjects but may profoundly affect P_aO_2 in patients with extensive lung disease. COMMON CAUSES OF HYPOXEMIA

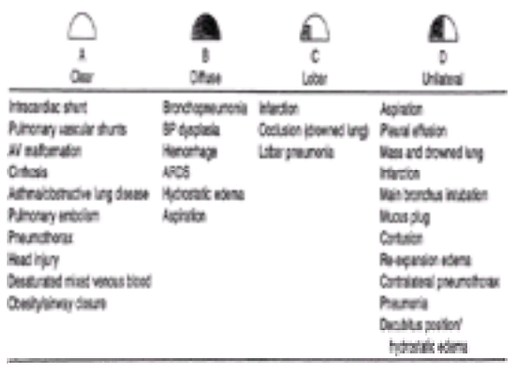
Oxygenation crises are conveniently categorized by their radiographic appearances, which give important clues to the appropriate management approach. Lung collapse (atelectasis), diffuse or patchy parenchymal infiltration, hydrostatic edema, localized or unilateral infiltration, and a clear chest x-ray (CXR) are common patterns (Fig. 3).



Clear	Diffuse	Lobar	Unilateral
Intracardiac shunt	Bronchopneumonia	Infarction	Aspiration
Pulmonary vascular shunts	BP dysplasia	Occlusion (drowned lung)	Pleural effusion
AV malformation	Hemorrhage	Lobar pneumonia	Mass and drowned lung
Cirrhosis	ARDS		Infarction
Asthma/obstructive lung disease	Hydrostatic edema		Main bronchus intubation
Pulmonary embolism	Aspiration		Mucus plug
Pneumothorax			Contusion
Head injury			Re-expansion edema
Desaturated mixed venous blood			Contralateral pneumothorax
Obesity/airway closure			Pneumonia
			Decubitus position/ hydrostatic edema

FIG. 3. Classification of oxygenation failure by radiographic pattern. (Reprinted with permission from Marini JJ, Wheeler AP. *Critical care: the essentials,* 2nd ed. Baltimore: Williams & Wilkins, 1997.)

Atelectasis

Variants of Atelectasis

There are several morphologic types and mechanisms of atelectasis. Regional microatelectasis spontaneously develops in a healthy lung during shallow breathing when it is not periodically stretched beyond its usual tidal range. Plate-like atelectasis may be an exaggeration of this phenomenon caused by regional hypodistention (i.e., pleural effusion or impaired diaphragmatic excursion). Both micro- and plate-like atelectasis occur most commonly in dependent regions. Lobar collapse usually results from gas absorption in an airway plugged by retained secretions, a misplaced endotracheal tube, or a central mass. External bronchial compression and regional hypoventilation are important in some patients. Micro- and plate-like atelectasis occur routinely in patients at prolonged uninterrupted bed rest and in postoperative patients who have undergone upper abdominal incisions.

Potential consequences of acute atelectasis are worsened gas exchange, pneumonitis, and increased work of breathing. The P_aO_2 drops precipitously to its nadir within minutes to hours of a sudden bronchial occlusion, but it then improves steadily over hours to days as hypoxic vasoconstriction and mechanical factors increase pulmonary vascular resistance through the local area. Whether an individual patient manifests hypoxemia depends heavily on the vigor of the hypoxic vasoconstrictive response, the abruptness of collapse, and the tissue volume involved. If small areas of atelectasis develop slowly, hypoxemia may never surface as a clinical problem.

Diffuse microatelectasis may be radiographically silent but detectable on physical examination by dependent (posterior or basilar) end-inspiratory rales that improve after several sustained deep breaths (“sighs”) or coughs. Plate atelectasis yields similar physical findings plus tubular breath sounds and egophony over the involved area. Lobar atelectasis gives a dull percussion note and diminished breath sounds if the bronchus is occluded by secretions but tubular breath sounds and egophony if the central airway is patent. (The latter findings correlate well with the presence of air bronchograms on CXR.) Plate atelectasis most frequently develops at the lung base above a pleural effusion or above a raised, splinted, or immobile hemidiaphragm. Lobar atelectasis most commonly occurs in patients with copious airway secretions and limited power to expel them. Acute upper lobe collapse is less common and tends to resolve quickly because of comparatively good gravitational drainage. Collapse of the left lower lobe is more frequent than collapse of the right lower lobe, perhaps because of its retrocardiac position and its smaller-caliber, sharply angulated bronchus. Lobar atelectasis may be complete or partial, but in either case it is radiographically recognized by opacification, displaced fissures, compensatory hyperinflation of surrounding tissue, and obliterated air–soft tissue boundaries. Small amounts of pleural fluid are a natural concomitant of lobar collapse and do not necessarily signify an additional pathologic process.

Management of Atelectasis

Prophylaxis

Effective prevention of atelectasis in high-risk patients counteracts shallow breathing and improves secretion . Obesity, chronic bronchitis, secretion retention, neuromuscular weakness, pain, and advanced age are predisposing factors. Atelectasis is to be expected whenever the patient is prevented from taking a deep breath by pain, splinting, or weakness. Upper abdominal, thoracic, and lower abdominal incisions are associated with the highest incidence of postoperative atelectasis (in that order). Preoperatively, the airways should be maximally dilated and free of infection. Postoperatively, patients should be encouraged to breathe deeply, to sit upright, and to cough vigorously. Pain should be relieved, but alertness preserved. Frequent turning and early mobilization are among the most important prophylactic maneuvers. Continuous positive airway pressure (CPAP) may be helpful, especially in intubated patients. Respiratory therapy (RT) techniques such as airway suctioning, incentive spirometry, and chest physiotherapy are prophylactically (as well as therapeutically) effective in well-selected patients.

Treatment

Whenever possible, mobilization is the best treatment. Periodic deep breathing effectively reverses plate and microatelectasis. Sustained deep breaths are particularly effective. Whether a higher lung volume is achieved by positive airway pressure or by negative pleural pressure is immaterial, assuming that a similar extent and distribution of distention occurs in both cases. Although rational, the place of positive end-expiratory pressure in treatment of *established* collapse has not been clarified. Relief of chest wall pain helps to reduce splinting and enables more effective coughing. Intercostal nerve blocks with anesthetic agents such as bupivacaine may be effective for 8 to 12 hrs. Intrapleural instillation of lidocaine or bupivicaine (via catheter) can occasionally be effective, but pleural anesthesia may induce temporary ipsilateral diaphragmatic paralysis. Epidural narcotics may also be effective in certain settings. Retained secretions must be dislodged from the central airways. In the unintubated patient, effective bronchial hygiene is inconsistently accomplished with blind tracheal suctioning alone. Pharyngeal airways certainly help, but they are not well tolerated in awake patients and are not intended for extended care. Vigorous respiratory therapy initiated soon after the onset of lobar collapse can reverse most cases of atelectasis secondary to airway plugging within 24 to 48 hrs. As a general rule, fiberoptic bronchoscopy should be reserved for patients with symptomatic lobar collapse who lack central air bronchograms and who cannot undergo (or fail to respond to or tolerate) 48 hrs of vigorous respiratory therapy (external chest physiotherapy, internal percussive ventilation at pulmonary resonant frequency, etc.). Even whole-lung collapse usually merits at least one respiratory therapy treatment before bronchoscopy is performed. After reexpansion, a prophylactic respiratory therapy program should be initiated to prevent recurrence. Adjunctive measures (e.g., bronchodilators, hydration, and frequent turning) should not be ignored.

Diffuse Pulmonary Infiltration

When fluid or cellular infiltrates cause alveolar flooding or collapse, severe refractory hypoxemia may result. Fluid confined to the interstitial spaces may cause hypoxemia as a result of peribronchial edema, *V/Q* mismatching, and microatelectasis; however, interstitial fluid itself does not interfere with oxygen exchange. Very few processes are confined exclusively to the air spaces or to the interstitium. Radiographic signs of alveolar filling include segmental distribution, coalescence, fluffy margins, air bronchograms, rosette patterns, and silhouetting of normal structures. A diffuse infiltrate is said to be largely interstitial if these signs are largely absent and the infiltrate parallels the vascular distribution. Any diffuse interstitial process will appear more radiodense at the bases than at the apices, in part because there is more tissue to penetrate and because vascular engorgement tends to be greater there. Alveoli are also less distended at the bases, so the ratio of aerated volume to total tissue volume declines.

The major categories of acute disease that produce diffuse pulmonary infiltration and hypoxemia are pneumonitis (infection and aspiration), cardiogenic pulmonary edema, intravascular volume overload, and the acute respiratory distress syndrome (ARDS). From a radiographic viewpoint, these processes may be difficult to distinguish; however, a few characteristic features are helpful.

Hydrostatic Edema

Perihilar infiltrates (sparing the costophrenic angles), a prominent vascular pattern, and a widened vascular pedicle suggest volume overload or incipient cardiogenic edema (Fig. 4). A gravitational distribution of edema is highly consistent with well-established left ventricular failure (or long-standing severe volume overload), especially when accompanied by cardiomegaly and a widened vascular pedicle. Patchy peripheral infiltrates that lack a gravitational predilection and show reluctance to change with position suggest ARDS. Interestingly, septal (Kerley) lines and distinct peribronchial cuffing are very seldom seen in classical ARDS. On the other hand, prominent air bronchograms are quite unusual with hydrostatic etiologies but occur commonly in permeability edema (ARDS) and pneumonia.

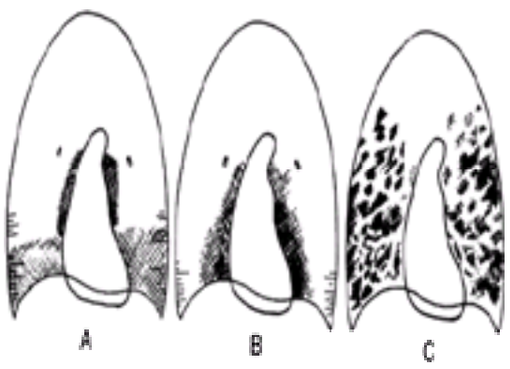


FIG. 4. Radiographic patterns in patients with impaired oxygenation as a result of congestive heart failure **(left),** vascular congestion caused by volume overload **(middle)**, and acute respiratory distress syndrome **(right)**. Kerley lines, widened vascular pedicle, costophrenic angle sparing, blurred hilar structures, and paucity of air bronchograms help distinguish congestive heart failure from ARDS. (Reprinted with permission from Milne et al. *Am J Roentgenol* 1985;144:879–894.)

Variants of Hydrostatic Edema

Hydrostatic edema (high-pressure edema, HPE) may occur in multiple settings that have different implications for prognosis and treatment. The most familiar form of HPE accompanies left ventricular failure. In this setting, signs of systemic hypoperfusion and inadequate cardiac output often accompany oxygenation failure. However, HPE can develop even with a normally well-compensated ventricle during transient heart dysfunction (ischemia, hypertensive crisis, arrhythmias). When the myocardium fails to relax fully during diastole (“diastolic dysfunction”), superimposed loading or temporary disturbances of left heart contractility (e.g., ischemia), mitral valve functioning, or heart rate or rhythm may cause rapid, transient alveolar flooding known as “flash pulmonary edema.” In this setting, extensive radiographic infiltrates may both develop and resolve with impressive speed.

Acute Lung Injury and Acute Respiratory Distress Syndrome

The acute respiratory distress syndrome (ARDS) was originally called *adult* respiratory distress syndrome. In current parlance, acute lung injury is the general term that refers to all degrees of radiographically apparent, diffuse hypoxemic lung injury. The ARDS is the most severe form of acute lung injury. Acute respiratory distress syndrome is an imprecise term, often applied to any acute diffuse parenchymal infiltration associated with severe hypoxemia and not attributable to HPE. However, the ARDS designation is most useful when restricted to acute noncardiogenic pulmonary edema with certain characteristic features:

1. Delay between the precipitating event and the onset of dyspnea.
2. Impaired respiratory system compliance.
3. Markedly reduced aerated lung volume.
4. Refractory hypoxemia.
5. Delayed resolution.

The pathogenesis of permeability edema is almost certain to vary with the inciting event. Despite its many diverse causes, sepsis, aspiration, and multiple trauma account for the vast majority of cases. The core pathophysiology of ARDS is sufficiently similar to warrant a common treatment approach. A prominent feature of all forms of ARDS is injury to the alveolar–capillary membrane from either the gas side (e.g., smoke inhalation, aspiration of gastric acid) or the blood side (e.g., sepsis, fat embolism). Increased membrane permeability allows seepage of protein-rich fluid into the interstitial and alveolar spaces. Such fluids inhibit surfactant, contributing to widespread atelectasis. Although wedge pressure usually remains normal, increased pulmonary vascular resistance and some degree of pulmonary hypertension are almost invariable in the latter stages of severe disease. Extreme pulmonary hypertension is a very poor prognostic sign. Diffuse pulmonary infiltration with a normal wedge pressure can be seen in other problems, such as flash pulmonary edema and partially treated heart failure. Apart from any difference in capillary pressure,

permeability edema differs from hydrostatic edema in that it resists clearance by diuretic therapy and initiates a cellular inflammatory response that may require weeks to recede and even longer to heal.

Rapidly Resolving Noncardiogenic Edema

A few disorders that fall loosely under the heading of ARDS are worth noting because of their fundamentally different pathophysiology and clinical course. In certain settings, transient disruption in the barrier function of the pulmonary capillary can occur without overt endothelial damage. Neurogenic and heroin-induced pulmonary edema, for example, are two problems in which a transiently elevated pulmonary venous pressure is believed to open epithelial tight junctions, forcing extravasation of proteinaceous fluid. However, resealing and resolution of edema occur promptly without widespread endothelial damage or protracted inflammation. A similar process may be seen in settings such as severe metabolic acidosis and cardiopulmonary resuscitation. From the alveolar side, certain inhalational injuries (e.g., limited chlorine gas or ammonia exposure) can produce a dramatic initial picture, only to clear rapidly over a brief period.

Hypoxemia with a Clear Chest X-Ray

It is not uncommon for patients to present with life-threatening hypoxemia without major radiographic evidence of infiltration. In such cases, occult shunting and severe *V/Q* mismatching are the most likely mechanisms (Table 1). Intracardiac or intrapulmonary shunts, asthma and other forms of airway obstruction, low lung volume superimposed on a high closing capacity (i.e., bronchitis in a supine obese patient), pulmonary embolism, and occult microvascular communications (such as occur in patients with cirrhosis) are potential explanations. Hypoxemia is amplified by profound desaturation of mixed venous blood, by reversal of hypoxic vasoconstriction with therapeutic vasoactive agents (i.e., nitroprusside, calcium channel blockers, and dopamine), and by the severe *V/Q* imbalance consequent to acute head injury. (Acute oxygenation crises following head trauma has been termed “nonedematous respiratory distress syndrome,” NERDS).

Unilateral Lung Disease

Unilateral infiltration or marked asymmetry of radiographic density suggests a confined set of etiologic possibilities, most of which occur in highly characteristic clinical settings (Fig. 3). Marked asymmetry of radiographic involvement should prompt an especially careful search for an unaddressed and readily reversible cause of hypoxemia. In some cases, especially pneumonitis or airway plugging, precautions (i.e., positioning, careful airway suctioning) should also be taken against generalization of the process.

Techniques to Improve Tissue Oxygenation

Basic Therapeutic Principles

Although atelectasis, fluid overload, and infection (Table 2) often yield to specific measures, the treatment of diffuse lung injury remains largely supportive. The primary therapeutic aims are to maintain oxygen delivery, to relieve an excessive breathing workload, and to establish electrolyte balance while preventing further damage from oxygen toxicity, barotrauma, infection, and other iatrogenic complications. To these ends, the clinician should bear in mind a few fundamental principles.

Increase F_{IO_2}
Increase mean lung volume and alveolar pressure
PEEP/Auto-PEEP
Extend inspiratory time fraction
Decubitus, upright, or prone positioning
Bronchodilation
Improve O_2 delivery/consumption ratio
Reduce O_2 requirements
Work of breathing
Fever
Agitation
Increase cardiac output
Increase hemoglobin
Remove pulmonary vasodilators (e.g., nitroprusside)
Consider adjunctive support
Vibration
Nitric oxide or inhaled prostacyclin

TABLE 2. *Techniques to improve tissue oxygenation*

Minimize the Risk/Benefit Ratio

Positive airway pressure, oxygen, and vasoactive drugs are potentially injurious. Therefore, there should be frequent reassessment of the need for current levels of positive end-expiratory pressure (PEEP), F_IO_2, and use and intensity of ventilator support. An oxygen saturation of 85% may be acceptable if the patient has adequate oxygen-carrying capacity and circulatory reserve without signs of oxygen privation (e.g., lactic acidosis cardiac ischemia, arrythmia, and cerebral dysfunction). On the other hand, a reduced O_2 saturation may stimulate ventilatory drive and increase dyspnea in a patient with ventilatory insufficiency. Allowing P_aCO_2 to climb slowly (buffering pH, if necessary, with $NaHCO_3$) may minimize the ventilatory requirement and reduce the risk of barotrauma. Mean intrathoracic pressure can be reduced by allowing the patient to provide as much ventilatory power as possible, compatible with ventilatory capability and comfort.

Prevent Therapeutic Accidents

Patients should be kept under direct observation at all times by well-trained personnel prepared to intervene appropriately, 24 hrs per day. Paralyzed patients must be watched with special care, as ventilation is totally machine-dependent. Furthermore, the hands must be restrained in semiconscious, agitated, confused, or disoriented patients who receive mechanical ventilation; abrupt ventilator disconnections and extubations can produce lethal bradyarrhythmias, hypoxemia, asphyxia, or aspiration. Special caution is warranted in orally intubated patients, who tend to self-extubate readily. In the setting of pulmonary edema, the interruption of PEEP for even brief periods (suctioning, tubing changes) may cause profound, slowly reversing desaturation as lung volume falls and the airways rapidly flood with edema fluid. The stomach should be decompressed in most recently intubated patients who demonstrate air swallowing or ileus. In mechanically ventilated patients, the clinician must stay alert to the possibility of tension pneumothorax, especially in patients with radiographic evidence of pneumomediastinum or subcutaneous emphysema. Because of the very high incidence of tissue rupture, prophylactic chest tubes may be indicated for patients who form tension cysts that evolve on serial films.

Optimize Extrapulmonary Management

Intravascular volume must be carefully regulated. Although excessive administration of fluids must clearly be avoided to minimize lung water and improve oxygen exchange, severe fluid restriction may compromise perfusion of gut and kidney. Appropriate levels of nutritional support and prophylaxis for deep venous thrombosis, skin breakdown, and gastric stress ulceration should be considered for all mechanically ventilated or immobile patients.

The routine early use of corticosteroids is not justified; adverse changes in immunity, mental status, metabolism, and protein wastage tend to outweigh any potential therapeutic benefit in the first week of the course. Acute respiratory distress syndrome caused by known vasculitis, fat embolism, or allergic reactions may be exceptions to this rule. Corticosteroids may also be life saving in certain steroid-responsive diseases that mimic ARDS (i.e., bronchiolitis obliterans with organizing pneumonia, pulmonary hemorrhage syndromes, *Pneumocystis carinii* pneumonia). Moreover, under such life-threatening circumstances, adrenal insufficiency occurs with certain frequency; if the presentation is compatible, this problem should be pursued diagnostically and stress doses of hydocortisone given. Corticosteroids may also help resolution in the fibroproliferative stage of this illness, but there is no firm consensus on this point. Ibuprofen appears to hold promise in blocking some of the systemic manifestations of inflammation, but the indications and risks of this drug for this specific setting need better definition.

Improving Tissue Oxygen Delivery

In the setting of acute lung injury, attention focuses on maintaining an adequate oxygen delivery/consumption ratio while reversing the underlying lung pathology. Oxygen delivery is the product of cardiac output and the O_2 content of each milliliter of arterial blood. [Oxygen content (ml/dl) equals 1.36 times the product of hemoglobin concentration (g/dl) and percentage saturation/100, plus 0.003 times the P_aO_2.] The O_2 carrying capacity can be improved by increasing hemoglobin (Hgb) concentration and optimizing its dissociation characteristics. Both factors may be important. Increasing Hgb tends to increase mixed venous oxygen saturation as it

reduces the need for any rise in cardiac output compensatory to anemia. Both of these actions (lower cardiac output and higher mixed venous O_2 saturation) tend to reduce venous admixture. Hemoglobin performance is improved by reversing alkalemia to facilitate O_2 offloading. As Hgb concentration rises, blood viscosity increases, retarding passage of erythrocytes through capillary networks. Thus, actual O_2 delivery can be impaired as hematocrit (Hct) rises over 50%. Although the optimal Hct in patients with an oxygenation crisis is unknown, it makes sense to restore Hct to 35% to 40%. More extensive supplementation increases the risks of transfusion without proven benefit.

A very high percentage of the oxygen contained in blood is bound to Hgb; the proportion solubilized in plasma is very small (3%) at ambient pressure. However, in severe anemia, the Hgb-bound fraction is disproportionately small, so that total O_2-carrying capacity is significantly boosted when 100% O_2 is used, and breathing pure oxygen helps dissociate carbon monoxide from Hgb. After carbon monoxide exposure, high partial pressures of O_2 (particularly those delivered under hyperbaric conditions) can deliver life-sustaining quantities of dissolved O_2.

Because extravascular water accumulates readily in the setting of permeability edema, fluids should be used judiciously to keep the wedge pressure as low as feasible consistent with adequate oxygen delivery. Liberal use of inotropes and other vasoactive drugs can occasionally be helpful, especially in certain postoperative or posttrauma settings. Driving the cardiac output to supraphysiological levels, however, appears not to improve the mortality rate of medical patients with ARDS.

Oxygen Therapy

Increasing the F_IO_2 improves P_aO_2 in all instances in which shunt is not responsible for desaturation. The goal is to increase the saturation of Hgb to 85% to 90% or more without risking O_2 toxicity. Oxygen toxicity is both concentration- and time-dependent. As a general rule, very high inspired fractions of oxygen can safely be used for brief periods as efforts are made to reverse the underlying process. Sustained elevations in $F_IO_2 > 0.6$ result in inflammatory changes and eventual fibrosis in experimental models; therefore, it seems logical that efforts be made to keep $F_IO_2 < 0.65$ during the support phase of acute lung injury.

Positive End-Expiratory Pressure, Positioning, and Other Techniques for Raising Lung Volume

Positive end-expiratory pressure (PEEP) and other techniques (e.g., inverse-ratio ventilation) for increasing mean alveolar pressure are often successful in maintaining lung volume recruitment. Virtually all patients benefit from low levels of PEEP (3 to 5 cm H_2O), which help to compensate for the loss of volume that accompanies the supine posture and translaryngeal intubation. There is no evidence, however, that low to moderate levels of PEEP help in prophylaxis against the onset of ARDS. Although PEEP may be highly effective in the relaxed subject, its volume-recruiting effects can be negated by patient effort. Vigorous expiratory muscle action forces the chest to a lung volume lower than the equilibrium position. When this happens, silencing the expiratory muscles by sedation (and/or paralysis, if needed) can prove very helpful. When infiltration is predominately unilateral, PEEP may be ineffective or hazardous, as PEEP causes already-functional lung units to overdistend. In this setting, repositioning the patient (i.e., to a lateral decubitus posture) or the combination of selective intubation and independent lung ventilation may allow individual tailoring of the pattern of lung inflation, F_IO_2, and PEEP, thereby improving oxygenation and reducing the risk of barotrauma.

The potential benefits of position changes are often overlooked. Alert patients should remain upright, if possible, and recumbent patients should be turned every few hours. (This is especially important during coma or paralysis.) Intermittent shifts from the supine to the prone position often help dramatically in reversing hypoxemia in the early stage of ARDS. Alternating lateral decubitus positions puts different regions of the lung on maximal stretch and improves the secretion drainage of the upper lung. Indeed, the incidence of pulmonary infections may be reduced by such mechanisms. Several types of motorized beds perform this function continuously, although the patient is generally rotated through less extreme angles. When one lung is differentially affected, oxygenation occasionally improves dramatically with the good lung in the dependent position, but this is not reliably observed. Care should be taken to ensure that secretions from the infiltrated lung are not aspirated into the airway of the dependent viable lung during this process.

Recruiting Maneuvers

It must be remembered that PEEP itself does not recruit atelectatic lung units but only keeps recruited units from recollapsing. Maintaining patency of inflamed airways and alveoli may be instrumental in allowing healing to occur. To accomplish maximal recruitment, sufficient pressure must be applied to exceed the airway opening pressure, and sufficient total PEEP must be utilized to exceed the closing pressure. It stands to reason, therefore, that periodic application of sustained high recruiting pressure (e.g., 35 to 45 cm H_2O CPAP applied for at least 10 to 15 sec) may be needed to achieve and sustain optimal arterial oxygenation when small tidal volumes are used in patients with acute oxygenation failure, as they often are in ARDS.

Secretion Management and Bronchodilation

Although ARDS is often regarded as a problem of parenchymal injury, airway edema, bronchospasm, and secretion retention often contribute to hypoxemia. Retained secretions pose an overlooked problem that increases endotracheal tube resistance, infection risk, the hazard of barotrauma, and maldistribution of ventilation. In some patients with diffuse lung injury, profound bradycardia develops during ventilator disconnections, discouraging airway suctioning. Although hypoxemia occasionally contributes, this bradycardia is usually reflex in nature and responds to prophylactic (parenteral) atropine or reapplication of positive airway pressure. Circuits that do not interrupt PEEP during suctioning may offer some advantage.

Reducing Oxygen Requirements

Reducing the tissue demand for O_2 can be as effective as improving oxygen delivery. Fever, agitation, overfeeding, vigorous respiratory activity, shivering, sepsis, and a host of other commonly observed clinical conditions can markedly increase V_{O_2}. Fever reduction may have therapeutic value, but shivering must be prevented in the cooling process. Sedation and the use of antipyretics rather than cooling blankets make good therapeutic sense. (Although phenothiazines may prevent shivering, their use may inhibit the cutaneous vasodilation necessary for rapid heat loss.)

Paralysis is a valuable adjunct to reduce oxygen consumption and improve P_aO_2 in patients who remain agitated or fight the ventilator despite more conservative measures. Although paralysis is helpful in the first hours of machine support, protracted paralysis must be avoided for several reasons. Paralysis places the entire responsibility for achieving adequate oxygenation and ventilation with the medical team. Furthermore, the patient is defenseless in the event of an unobserved ventilator disconnection. Paralysis also silences the coughing mechanism and creates a monotonous breathing pattern that encourages secretion retention in dependent regions. Finally, protracted and unmonitored paralysis may cause weakness or devastating neuromyopathy.

Mechanical Ventilation of Acute Lung Injury and ARDS

Conventional Approach to Ventilatory Support

The basic principles of managing acute lung injury (ALI) are well accepted. The primary objective is to accomplish effective gas exchange at the least inspired oxygen fraction (F_IO_2) and pressure cost. On the basis of recent experimental and clinical information, an objective of crucial importance is to establish and maintain patency of all potentially recruitable lung units. The relative hazards of oxygen therapy, high-pressure ventilatory patterns, and abnormal target values for arterial blood gases, pH, and cardiac output are vigorously debated (Table 3).

Conventional	"Lung protective"
Large tidal volume	Small tidal volume
Minimum PEEP	"Sufficient" PEEP
Normalize P_aCO_2	Permissive hypercapnia
Unrestrained P_{pl}	Pressure limitation

TABLE 3. *Approaches to ARDS ventilation*

Most traditional ventilatory strategies used in intensive care evolved directly from anesthetic and surgical postoperative practice. When the lungs are uninjured, and their capacity to expand remains normal (as is common in the perioperative period), large tidal volumes (V_T) of 10 to 15 mL/kg generate only modest end-inspiratory transalveolar pressure. In fact, large tidal volumes prevent the microatelectasis that accompanies monotonous shallow breathing and are needed by many spontaneously breathing patients to satisfy high ventilatory demands (i.e., metabolic acidosis). Postoperatively, the mandatory respiratory rate is usually adjusted to "normalize" pH and/or P_aCO_2, and sufficient positive end-expiratory pressure (PEEP) is used to achieve acceptable O_2 delivery at what is assumed to be a nontoxic F_IO_2. (An $F_IO_2 < 0.65$ is commonly targeted.) Typically, airway pressures are monitored but not rigidly constrained.

With few modifications, this high-tidal-volume, normoxic, normocapnic ventilation paradigm developed as the standard approach to supporting most critically ill patients as well. Consequently, tidal volumes that exceed 800 ml and end-tidal (plateau) alveolar pressures > 50 cm H_2O are still common in many intensive care units during the ventilation of ARDS. How best to select "optimal" PEEP remains controversial, but many practitioners advocate using the *least* PEEP consistent with accomplishing acceptable arterial oxygenation. Others rely on computations of systemic oxygen delivery or best tidal compliance to make their selections of PEEP and V_T. Unfortunately, the machine settings that achieve all important clinical objectives do not invariably coincide. A relatively small but growing number of practitioners are now shifting first priority from optimizing gas exchange, oxygen delivery, or respiratory system compliance to a strategy that minimizes the potentially injurious effects of mechanical ventilation.

Ventilator-Induced Lung Damage

Implications of Evolving Histology

Histologic findings evolve continuously (but heterogeneously) over the course of acute lung injury (Table 4). It is reasonable to assume that all lung regions sustain the initial insult more or less simultaneously and that, in the most severe cases, proliferation, organization, remodeling, and fibrosis sequentially follow an initial phase of edema and atelectasis. Although parenchymal damage is widespread, the nature, severity, pace of evolution, and perhaps even stage of injury vary from site to site within the damaged lung. Early in the course of ARDS, gravitationally dependent areas are extensively consolidated and atelectatic, whereas nondependent regions tend to aerate better. Regional blood flows and vascular pressures also vary (Fig. 5). Changes of body position alter lung (or chest wall) mechanics, influence the radiographic findings, and affect gas exchange. Although counterexamples occasionally occur, perhaps 60% to 70% of patients respond to prone positioning by improving P_aO_2 significantly during this early phase of ARDS. The efficacy of PEEP in improving oxygen exchange relates directly to the reversal of atelectasis and the redistribution of lung water. It is not surprising, therefore, that PEEP's effectiveness in improving oxygen exchange tends to decline as time passes.

	Early phase (0–3 days)	Late phase (>7 days)
Structural collagen	Strong	Degraded
Atelectasis	Prevalent	Less prevalent
Edema	Prevalent	Less prevalent
Mechanics	Heterogeneous	Less heterogeneous
Ventilator lung injury	Edema and hemorrhage	Pneumothorax Cystic barotrauma

TABLE 4. *Characteristics of early- and late-phase ARDS*

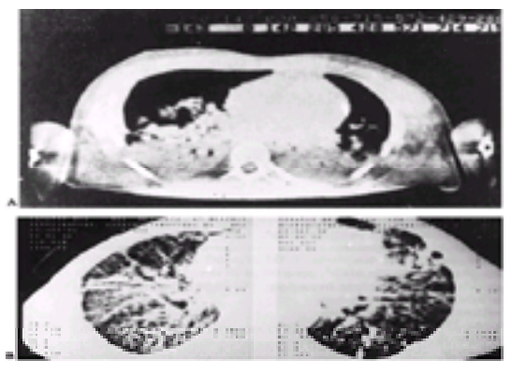

FIG. 5. Computed tomography (CT) appearance of the chest in early **(A)** and late **(B)** phases of ARDS. Although on chest radiographs the lungs appear to be diffusely and uniformly affected in the early stage, the CT image demonstrates a preponderance of atelectasis in the dependent (dorsal) regions. Later, infiltrates are more widely distributed, and cystic spaces often form. In this stage, atelectasis is less prevalent, and infiltrates are more evenly distributed in the transverse plane, as seen in this CT image.**(A)** Reprinted with permission from Gattinoni L, et al. Body position changes redistribute lung computer tomography density in patients with acute respiratory failure. *Anesthesiology* 1991;74:15–23. **(B)** Reprinted with permission from Meduri G. Late adult respiratory distress syndrome. *New Horizons* 1993;1:563–577.]

The collagen framework of the normal lung remains relatively intact during the first days of injury but later weakens as inflammation gradually degrades structural protein and nonuniformly remodels the lung's architecture. Therefore, the same pressures that were withstood acceptably well initially may cause alveolar disruption after the disease is well established. This may explain the tendency for radiographically detectable barotrauma to occur late in the course of the disease—often well after gas-exchange abnormalities have noticeably improved and ventilatory pressures have declined.

Dangers of Excessive and Insufficient Lung Volumes

After acute injury, only a fraction of the injured lung is accessible to gas; in severe cases, no more than one-third of all alveoli remain patent. Because well-ventilated lung units may retain nearly normal elastance and fragility, the apparent "stiffness" of the lung in the early phase of ALI is explained better by fewer functioning alveoli than by a generalized increase in recoil tension. Increased tissue recoil contributes more significantly later on, when cellular infiltration is intense, edema has been reabsorbed or organized, atelectasis is less extensive, and fibrosis is under way. Because the lung's reduced functional compartment must accommodate the entire tidal volume, large (conventional) tidal volumes may cause overdistention, local hyperventilation, and inhibition or depletion of surfactant. Moreover, during rapid inflation to high transalveolar pressures, intense shearing forces may develop at the junctions of structures that are mobile (aerated lung units) with those that are immobile (collapsed or consolidated alveoli, distal conducting airways).

Tidal pressures within the alveolus must neither rise too high at any time during the disease course nor fall too low during the first 3 to 5 days of treatment. Experimental damage resulting from overdistension of the alveolar-capillary membrane has been convincingly documented. The absolute value of peak inflation pressure is not the stretching pressure or the true causative variable of barotrauma; rather, peak transalveolar pressure (roughly approximated by the difference between alveolar and pleural pressures) is the relevant variable. The plateau pressure is perhaps the best clinical correlate of peak alveolar (but not necessarily transalveolar) pressure. The severity of stretch injury appears greatest when maximum transalveolar pressures exceed 25 to 30 cm H_2O and insufficient PEEP cannot keep dependent lung units fully recruited. Failure to maintain a certain minimum alveolar volume in the early phase of ALI may induce or accentuate lung damage.

Unsupported by PEEP, certain collapsible alveoli may wink open and closed with every tidal cycle, generating shearing stresses within junctional tissues and tending to deplete surfactant. Increases in cycling frequency and duration of exposure to adverse ventilatory patterns accentuate any tendency for damage. The magnitude of blood flow in these stressed areas may also play an important role.

Bronchiolar dilation, cystic changes, and/or microabscesses can be demonstrated in the large majority of patients with ALI ventilated for lengthy periods with peak airway pressures considered modest by traditional clinical standards. Such airway damage not only impairs gas exchange but also predisposes to secretion retention and pulmonary infection.

Importance of Cycling Frequency

At levels of minute ventilation and tidal volume that are traditionally accepted, the ventilator may cycle in excess of 30,000 times per day (20 breaths/min × 60 min/hr × 24 hr/day). Even if the tidal pressure profile is only slightly damaging, the cumulative effect can be severe. It is very important to reduce V_E requirements and cycling frequency whenever high cycling pressures are in use.

P_{flex} *and the Choice of* ***PEEP***

A lower inflection (P_{flex}) region on the static pressure–volume curve of the passive respiratory system suggests the existence of a population of alveoli at risk for excessive tidal stresses (Fig. 6). Not all patients exhibit a lower P_{flex} region, but those who do are likely to experience extensive end-expiratory atelectasis at lower levels of PEEP. Indeed, arterial oxygenation often improves markedly as the end-expiratory pressure range just below P_{flex} is exceeded. Many investigators currently believe that tidal excursions into the lower inflexion range must be avoided. Either provision of sufficient PEEP or the progression of disease over time obliterates the "P_{flex} point" as well as narrows the hysteresis of the static pressure–volume curve. In contrast, in late-stage ARDS, high PEEP levels may simply add to the risk of lung rupture, or, when peak pressure is capped (out of a concern for barotrauma), increasing PEEP may reduce the safe operating tidal volume.

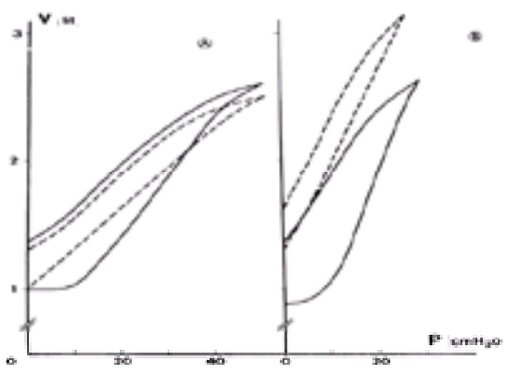

FIG. 6. Pressure–volume curves of the respiratory system from two patients in the earlier and late stages of ARDS. In the earlier stage of ARDS *(solid lines),* distinct lower inflection and upper deflection limbs are prominent. Later *(dashed lines),* the inflection and deflection zones are less well demarcated, and hysteresis is reduced. (Reprinted with permission from Matamis et al. Total respiratory pressure–volume curves in the adult respiratory distress syndrome. *Chest* 1984;86:58–66.)

As a composite of the behaviors of all alveoli within the heterogeneous lung, the contours of the static pressure–volume curve obscure very important regional differences. Alveoli in dependent regions are most susceptible to collapse, and those in nondependent regions are vulnerable to overdistention. This variability of opening pressures helps account for the *zones* (rather than *points*) of lower and upper inflection.

Implications of Pressure Limitation for Tidal Volume

The tidal volumes that correspond to the restricted range of safe ventilating pressures are generally »4 to 8 mL/kg of lean weight, or 300 to 600 mL for a 75-kg patient. However, because values for lung and chest wall compliance vary through wide ranges in different patients, unique values for tidal volume that are consistent with desirable pressure limits cannot be prespecified. Therefore, when a flow-controlled volume-cycled mode of ventilation is used, V_T should be adjusted with guidance by plateau pressure and the response of oxygen exchange to increments of tidal volume. The need to constrain tidal volume suggests the potential value of high frequency ventilation.

Modes of Mechanical Ventilation in ARDS

Something of a mystique has grown up around the topic of mode selection in ARDS. Although many would disagree, we believe that many choices are equivalent, so long as the practitioner assures adequate O_2 delivery at a safe F_IO_2, follows the same guidelines for lung protection, and remains alert to the potential shortcomings and complications of the mode in use. As a general rule, spontaneous ventilation should be encouraged except when oxygenation is marginal, heart function is seriously compromised, or ventilatory efforts are labored. It has been argued that newer techniques such as pressure control, pressure-regulated volume control, inverse-ratio ventilation, and airway pressure release ventilation confer advantages over more traditional approaches, but none has yet been shown in a fair comparison to be consistently superior to its alternatives. The important difference in managing patients with ARDS is that the choices of maximum allowed tidal pressure and chosen level of PEEP may be crucial to safe ventilatory support.

Alternative Ventilatory Strategies

Permissive Hypercapnia

Carbon dioxide retention may be an inevitable consequence of a "lung protective" strategy that tightly restricts applied pressure and maintains a certain minimum (end-expiratory) lung volume. Maintaining normocapnia may not be appropriate if the cost is impaired lung healing and a heightened risk of extending tissue damage. "Permissive hypercapnia," a strategy that allows alveolar ventilation and peak ventilatory pressures to fall and P_aCO_2 to rise, may reduce barotrauma and enhance survival in status asthmaticus and ALI, as several nonrandomized or retrospective studies without concurrent controls have suggested. The basis for any survival advantage there might be has not yet been determined. However, the lung acutely damaged by stretch injury is susceptible to pneumonia and may be a source of inflammatory mediators transferred to the systemic circulation. Disruption of the lung's architecture may also promote bacteremia.

Physiologic Effects of Hypercapnia. The physiologic effects of CO_2 retention are determined by the severity of hypercapnia and the rate of its buildup (Table 5). Except in the most severe cases or those complicated by extraordinary CO_2 production, the CO_2 retention that results from the pressure-targeted ventilation itself is generally modest (P_aCO_2 < 70 mmHg). Chronic hypercapnia of this magnitude appears to have few notable side effects apart from the reduction in ventilatory drive attendant to compensatory metabolic alkalosis. Although gradual elevations of P_aCO_2 (<5 mmHg increase per hour) are often tolerated remarkably well, the rapid development of respiratory acidosis can evoke impressive sympathetic discharge. Allowing hypercapnia may not be advisable for all patients with ALI, i.e., patients with coexisting head injury, recent cerebral vascular accident, or significant cardiovascular dysfunction (Table 6). Acute elevations in P_aCO_2 increase sympathetic activity, raise cardiac output, heighten pulmonary vascular resistance, alter bronchomotor tone, impair skeletal muscle function, dilate cerebral vessels, and impair central nervous system function. Carbon dioxide retention may be poorly tolerated by patients with autonomic insufficiency, b-blockade, or other conditions interfering with sympathetic tone and compensatory mechanisms.

System	Effect[a]
Respiratory	Reduced alveolar P_{O_2}
	Rightward shift of oxygen/hemoglobin curve
	Impaired diaphragm function
	Pulmonary vasoconstriction
	Worsened V/Q mismatching
Renal	Enhanced bicarbonate reabsorption
CNS	Cerebral vasodilation
	Increased intracranial pressure
	Depressed consciousness
	Biochemical changes
Cardiovascular	Reduced cardiac contractility[b]
	Stimulation of sympathoadrenal axis
	Lower systemic vascular resistance

[a] Most effects wane with time as cellular and extracellular pH readjust.
[b] Only if not offset by adrenergic reflex compensation.

TABLE 5. *Consequences of hypercapnia*

Intracranial hypertension
Head trauma
Hemorrhage
Severe systemic hypertension
Space-occupying lesions
Cardiovascular instability
Cor pulmonale
β-Blockade
Severe uncorrected metabolic acidosis or hypoxemia

TABLE 6. *Contraindications to permissive hypercapnia*

Especially over the short term, arterial pH may not closely reflect the pH of the intracellular environment. The magnitude of any intracellular acidosis resulting from permissive hypercapnia, however, is almost certain to be less than the profound intracellular pH changes produced by ischemia. Because CO_2 affects cardiac output and influences vascular and bronchomotor tone, it is uncertain if hypercapnia disturbs ventilation/perfusion matching or modulates the extent of lung injury and edema during the course of mechanical ventilatory support. Implementation of permissive hypercapnia often requires deep sedation and/or paralysis, a requirement that may be associated with serious side effects: impaired secretion clearance, fluid retention, and residual muscle weakness. Moreover, permissive hypercapnia may not be advisable (or even possible to implement safely) in the setting of coexisting metabolic acidosis or uncorrected hypoxemia.

Adjuncts to the Ventilatory Management of ARDS

In recent years, there has been renewed interest in devising ways in which to accomplish effective arterial oxygenation without inflicting further damage on the injured lung. Some of these innovations modify the fundamental nature of ventilatory support (high-frequency ventilation), but others provide gas exchange external to the lungs (extracorporeal or intravenacaval gas exchange), alter body position (prone positioning), or administer therapeutic agents designed to improve ventilation/perfusion matching (nitric oxide, aerosolized prostacyclin). One technique modifies the nature of the gas-carrying medium itself (partial liquid ventilation). Each of these adjuncts should be considered as a promising technique that is currently just beyond the perimeter of routine clinical practice.

High-Frequency Ventilation

When conducted at an appropriate lung volume and frequency, HFV seems well aligned with current principles of lung protection and has a clear rationale. To this point, however, its superiority has neither been shown nor disproven.

Extrapulmonary Gas Exchange

Partial substitution for the lung's gas-exchanging function reduces the requirement for ventilating pressure. Methods for assisting in the process of exchanging respiratory gases include extracorporeal membrane oxygenation (ECMO), extracoporeal CO_2 removal ($ECCO_2R$), and intravenacaval gas exchange (IVOX). All are costly, highly technical methods best undertaken by an experienced and dedicated team. Each has a good rationale, and laboratory experience and various clinical reports have been encouraging; yet, for adult patients none has been confirmed by well-controlled trials to add consistently to routine measures. Although initial experience with these techniques has been frustrating, they continue to hold promise for well-selected patients.

Prone Positioning

Frequent changes of body posture are integral to normal activity, but positional variation is forgone for lengthy periods in the bedridden, critically ill patient. By tradition, the patient is cared for in the supine position, which allows more direct eye contact with the caregivers, family, and visitors as well as better access to the vascular system and vital structures, thereby facilitating nursing care. Cardiopulmonary resuscitation must be conducted in the supine position. Despite these undeniable advantages, there is good reason to question our current practice of utilizing only the supine orientation. A growing interest in therapeutic positioning has been stimulated by the observation that the prone position improves oxygen exchange in 50% to 70% of patients treated in the early phase of ARDS, allowing the physician to reduce both $F_{I}O_2$ and PEEP. Recruitment of dorsal lung units with a more even distribution of pleural pressure and improved ventilation/perfusion matching seems best to explain this benefit. Airways serving the expansive dorsal regions are generally better drained in this position as well. Based on theoretical considerations and limited personal experience, prone positioning is less likely to benefit patients with large continuous pleural air leaks, especially if pneumothorax is radiographically evident and bilateral. Once the lung is surrounded by gas, the normal pleural gradient of pressure is erased or substantially altered, making the effect of prone positioning unpredictable. Under such circumstances, prone positioning should only be attempted with caution—if at all.

Practical Points in Prone Positioning

Although hemodynamic parameters tend to remain unchanged, hypotension, desaturation, and arrhythmias may occur during the process of turning from the supine to the prone position (Table 7). These transient problems do not generally persist and can be minimized by using sedation, prior airway suctioning, and 100% oxygen during the maneuver. Continuous arterial pressure monitoring, electrocardiography, and pulse oximetry are strongly advised. Deep sedation and occasionally paralysis will be required to secure patient compliance. Attention must also be given to preserving the position and patency of intravascular lines and endotracheal tubes during the turning process. Use of a soft (air-cushioned) bed is all but mandatory for comfort. Pillows must be used to support the hips, pelvis, shoulders, and head. Patients with tracheostomies present a particular challenge. The compliance of the respiratory system generally changes little in shifting to the prone position. This is variable, however; tidal volume should be monitored (and adjusted if necessary) during pressure-controlled ventilation, which is influenced by any position-related changes in chest wall compliance. Furthermore, for the same plateau pressure, peak pressures may change if flow-controlled volume-cycled ventilation is used. For similar reasons, a given level of PEEP may be more or less effective in one position than in another. Although the optimal frequency of supine–prone interconversions is not clear, in current practice, most experienced centers “flip” patients once or twice daily. Supine repositioning allows certain nursing procedures (washing, line dressing changes, etc.) to be delivered and helps resolve facial edema. It seems reasonable to assign the relative duration of each position in proportion to the gas-exchange response. (For example, equal times would be assigned if only a minor important gas-exchange difference is observed between positions.) Prone repositioning should be reevaluated often in the first 3 to 5 days of illness, after which time it tends to lose its oxygen-exchange effectiveness.

Soft bed
Secure endotracheal tube and all lines before transition
Sedate and preoxygenate before turning
Monitor carefully during transitions
Support shoulders and hips
Adjust PEEP and tidal volume after positioning
Protect eyes, facial areas
Exercise special caution if bronchopleural fistula present
Alternate prone and supine positions one to three times daily

TABLE 7. *Practical points for prone positioning in ARDS*

Partial Liquid Ventilation

Perfluorochemicals (PFCs) proposed for clinical purposes are environmentally innocuous liquids at room temperature that dissolve extraordinary volumes of oxygen and carbon dioxide, allowing effective gas exchange to take place. Biologically inert and immiscible in both aqueous and lipid media, they cause no known tissue reaction—even during extended use. Perfluorooctyl bromide (Perflubron), a PFC currently undergoing clinical trials, has a desirably low vapor pressure (it clears itself by evaporating slowly), a high spreading coefficient (it distributes homogeneously), and a low surface tension. Although its viscosity is similar to water, perflubron has nearly twice the density; airway secretions and alveolar exudates float on it, allowing such debris to migrate centrally for airway suctioning. Infections may occur less commonly in a lung filled with inert, nonnutritive liquid hostile to bacterial growth, but this is unproven. Its radiodensity may interfere with conventional imaging (Fig. 7). Perflubron has the potential to keep surfactant-deficient alveoli open by two distinct mechanisms: (1) reduction of interfacial surface tension and (2) physical distention by noncompressible fluid ("liquid PEEP"). The former property may be especially important in the infant respiratory distress syndrome, whereas alveolar splinting may assume primacy in ARDS.

FIG. 7. Computed tomographic scan of a patient with ARDS receiving partial liquid ventilation with Perflubron. (Reprinted with permission from Marini JJ. Evolving concepts in the ventilatory management of acute respiratory distress syndrome. *Clin Chest Med* 1996;17:555–575.)

Sustained *partial* liquid ventilation (PLV) preserves the key benefits of liquid breathing while allowing gas ventilation to proceed with standard mechanical ventilators and connecting circuitry. Initial clinical experience has been promising. In stark contrast to total liquid ventilation, PLV is rather simply implemented. The liquid preferentially distends the dependent alveoli most in need of expansion during the initial phase of ARDS, providing the vertically graded PEEP-like effect required by the underlying pathoanatomy. Simultaneously, blood flow diverts toward nondependent regions, which receive a disproportionate share of the gaseous tidal volume. Reduced venous admixture, therefore, has at least two explanations—effective oxygen exchange directly across alveolar units reopened by liquid, and redirection of pulmonary arterial blood toward the better ventilated nondependent regions. The exciting potential of perfluorocarbons in ARDS has yet to be confirmed.

Tracheal Gas Insufflation

An alternative to allowing extreme or rapidly developing hypercapnia or to using extrapulmonary techniques for gas exchange in ARDS is to enhance the efficiency of CO_2 elimination at low V_T and cycling pressures by the tracheal insufflation of fresh gas (TGI). This minimally invasive approach reduces the effective series (anatomic) dead space by bypassing the airway proximal to the carina during inspiration, by washing out the PCO_2 of this same region during expiration, or both (Fig. 8). During TGI-aided ventilation, fresh gas delivery occurs either throughout the respiratory cycle (continuous catheter flow) or only during a segment of it (phasic catheter flow). In either mode, the crucial variable appears to be the volume of fresh gas injected per breath during expiration. During expiration, low to moderate continuous flows of fresh gas introduced near the carina dilute the proximal anatomic dead space (dead space flushing). At high catheter flow rates, turbulence generated at the catheter tip can also enhance gas mixing in regions beyond its orifice, thereby contributing to CO_2 elimination. Expiratory insufflation appears to be the safest and most effective modality of implementing TGI, avoiding problems with overpressuring the airway, allowing manipulation of the inspiratory time fraction without influencing inspired tidal volume, and minimizing the volumes of fresh gas that must be injected to achieve a given level of CO_2 elimination.

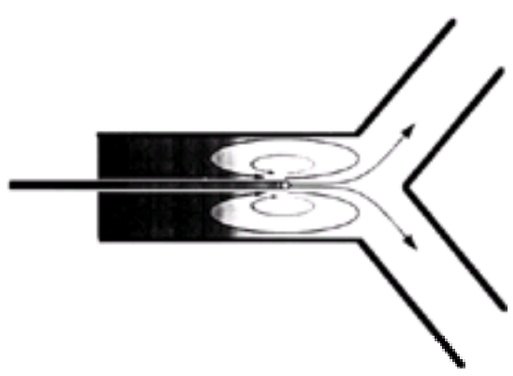

FIG. 8. Tracheal gas insufflation (TGI). CO_2-laden gas that fills the central airways at end-expiration is recycled to the alveolus with the subsequent inspiration. Expiratory flushing of CO_2 from the central airway by fresh gas helps improve CO_2 elimination and reduces dead space. The effectiveness of TGI is reduced when a high alveolar dead space lowers the end-expiratory tracheal CO_2.

Because much lower concentrations of CO_2 are delivered to the central airway, TGI loses its effectiveness when there is a large amount of alveolar (as opposed to anatomic and apparatus) deadspace. Acute respiratory distress syndrome, emphysema, and pneumonia are typical examples of such diseases. Conversely, permissive hypercapnia boosts the CO_2 concentration, improving the utility of TGI.

Used improperly, TGI has the clear potential to cause mucosal damage, secretion retention, and interference with catheter suctioning. These effects should be mitigated by adequate humidification, using selective expiratory TGI, and the injection of fresh gas via channels imbedded within the walls of the endotracheal tube itself. Injection of catheter gas retrograde to the exhalation stream tends to increase expiratory resistance and generate auto-PEEP; continuous gas injection allows the TGI injector to act as a constant-flow generator during inspiration, when the machine's valves are closed, risking overdistention. Auto-PEEP and barotrauma are

distinct possibilities when high gas flow rates are used—whatever the injection mode (selective expiratory or continuous). The experience of workers using transtracheal ventilation in outpatients with COPD as well as other results with TGI in critically ill patients indicates that once perfected, it may eventually prove helpful in a variety of acute and chronic settings. Because of its potential to moderate the rate and extent of CO_2 retention, TGI appears particularly well suited to serve as an adjunct to a pressure-targeted, lung-protective ventilatory support for ARDS.

Inhaled Nitric Oxide and Prostacyclin

Nitric oxide (NO) is a key biological mediator of smooth muscle relaxation. When inhaled, NO has the therapeutic potential to dilate the pulmonary vasculature in well-ventilated regions, tending to reduce pulmonary hypertension and improve the matching of ventilation and perfusion in an unevenly damaged lung. Inhaled nitric oxide is active only locally, as it is quenched immediately on exposure to hemoglobin. Because inhaled NO cannot influence the vasculature of collapsed lung units that it cannot access, the effectiveness of NO often depends on the provision of sufficient PEEP to fully recruit the lung and maintain alveolar patency. Extremely low concentrations of NO achieve nearly full effect; biological activity is often detectable at concentrations as low as 2 parts per million, and beneficial effects on gas exchange are fully saturated at 5 to 20 ppm in most patients. Somewhat higher concentrations of NO may be needed to maximize its pulmonary vasodilating effects. Nitric oxide's physiological effects in ARDS are highly variable—sometimes dramatic, but often quite modest. Although the onset and offset of NO's effects are extremely rapid, gradual accommodation to its beneficial vasodilatory effects can result in rebound vasoconstriction when it is abruptly terminated. High concentrations of NO and minute quantities of its associated oxides (NO_2^{1-} and NO_3^{2-}) are histotoxic and must be avoided. Although it is extremely appealing physiologically, the eventual place of NO in the management of ARDS has not yet been settled. At present, it appears most likely to benefit those cases whose hypoxemia is refractory to other measures or those in whom hypoxic vasoconstriction accentuates symptomatic pulmonary hypertension.

Vasodilating aerosols (inhaled prostacyclin and lysosome-encapsulated prostaglandin F_2) operate by the same principle of selectively increasing perfusion to well-ventilated regions. Each may also inhibit inflammation and reduce pulmonary artery pressure. Although their physiological effects can be dramatic, their routine clinical benefit has yet to be demonstrated.

A Pressure-Targeted Approach to Ventilating ALI and ARDS

Although definitive clinical data are needed to confirm the wisdom of adopting a “pressure-targeted” approach, a rational strategy for ventilating patients with ALI can be formulated grounded on a firm theoretical and experimental basis (Table 8). Such a strategy recognizes that several mechanically distinct alveolar populations coexist within the acutely injured lung, that a poorly chosen ventilatory pattern can be damaging, and that the underlying pathophysiology changes over time. This approach gives higher priority to controlling maximal and minimal transalveolar pressures than to achieving normocapnia. Establishing and maintaining full alveolar recruitment while avoiding lung overdistention is the primary guiding principle.

Tailor ventilatory strategy to the phase of the disease (generous PEEP in early stage; withdraw PEEP later)
Minimize oxygen demands
Minimize pulmonary vascular pressures
Control alveolar pressure, not P_aCO_2
Maintain total end-expiratory P_{aw}[a] (PEEP + auto-PEEP) several centimeters of water above P_{aw}[a]. In general, this will be more than 7 cm H_2O but less than 20 cm H_2O
Avoid large V_t and use least P_{aw} required to meet *unequivocal* therapeutic goals
Hold transalveolar pressure <35 cm H_2O
Consider making necessary increases in mean P_{aw} by changing T_I/T_{tot}
Consider specialized adjunctive measures to improve gas exchange and O_2 delivery[b]

[a] Abbreviations: P_{aw}, alveolar pressure; P_{flex}, lower inflection point of the static pressure–volume relationship of the respiratory system.

[b] In addition to such standard measurements as skillful management of pulmonary vascular pressure, repositioning, use of cardiotonic agents, specialized adjunctive measures might include (where available) such experimental methods as ECCO$_2$R, inhaled Nitric Oxide or prostacyclin, partial liquid ventilation, and intravenous (IVOX) or intratracheal catheter-assisted gas exchange (TGI).

TABLE 8. *A lung protective strategy for ventilating ARDS*

Once oxygen and ventilatory demands have been minimized and fluid balance and cardiac function have been optimized, the essential strategic elements are as follows:

First, sufficient end-expiratory transalveolar pressure must be used to avert tissue damage resulting from surfactant depletion or stresses associated with persistent collapse or repeated opening and closure of collapsible units during the tidal breathing cycle. The total PEEP applied (the sum of PEEP and auto-PEEP) should be sufficient to obliterate any lower inflection “point” of the pressure–volume curve of the respiratory system, which, at tidal volumes of 7 to 8 mL/kg, generally occurs at a pressure of 10 to 15 cm H_2O in the early phase of ARDS. (For a patient with a stiff chest wall, the PEEP required may be considerably higher.) In truth, there is an inflection *range* rather than a single inflection point, as dependent alveoli in the lower regions of the lung require a greater end-expiratory alveolar pressure to maintain patency than those above them. Improved arterial oxygenation tends to parallel effective recruitment, and CO_2 retention is a consequence of alveolar overdistention. Although actual construction of the pressure–volume curve (by any of a variety of static or dynamic methods) is theoretically appealing, in some patients it is inadvisable to eliminate spontaneous breathing efforts. One simple way to select PEEP (with or without spontaneous efforts) is first to choose the operating tidal volume (4 to 7 ml/kg), initially setting PEEP at 8 to 10 cm H_2O. The PEEP is then increased in small (2 cm H_2O) steps, looking for (1) an increase in peak static (plateau) pressure that substantially exceeds the previous PEEP increment (by 2 cm H_2O), signaling overdistention, and (2) markedly improved oxygenation that corresponds to obliteration of the P_{flex} point. (Under certain circumstances, a reasonable alternative to the empirical PEEP step approach is gradually to extend the inspiratory time fraction to create auto-PEEP.) Failure of oxygenation to improve significantly after two successive PEEP steps and a recruitment maneuver (see below) strongly suggests that nearly full recruitment had been achieved with that tidal volume at a lower PEEP value. The PEEP should be lowered accordingly.

Second, because alveolar subpopulations with nearly normal elastic properties may coexist alongside flooded or infiltrated ones, the clinician must avoid applying transalveolar pressures greater than normal lung tissue is able to sustain at its maximum capacity (30 to 35 cm H_2O). This pressure generally corresponds to end-inspiratory static airway pressures (“plateau” pressures) of 35 to 50 cm H_2O, depending on the stiffness of the chest wall. Pressures in this range are generally sufficient to reopen closed airways. Whatever the appropriate maximal pressure setting might be for an individual patient, it seems wise to avoid the upper inflection range of the static pressure–volume curve whenever possible. Incursion into this zone is signaled by deterioration of tidal compliance and, in a passively inflated patient, by convexity of the inspiratory airway pressure curve to the horizontal (time) axis during constant-flow ventilation.

Relatively small tidal volumes often result from imposing these upper and the lower bounds on ventilatory pressure. Therefore, periodic recruiting breaths (e.g., pressures of 35 to 45 cm H_2O sustained for 5 to 15 sec every 10 min) may be needed in some patients to maintain adequate lung volume and avoid hypoxemia. One interesting approach to making selections of PEEP and tidal volume when using pressure-controlled ventilation is to fix maximal airway pressure at »30 to 35 cm H_2O and begin with PEEP of 8 cm H_2O. (Somewhat higher maximum and minimum pressures are more appropriate for a patient with an inflexible chest wall.) Positive end-expiratory pressure is then increased gradually while maximal airway pressure remains constant (allowing V_T to fall) until the point at which calculated tidal compliance begins to decline—one definition of the optimum PEEP value.

Third, under conditions of passive inflation (no spontaneous efforts), the practitioner should adjust mean airway opening pressure ($\bar{P}_{aw}$) to achieve acceptable pulmonary O_2 exchange by extending the duty cycle (T_I/T_T) or by raising PEEP. Cardiac output is supported as necessary to offset any detrimental effects of rising $\bar{P}_{aw}$. Extending the duty cycle improves the distribution of ventilation and may help to recruit or hold open otherwise collapsible lung units. Raising PEEP (and preserving a well-tolerated T_I/T_T) may be the preferred option, however, when the patient retains control of the breathing rhythm.

Fourth, when not contraindicated, hypercapnia should be accepted from the onset of therapy (buffered, when necessary, by judiciously infused sodium bicarbonate or other buffer) in preference to violating the guidelines of controlling alveolar pressure. Pharmacologic buffering may also be needed to allow hypercapnia when deep sedation and/or paralysis is not used. The strategy of permissive hypercapnia may be difficult to implement in the presence of metabolic acidosis, when other measures (i.e., dialysis) may be needed adjunctively.

Fifth, consider the prone position from the outset of management. Prone positioning generally offers its greatest oxygenation benefit early in the course of illness. When both available and necessary, consider the use of such adjunctive measures as nitric oxide, tracheal gas insufflation, or partial liquid ventilation.

Sixth, after the first 3 to 5 days of treatment, begin to reduce PEEP and the frequency of prone positioning as oxygenation allows, seeking to reduce maximum alveolar pressure and prevent alveolar rupture.

CHAPTER

48 Mechanical Ventilatory Support

Neil R. MacIntyre

N.R. MacIntyre: Division of Pulmonary and Critical Care, Duke University Medical Center, Durham, North Carolina 27710.

INTRODUCTION

Mechanical ventilation serves two basic functions: ventilatory support and oxygenation support. Ventilatory support is designed to provide, either totally or partially, gas transport between the environment and the alveoli. Usually this is done by using positive airway pressure in a manner that mimics the normal tidal volume and breathing frequency pattern. In contrast, oxygenation support is designed to optimize ventilation–perfusion *(VQ)* matching in order to effect alveolar–capillary gas transport. The most common technique to accomplish this goal is the application of positive end-expiratory pressure (PEEP), but manipulations of the ventilatory pattern and other strategies can also be employed.

Ventilatory failure is defined as failure of the respiratory system to move gas adequately between alveoli and the environment. Ventilatory failure results in abnormalities in both P_aO_2 and P_aCO_2. However, it is usually defined and quantified by an abnormal P_aCO_2 (and resulting acidemia) because CO_2 transport is predominantly determined by ventilation and is much less affected by *VQ* matching and diffusion than is O_2. Ventilatory failure is usually defined as an elevation in P_aCO_2 that results in an arterial pH of 7.25 or less. This corresponds to a P_aCO_2 of 55 torr in patients with normal baseline values for P_aCO_2. In patients with chronic CO_2 elevations, however, ventilatory failure would be defined by higher values for P_aCO_2. Ventilatory failure can result from several factors with different manifestations and potential causes (Table 1).

Pathophysiology	Clinical criteria	Potential causes
Decreased respiratory drive	P_aCO_2 (>55 torr) Bradypnea–apnea	Neurologic dysfunction, drugs
Ventilatory muscle fatigue resulting from working on stiff or obstructed lungs	P_aCO_2 (>55 torr) Tachypnea (>35 torr) Muscle weakness (<25 cm H_2O negative inspiratory force) ↓CL ↑RAW	Obstructive lung disease Restrictive lung disease
Ventilatory muscle fatigue resulting from large deadspace ventilation requirements	P_aCO_2 (>55 torr) Tachypnea (>35 torr) ↑MDINT (>30 l/l)	Pulmonary vascular disease

TABLE 1. *Ventilatory failure*

Oxygenation failure is characterized by impairment of the alveolar-to-arterial transport of oxygen (A-aDO_2). This occurs physiologically because of disease-imposed *VQ* mismatch, shunts, and (occasionally) diffusion block. Oxygenation failure is usually defined as an arterial PO_2 that is less than 55 to 60 torr (hemoglobin saturation less than 86%). Oxygenation failure can also be defined by inadequate oxygen delivery (DO_2) to tissues (e.g., DO_2 less than 300 to 400 ml/min per m^2).

CONVENTIONAL MECHANICAL VENTILATOR DESIGN PRINCIPLES

Conventional mechanical ventilation uses positive-pressure breaths to provide ventilatory support. Gas transport is thus by bulk flow. Devices to deliver these positive-pressure breaths have a number of important features (Fig. 1).

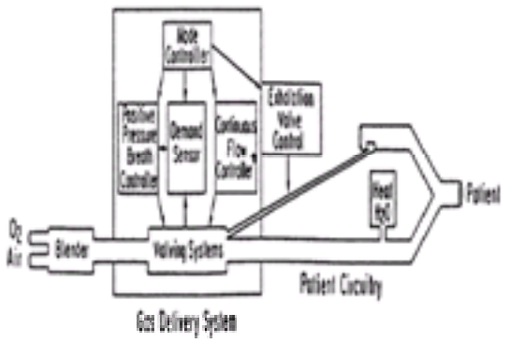

FIG. 1. Ventilator design principles. Modern mechanical ventilatory support systems take blended fresh gas and regulate its flow through complex valving systems (that may include pistons or bellows). The positive-pressure breath controller sets the characteristics for machine-delivered breaths. Circuit demand (effort) sensor provides input for interactive breaths. A continuous-flow circuit for unassisted breathing exists on some systems. The mode controller sets the desired combination of controlled, interactive, and unassisted breaths. The exhalation valve control interacts with the valving system and the mode control to determine expiratory pressure. The patient circuitry delivers these gases to the patient. Heat and moisture are added to the gases delivered. (From MacIntyre NR. Mechanical ventilation. *ACCP Pulm Clin Update* 1985;1:21, with permission.)

Gas Delivery Systems

The important components of the gas delivery system are as described in the following paragraphs.

Positive-Pressure Breath Controller

Most modern adult ventilators utilize piston/bellows systems or controllers of high-pressure sources to drive gas flow. Tidal breaths are generated by this gas flow and can either be controlled entirely by the ventilator or be interactive with patient efforts. Generally, pneumatic, electronic, or microprocessor systems provide for various breath types to be available. These can be classified by what initiates the breath (trigger variable), what controls gas delivery during the breath (limit variable), and what terminates the breath (cycle variable). Trigger variables are generally either patient effort (see patient-circuit sensors, below) or a set machine timer. Limit variables are either a set flow or a set inspiratory pressure. Cycle variables are generally a set volume, a set inspiratory time, or a minimal flow. On current mechanical ventilators, five basic positive-pressure breaths can be delivered, and they can be described by these three variables (Fig. 2).

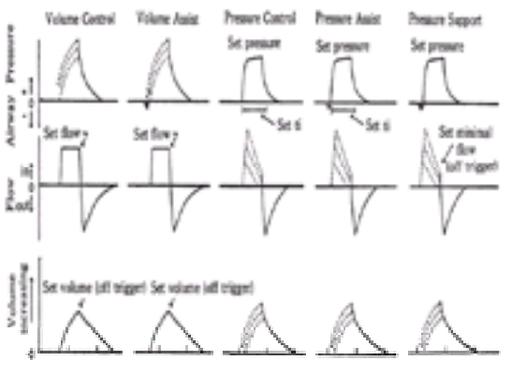

FIG. 2. The five basic breaths. These breaths are categorized by the trigger variable (patient effort or machine timer), the limit variable (flow or pressure), and the cycle variable (volume, flow, or time).

The current generation of mechanical ventilators provides wide versatility. Breathing frequencies to 150 breaths/min, tidal volumes to 2500 mL, peak inspiratory pressures to 150 cm H_2O, flow rates to 180 L/min, inspiratory:expiratory (I:E) timing ratios ranging from 1:5 to 4:1, and a variety of inspiratory flow profiles (i.e., accelerating, decelerating, square, or sine wave) are commonly available. These delivery systems should be equipped with pressure relief valves to avoid dangerously high airway pressures.

Mode Controller

The desired combination of ventilator and spontaneous breaths is termed the mode of mechanical ventilatory support. The mode controller is an electronic, pneumatic, or microprocessor-based system that is designed to provide the proper combination of breaths according to set algorithms and feedback data (conditional variables) (Table 2). Newer designs can incorporate advanced monitoring and feedback functions into these controllers to allow for continuous adjustments in mode algorithms as patient conditions change.

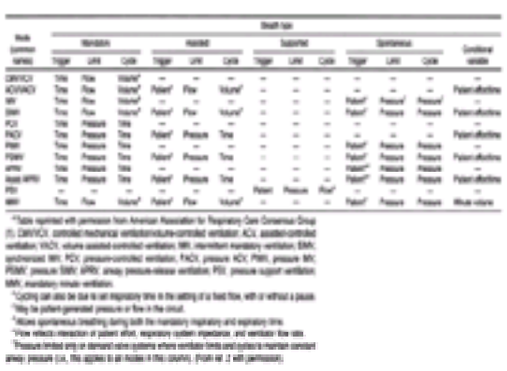

TABLE 2. *Classification of commonly used modes of ventilation*[a]

Effort (Demand) Sensors

Current ventilators allow for a number of patient ventilator interactions. Examples of these interactions include patient-triggered breaths (ventilator initiates flow in response to patient demand) and pressure-limited breaths (ventilator adjusts flow in response to patient demand). Patient effort sensors are needed to allow the ventilator to properly deliver these interactive breaths. These sensors are usually either pressure or flow transducers in the ventilatory circuitry.

Effort sensors are characterized by their sensitivity and responsiveness. Sensitivity refers to how much of a circuit pressure or flow change must be generated to initiate a ventilator response. Responsiveness refers to the delay in providing this response. Both properties are critical in providing a proper response to patient efforts. The work imposed on a patient as a consequence of insensitivity/unresponsiveness of interactive systems is termed “dyssynchrony” (see “Complications,” below).

Subsystems of Mechanical Ventilators

In addition to the gas delivery system, several additional components exist on modern mechanical ventilators.

Gas Blenders

These mix air and O_2 to produce a delivered F_IO_2 from 0.21 to 1.0.

Humidifiers

With the upper airway bypassed by tracheal intubation, sufficient heat and moisture must be added to the inspired gas mixtures to avert mucosal desiccation. Used effectively, humidifiers can adjust blended gas mixtures to near body conditions. Although most systems warm the gas to increase water vapor content, particulate nebulizers have also been employed. Simple and inexpensive heat and moisture exchange humidifiers (HME, “artificial noses”) reutilize moisture trapped from expired gas. These disposable units usually supply adequate heat and moisture (i.e., greater than 28° to 30°C and greater than 25 mg H_2O/L of ventilation) for many patients, particularly those requiring mechanical ventilation for only short periods of time.

Expiratory Pressure Generator

Positive airway pressure can be sustained throughout expiration (PEEP) to help maintain alveolar patency and improve *VQ* matching (see “Physiologic Effects,” below). The PEEP is usually applied by regulating pressure in the expiratory valve of the ventilator system, but a continuous flow of source gas during the expiratory phase can provide a similar effect. Note that some expiratory valves, even when fully open, have measurable resistance, which may result in some inadvertent applied PEEP.

Gas Delivery Circuit

This usually consists of flexible tubing that often has pressure or flow sensors and exhalation valves included. It is important to remember that this tubing has measurable compliance (4 mL/cm H_2O is a representative figure), and significant amounts of delivered gas may serve only to distend this circuitry rather than enter the patient's lungs when high airway pressures are encountered.

PHYSIOLOGICAL EFFECTS OF POSITIVE-PRESSURE VENTILATION

A positive-pressure breath has a number of important effects in the lung–thorax system (Fig. 3).

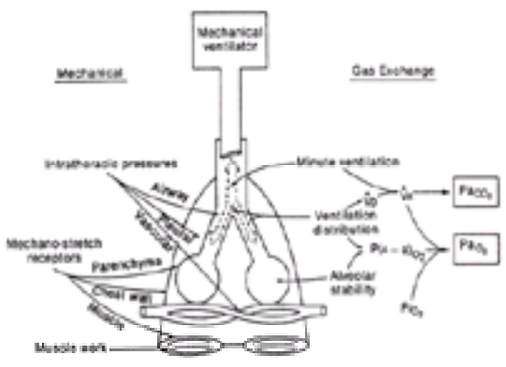

FIG. 3. Physiological effects of mechanical ventilation. Gas exchange is influenced by the delivered minute ventilation, the distribution of that ventilation with respect to perfusion, the alveolar stability, and the F_IO_2. Mechanical effects result from the developed intrathoracic pressures, the ventilatory pattern interactions with thoracic mechanoreceptors, and the ventilatory pattern interactions with the inspiratory muscle efforts. (From MacIntyre NR. Mechanical ventilation. *ACCP Pulm Clin Update* 1985; 1:21, with permission.)

Relationship of V_A, P_aCO_2, and VCO_2

Conventional mechanical ventilation provides fresh gas by periodically inflating the lungs with positive pressure. Such “bulk flow” or “convective transport” results in alveolar or “effective” ventilation (V_A) that is often defined by the ability of the lungs to remove CO_2. This relationship of V_A to P_aCO_2 and CO_2 production is expressed by $V_A = VCO_2/P_aCO_2 \times k$. Alveolar ventilation is also quantified mechanically by the expression: alveolar ventilation (V_A) = breathing frequency (f) × [tidal volume (V_T) - wasted or dead space volume (V_D)]. For given values of VCO_2 and V_D, changes in P_aCO_2 can be predicted by changes in delivered f or V_T using these relationships (Fig. 4). Note, however, that VCO_2 and V_D may change depending on both the underlying disease and the mechanical ventilatory support parameters utilized. For example, VCO_2 can change because the patient's work of breathing and comfort significantly affect the overall metabolic requirement, and V_D can change as a consequence of airway pressures producing regional decreases in blood flow.

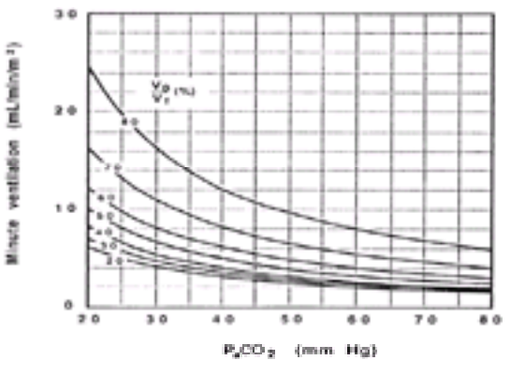

FIG. 4. Relationship of minute ventilation *(vertical axis)* to alveolar ventilation *(P_aCO_2,horizontal axis)*. Isopleths represent different dead space conditions. In this example, CO_2 production is 112 ml/min per m^2, P_B is 760 torr, and temperature is 37°C. (From Chatburn R, Lough M. *Handbook of Respiratory Care.* Chicago: Yearbook, 1990, with permission.)

Delivered V_A and the V_T, f Relationship

The overall amount of ventilation supplied by the ventilator is the product of the tidal volume and the frequency (minute ventilation = $V_T \times f$). Normal values are (5 to 7 mL/kg) × (12 to 20 breaths/min). Minute ventilation requirements in sick patients, however, are often higher than this because of increased metabolic needs (i.e., VO_2 and VCO_2) and increased V_D. Supplying adequate ventilatory support thus often requires increases in V_T, f, or both. In increasing minute ventilation, increases in V_T (rather than f) offer the advantage of a lower V_D/V_T ratio (given a constant V_D) and thus a lower total $f \times V_T$ requirement. On the other hand, increases in V_T will increase maximal alveolar distention and the risk for lung injury (see “Complications,” below). Regardless of whether V_T or f is used to increase V_A, airway resistance to flow and the need to exhale place practical limits on the amount of minute ventilation that can actually be given to patients.

The Inspiratory Flow Pattern

The inspiratory flow pattern (i.e., flow magnitude and flow patterns during either flow-limited or pressure-limited breaths) affects both the distribution of delivered gases and the synchrony of ventilatory support with patient effort during assisted or supported breaths.

Distribution

The distribution of gas from a positive-pressure breath is a complex interaction of delivered flow and regional compliance and resistance that is beyond the scope of this discussion. However, a few general clinical points can be made about inspiratory flow and ventilation distribution: (1) The longer the inspiratory time, the more even is gas distribution among alveoli with different mechanical properties. (2) On the other hand, the longer the inspiratory time, the shorter is the expiratory time, and thus, the greater is the potential for air trapping. (3) The flow pattern (square versus sine versus decelerating versus accelerating) has not been shown to have marked effects on overall ventilation effectiveness, although the patterns with more rapid initial flows may augment gas mixing in the lung and thereby improve gas exchange. In practice, ventilation distribution goals are generally met when the inspiratory:expiratory ratio is in the physiological 1:2 range and flow is delivered as either a decelerating or square wave. Lengthening the inspiratory time beyond this physiological range is discussed below under ventilation strategies.

Synchrony

Synchrony refers to the matching of ventilator-delivered flow to patient-demanded flow during assisted or supported breaths. Flow below that demanded by the patient can result in significant imposed work on the patient and further worsening of P_aO_2 and P_aCO_2 ("flow dyssynchrony"; see "Complications," below).

Inspiratory and expiratory time relationships affect the lung's ability to return to the FRC determined by the set PEEP and the respiratory system's recoil pressure. In general, as compliance increases, resistance increases, and expiratory time shortens, the potential for an "intrinsic" PEEP and air trapping to develop increases. This is discussed in more detail under "Complications," below.

Total Versus Partial Ventilatory Support

Positive-pressure breaths can be used to supply either all or part of the V_A. In supplying all of the V_A, these breaths perform all of the work of breathing and thereby rest the ventilatory muscles. This is termed *total* mechanical ventilatory support. Total support is guaranteed when modes of ventilation are used that provide only controlled breaths in sedated/paralyzed patients. Near-total support is also delivered by using modes that provide mixtures of assisted and controlled breaths if the assisted breaths are properly synchronized to patient demand. Near-total support can also be delivered by using modes providing pressure-supported breaths if the level of machine support is adequate for the work of each breath.

On the other hand, if positive-pressure breaths are used to supply only *part* of the V_A and thus only *part* of the work of breathing (with the patient supplying the remainder), this is termed *partial* ventilatory support. Partial support is generally provided in one of two ways: (1) using modes that allow intermittent spontaneous breaths among assisted/controlled breaths; or (2) using assisted or supported pressure-limited breaths that provide a level of support for each breath that is less than that required for total support.

Total support is usually used in the initial phases of severe respiratory failure, when muscles are fatigued, and when the ventilatory drive is either absent or unreliable. Partial support is usually used during the weaning process. Partial support is also used in patients requiring substantial ventilatory support (i.e., are not ready for active weaning) but who have a reliable ventilatory drive and relatively stable mechanics. In this setting, partial ventilatory support results in (1) less airway pressure being delivered by the ventilator (and thus perhaps a lower lung injury risk; see below) and (2) some level of patient muscle activity (which may forestall muscle atrophy).

Alveolar PO_2 (P_AO_2)

There are essentially two ways to increase the alveolar P_AO_2: (1) increase the P_IO_2 through increases in the F_IO_2 (or, less commonly, through increases in barometric pressure, P_B), and (2) increase the V_A. The relationship among these factors is expressed in the simplified alveolar air equation:

$$P_AO_2 \propto P_IO_2 - P_aCO_2/R \quad \textbf{(1)}$$

which can be rearranged to:

$$P_AO_2 \propto P_IO_2 - VCO_2/V_A/R \quad \textbf{(2)}$$

Note from these relationships that P_IO_2 has a linear relationship with P_AO_2, whereas the effect of an increase in V_A on P_AO_2 is curvilinear (Fig. 5).

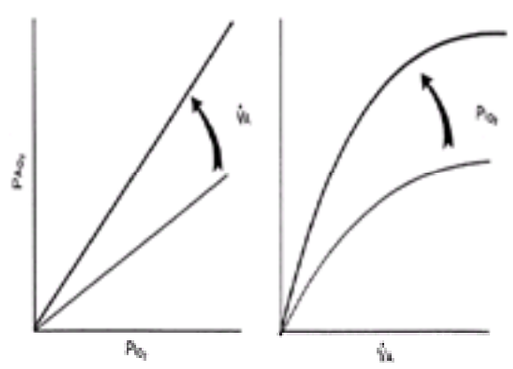

FIG. 5. Relationship of alveolar PO_2 (P_AO_2) to inspired PO_2 (P_IO_2 a P_B and F_IO_2) and to alveolar ventilation (V_A). Note that the relationship of P_AO_2 to P_IO_2 is linear and that V_A affects the slope. On the other hand, the relationship of P_AO_2 to V_A is a curvilinear one that asymptotically approaches the P_IO_2. (From MacIntyre NR. In Dantzker D, MacIntyre N, Bakow E, eds. *Comprehensive Respiratory Care.* Philadelphia: WB Saunders, 1995, with permission.)

The effect of an increase in P_AO_2 on ultimate arterial O_2 content depends on the other factors in O_2 transport affecting the A-aDO_2, especially ventilation–perfusion mismatch and shunt. Thus, predicting the effects of a change in F_IO_2 on P_aO_2 is an approximation at best.

Baseline/Expiratory Pressure

A commonly used technique to improve *VQ* matching is to recruit and stabilize unventilated alveoli with the application of an elevated baseline or expiratory pressure (Fig. 6). Properly applied, expiratory pressure maintains alveolar patency and improves compliance, possibly through improved surfactant function (Fig. 7, curve A to B). Excessive expiratory pressure, however, may serve only to overdistend already recruited alveoli (Fig. 7, curve B to C). In adults with diffuse lung injury, alveoli that are potentially recruitable appear to require between 5 and 20 cm H_2O expiratory pressure. Levels above this, although possibly recruiting some additional alveoli, are probably counterproductive because of overdistention of the already patent alveoli (see "Ventilator Strategies," below).

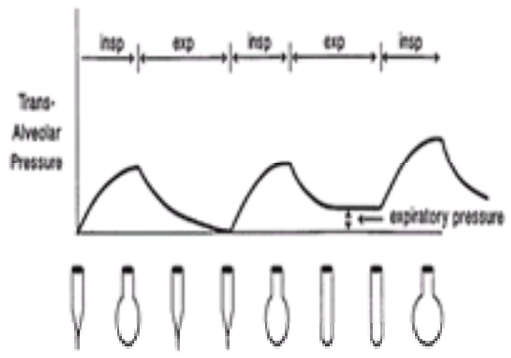

FIG. 6. Behavior of unventilated but recruitable alveoli when expiratory pressure is applied. Note that alveolar patency and the functional residual capacity are restored with appropriate PEEP (recruitment). (From MacIntyre NR. In Dantzker D, MacIntyre N, Bakow E, eds. *Comprehensive Respiratory Care.* Philadelphia: WB Saunders, 1995, with permission.)

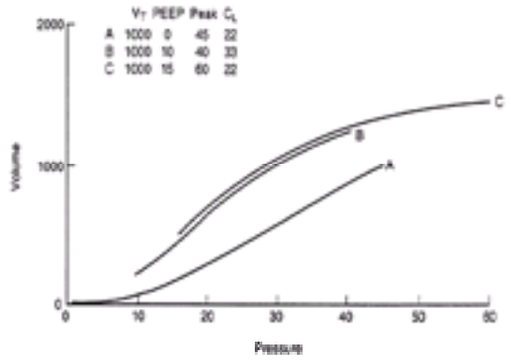

FIG. 7. Mechanical changes in alveoli when ventilated with increasing levels of end-expiratory pressure (PEEP). *Curve A* represents alveoli that remain unventilated until 7 cm H_2O pressure is applied (opening pressure). Subsequent delivery of a 1000-ml tidal volume (V_T) produces a peak pressure of 45 cm H_2O and a calculated compliance (C_L) of 22 mL/cm H_2O. Maintaining alveolar patency during expiration with 10 cm H_2O PEEP improves C_L *(curve B)* Levels of PEEP above this opening pressure, however, may serve only to overdistend the alveoli, thereby worsening C_L *(curve C)* (From MacIntyre NR. In Dantzker D, MacIntyre N, Bakow E, eds. *Comprehensive Respiratory Care.* Philadelphia: WB Saunders, 1995, with permission.)

When used in a spontaneously breathing patient, expiratory pressure can be applied either only during exhalation (EPAP) or else as part of a constant positive airway pressure (CPAP). The CPAP approach minimizes the inspiratory pressure drop (and thus muscle work) that must occur to provide a V_T. Thus, EPAP is rarely used. When it is used in mechanically ventilated patients, the elevated baseline pressure is referred to as positive end-expiratory pressure (PEEP).

COMPLICATIONS OF POSITIVE-PRESSURE VENTILATION

There are a number of hazards associated with positive-pressure mechanical ventilatory support that can result in significant morbidity and mortality if not appropriately recognized and minimized by clinicians.

Hazards Associated with the Endotracheal Tube

There are several potential hazards associated with the “artificial airway.” First, endotracheal tube dislodgement can occur in as many as 5% to 10% of all patients. If monitored and alarmed properly, this usually poses no serious threat to the patient. However, an unrecognized ventilator disconnect can be fatal. Endotracheal tubes also bypass the normal gas-conditioning process of the upper airway. Thus, the mechanical ventilatory support system must supply appropriate heat and humidity as described above. Inadequate heat and humidity can result in tracheal mucosal injury as well as plugging of the endotracheal tube and airways with dried secretions. Another hazard of the endotracheal tube is the fact that it imposes a significant resistive load on spontaneous breaths. This obviously becomes worse with narrow tubes and high patient demand. This form of imposed muscle load has been reported to increase the normal baseline work of breathing severalfold under certain conditions. This imposed work always should be considered in assessing a patient who is difficult to wean from the mechanical ventilator.

Mechanical Malfunctions

The modern generation of mechanical ventilators is remarkably reliable. Nevertheless, any mechanical system can fail. The most common mechanical failure is the exhaled flow transducer (up to 2% failure rate per year). This is not surprising because it is the one part of the machine that is exposed to patient secretions and nebulized solutions. Modern microprocessor systems usually have a variety of self-checks and alarms available. Alarms themselves rarely fail. Of more concern is the fact that alarms are often turned off. This may be a consequence of the fact that too many alarms are set too tightly and thus create so many false alarms that the normal reaction is to shut the alarm down. Clinician awareness of what alarms are important and what alarms may serve only to annoy is critical.

Patient–Ventilator Dyssynchrony

A mechanical ventilator must interact with patient efforts during assisted, supported, and spontaneous breaths. This interaction exists during all three phases of the breath: trigger, limit, and cycle. Inappropriate effort sensors (poor sensitivity or responsiveness) can impose significant loads on patients during triggering. Equally important is that during breath delivery to a patient with an active ventilatory drive, the machine limit and cycling settings can also impose significant loads if not properly “synchronized” to the patient's muscular efforts. This appears to be particularly true when fixed, flow-limited, volume-cycled breaths are used, especially in patients with very active ventilatory drive. Improving synchrony with these types of breaths can sometimes be achieved by adjusting the flow pattern, increasing the assisted breath rate, or else by sedating the patient. Perhaps a better approach to improving synchrony is to utilize the variable flows that exist with a pressure-limited breath (Fig. 8). This capability has recently been enhanced by the addition of a pressure rise time adjustor on newer systems. A consideration of patient–ventilator dyssynchrony ought to be made in all cases of patient agitation and/or weaning difficulty.

FIG. 8. Flow (V), volume (V_T), airway pressure (P_{aw}), and esophageal pressure (P_{es}) in a patient receiving flow-limited, volume-cycled breaths **(left panel)** and pressure-limited, flow-cycled breaths **(right panel).** Patient-imposed load from flow dyssynchrony is reflected by the area under the baseline of the P_{es} tracing during inspiration. In this example, the variable flows of the pressure-limited breath synchronize with patient effort better than the fixed flows of the volume-cycled breath.

Thus, imposed load is less.

Air Trapping or Intrinsic PEEP ($PEEP_i$)

An inadequate expiratory time can result in air trapping and the development of so-called intrinsic or auto-PEEP. This can have profound effects on delivered ventilation and intrathoracic pressures (Fig. 9). Although intrinsic PEEP is sometimes recommended as a goal in strategies designed to lengthen inspiratory time (see "Ventilator Strategies," below), usually this phenomenon is undesirable because it is difficult to monitor and can cause unrecognized pressure-related hazards. One of the best ways to monitor the development of inadequate expiratory time is to follow a flow graphic. When expiratory time is inadequate, the expiratory flow signal does not return to the zero baseline (Fig. 9, middle panels). In the absence of a flow graphic, one should suspect inadequate expiratory time in the setting of patients with high ventilatory demands, especially those patients with airway dysfunction. Clinically, the development of intrinsic PEEP is manifested by applied high peak airway pressures (if using volume-cycled ventilation), loss of tidal volume (if using a pressure-limited mode), patient discomfort, or cardiac compromise. Ventilator adjustments to reduce intrinsic PEEP from inadequate expiratory time include a slower frequency (longer expiratory time) or a shorter inspiratory time from either faster flows or lower tidal volumes.

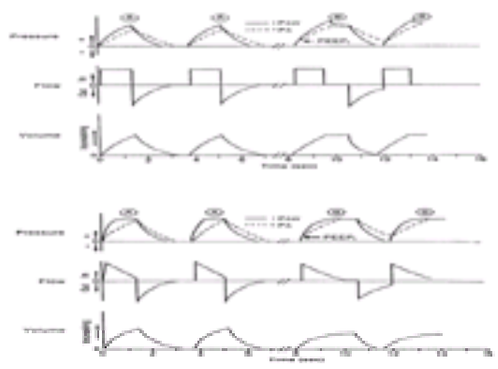

FIG. 9. Intrinsic positive end-expiratory pressure ($PEEP_i$) developing from shortened expiratory times during volume-targeted ventilation **(upper panel)** and pressure-targeted ventilation **(lower panel). Top:** airway pressure *(solid line)* and alveolar pressure *(dotted line)* are plotted. **Center:** flow is plotted. **Bottom:** volume is plotted. Volume-targeted breaths are delivered either without **(A)** or with **(B)** inspiratory holds that affect expiratory time. In the **A** curves, expiratory time allows complete lung emptying such that expiratory flow is zero before the next inspiration. There is no air trapping, and $PEEP_i$ is zero. In the **B** curves, expiratory time does not allow complete lung emptying, such that expiratory flow is greater than zero before the next inspiration. Now there is air trapping, and $PEEP_i$ is greater than zero. Note that $PEEP_i$ in volume-targeted ventilation raises peak pressure but keeps delivered volume constant. In contrast, $PEEP_i$ in pressure-targeted ventilation reduces delivered volume because airway pressure is limited. (From MacIntyre NR. In Fulkerson W, MacIntyre NR, eds. *Complications of Mechanical Ventilation. Problems in Respiratory Care.* Philadelphia: JB Lippincott, 1991, with permission.)

Air trapping can also develop as a consequence of dynamic airway collapse, even in the presence of a reasonable expiratory time. In addition to the above-mentioned effects of intrinsic PEEP, this type of air trapping is often associated with a difficulty in triggering assisted or supported breaths. Under these circumstances, a small amount of applied PEEP (less than the intrinsic PEEP) will reduce this imposed load (Fig. 10).

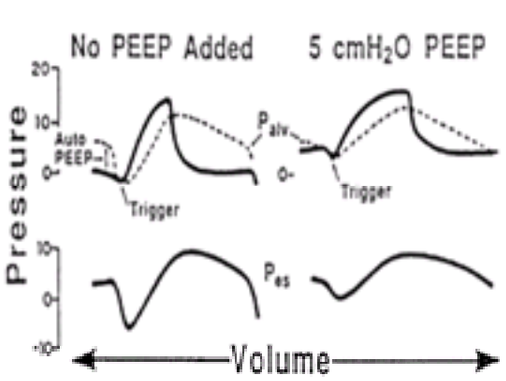

FIG. 10. Impact of auto-PEEP (intrinsic PEEP) on trigger sensitivity and inspiratory effort. To trigger a machine cycle, alveolar pressure (P_{alv}) must fall by the amount of auto-PEEP plus the set trigger sensitivity. The large dip in esophageal pressure (P_{es}) reflects this effort. The addition of PEEP downstream from dynamically compressed airways reduces the P_{alv}–P_{aw} gradient and attenuates the breathing workload without a significant increase in end-inspiratory P_{alv}. (From Marini JJ. In Cherniak NS, ed. *Chronic Obstructive Pulmonary Disease.* Philadelphia: WB Saunders, 1990, with permission.)

Oxygen Toxicity

Raising the P_AO_2 can cause alveolar capillary injury through the toxic effects of oxygen radicals. Depending on the baseline lung pathology, the presence of certain drugs (e.g., bleomycin) and perhaps mechanical forces from positive-pressure breaths, even mild increases in P_AO_2 have been associated with oxygen toxicity. Generally, most clinicians accept the concept that an F_IO_2 below 0.4 can be tolerated for prolonged periods, whereas F_IO_2 values exceeding 0.6 are associated with increased risk. In addition, an F_IO_2 approaching 1.0 can result in absorption atelectasis and worsening of ventilation perfusion (*VQ*) mismatch and shunt.

Stretch Injury (Volutrauma/Barotrauma)

Stretch injury refers to lung damage caused by alveolar overdistention. Alveolar overdistention tends to occur in the less injured lung regions that become overinflated by a high intrathoracic pressure. Although damage appears to be caused primarily by the magnitude of the physical stretching, confounding factors include the duration of stretch and the frequency of stretch. Use of PEEP also plays an important role in stretch injury in two ways. First, in injured alveoli subjected to repeated opening and closing from positive-pressure breaths, a certain minimal PEEP to recruit and prevent collapse may *reduce* stretch injury (Fig. 7, curve A to B). On the other hand, PEEP in already patent alveoli may serve only to increase the end-inspiratory stretch and thus *potentiate* stretch injury (Fig. 7, curve C). Optimal PEEP is conceptually a balance between these two effects (see "Ventilator Strategies," below).

End-inspiratory alveolar stretch is usually assessed by the "plateau" pressure. This is the airway pressure at end-inspiration under no-flow conditions. Provided that chest wall and/or abdominal compliances are not low, this pressure is a reasonable guide to the level of alveolar stretch that is occurring during positive-pressure ventilation. Normal end-inspiratory transalveolar pressures at total lung capacity are 30 to 40 cm H_2O.

The manifestations of stretch injury are of two types. The most obvious type is alveolar rupture, which results in mediastinal emphysema, subcutaneous emphysema, and pneumothorax. The risk is high when alveolar (plateau) pressures exceed 60 cm H_2O. A less appreciated form of stretch injury, however, is tissue injury without rupture. This form of tissue injury can mimic many features of the adult respiratory distress syndrome and may worsen the underlying lung disease. This injury may be potentiated by concurrent oxygen injury and appears to occur in relatively normal alveoli that are overdistended with end-inspiratory pressures above the normal maximum of 30 to 40 cm H_2O.

Infections

Pulmonary infections are also a common complication of mechanical ventilatory support (estimates range from 15% to 40% of all ventilated patients). The reasons for this are several: (1) the endotracheal tube impairs the lung's physical defense against invading organisms and impairs cough and mucus clearance; (2) cough is often decreased by disease and sedation; and (3) atelectasis occurs frequently in patients on mechanical ventilators. A common source of infecting organisms is the GI tract. Prophylactic antibiotics, gut sterilization, and maintaining acidity in the stomach have been advanced as ways to protect against infectious complications, but the results of these interventions have not been shown to improve outcome. Contaminated circuits and humidifiers are also a potential source of infecting organisms. One of the best ways to prevent nosocomial infections, however, is the simple step of hand washing when working with the patient's ventilator circuitry.

Cardiovascular Effects

Increased intrathoracic pressure can affect cardiovascular function. These increased pressures can be the result of ventilation pressures (i.e., tidal breaths and inspiratory time), applied expiratory pressure, and alveolar expiratory pressure resulting from air trapping (“intrinsic” PEEP). Although many mechanisms for consequent cardiac depression have been proposed, it appears the most important is the fact that elevated intrathoracic pressure impedes venous return and thus cardiac filling. Indeed, it has been known for years that to compensate for a reduction in cardiac output with high ventilatory pressures, one should increase the intravascular volume. The airway pressure measurement that seems to correlate best with cardiovascular filling difficulties is the mean airway pressure.

One of the more interesting approaches to manipulation of airway pressure to affect cardiac function is the use of a ventilator breath synchronized to cardiac systole. If the positive airway pressure is timed to occur during systole, and the airway pressure is released during diastole, cardiac output can sometimes be increased such that the ventilator, rather than being a hindrance to cardiac function, can actually function as a partial ventricular assist device. Note that although this approach is still experimental, it does offer an interesting and important lesson in the physiology of heart–lung interactions.

VENTILATOR STRATEGIES TO PROVIDE TOTAL VENTILATORY SUPPORT

Current approaches to total ventilatory support generally attempt to duplicate the normal bulk flow ventilatory pattern and use tidal volumes of 7 to 12 mL/kg, machine breath rates of 10 to 30 breaths/min, and inspiratory to expiratory ratios of 1:4 to 1:2. These positive-pressure breaths are generally delivered as either flow-limited, volume-cycled breaths or pressure-limited, time-cycled breaths. Positive-pressure ventilatory support is usually used in conjunction with elevations in baseline (end-expiratory) pressure (PEEP) and supplemental O_2.

These settings generally provide safe and effective total ventilatory support in most patients in respiratory failure. There are, however, patients in whom these conventional approaches either do not provide adequate blood gas values or else do so with excessive intrathoracic pressures (e.g., plateau pressure exceeding 30 to 40 cm H_2O). Under these circumstances, strategies that balance potential tradeoffs between lung protection and gas exchange must be considered.

Balancing Alveolar Recruitment with Alveolar Overdistention Using PEEP

On the one hand, as noted above, PEEP is used to recruit unventilated alveoli (Fig. 7, curves A to B). Recruited alveoli generally provide better gas exchange and thus a lower F_IO_2 requirement. Moreover, recruited alveoli may be less prone to injury related to the stress of repeated opening and closing. On the other hand, providing high levels of PEEP in an attempt to “normalize” P_aO_2 may be counterproductive if it results in alveolar overdistention in already patent alveoli (Fig. 7, curve C). Several clinical studies in patients with diffuse lung injury have used static pressure–volume plots to show that a reasonable balance between recruitment potential and overdistention risk is generally achieved with PEEP levels of only 5 to 20 cm H_2O. Because this balanced PEEP approach may not provide the maximal P_aO_2, tradeoffs occur. Specifically, a higher F_IO_2 may be required, or a lower S_aO_2 may need to be tolerated (“permissive hypoxemia”). The effects of a lower S_aO_2 (e.g., in the 85% to 89% range) can sometimes be ameliorated by lowering oxygen consumption (e.g., sedation, pain control, fever control) or by increasing other components of oxygen delivery (e.g., hemoglobin concentration, cardiac output).

Balancing Alveolar Ventilation with Alveolar Overdistention Using the V_T

As noted above, the two determinants of end-inspiratory alveolar distention are the baseline distention (see PEEP discussion above) and the tidal distention. Historically, delivered tidal volumes were often recommended to be as high as 15 to 20 mL/kg. This, however, was a reflection of practice in anesthesia before the development of PEEP, when large tidal volumes were required to overcome atelectasis. Lowering tidal volumes to 6 to 8 mL/kg will clearly reduce alveolar pressures and alveolar distention if more conventional V_T settings result in unacceptable plateau pressures (e.g., >30 to 40 cm H_2O). Under these circumstances, alveolar ventilation can be maintained up to a point by increasing the respiratory frequency. Ultimately, however, rapid rates cannot compensate for the loss of tidal volume, and alveolar ventilation will fall, arterial PCO_2 will rise, and arterial pH will fall, creating a respiratory acidosis. This tradeoff is often referred to as “permissive hypercapnia,” and pHs with this strategy have been reported to fall below 7.0. The effects of normoxic hypercapnia under those circumstances are only beginning to be understood. In general, however, humans seem to tolerate an arterial pH of 7.15 and PCO_2 of 80 torr quite well. The rate at which the P_aCO_2 is allowed to rise should probably be slow (e.g., 10 torr/hr) to permit intracellular pH to adjust.

Caution should be used in permitting respiratory acidosis in patients with intracranial mass effects, recent myocardial infarcts, pulmonary hypertension, and possibly gastrointestinal bleeding. Respiratory acidosis may also contribute to dyspnea and agitation in critically ill patients and thus may require heavy sedation or paralysis. In animal models with acute lung injury, pulmonary shunt was higher when ventilation was achieved with smaller tidal volumes. Thus, smaller tidal volumes may require an increased level of PEEP and/or F_IO_2 to maintain acceptable levels of arterial oxygenation.

A low-tidal-volume strategy has resulted in lower mortality when compared to historical controls matched for physiological scores. More compelling is a recent preliminary report of a controlled trial using static pressure–volume plots to determine the lower (recruitment) and upper (overdistention) “inflection” points (Fig. 11). This strategy places baseline pressures (PEEP) above the lower inflection point and limits V_T to pressures below the upper inflection point. Patients ventilated with this approach appear to have less lung stretch injury and improved outcome.

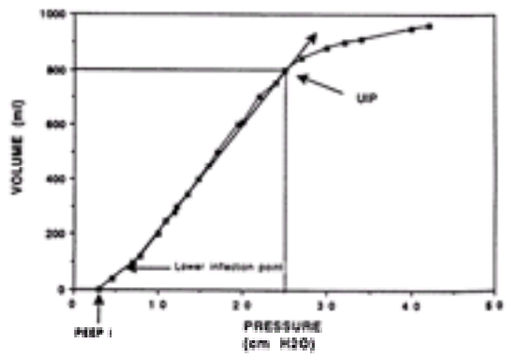

FIG. 11. Static pressure–volume curve of the respiratory system obtained in a patient with diffuse lung injury. Intrinsic PEEP ($PEEP_i$), present during the course of mechanical ventilation, represents the starting point of the curve. Inflection points were defined as lower (LIP) and upper (UIP) points on this sigmoid curve, where data consistently separated from the middle linear part of the curve. (From Rouple E, Dambrosio M, Serviool G, Mentec H, El Altrous S, Beydon L, Brun-Buisson C, Lemaire F, Brochard L. Titration of tidal volume and induced hypercapnia in acute respiratory distress syndrome. *Am J Respir Crit Care Med* 1995;152:121–128, with permission.)

Long-Inspiratory-Time Strategies as an Alternative to PEEP/F_IO_2

The conventional inspiratory-to-expiratory (I:E) ratio is generally 1:2 to 1:4. This range of I:E ratios tends to synchronize with the patient's spontaneous ventilatory drive

and permits adequate expiratory time for the lung to return to functional residual capacity (FRC) using the recoil pressure of the respiratory system.

Lengthening the inspiratory time to I:E ratios approaching 1:1 or even exceeding it (so-called inverse-ratio ventilation) can be accomplished in either volume-cycled or pressure-limited modes by either providing a very slow inspiratory flow pattern or by holding the alveoli fully inflated for a period of time (inspiratory “pause”). Prolonging inspiration has several physiological effects. First, the alveolus is held at its inspiratory volume for a longer period of time. Theoretically, this should allow more mixing time between alveolus and conducting airway and more exposure of capillary blood to fresh gas. The few clinical studies that have studied only this longer gas mixing and alveolar “dwell time” phenomenon have tended to show improvement in ventilation–perfusion (*VQ*) matching and modest increases in P_aO_2.

A second effect of longer inspiratory times is the potential for incomplete lung emptying. Under these conditions, the lung cannot return to its normal FRC, and “intrinsic” PEEP develops (Fig. 9). Much like applied PEEP, intrinsic PEEP, by increasing FRC, can affect gas exchange by improving *VQ* matching. Indeed, many of the studies on long inspiratory time and inverse-ratio ventilation showing improvement in gas exchange have probably had this occur as a consequence of intrinsic PEEP.

It is important to separate these two effects of longer inspiratory times from a mechanical perspective. Specifically, a longer inspiratory time *without* air trapping is designed to provide *VQ* improvement without affecting tidal volume, baseline alveolar pressure, or maximal alveolar pressure. Conversely, a longer inspiratory time *with* air trapping may also improve *VQ* matching, but, because it functions like applied PEEP, it will necessarily raise baseline alveolar pressure. This will reduce tidal volume in a pressure-limited mode and raise maximal alveolar pressures in a volume-cycled mode (Fig. 9). It is also important to note that once one exceeds the normal I:E ratio, the need for sedation and even paralysis starts to increase.

Investigational Strategies

There are a number of total-support strategies in the adult that may find clinical utility in the future. These include high-frequency ventilation (frequencies exceeding 150 breaths/min and tidal volumes approaching dead space), nitric oxide inhalation, surfactant replacement therapy, and liquid ventilation (using an oxygen-soluble fluorocarbon to function as “liquid” PEEP). All of these are in various stages of development, and we must await definitive outcome data before widespread clinical application can be recommended.

VENTILATOR STRATEGIES TO PROVIDE PARTIAL VENTILATORY SUPPORT

Partial ventilatory support, as defined above, is designed to provide only part of the work of breathing. Generally this form of support is given to patients as they recover from lung injury and recover the ability to do some of the work of breathing. Reducing partial support is often termed *weaning*

The argument is sometimes made that weaning is an unnecessary process. This argument states that total support should be given to patients until they can breathe entirely on their own. At this point, the ventilator is then discontinued. This approach is certainly appropriate for rapidly resolving processes such as anesthesia recovery. However, it is probably inappropriate in patients with much slower recovery process for two reasons: (1) partial support (as opposed to total support) requires less positive pressure in the thorax and thus a lower risk of stretch injury or hemodynamic compromise; (2) partial support (as opposed to total support) demands some patient activity, which will help prevent muscle atrophy and may even contribute to a muscle-conditioning process. These two effects would seem desirable in a patient requiring prolonged support.

There are at least three established ways of providing partial support during the weaning process. The oldest technique is *intermittent spontaneous breathing* alternating with periods of total support (“T-piece” weaning). Weaning progresses by having the patient take longer and longer periods of spontaneous breathing. In between these periods, the ventilator takes over all of the work of breathing and allows the patient to rest. A second technique is *intermittent mandatory ventilation* (IMV). With IMV, patients take spontaneous breaths interspersed among mandatory ventilator breaths. Weaning progresses by providing decreasing numbers of ventilator breaths such that patients take increasing numbers of spontaneous breaths. A variation on this approach is synchronized IMV (SIMV), which utilizes volume-assisted breaths along with backup volume-control breaths. Another variation is the addition of 5 to 10 cm H_2O of pressure support to the spontaneous breaths of IMV to reduce (or eliminate) the imposed work of breathing through narrow endotracheal tubes. The third technique is stand-alone *pressure-limited ventilation* With this technique, partial support is provided with every breath by using a pressure-limited, patient-triggered breath. Usually this is provided by the pressure-support breath, although a pressure-assist breath (patient-triggered, pressure-limited, time-cycled breath; Table 2) can also provide a similar level of partial support while guaranteeing a certain inspiratory time. Weaning progresses from a high level of inspiratory pressure (enough to provide virtually all the work of each breath, usually associated with tidal volumes of 7 to 10 mL/kg) to lower levels of pressure where the patient contributes substantial work to each breath.

“T-piece” breathing trials and IMV offer the advantage of a certain mandatory minute ventilation being provided by the ventilator. In contrast, stand-alone pressure-limited breaths cannot guarantee a minimum minute ventilation but do offer the theoretical advantage of being a more comfortable and physiological way to have the muscles work because a pressure “boost” is provided with each ventilatory effort (Fig. 8). Clinical studies comparing outcomes of these different approaches have given conflicting results (Fig. 12). In general, however, it appears that aggressive weaning approaches (e.g., T-piece) are appropriate in rapidly resolving lung injury, whereas more comfortable approaches (e.g., pressure support) are more appropriate in a more slowly resolving lung injury. The use of short spontaneous breathing trials each morning may be useful to distinguish these different types of patients recovering from lung injury.

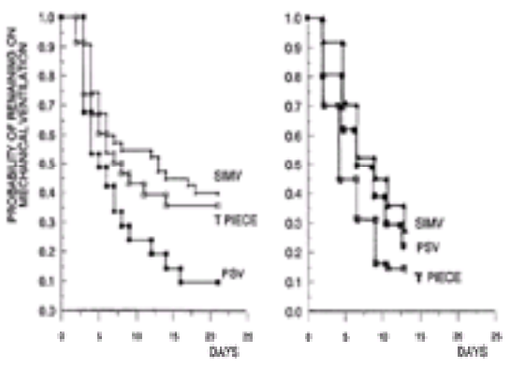

FIG. 12. Results of two large randomized weaning trials. On the *vertical axis* is probability of remaining on the ventilator. On the *horizontal axis* is number of days after randomization to one of three weaning protocols: spontaneous breathing trials (T-piece), synchronized intermittent mandatory ventilation (SIMV), and stand-alone pressure support (PSV). **Left panel** represents data from Brochard L, Rauss A, Benito S, Conti G, et al. Comparison of three methods of gradual withdrawal from ventilatory support during weaning from mechanical ventilation. *Am J Respir Crit Care Med* 1994;150:896–903. **Right panel** represents data from Esteban A, Frutos F, Tobin MJ, Alia I, Solsona JF, et al. A comparison of four methods of weaning patients from mechanical ventilation. Spanish Lung Failure Collaborative Group. *N Engl J Med*1995;332:345–350.

Regardless of which technique is used, proper monitoring of the weaning process is crucial for proper aggressiveness and safety in advancing the weaning process. Because the goal is to return ventilatory work to the patient as quickly as tolerable, indicators of patient load tolerance should be the best parameters to monitor during weaning (Table 3). The respiratory rate is a particularly useful sign in this regard. Specifically, tachypnea is one of the earliest signs of respiratory muscle overload and fatigue and is an excellent guide to setting the appropriate level of partial support. Arterial blood gases are also useful to monitor during the weaning process, but it should be noted the changes in PCO_2 and PO_2 may not occur until long after respiratory muscle fatigue has begun to develop. Arterial blood gases thus should not be the exclusive guide to weaning. Other indirect indications of a patient tolerating the weaning process include stable hemodynamics, subjective comfort, and a regular breathing pattern.

Respiratory rate
Arterial blood gases
Work (normal <5–10 joules/min)
Pressure–time product (nonfatiguing if less than 15% of maximal diaphragmatic pressure)
Patient assessment for comfort, tachycardia, blood pressure stability

TABLE 3. *Monitoring patient tolerance of partial support*

When the weaning process has progressed to a fairly low level of partial support (e.g., spontaneous breathing trials lasting 30 to 60 min, IMV rates less than 4 breaths/min, pressure support levels less than 10 cm H_2O), the patient's ability to tolerate prolonged spontaneous breathing without any support needs to be assessed (Table 4). Again, the respiratory pattern may be the best predictor of success, and a frequency to tidal volume ratio less than 105 has been found to be among the best of these. Extubation criteria also need to take into account the patient's ability to protect the airway and to provide an adequate cough for secretion clearance.

Negative inspiratory force stronger than 25 cm H_2O
Vital capacity >10 ml/kg
Minute ventilation <10 liters/min
Frequency/tidal volume <105/liter
"CROP" index [(compliance X negative inspiratory force X P_aO_2/P_AO_2)/respiratory rate] >13 ml/breath per min

TABLE 4. *Extubation criteria*

In addition to treating the underlying disease and setting the proper level of partial support, there are a number of other aspects that must be considered for total management of the patient requiring prolonged support. First, the ventilator mode should be a comfortable one for the patient. Specifically, required triggering efforts should be small, and ventilator flows should be in accordance with patient demand. Pressure-limited breaths with adjustable "rise times" seem beneficial in this regard. In addition, an experimental interactive breath that uses a flow "gain" setting based on lung impedances (proportional-assist ventilation) may be even better. Second, airway management must be meticulous with proper suctioning techniques, aspiration precautions, humidification, and circuit hygiene. Third, nutritional considerations are important, particularly in the patient who may have undergone a serious stress such as surgery or complicating sepsis. Fourth, cardiovascular management must include proper fluid balance and an appropriate cardiac output. During the weaning process, the ventilatory muscles are being asked to take over an increasing workload, and proper oxygen delivery is critical. Finally, patience is needed on the part of the clinicians. Remember, weaning can progress no faster than respiratory system healing. The ventilator management goal is thus not to "cure" the lung but rather to provide an adequate level of support and to not hinder the recovery process with iatrogenic complications.

NONINVASIVE TECHNIQUES FOR VENTILATORY SUPPORT

There are two fundamental approaches to providing ventilatory support without the use of an artificial airway: (1) techniques designed to expand the thorax by negative pressure and (2) techniques designed to inflate the chest with positive pressure applied through a mask. Because these approaches are often awkward to use and are usually incapable of high levels of ventilatory support, they are generally used as either intermittent partial support (e.g., nocturnal ventilation) or as a short-term technique to "buy time" in an acute situation.

Negative-Pressure Approaches

These approaches range from iron lungs to chest wraps to rocking beds. Although they all can provide some degree of lung inflation, they are generally very cumbersome, incapable of any synchrony with patient efforts, and provide no airway protection. Because of this, application is generally limited to patients with neuromuscular dysfunction in whom some nocturnal assistance and muscle "rest" results in improved ventilatory function during the day. See chapter 50.

Positive-Pressure Mask Approaches

Ventilatory support or continuous positive airway pressure (CPAP) can be provided by positive pressure applied through mask systems. Full-face mask ventilation using either pressure-limited or flow-limited breaths can be done through tight-fitting masks. Such systems can respond to patient effort to provide either assisted or supported breaths. However, leaks are common, and gastric overdistention can result in vomiting and aspiration. These systems would appear to be a reasonable strategy for short-term support in acute respiratory failure if monitored properly. Indeed, several studies have suggested that short-term face-mask ventilation may prevent the need for endotracheal intubation in patients with rapidly reversible respiratory failure (e.g., asthma). The role of this technique in long-term support without close monitoring (e.g., home care) is less clear because of concerns over leaks, undetected circuit occlusions, and gastric distention.

Positive airway pressure can also be provided by nasal mask. The inevitable mouth leak can be compensated for by continuous gas flows. This approach to providing CPAP has been very effective in managing obstructive sleep apnea and probably has a role in noninvasively restoring FRC and improving *VQ* mismatch in mild to moderate pulmonary edema. It may also have a role in overcoming some intrinsic PEEP caused by dynamic airway collapse in patients with airway dysfunction (Fig. 10). The role of nasal-mask positive-pressure breaths in providing ventilatory support (generally using pressure-limited breaths) is less clear. Reports exist suggesting short-term nasal-mask ventilation can be useful in preventing endotracheal intubation in reversible respiratory failure. However, mask function, leak tolerance, and patient synchrony with these systems are variable, and thus, they usually require close monitoring to be effective for short-term support in dyspneic patients. An advantage to a nasal mask is that, because the mouth is open, there is less concern about vomiting and aspiration and the danger of undetected circuit occlusion. Long-term usage is thus a potential application of such systems (e.g., nocturnal support), and, indeed, treatment of some obstructive sleep apnea patients appears enhanced when positive pressure during inspiration is added to the elevation in baseline pressure. However, the long-term role of such systems in patient with intrinsic lung disease and dyspnea is unknown.

CONCLUSION

Mechanical ventilation utilizes positive pressure to support ventilation (through tidal breath delivery) and oxygenation (through ventilation distribution effects and alveolar recruitment in expiration). Potential hazards include "stretch" injury, cardiac compromise, endotracheal tube dysfunction, oxygen toxicity, patient discomfort, and infections. Ventilatory support can either be total or partial. During total ventilatory support, the ventilator supplies all the work of respiration. Under these conditions, tradeoffs between gas-exchange goals and the risks associated with high intrathoracic pressures must sometimes be made. During partial ventilatory support, the ventilator supplies only a portion of the work of respiration, with the patient supplying the remainder. Reduction in partial support is termed weaning. Under these conditions, the need to aggressively reduce support must be balanced against the potential to fatigue the patient. It must always be remembered that mechanical ventilation provides *support*, not *therapy*, for respiratory failure. As such, it cannot be expected to cure lung disease. Rather, it can only be expected to support life with minimal complications while more definitive therapies are given time to work.

CHAPTER

49 Weaning from Ventilatory Support

Patrick J. Fahey · Martin J. Tobin

P.J. Fahey and M.J. Tobin: Department of Medicine, Edward Hines Veterans Affairs Hospital and Department of Medicine, Loyola University of Chicago Stritch School of Medicine, Hines, Illinois 60141.

INTRODUCTION

The term weaning is open to misunderstanding. In the strict sense, it means a slow, gradual decrease in the amount of ventilator support. More commonly, it is used to refer to all methods of discontinuing mechanical ventilation, although this usage of the term is incorrect in the strict literal sense. In most instances of mechanical ventilation, weaning is quite straightforward, and patients can resume spontaneous breathing with little or no difficulty. About 20% to 30% of patients fail initial attempts at discontinuing mechanical ventilation, and these difficult-to-wean patients account for a disproportionate amount of health care resources. Overall, about 40% of the time that a patient receives mechanical ventilation is spent trying to wean the patient from the ventilator, and in patients with certain disease states, such as chronic obstructive pulmonary disease, the weaning process accounts for about 60% of ventilator time.

PATHOPHYSIOLOGICAL DETERMINANTS OF WEANING OUTCOME

A patient's ability to tolerate discontinuation of ventilator support is determined by the adequacy of pulmonary gas exchange, the performance of the respiratory muscle pump, and psychological factors.

Adequacy of Pulmonary Gas Exchange

During failed attempts at weaning from mechanical ventilation, hypoxemia may result from hypoventilation, impaired gas exchange, or decreased oxygen content of venous blood. By and large, severe hypoxemia is a relatively uncommon mechanism of weaning failure, because weaning is not attempted in patients who appear prone to problems in oxygenation.

Respiratory Muscle Performance

Failure of the respiratory muscle pump is the most common cause of failure to wean from mechanical ventilation. This may result from decreased neuromuscular capacity, increased respiratory muscle pump load, or a combination of both factors (Table 1).

Decreased respiratory neuromuscular capacity
Decreased respiratory center output
Phrenic nerve dysfunction
Neuromuscular disorders
Decreased respiratory muscle strength and/or endurance
Hyperinflation
Malnutrition
Decreased oxygen supply
Respiratory acidosis
Mineral and electrolyte abnormalities
Renal failure
Endocrinopathy
Drug-induced abnormalities
Disuse muscle atrophy
Respiratory muscle fatigue
Increased respiratory muscle pump load
Increased ventilatory requirements
Increased CO_2 production
Increased deadspace ventilation
Inappropriately increased respiratory drive
Increased work of breathing

TABLE 1. *Causes of respiratory muscle pump failure*

Decreased Respiratory Neuromuscular Capacity

Respiratory Center Output

Patients who fail a weaning trial commonly develop respiratory acidosis, raising the possibility that respiratory center drive may be decreased. However, indices of respiratory drive, such as airway occlusion pressure at 0.1 sec ($P_{0.1}$) or mean inspiratory flow (tidal volume divided by inspiratory time interval; V_T/T_I), are usually above the normal range in such patients. Furthermore, an increase in V_T/T_I has been observed in patients who developed severe alveolar hypoventilation (Fig. 1).

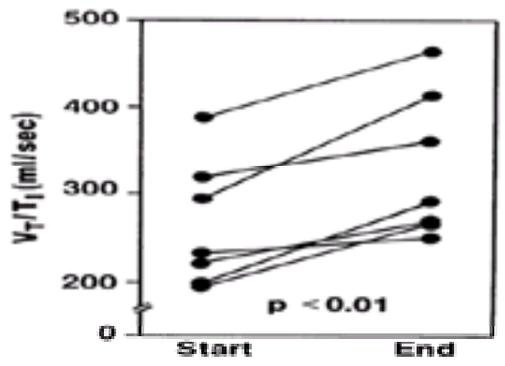

FIG. 1. Measurements of mean inspiratory flow (V_T/T_I) at the beginning and end of a trial of spontaneous breathing in patients who required the reinstitution of mechanical ventilation. (From Tobin MJ, Perez W, Guenther SM, et al. The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation. *Am Rev Respir Dis* 1986;134:111, with permission.)

Phrenic nerve dysfunction results in raised left hemidiaphragm, and electrophysiological studies reveal evidence of phrenic nerve injury in about 10% of these patients. Factors that appear to be important in causing phrenic nerve injury include inadvertent sectioning, stretching or compression of the nerve, or compromise of blood flow to the vaso vasorum of the nerve. However, attention has mainly focused on another mechanism: hypothermic injury caused by the use of topical cardioplegia, which involves filling the pericardium with crushed ice or chilled saline. The precise nature of the phrenic nerve injury is unknown, although the clinical course is most compatible with axonal degeneration. A small number of patients develop bilateral diaphragmatic paralysis resulting in prolonged ventilator dependency.

Respiratory Muscle Function

Respiratory muscle function may be impaired by a variety of conditions commonly observed in critically ill patients (Table 1). Of the clinical conditions that cause a decrease in respiratory muscle strength and/or endurance, *hyperinflation* is one of the most important. Worsening of lung mechanics leads to prolongation of the respiratory time constant (i.e., resistance × compliance) and is commonly associated with an increase in respiratory rate. As a result, expiratory time becomes insufficient for lung emptying, and dynamic hyperinflation occurs. Hyperinflation has a number of adverse effects (Fig. 2): respiratory muscles operate at an unfavorable position of their length–tension curve; flattening of the diaphragm increases the radius of curvature, and, thus, according to Laplace's law, tension within the muscle is less effectively translated into transdiaphragmatic pressure; chest wall efficiency is impaired as a result of the medial orientation of the diaphragmatic fibers, the decrease in the zone of apposition, and the horizontal (rather than oblique) orientation of the fibers; and the inwardly directed elastic recoil of the chest wall poses an added elastic load.

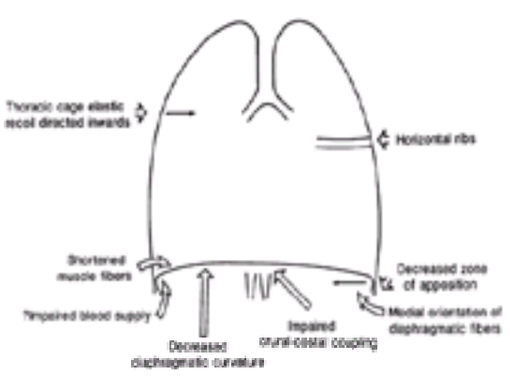

FIG. 2. The detrimental effects of hyperinflation on respiratory muscle function (see text for explanation). (From Tobin MJ. Respiratory muscles in disease. *Clin Chest Med* 1988;9:263–286.)

Malnutrition is common in critically ill patients and has a number of adverse effects on respiratory function: a decrease in the ventilatory response to hypoxia, a decrease in muscle mass and thickness, and a reduction in respiratory muscle strength and endurance. The O_2 supply to a muscle is decreased if cardiac output falls, the O_2 content of arterial blood decreases, or O_2 extraction is impaired. In a study of patients who failed a trial of weaning from mechanical ventilation, increases in pulmonary artery wedge pressure and left ventricular end-diastolic volume were observed (Fig. 3); these changes were attributed to augmentation of venous return (because of low pleural pressure during spontaneous breathing and central translocation of blood volume secondary to peripheral venoconstriction) and increased left ventricular afterload (because of markedly negative pleural pressure swings and increased catecholamine release). In a study employing thallium-201 (^{201}Tl) myocardial scintigraphy, resumption of spontaneous breathing was found to result in isotope redistribution in the myocardium and/or transient left ventricular dilation. Both of these changes were interpreted as being ischemic in origin and were thought to result from increased left ventricular preload and afterload. A number of studies have shown that moderate hypoxemia exacerbates respiratory muscle endurance and fatigability, whereas hyperoxia enhances respiratory muscle endurance.

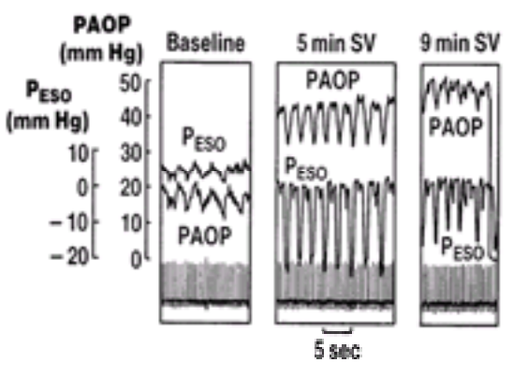

FIG. 3. Measurements of esophageal pressure (P_{eso}) and transmural pulmonary artery occlusion pressure (PAOP) in a patient who failed a weaning trial. Measurements were obtained during mechanical ventilation (baseline) and after 5 and 9 min of spontaneous ventilation (SV). Note that markedly negative swings in P_{eso} and the increase in PAOP during spontaneous ventilation. (Reproduced with permission from Lemaire F, Teboul JL, Cinotti L, et al. Acute left ventricle dysfunction during unsuccessful weaning from mechanical ventilation. *Anesthesiology* 1988;69:171–179.)

Acute respiratory acidosis has been shown to cause a decrease in the contractility and endurance time of the diaphragm in healthy subjects. A number of metabolic abnormalities commonly observed in critically ill patients, such as abnormalities of phosphate, potassium, calcium, or magnesium, may adversely affect respiratory muscle function. Endocrine disturbances such as hyperthyroidism or hypothyroidism may impair respiratory muscle function. Probably more relevant to the weaning situation is the use of corticosteroid therapy. Several reports have drawn attention to the development of myopathic changes (including respiratory muscle involvement) in patients receiving corticosteroid therapy. A number of pharmacologic agents may cause respiratory muscle weakness. Recently, there have been a number of disturbing reports describing prolonged respiratory muscle weakness after discontinuation of neuromuscular blocking agents such as pancuronium and vecuronium.

Respiratory muscle atrophy may develop during a period of prolonged mechanical ventilation. In baboons, controlled mechanical ventilation for 11 days caused decreased performance of the respiratory muscles. Studies of limb immobilization have shown that disuse of skeletal muscle produces a marked decline in muscle

mass. This occurs rapidly, and the greatest reduction in muscle size is observed in the early stages of immobilization.

The question of whether respiratory muscle fatigue occurs during the weaning process is of major importance. Patients who fail a weaning trial commonly display severe abnormalities in respiratory mechanics, and their respiratory muscles perform in an inefficient manner, which places them at considerable risk of developing respiratory muscle fatigue. Resting the respiratory muscles with mechanical ventilation is the major method of reversing fatigue, but if rest is excessive, muscle atrophy can occur. Consequently, the optimal timing and pace of weaning are problematic in these patients. The first study to provide evidence that respiratory muscle fatigue may be a common cause of weaning failure was that by Cohen et al. They studied 12 patients exhibiting difficulty during weaning and found that seven patients developed a power-spectral shift on surface recordings of the diaphragmatic electromyogram (EMG), which was considered indicative of diaphragmatic fatigue. Six of the seven patients displaying EMG changes also exhibited paradoxic motion of the abdomen (inward displacement during inspiration), which was accompanied by tachypnea and “respiratory alternans” (phasic alternation in the contribution of the rib cage and abdomen to tidal volume) in four patients. None of these signs was observed in the patients who did not develop EMG changes. The investigators considered that these changes in breathing pattern permit a diagnosis of respiratory muscle fatigue to be made with reasonable certainty. However, certain factors need to be considered before this interpretation can be accepted. All of the patients, including those without EMG changes and an abnormal breathing pattern, were returned to mechanical ventilation within 40 min, thus limiting the clinical significance of these findings. Also, a shift in the power spectrum of the EMG has not been shown to bear a relationship to the form of fatigue that is physiologically important, i.e., low-frequency fatigue; it is affected by factors other than fatigue, and its physiological basis remains unknown. In addition, no attempt was made to separate the effect of work of breathing from fatigue in these patients.

In a subsequent study, patients who failed a weaning trial were found to display an immediate onset of rapid shallow breathing and abnormal rib cage–abdominal motion on discontinuation of ventilator support, with no further progression during the period of the weaning trial (Fig. 4 and Fig. 5). Conceptually, it is difficult to reconcile this pattern of immediate alteration in the breathing pattern without subsequent progression with the development of respiratory muscle fatigue. In a study conducted in healthy subjects breathing against resistive loads and using an experimental design that permitted the separation of the effect of loading from fatigue, fatigue was shown to be neither necessary nor sufficient to induce asynchrony, paradox, or increased variability in rib cage–abdominal motion (Fig. 6). In contrast, respiratory loading was sufficient to induce abnormal motion.

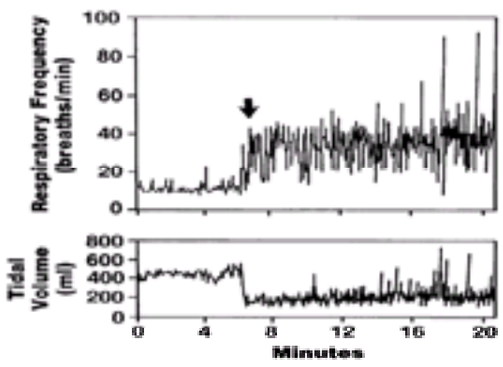

FIG. 4. A time-series, breath-by-breath plot of respiratory frequency and tidal volume in a patient who failed a weaning trial. The *arrow* indicates the point of resuming spontaneous breathing following discontinuation of ventilator support. Rapid, shallow breathing developed almost immediately, suggesting the prompt establishment of a new steady state. Although it has been considered that rapid, shallow breathing may reflect the presence of respiratory muscle fatigue, its almost instantaneous development without subsequent progression is difficult to reconcile with the development of respiratory muscle fatigue. (From Tobin MJ, Perez W, Guenther SM, et al. The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation. *Am Rev Respir Dis* 1986;134:1111, with permission.)

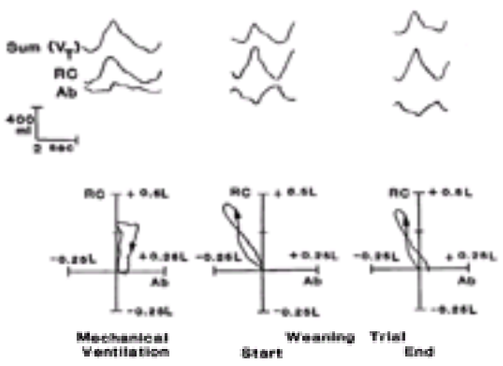

FIG. 5. Analog tracing of the sum (V_T), ribcage (RC), and abdominal (Ab) signals during mechanical ventilation and at the beginning and end of a weaning trial in a patient with an unsuccessful weaning outcome. The terminal portion of the preceding breath and the initiation of the subsequent breath are also shown. For clarity, the baselines of the individual analog signals have been arbitrarily adjusted to provide visual separation of the signals. The respective Konno–Mead plots of the RC–Ab relationship are displayed below each of the breaths. During mechanical ventilation, there is some Ab paradox, which increases immediately on discontinuation of the ventilator. There is no progression in the extent of abnormal RC–Ab motion from the beginning to the end of the weaning trial 24 min later. (From Tobin MJ, Guenther SM, Perez W, et al. Konno–Mead analysis of rib cage–abdominal motion during successful and unsuccessful trials of weaning from mechanical ventilation. *Am Rev Respir Dis* 1987;135:1320, with permission.)

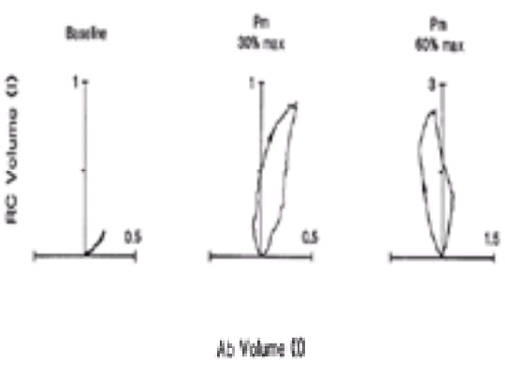

FIG. 6. Konno–Mead plots of rib cage (RC)–abdominal (Ab) motion in a subject during resting breathing and while breathing against a resistive inspiratory load of sufficient magnitude to require the generation of 30% and 60% of maximum mouth pressure (P_{mmax}). At 30% of P_{mmax}, a loop forms, indicating RC-Ab asynchrony, and some Ab paradox is also evident. At 60% of P_{mmax}, the degree of Ab paradox increases further, as indicated by the leftward shift in the plot. The presence of abnormal RC-Ab motion at 30% of P_{mmax} is of significance, since this level of pressure can be sustained indefinitely without the development of respiratory muscle fatigue. (From Tobin MJ, Perez SM, Guenther SM, et al. Does the rib-cage abdominal paradox signify respiratory fatigue? *J Appl Physiol* 1987;63:851.)

Increased Respiratory Muscle Pump Load

An increase in the load on the respiratory muscle pump may result from increased ventilatory requirements or increased work of breathing (Table 1).

Increased Ventilatory Requirements

Factors causing an increase in ventilatory requirements include increased CO_2 production, increased deadspace ventilation, and an inappropriately elevated respiratory

drive. Although an increase in CO_2 production predisposes to the development of CO_2 retention, it is never the sole cause of hypercapnia. An increase in CO_2 production may occur as a complication of excessive use of carbohydrate calories during nutritional support. In normal subjects, an increase in alveolar ventilation prevents the development of hypercapnia. This is not possible in patients with respiratory compromise, and several patients have been reported to develop hypercapnia when given excessive nutritional support at the time of being weaned from mechanical ventilation.

Dead Space Ventilation

Physiological dead space is usually related to tidal volume and expressed as V_D/V_T; in healthy subjects the V_D/V_T ratio is between 0.33 and 0.45. Dead space is increased in a number of disease states associated with regions of lung possessing high $\dot{V}_A/\dot{Q}$ ratios, and this requires an increase in minute ventilation if hypercapnia is to be prevented. If CO_2 production is high, an increase in V_D/V_T to 0.6 or above is generally considered to predict an unsuccessful weaning outcome because the associated increase in minute ventilation necessary for satisfactory gas exchange causes marked encroachment on ventilatory reserve.

Increased Respiratory Drive

An inadequate level of respiratory drive causes hypoventilation and respiratory acidosis, but an inappropriately heightened drive places unnecessary stress on the respiratory muscle pump and predisposes to fatigue.

Work of Breathing

Patients requiring ventilator support may have an increase in airway resistance or a decrease in pulmonary compliance, and, thus, the level of respiratory work could be a major determinant of their ability to resume and sustain spontaneous ventilation. Measurements of work of breathing in patients being weaned from mechanical ventilation have been obtained by a number of investigators, and although work was greater in weaning failure patients, the threshold values separating weaning success from weaning failure patients differed among the various studies. Furthermore, these threshold values were determined on a *post-hoc* basis, and the value of work measurements as a predictor of weaning outcome has not been examined in a prospective fashion. Respiratory workload can also be assessed by measuring the O_2 cost of breathing. This is usually taken as the difference in total body O_2 consumption between spontaneous breathing and that when a patient is relaxed and receiving mechanical ventilation. In resting healthy subjects, the O_2 cost of breathing is <5% of the total body O_2 consumption, but it can exceed 50% in patients being weaned from mechanical ventilation. Such a marked increase in the O_2 cost of breathing decreases the availability of O_2 for delivery to other vulnerable tissue beds and may precipitate myocardial ischemia or other problems.

Psychological Factors

Psychological factors may seriously interfere with the weaning process in some patients. Dependence on mechanical ventilation can be associated with feelings of insecurity, anxiety, fear, agony, and panic. Many patients develop a fear that they will remain dependent on mechanical ventilation and that discontinuation of ventilator support will result in sudden death. Apart from a few isolated reports, however, there is little information on the extent to which psychological disturbances contribute to ventilator dependency.

PREDICTING WEANING OUTCOME

One of the major challenges in mechanical ventilation is deciding when is the best time to wean a patient from the ventilator. If a physician is too conservative and postpones weaning onset, the patient is placed at an increased risk of life-threatening ventilator-induced complications. If weaning is commenced prematurely, the patient may suffer severe cardiopulmonary and/or psychological decompensation, which sets the patient back in his or her clinical course. The first prerequisite for initiation of weaning is that the disease process that precipitated the need for mechanical ventilation has resolved sufficiently so that the patient has a reasonable chance of being able to sustain spontaneous ventilation. Although careful clinical assessment is necessary in deciding when to wean a patient, this alone is not sufficient, and recent studies have shown that experienced clinicians frequently err in their predictions. Accordingly, functional tests are helpful in determining a patient's readiness for weaning (Table 2).

Gas exchange
$P_aO_2 \geq 60$ torr with $F_IO_2 \leq 0.35$
Alveolar–arterial P_{O_2} gradient <350 torr
P_aO_2/F_IO_2 ratio >200
Ventilatory pump
Vital capacity >10–15 ml/kg body weight
Maximum negative inspiratory pressure less than −30 cm H_2O
Minute ventilation <10 liters/min
Maximum voluntary ventilation more than twice resting minute ventilation

TABLE 2. *Variables used to predict weaning success*

Pulmonary Gas Exchange

Discontinuation of ventilator support is generally not contemplated in a patient with persistent hypoxemia, e.g., arterial oxygen tension (P_aO_2) <55 mmHg with an inspired oxygen concentration (F_IO_2) ³0.40. A number of indices derived from arterial blood gas (ABG) measurements have been proposed as predictors of weaning outcome (Table 2), although these criteria are not based on prospective investigation. In a retrospective study, an arterial to inspired O_2 ratio (P_aO_2/F_IO_2 ratio) of 238 (equivalent to a P_aO_2 of 50 torr with an F_IO_2 of 0.21) had a positive predictive value (the probability that a patient will be successfully weaned when the test predicts success) of 90%. However, its negative predictive value (the probability that a patient will fail a weaning trial when the test predicts failure) was only 10%. In another study, an arterial/alveolar O_2 tension (P_aO_2/P_AO_2) of 0.35, which was the value that provided best separation between weaning success and weaning failure in an initial "training data set," was found to have a positive predictive value of only 0.59 and a negative predictive value of only 0.53.

Maximal Inspiratory Pressure

Maximal inspiratory pressure (P_{Imax}) is one of the standard measurements used to predict weaning outcome, based on its excellent performance in a classic study by Sahn and Lakshminarayan. They studied 100 patients and found that all patients who generated P_{Imax} values of -30 cm H_2O were successfully extubated, whereas all those with a P_{Imax} less negative than -20 cm H_2O were unable to sustain spontaneous ventilation. However, in a subsequent prospective study, Tahvanainen et al. found that a P_{Imax} value of -30 cm H_2O was falsely negative in 100% of patients (predicted failure but actually succeeded) and falsely positive in 26% (predicted success but actual failure). Other investigators have also found that P_{Imax} has limited power in predicting weaning outcome, which may reflect the difficulty of making the measurement in uncooperative patients. A modified technique has been developed in an attempt to make the measurements more reliable. A one-way valve is attached to the airway to ensure that inspiratory efforts are made at a low lung volume, and the period of occlusion is maintained for 20 sec. In a study that employed this technique, a P_{Imax} value of -30 cm H_2O continued to be a poor predictor of weaning outcome: positive predictive value of 0.58 and negative predictive value of 0.55. Thus, standardizing the method of measurement did not improve its usefulness as a predictor of weaning outcome.

Vital Capacity

A vital capacity of 10 mL/kg or more has been suggested to predict a successful weaning outcome. However, in a study of weaning outcome, a vital capacity of 15 mL/kg was falsely positive in 15% and falsely negative in 63% of patients.

Minute Ventilation and Maximum Voluntary Ventilation

A minute ventilation of less than 10 L/min is considered to predict a successful weaning outcome. However, in a subsequent study, this criterion was very inaccurate: positive and negative predictive values were only 0.50 and 0.40, respectively. In the study of Sahn and Lakshiminaryan, the combination of a minute ventilation of less than 10 liters/min and the ability to double this value during a MVV maneuver was able to predict 100% of the weaning successes and 71% of the failures. However, Tahvanainen et al. found that the MVV criterion was falsely positive in 14% of patients and falsely negative in 76%.

Airway Occlusion Pressure

Airway occlusion pressure is measured as the pressure at 0.1 sec after commencing an inspiratory effort against an occluded airway and is commonly termed $P_{0.1}$. In a study of patients with COPD, when $P_{0.1}$ values were >6 cm H_2O, all of the patients failed the weaning trial, whereas all patients who were successfully weaned had $P_{0.1}$ values <6 cm H_2O. In another study, measurements during a hypercapnic challenge (inhaling 3% CO_2) were similar in weaning success and weaning failure patients, 7.0 ± 1.0 and 6.6 ± 1.6 cm H_2O, respectively. However, hypercapnic augmentation of $P_{0.1}$, expressed as the ratio of the CO_2-stimulated $P_{0.1}$ to the baseline $P_{0.1}$, was greater in the patients who were successfully weaned, 2.04 ± 0.25, than in the failure group, 1.17 ± 0.03.

Rapid Shallow Breathing

Patients who fail a weaning trial commonly develop an immediate increase in respiratory frequency and decrease in tidal volume on discontinuation of ventilator support (Fig. 4). Yang and Tobin measured tidal volume and respiratory frequency with a simple bedside spirometer attached to the patient's endotracheal tube while the patient spontaneously breathed room air for 1 min. Measurements of frequency (f) and tidal volume (V_T) were combined into an index of rapid shallow breathing—the f/V_T ratio. In an initial "training data set" obtained in 36 patients, they found that an f/V_T value of 105 breaths/min per liter best differentiated patients who were successfully weaned from those in whom weaning failed. The predictive power of this value was then assessed in 64 patients who constituted the "prospective-validation data set" (Fig. 7). The positive and negative predictive values were 0.78 and 0.95, respectively, which were the highest values noted for any of the predictive indices in the study. In a recent study, Lee et al. reported that eight of nine patients who failed a weaning trial had f/V_T < 105 breaths/min per liter. In the original report, f/V_T was measured with a hand-held spirometer over 1 min of spontaneous breathing after the patient was disconnected from the ventilator circuit, whereas Lee et al. made the measurements during pressure support (level not stated), which is known to decrease f and increase V_T; it is hardly surprising that the f/V_T threshold value developed during unassisted breathing will not apply during pressure support. As a predictive index, the f/V_T ratio has a number of attractive features: it is easy to measure, it is independent of the patient's effort and cooperation, it appears to be quite accurate in predicting the ability to sustain ventilation, and, fortuitously, it has a "rounded off" threshold value (100) that is easy to remember.

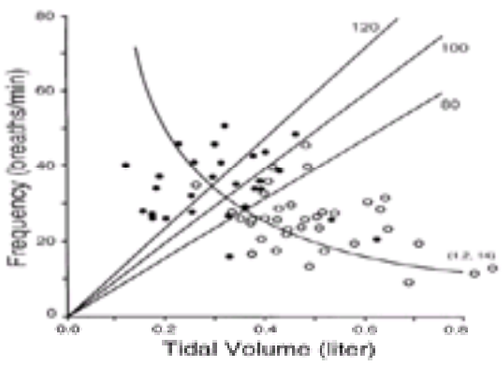

FIG. 7. Isopleths for the ratio of frequency to tidal volume (f/V_T), representing different degrees of rapid shallow breathing. Patients who fell to the left of the 100 breaths/min per liter isopleth had a 95% likelihood of failing a weaning trial, whereas patients who fell to the right of this isopleth had an 80% likelihood of a successful weaning outcome. The hyperbola represents a minute ventilation of 10 liters/min, a criterion commonly used to predict weaning outcome; it is apparent that this criterion was of little value in discriminating between weaning success *(open circles)* and weaning failure patients *(solid circles).* Values for one patient (V_T 1.2 liters, f 14 breaths/min) lay outside the graph. (Reproduced with permission from Yang KL, Tobin MJ. A prospective study of indexes predicting the outcome of trials of weaning from mechanical ventilation. *N Engl J Med* 1991;324:1445–1450.)

Integrative Indices

Weaning failure is commonly multifactorial in origin, and, thus it is not very surprising that an index that assesses a single function is unreliable. Accordingly, an index that integrates a number of physiological functions should have greater predictive accuracy. Such an index is the CROP index, which incorporates a measure of pulmonary gas exchange and an assessment of the demands placed on the respiratory system and the capacity of the respiratory muscles to handle them. The rationale for this index is the following:

$$\text{fraction of inspiratory effort reserve/breath} = P_{br}/P_{Imax} \quad \textbf{(1)}$$

where P_{br} is the pressure required for the generation of each breath, and P_{Imax} is the maximal inspiratory pressure. Measurement of P_{br} during spontaneous breathing poses logistic problems (e.g., insertion of an esophageal balloon catheter). However, for a given tidal volume during mechanical ventilation, pressure is inversely proportional to the "dynamic compliance" of the respiratory system (C_{dyn}); thus, equation 1 can be expressed as follows:

$$\text{fraction of inspiratory effort reserve/breath} \propto (1/C_{dyn})/P_{Imax} \quad \textbf{(2)}$$

Likewise, an index of the rate of energy expenditure per minute can be obtained by multiplying equation 2 by the respiratory rate:

$$\text{rate of energy expenditure/minute} \propto rate/[C_{dyn} \times P_{Imax}] \quad \textbf{(3)}$$

For convenience, the elements in equation 3 can be inverted so that a high value indicates that respiratory demands are well matched by respiratory muscle strength. A measure of gas exchange, the P_aO_2/P_AO_2, is also incorporated because some patients fail a weaning trial as a result of impaired oxygenation rather than ventilatory pump failure. The final form of the equation is

$$\text{integrative index} = C_{dyn} \times P_{Imax} \times (P_aO_2/P_AO_2)/rate \quad \textbf{(4)}$$

(4)and is labeled the CROP index, an acronym for compliance, rate, oxygenation, and pressure. When this index is prospectively evaluated, positive and negative predictive values are 0.71 and 0.70, respectively.

Another integrative index was recently developed by Jabour et al. This consists of a measure of ventilatory endurance (pressure–time index, PTI) and an estimate of the efficiency of gas exchange, $\dot{V}_{E40}$, which is the minute ventilation needed to bring P_aCO_2 to 40 torr:

$$\text{weaning index} = \text{PTI} \times (V_{E40}/V_{Tsb})$$

where V_{Tsb} is the tidal volume during spontaneous breathing. This index had a positive predictive value of 0.96 and a negative predictive value of 0.95 on *post-hoc* analysis, but the investigators did not examine its accuracy prospectively.

WEANING TECHNIQUES

Clinical Approach to Weaning

Attention must be directed to several factors before mechanical ventilation is discontinued, especially in patients with limited cardiorespiratory reserve or unusually high workloads. An organized plan of action and a team approach are particularly helpful in the difficult-to-wean patient. Adequate control of pain, fever, arrhythmias, and infection is necessary. Correction of fluid and electrolyte imbalance is imperative. Metabolic alkalosis, which decreased the ventilatory drive, can usually be corrected by chloride and potassium replacements. Although adequate sleep is necessary, medications that cause excessive sedation or impairment of respiratory muscle function can be harmful. The patient should receive adequate nutrition and be psychologically prepared for the weaning process. Promoting verbal communication helps in relieving a patient's fear. A tracheostomy can be advantageous in a patient requiring prolonged mechanical ventilation because it promotes comfort, enhances a patient's ability to swallow, and improves oral hygiene. In patients with airways obstruction, suctioning of the airways and administration of bronchodilators may facilitate weaning by reducing airway resistance and, thus, the work of breathing. Bronchodilators can be delivered effectively and conveniently to mechanically ventilated patients with a metered-dose inhaler and spacer in the inspiratory limb of the ventilator circuit. During a weaning trial, the ideal posture for a patient depends on the underlying pathophysiology. Although most patients do better while sitting, some find greater relief from dyspnea in the supine position. A variety of measures have been suggested to help with difficult-to-wean patients, such as biofeedback and endurance training of the respiratory muscles, but their application has been limited to a select group of patients, and further studies are needed to document their efficacy in a broader range of patients.

Trials of Spontaneous Breathing

To assess a patient's ability to sustain spontaneous ventilation, he or she can be disconnected from the ventilator and receive supplemental O_2 through a T-tube system. During such a trial, the patient's clinical status should be closely monitored. The traditional approach has been to employ relatively brief trials of spontaneous breathing (approximately 5 min) interposed with resumption of mechanical ventilation and gradually to increase their duration according to a patient's performance. Another approach is to go directly from a high level of ventilator assistance to a spontaneous breathing trial, and if the patient does not develop signs of intolerance, extubation is performed without any further weaning. In a study of over 500 patients, Esteban et al. reported that two-thirds of the patients could be extubated after an initial trial of spontaneous breathing. If a patient develops respiratory muscle fatigue during such a trial, the duration of mechanical ventilation required to rest the respiratory muscles has not been defined. Laghi et al. recently demonstrated that diaphragmatic contractility remains significantly depressed for at least 24 hrs following the induction of fatigue. Similar studies have not been undertaken in patients who fail a weaning trial, and it is conceivable that the rate of recovery may be even further delayed.

Intermittent Mandatory Ventilation

Intermittent mandatory ventilation (IMV) is the most popular weaning technique in North America. This is a unique mode of ventilation in that it allows the patient to breathe spontaneously between periodic positive-pressure breaths delivered at a preset volume and rate from the ventilator. When the patient is considered ready for weaning, the mandatory rate from the ventilator is reduced in steps of 1 to 3 breaths/min, and an arterial blood gas is obtained after about 30 min. Intermittent mandatory ventilation was introduced with claims of superiority over other management strategies. About 10 years after the introduction of IMV, it was shown that the demand valve, which was incorporated in the ventilator circuit to achieve synchronized IMV, resulted in a twofold or greater increase in the work of breathing by the patient. This problem has now been largely overcome with newer valves. Another and probably more fundamental problem is that patients have difficulty in adapting to the intermittent nature of ventilator assistance during IMV (Fig. 8). It had been assumed that the degree of respiratory muscle rest with IMV was proportional to the number of mandatory breaths delivered by the machine. Recent studies show that a patient's respiratory centers are unable to adapt to this type of intermittent unloading. Indeed, at IMV rates of 14 breaths/min or less, inspiratory efforts of the patient are increased to a level likely to cause respiratory muscle fatigue, and this occurs not only for the intervening spontaneous breaths but also with ventilator-assisted breaths. As a result, use of IMV may actually contribute to the development of respiratory muscle fatigue or prevent its recovery. The originators of IMV recommended that the number of breaths from the ventilator should be titrated in accordance with the results of arterial blood gases. This can result in a false sense of security because two to three positive-pressure breaths per minute can achieve acceptable blood gas values, but these values provides no information regarding the patient's work of breathing, which may be excessive.

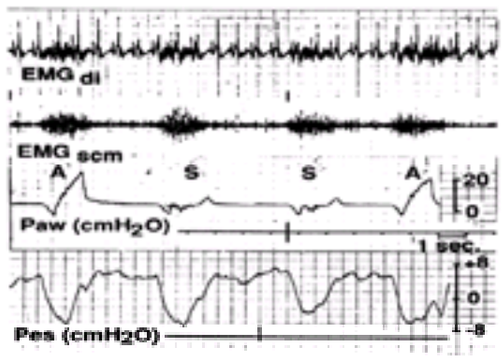

FIG. 8. Electromyograms of the diaphragm (EMGdi) and of the sternocleidomastoid muscles (EMGscm) in a representative patient receiving synchronized intermittent mandatory ventilation, showing similar intensity and duration of electrical activity in successive assisted (A) and spontaneous (S) cycles. P_{aw}, airway pressure; P_{es}, esophageal pressure. (Reproduced with permission from Imsand C, Feihl F, Perret MD, Fitting JW. Regulation of inspiratory neuromuscular output during synchronized intermittent mechanical ventilation. *Anesthesiology* 1994;80:13–22.)

Pressure Support

With pressure support, the ventilator augments spontaneous breathing with a fixed amount of positive pressure. When pressure support is used for weaning, the level of pressure is reduced gradually in decrements of 3 to 6 cm H_2O, titrated on the basis of respiratory frequency. Several investigators have shown that pressure support can be used to counteract the work of breathing imposed by endotracheal tube and ventilator circuit. This has led to the notion that if a patient can sustain spontaneous ventilation at this “compensatory level” of pressure support, he or she will tolerate extubation. The problem with this strategy is that a compensatory level of pressure support varies between 3 and 14 cm H_2O, and there is no reliable method for accurately determining the required level in an individual patient. The algorithm used to cycle from inspiration to expiration during pressure support is based on a decrease in inspiratory flow to a preset level, such as 25% of peak inspiratory flow. Patients with airway obstruction have a long time constant, and more time will be required for flow to fall to this threshold; consequently, mechanical inflation may persist into neural expiration. To counteract such neural–mechanical asynchrony, patients may activate their expiratory muscles at a time when the ventilator is inflating the thorax, causing the patient to “fight the ventilator” (Fig. 9).

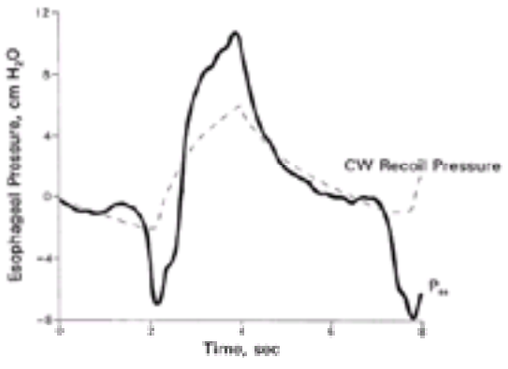

FIG. 9. Tracings of esophageal pressure (P_{es}, *continuous line*) and estimated recoil pressure of the chest wall (P_{escw}, *interrupted line*) in a patient receiving pressure-support ventilation of 20 cm H_2O. Pressure tracings have been superimposed so that P_{escw} is equal to P_{es} at the onset of the rapid fall in P_{es} during late expiration. Times at which P_{es} tracing are higher than P_{escw} represent lower-bound expiratory effort. Note the presence of expiratory muscle activation during late inspiration. Variability of patient–ventilator interaction with pressure support ventilation in patients with chronic obstructive pulmonary disease. *Am J Respir Crit Care Med* 1995;152:129–136.)

Relative Efficacy of Weaning Techniques

Recently, two rigorously controlled studies have prospectively compared the efficacy of three different weaning techniques: IMV, pressure support, and trials of spontaneous breathing. Brochard et al. found that weaning time was significantly shorter with pressure support [5.7 ± 3.7 (SD) days] than with IMV (9.9 ± 8.2 days) or trials of spontaneous breathing (8.5 ± 8.3 days). In contrast, using a similar experimental design, Esteban et al. found that a once-daily trial of spontaneous breathing led to extubation about three times more quickly than did IMV and about twice as quickly as pressure support (Fig. 10). There was no difference in the rate of successful weaning between a once-daily trial of spontaneous breathing and intermittent trials of spontaneous breathing (attempted at least twice a day), nor between IMV and pressure support. The reason for the different outcomes in the two studies is probably related to the constrained manner in which IMV and trials of spontaneous breathing were employed in the study of Brochard et al. During application of IMV, patients had to tolerate a ventilator rate of under four breaths per minute for at least 24 hrs before extubation; this constitutes a significant ventilatory challenge. In contrast, Esteban et al. extubated patients when they tolerated a ventilator rate of five breaths per minute for 2 hr. For the trials of spontaneous breathing in the study of Brochard et al., physicians could request up to three separate trials over a 24-hr period, each lasting 2 hr, before deciding to extubate a patient, whereas in the study of Esteban et al., patients in the once-daily trials of spontaneous breathing were extubated when this was tolerated for 2 hr. The findings in these two studies are complementary; both demonstrate that the pace of weaning depends on the manner in which the technique is applied. When IMV and trials of spontaneous breathing are employed in a constrained manner, weaning is delayed compared with pressure support. When a spontaneous breathing trial is employed once a day, weaning is expedited.

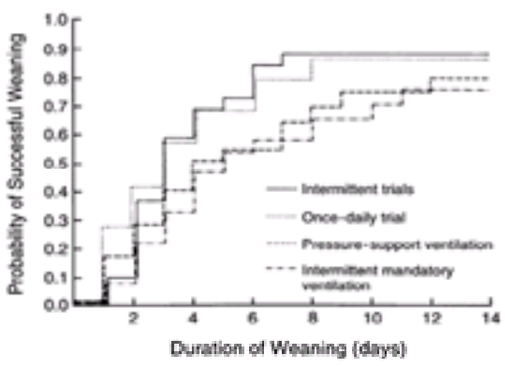

FIG. 10. Kaplan–Meier curves of the probability of successful weaning with intermittent mandatory ventilation, pressure-support ventilation, intermittent trials of spontaneous breathing, and a once-daily trial of spontaneous breathing. After adjustment for baseline characteristics in a Cox proportional-hazards model, the rate of successful weaning with a once-daily trial of spontaneous breathing was 2.83 times higher than that with intermittent mandatory ventilation ($p < 0.006$) and 2.05 times higher than that with pressure-support ventilation ($p < 0.04$). (Reproduced with permission from Esteban A, Frutos F, Tobin MJ, et al. A comparison of four methods of weaning patients from mechanical ventilation. *N Engl J Med* 1995;332:345–350.)

EXTUBATION

Patients who can sustain spontaneous ventilation without distress may have difficulty following extubation as a result of upper airway obstruction, inability to protect the upper airway, or inability to clear secretions. In contrast to the many parameters that have been introduced to predict the outcome of a weaning trial, indices that reliably predict the likelihood of complications following extubation have not been developed. Instead, evaluation consists of clinical assessment of factors such as the level of consciousness, the quantity of secretions, and the patient's ability to cough.

SUMMARY

In summary, up to 30% of patients of patients receiving mechanical ventilation pose considerable difficulty in being weaned. These patients present enormous clinical, economic, and ethical problems. The major determinants of weaning outcome are respiratory muscle function with the adequacy of pulmonary gas exchange and psychological problems playing subsidiary roles. Many of the physiological indices that have been used to predict weaning outcome are frequently inaccurate, and of those available, the ratio of frequency to tidal volume appears to be the most reliable. A number of techniques can be used for weaning, and of these a once-daily trial of spontaneous breathing appears to be the most expeditious.

CHAPTER

50 Chronic Respiratory Failure and Noninvasive Ventilation

Nicholas S. Hill

N.S. Hill: Department of Medicine, Brown University, and Pulmonary Division, Rhode Island Hospital, Providence, Rhode Island 02903.

INTRODUCTION

Chronic respiratory failure refers to the sustained inability to maintain normal gas exchange. Usually, the term indicates ventilatory failure and is diagnosed when blood gases show a chronic respiratory acidosis in the absence of symptoms to suggest an acute deterioration. The term chronic respiratory insufficiency is sometimes used interchangeably, denoting compromised respiratory function but not necessarily abnormal gas exchange. Chronic respiratory failure arises from dysfunction of any component or combination of components of the respiratory system. Therapy is contingent on delineation of the dysfunctional component(s). Before ventilatory support is contemplated, reversible contributing factors should be sought. In the past, if treating these was unsuccessful, invasive ventilation via a tracheostomy was often deemed necessary. In recent years, however, with the increasing use of nasal ventilation, noninvasive ventilation has become the preferred means of ventilatory support. This chapter considers the various mechanisms that lead to chronic respiratory failure, presenting manifestations and diagnostic and therapeutic approaches. The various modes of noninvasive ventilation are then discussed, including mechanisms of action, applications, selection of appropriate patients, and possible complications, with a focus on noninvasive positive-pressure ventilation (NPPV).

PATHOPHYSIOLOGY OF CHRONIC RESPIRATORY FAILURE

Normal function of the respiratory system depends on the integrity of each of its components. Chronic respiratory insufficiency arises from compromise of any one component or combination of components (Table 1). Respiratory failure occurs when the compromised system is unable to meet the demand for ventilatory work, either because of limitations in the ability to supply ventilatory work or because of excessive demands for ventilatory work, or both. Thus, any pathologic process that interferes with transmission of the signal to breathe, from the respiratory center, through central and peripheral neurons, to the myoneural junction, or the ability of the respiratory muscles to respond to the signal, may reduce ventilatory function enough to cause respiratory failure. CO_2 retention is likely when maximal inspiratory force (P_{Imax}) is less than 30% of predicted. In addition, processes that increase the work of breathing, such as airway obstruction, pulmonary fibrosis, or chest wall deformity, shift the supply–demand balance toward respiratory failure, particularly if respiratory muscle function is compromised. For chest wall deformity, the onset of respiratory failure correlates with an angle of scoliosis exceeding 120°.

TABLE 1. *Causes of chronic respiratory failure*[a]

If the factors contributing to respiratory failure are overwhelming or occur precipitously, acute respiratory failure ensues. If the dysfunction occurs gradually, however, the respiratory system may compensate by permitting the accumulation of carbon dioxide (CO_2). In essence, chronic respiratory failure represents a compromise in which the efficiency of carbon dioxide excretion is improved; i.e., more carbon dioxide can be excreted with each breath; at the expense of an increase in both alveolar and arterial PCO_2 and a decrease in arterial PO_2. The tendency to make this compromise is partly determined by the sensitivity of the ventilatory control center for carbon dioxide. Evidence for this derives from studies of patients with chronic obstructive pulmonary disease (COPD) who are chronic CO_2 retainers. Close relatives of these patients have less ventilatory sensitivity to CO_2 and to hypoxia than relatives of patients with equally severe COPD who are not CO_2 retainers. Thus, even though patients with severe COPD and CO_2 retention usually have elevated respiratory drive compared to normals, a relatively low inherited respiratory center sensitivity to CO_2 compared to normocapnic COPD patients may contribute to CO_2 retention.

Other factors thought to contribute to chronic respiratory failure include respiratory muscle weakness or fatigue. Defined as a reduction in muscle contractility during exhausting work, respiratory muscle fatigue contributes to acute respiratory failure and occurs during exercise in patients with severe COPD. However, the contribution of respiratory muscle fatigue to chronic respiratory failure, if any, has not been clearly defined. Recently, the concept of central fatigue has been advanced as a mechanism contributing to the development of chronic CO_2 retention. The concept proposes that the respiratory center fatigues before actual respiratory muscle fatigue occurs, permitting the gradual accumulation of CO_2. In this way, the overloaded respiratory system avoids or at least postpones the onset of muscle fatigue that would likely presage an acute deterioration.

Other attributes of patients who develop respiratory failure include the development of a rapid shallow breathing pattern. Patients with severe COPD and CO_2 retention breathe more rapidly and may have more ventilation–perfusion mismatching and higher dead space ratios than those without CO_2 retention. In addition, during sleep, respiratory drive is blunted, and muscle tone of upper airway structures is reduced. These effects are magnified in patients with respiratory insufficiency leading to sleep-disordered breathing and contributing to CO_2 retention. Thus, although patients with chronic respiratory failure have identifiable primary functional disturbances, they also undergo secondary central adaptations, leading to alterations in breathing pattern and to breathing disturbances during sleep, providing opportunities for

therapeutic interventions.

OCCURRENCE OF VARIOUS ETIOLOGIES FOR CHRONIC RESPIRATORY FAILURE

The most common cause of chronic respiratory failure at most centers in the United States is COPD. To gain insight into rates of occurrence of the various etiologies of chronic respiratory failure, Strumpf et al. recorded the diagnoses of patients seen at an outpatient chest clinic in a teaching hospital during a 6-month period. As shown in Table 2, these authors confirmed that COPD was responsible for chronic CO_2 retention in the majority of cases. The next most common single cause was the obstructive sleep apnea (OSA) syndrome, which should be considered in any patient with unexplained chronic hypoventilation. Sleep apnea also commonly contributes to chronic hypoventilation in patients with severe COPD or kyphoscoliosis. Restrictive chest wall disease was also a common cause of chronic hypoventilation in this series, but restrictive lung disease was a relatively unusual cause. Chronic respiratory failure in patients with interstitial lung disease is relatively uncommon. The CO_2 retention in these patients is usually transient, occurring late in the course as a preterminal event.

Etiology	Number	Percentage of total
COPD	46	58
Sleep apnea	6	8
Chest wall deformity		
Thoracoplasty	4	5
Kyphoscoliosis	4	5
Muscular dystrophy	4	5
Interstitial lung disease	3	4
Lung resection for cancer	2	3
CHF	1	1
Multifactorial	9	11
Total	79	100

[a] Data were collected from all patients seen in the outpatient chest clinic at Rhode Island Hospital, a 719-bed general hospital, between January 1, 1989 and July 15, 1989 with P_aCO_2 > 45 mm Hg. Patients experiencing an acute exacerbation were excluded. The multifactorial category includes patients with two or more of the above etiologies as well as one patient with COPD and laryngeal carcinoma with recurrent aspiration. From Strumpf et al., *Chest* 1990; 98:474–480, with permission.

TABLE 2. *The etiology of chronic hypoventilation in an outpatient chest clinic*[a]

The second largest overall category responsible for chronic CO_2 retention in the Strumpf series was multifactorial, underscoring the fact that a variety of factors often contribute to chronic hypoventilation. As noted above, chronic respiratory failure should not be seen as the consequence of a single abnormality in the respiratory system but rather as the interplay of different factors at a number of levels. Chronic CO_2 retention may develop in a patient with severe COPD whose respiratory center is insensitive to CO_2 and who has an increased number of apneic episodes during sleep. Another patient with equally severe COPD who has a high sensitivity to CO_2 and normal sleep may not retain CO_2. Multiple factors may also contribute to chronic respiratory failure in patients with the obesity–hypoventilation syndrome. These patients have an increased mechanical load related to their adiposity, may have a relatively low central sensitivity to CO_2, and often have other contributing factors such as congestive heart failure; OSA as a contributing factor should be excluded. The possible multifactorial etiology of chronic respiratory failure should always be considered in the evaluation of patients in order to maximize therapeutic results.

CLINICAL MANIFESTATIONS OF CHRONIC RESPIRATORY FAILURE

Patients with chronic respiratory failure as a result of severe lung disease usually have prominent respiratory symptoms, prompting a pulmonary evaluation that reveals the hallmark arterial blood gas result showing compensated hypercarbia. However, patients with chronic respiratory failure secondary to neuromuscular disease, central ventilatory defects, or mixed disturbances commonly have few or no respiratory complaints. Their earliest symptoms are related to nocturnal exaggeration of CO_2 retention that disrupts normal sleep patterns and causes nightmares, enuresis, and morning headaches. During the day, fatigue, hypersomnolence, and mood disorders are common, often leading to the misdiagnosis of depression. The physician must be alert to the insidious manner in which chronic hypoventilation may present in these patients so that blood gases are obtained and the condition is not missed.

Although signs of chronic respiratory failure are nonspecific, the physical examination is nevertheless very important for detecting predisposing illnesses. Severe obstructive or restrictive lung diseases should be detectable on physical examination. Morbid obesity, retrognathia, tonsillar hypertrophy, and macroglossia point to the obstructive sleep apnea syndrome. An examination of the thoracic cage for scoliosis and a neurologic examination seeking muscle weakness suggestive of a neuromuscular syndrome or cerebrovascular disease are important components of the evaluation. A bedside evaluation of respiratory muscle function should seek evidence of accessory muscle use by inspection or palpation, or bilateral diaphragmatic paralysis. This is best achieved by having the patient lie supine and observing paradoxic motion of the abdomen during inspiration.

LABORATORY EVALUATION OF CHRONIC RESPIRATORY FAILURE

All patients with symptoms and signs suggestive of chronic hypoventilation should undergo a workup as outlined in Table 3 beginning with blood gases measured via arterial puncture. Noninvasive methods such as pulse oximetry or end-tidal CO_2 monitoring are not sufficiently sensitive to exclude the diagnosis but may be helpful for following trends. The evaluation should include a complete blood count to exclude polycythemia, thyroid function tests, and serum chemistry studies.

Routine
1. History and physical examination
2. Arterial blood gas
3. Laboratory studies
Complete blood count
Serum electrolytes
Thyroid function tests
Mg, PO_4
4. Pulmonary function tests
Spirometry
Lung volumes
Bronchodilator responses
Maximal inspiratory and expiratory pressure
Supine vital capacity
For selected patients
5. Nocturnal polysomnography
6. Transdiaphragmatic pressure measurements

[a] From Strumpf et al., *Chest* 1990; 98:474–480, with permission.

TABLE 3. *Diagnostic studies for patients with chronic respiratory failure*

Pulmonary function testing including spirometry, measurement of lung volumes, and determination of maximal inspiratory and expiratory pressures should also be routine. These measurements detect patients with severe obstructive or restrictive lung diseases as well as those with muscle weakness. If bilateral diaphragmatic paralysis is suspected, vital capacity should be measured in the supine and upright positions. In the presence of paralyzed diaphragms, supine vital capacity falls by 50% compared to the upright. Pulmonary functions may also help in identifying those patients with an additional contributing factor to their chronic hypoventilation besides lung disease alone. If the FEV_1 exceeds 1L in a patient with chronic respiratory failure, lung disease is probably not the sole cause, and other contributing factors should be sought.

Because of the frequency of sleep-disordered breathing in patients with chronic respiratory failure, polysomnography occupies a central role in the evaluation of such patients. Ideally, polysomnography should consist of an overnight sleep study with monitoring of the electroencephalogram, electromyogram, electrooculogram, airflow at the mouth and nose, chest wall motion, and oximetry. Noninvasive monitoring of carbon dioxide levels by end-tidal or transcutaneous techniques has not proven reliable, so if accurate measurements of PCO_2 are desired, arterial blood gas sampling via an indwelling catheter will be necessary. Afternoon nap studies and overnight monitoring of oximetry alone are useful if they yield positive results, but a negative study should not be used to exclude sleep apnea. Polysomnography is indicated for any patient with chronic respiratory failure and symptoms to suggest OSA, such as snoring or excessive daytime sleepiness, an FEV_1 exceeding 1 L, even in the

absence of suggestive symptoms, and anyone being considered for ventilatory assistance using a negative-pressure device.

In addition to the evaluation described above, some other studies may occasionally be useful. Measurement of transdiaphragmatic pressures using gastric and esophageal balloons is useful to confirm the diagnosis of bilateral diaphragmatic paralysis. Assessment of CO_2 or hypoxic ventilatory responsiveness is primarily a research technique. It is of little value clinically because studies are almost invariably abnormal because of pulmonary function abnormalities or blunting of respiratory drive secondary to chronic CO_2 retention.

THERAPY OF CHRONIC RESPIRATORY FAILURE

Reversal of Contributing Factors

The first priority in the therapy of patients with chronic respiratory failure is to treat reversible factors that have been identified in the course of evaluation. Reversal of airway obstruction using bronchodilators or steroids, treatment of congestive heart failure with diuretics, and correction of metabolic alkalosis may be the only interventions necessary to normalize ventilation. Hypothyroidism, hypophosphatemia, and hypomagnesmia are less often encountered, but correction may ameliorate hypoventilation. Drugs such as benzodiazepines or narcotics are uncommon causes of chronic CO_2 retention in otherwise normal individuals but may be contributory in patients with compromised pulmonary function or depressed respiratory drive, and discontinuation may be salutary.

Pharmacologic Management

Progestational agents stimulate ventilation during pregnancy and can be used to enhance ventilatory drive in normal nonpregnant subjects. They may reduce hypercarbia in patients with central hypoventilation or the obesity hypoventilation syndrome. Medroxyprogesterone doses of up to 50 mg orally three times daily are usually well tolerated, but adverse side effects may include acne, ageusia, and sexual dysfunction. Unfortunately, results with progestational agents in the therapy of uncomplicated OSA have been disappointing.

A number of other pharmacologic agents have been used to enhance respiratory drive in patients with chronic respiratory failure, but efficacy is limited, and none are widely used for this indication. Aminophylline is an acute respiratory stimulant and, when given intravenously to COPD patients with chronic CO_2 retention, may acutely reduce hypercarbia. However, long-term studies on effects of theophylline in patients with COPD and chronic hypercarbia have not shown consistent reversal of chronic respiratory failure. Almitrine bismesylate, a peripheral chemoreceptor agonist, has been used to enhance oxygenation in patients with COPD during both sleep and wakefulness. However, the drug's effect appears to be related more to an improvement in *V/Q* relationships rather than increased respiratory drive, and the role of almitrine in the treatment of chronic respiratory failure remains questionable. Doxapram hydrochloride is another agent shown to acutely stimulate ventilation in patients with exacerbations of COPD. Unfortunately, adverse side effects including muscle spasm, agitation, and seizures occur frequently, the drug is available only in the intravenous form, and use is not recommended for more than two consecutive hours. Thus, it has no role in the therapy of chronic respiratory failure.

Continuous Positive Airway Pressure

For patients with symptomatic OSA, nasal continuous positive airway pressure (CPAP) has become the therapy of choice and can be effective in reversing chronic respiratory failure of OSA. Its mechanism of action is to splint the upper airway open, preventing collapse and permitting unimpeded spontaneous ventilation. Although it does not provide ventilatory assistance, CPAP can reduce the work of breathing by raising FRC and allowing breathing to occupy a more favorable portion of the respiratory system compliance curve or by counterbalancing intrinsic PEEP in patients with severe COPD. Accordingly, CPAP has been used to treat respiratory failure in patients who stand to benefit by these mechanisms, such as those with acute deteriorations of COPD or congestive heart failure. Nasal CPAP may also be beneficial when used nocturnally in patients with other primary causes for their respiratory failure but in whom sleep-disordered breathing appears to be contributory. Many practitioners will initiate CPAP in such patients if the respiratory failure is mild and then proceed to nasal ventilation (see below) if the response to CPAP is inadequate.

Noninvasive Ventilation

Noninvasive ventilation, referring to mechanical ventilatory assistance administered without an invasive artificial airway, has become the therapy of choice in patients with many forms of chronic respiratory failure. Although noninvasive ventilators have been available for the past 150 years and were the mainstay of mechanical ventilatory assistance for the polio epidemics that occurred during the first half of the 20th century, invasive positive-pressure ventilators became the preferred means of acute mechanical ventilatory support in the 1960s. Noninvasive ventilators, mainly of the negative-pressure type, continued to be used for chronic respiratory failure until the early 1960s, but invasive positive-pressure ventilation became more widely used for this indication as well because of perceived effectiveness and reliability. In recent years, however, noninvasive positive-pressure ventilation (NPPV) has seen a resurgence, related to the development of nasal ventilation. This mode of administration has the potential of providing mechanical ventilatory assistance to selected individuals with greater convenience, comfort, safety, and less cost than invasive ventilation. The following describes the various techniques and equipment available for noninvasive ventilation, considers evidence for efficacy and appropriate indications in patients with chronic respiratory failure, and provides general guidelines for application, monitoring, and avoidance of complications.

Why Noninvasive Instead of Invasive Ventilation?

Invasive mechanical ventilation has certainly proven to be effective and reliable, but placement of an endotracheal airway carries attendant risks of complications. These complications have been described in detail by Pingleton and may be categorized in three ways. These include traumatic complications, such as vocal cord paralysis or tracheal laceration, complications related to the violation of the airway defense system, and discomfort-related complications, including pain and interference with communication and swallowing. These complications apply to acute translaryngeal intubations as well as to chronic tracheostomies. Furthermore, airway invasion interferes with normal airway clearance mechanisms such as cough and serves as a continual irritant, increasing mucus production and necessitating intermittent suctioning. The special skills required to care for patients with artificial airways increase personnel needs, adding to the total cost of care. By avoiding these complications, noninvasive ventilation has the potential of enhancing patient satisfaction and reducing the cost of care. However, it must be emphasized that the techniques are not interchangeable and that candidates for noninvasive ventilation must be selected carefully using established guidelines, which are discussed in detail later.

Techniques and Equipment for Noninvasive Ventilation

Various noninvasive techniques are available to assist ventilation. Although NPPV has become the preferred technique in the United States today, other techniques, such as negative-pressure or abdominal-displacement ventilation, may occasionally be useful. These other techniques are still popular in some centers around the world and may be effective when positive-pressure techniques are poorly tolerated or fail to adequately assist ventilation. Accordingly, although the emphasis of the following is on positive-pressure techniques, mechanisms of action and principles of application for the various forms of noninvasive ventilation are also discussed.

Noninvasive Positive-Pressure Ventilation

Noninvasive PPV requires a positive-pressure ventilator connected via tubing to an interface that applies positive air pressure to the nose or mouth. The interfaces and ventilators commonly used for NPPV are described below.

Interfaces

Nasal Masks

Nasal masks are the most commonly used interfaces for chronic respiratory failure because they are convenient and permit normal speech and swallowing. In addition, many different nasal masks are available commercially, largely because of the demand for such devices in the treatment of obstructive sleep apnea. Numerous manufacturers offer various modifications of three basic types of nasal mask. The standard nasal CPAP mask is a triangular clear plastic device that fits over the nose and utilizes a soft cuff to form an air seal (Fig. 1). Nasal pillows consist of soft rubber or silicone cones that are inserted directly into the nostrils (Fig. 2). Third, custom masks are molded to fit a variety of facial shapes.

FIG. 1. Standard nasal CPAP mask connected to a “bilevel” type of portable pressure-limited ventilator (BiPAP S/T, Respironics, Inc., Murrysville, PA).

FIG. 2. Nasal “pillows.” Note that the nasal bridge is uncovered.

Manufacturers of standard nasal CPAP masks include Respironics, Inc. (Murrysville, PA), Healthdyne, Inc. (Marietta, GA), Devilbiss, Inc. (Sunrise Medical, Inc., West Blake Village, CA), and Rescare, Inc. (San Diego, CA). These masks exert pressure over the bridge of the nose in order to achieve an adequate air seal, often causing redness and skin irritation and occasionally leading to ulceration. Modifications are available that minimize these complications, such as use of forehead spacers (Respironics, Inc.), or the addition of a thin plastic flap (Comfort Flaps, Respironics or Sullivan bubble mask, Rescare, Inc.) that permits air sealing with less mask pressure on the nose. Straps that hold the masks in place are also important for patient comfort. Double-strap systems that use Velcro tighteners are most popular, and various elastic caps have also been well received by patients.

Nasal pillows (Adam Circuit, Nellcor Puritan-Bennett, Inc., Lenexa, KA) or seals (Healthdyne) have been useful in patients with nasal bridge irritation or ulceration because they exert no pressure over the bridge of the nose. Occasional patients will alternate between different types of masks as a way of minimizing discomfort. Other patients prefer custom-fitted masks that use rapidly drying plastics (Sefam, Inc., available through Respironics) or heat-molded materials. However, most patients adapt successfully to one commercially available nasal mask interface or another, so custom fitting is usually unnecessary.

Oronasal Masks

These cover both the nose and mouth and, in the author's experience, are rarely tolerated for chronic home use. Oronasal masks have the capability of preventing air leaking through the mouth, but they interfere with speech and eating more than nasal masks, limiting patient acceptability. Currently available oronasal masks include those provided by Vital Signs, Inc. (Totowa, NJ) and Respironics (Spectrum) (Fig. 3). The latter comes with a quick-release strap and an antiasphyxia valve to prevent rebreathing in the event of ventilator failure. Further improvements, such as more comfortable cuffs and improved air-sealing capabilities, will be necessary to increase acceptability in the chronic setting.

FIG. 3. Oronasal face mask designed for use with noninvasive ventilation (Spectrum, Respironics, Inc., Murrysville, PA). The tubing is connected to the mask via an “antiasphyxia” valve, and a quick-release strap rests on the tubing below the mask.

Oral Interfaces

These may be preferable for use in patients requiring around-the-clock ventilatory assistance. Commercially available oral interfaces use a mouthpiece inserted into a lip seal (Nellcor Puritan-Bennett) strapped tautly around the head to minimize air leaking. In the author's experience, this device is poorly tolerated because of interference with speech and swallowing. Mouthpieces that are custom fitted by an orthodontist may not require a strap for adequate sealing and can be easily expectorated if necessary, even by patients with severe neuromuscular disease. Bach et al. have reported success using these devices in a large number of patients with neuromuscular disease, some with little or no measurable vital capacity. During the daytime, these patients receive ventilatory assistance via a mouthpiece held by a gooseneck attached to their wheelchairs.

Ventilators for NPPV

Volume-limited or pressure-limited portable positive-pressure ventilators have been used to deliver NPPV. The choice among ventilators depends largely on practitioner preference and patient needs. For example, sophisticated alarm systems are unnecessary for patients requiring only nocturnal ventilatory assistance and, in fact, may be counterproductive because they may needlessly interrupt sleep. For chronic use in the home, simplicity and portability are important features.

Volume-Limited Ventilators

Portable volume-limited ventilators commonly used to administer NPPV to patients with chronic respiratory failure include the PLV 100 and 102 (Respironics), the LP-10 (Aequitron, Inc., Minneapolis, MN), the Companion 2801 (Nellcor Puritan-Bennett, Inc., Carlsbad, CA), and many others used worldwide. The ventilators are usually set in the assist/control mode to allow for spontaneous patient triggering, and back-up rate is usually set at slightly below the spontaneous patient breathing rate. The only important difference relative to invasive ventilation is that tidal volume is usually set higher (10 to 15 mL/kg) to compensate for air leaking. Currently available volume-limited ventilators have more alarm and pressure-generating capabilities than most portable pressure-limited ventilators and may be better suited for patients in need of continuous ventilation or those with severe chest wall deformity or obesity who need high inflation pressures.

Pressure-Limited Ventilators

Simple pressure-limited ventilators to deliver IPPB have been available for many years (Bird 7, Bird, Inc.; PR2, Nellcor Puritan-Bennett, Inc.) but are rarely used to provide ventilatory support. Portable ventilators that deliver the newer pressure-support ventilation (PSV) mode have seen increasing use in recent years. This mode delivers a preset inspiratory positive airway pressure (IPAP) that can be combined with positive end-expiratory pressure (PEEP or EPAP). The difference between the IPAP and EPAP is the level of inspiratory assistance or pressure support. These ventilators have sensitive inspiratory triggering and expiratory cycling mechanisms, permitting excellent patient–ventilator synchrony, reducing diaphragmatic work, and improving patient comfort.

Portable devices that deliver PSV (BiPAP, Respironics; 321, Puritan-Bennett; Sullivan VPAP, Rescare; Quantum, Healthdyne; and others available outside of the United States such as the SEFAM and Onyx, Pierre Medical, FR) are used for both acute and chronic applications. These devices, sometimes referred to as “bilevel” devices, are lighter (5 to 10 kg) and more compact (< 1 ft^3) than critical-care ventilators, offering greater portability at lower expense. Some, such as the BiPAP, offer not only a spontaneously triggered (or S) mode but also a time cycled (or T) mode for patients with apnea or who fare better resting on a rate-controlled mode. However, these devices have limited IPAP capabilities (up to 20 to 35 cm H_2O, depending on the ventilator) and lack sophisticated alarm or battery back-up systems. Therefore, they are not recommmended for patients requiring high inflation pressures, dependent on continuous mechanical ventilation, or receiving invasive ventilation unless appropriately modified.

The bilevel devices, by virtue of their light weight and convenience, have proven ideal for home use in patients with chronic respiratory failure who require only nocturnal ventilatory assistance. In addition, unlike volume-limited ventilators, they are able to adjust inspiratory airflow to compensate for air leaks, thereby potentially providing better support of gas exchange during leaking. However, in addition to limited alarm capabilities, other concerns have been raised about bilevel ventilators. Because they use a single tube with a passive exhalation valve, rebreathing may occur if the patient exhales nasally. Ferguson et al. have found substantial rebreathing that may interfere with the ability of the BiPAP to augment alveolar ventilation, particularly during use of the whisper-swivel valve (Respironics, Inc.) at low EPAP settings. A recently developed plateau valve (Respironics, Inc.) eliminates the rebreathing, and use of EPAP pressures of 4 cm H_2O or greater reduces it.

Negative-Pressure Ventilation

Negative-pressure ventilators (NPVs) are used much less often now than at times in the past, but a knowledge of their characteristics and applications is still useful because they may be effective in patients who fail to adapt to NPPV. The NPVs include the very efficient and reliable tank ventilators (like the iron lung) and the smaller, more portable wrap (or jacket) and cuirass (or shell) ventilators. The wrap (Numowrap, Respironics, Inc.) consists of an impermeable nylon jacket suspended by a rigid chest piece that fits over the chest and abdomen. The cuirass is a rigid plastic or metal dome fitted over the chest and abdomen. Both must be connected to negative-pressure generators such as the Maxi-Vent (Nellcor Puritan-Bennett), Emerson NPV (J.H. Emerson, Inc., Cambridge, MA), or NEV 100 (Lifecare).

Negative-pressure ventilators expand the lungs by intermittently applying a subatmospheric pressure to the chest wall and abdomen, and expiration occurs passively by elastic recoil of the lung and chest wall. The efficiency of negative-pressure ventilation (tidal volume generated for a given negative pressure) is determined by the compliance of the chest wall and abdomen and by the surface area over which the negative pressure is applied. Thus, the tank is the most efficient and the cuirass the least efficient of the ventilators. Problems with air leaking may reduce efficiency of the wrap and chest shell ventilators and, to a lesser extent, the iron lung, which has to seal only around the neck.

The tank ventilator is reliable and relatively comfortable, but it is bulky (3 m long) and heavy (300 kg). It is also intolerable to claustrophobic patients and interferes with nursing care, although it does have portholes on the sides. A more portable fiberglass tank ventilator is available (Portalung, Nellcor Puritan-Bennett), but it still weighs approximately 50 kg. The chest shell and wrap are lightweight, but the negative-pressure generators used with them weigh 12 to 25 kg. Also, the tank and wrap ventilators restrict patients to the supine position, often inducing musculoskeletal back and shoulder pain. The chest shell may be used in the sitting position, but it can cause discomfort and pressure sores at points of skin contact, particularly if the fit is suboptimal. Patients with chest wall deformities are poor candidates for NPVs, although they can be managed with custom-fit cuirasses.

Most of these limitations of negative-pressure ventilation can be overcome with fitting adjustments or nonsteroidal antiinflammatory drugs. However, the tendency for negative-pressure ventilators to exacerbate or even induce OSA can limit use. Obstructive sleep apneas associated with severe oxygen desaturations are common in patients with neuromuscular disease using negative-pressure ventilators and may necessitate a switch to NPPV. The lack of preinspiratory contraction of pharyngeal muscles that prevents collapse of upper airway structures during a normal patient-initiated breath appears to be responsible for the apneas. Traditional negative-pressure ventilators lack patient-triggered modes, making the upper airway susceptible to collapse before ventilator-triggered breaths. It remains to be seen whether newer patient-triggered negative-pressure ventilators, such as the NEV-100 or Emerson NPV, will alleviate this problem.

Abdominal Displacement Ventilators

The rocking bed and pneumobelt both rely on displacement of the abdominal viscera to assist diaphragm motion and, hence, ventilation. The rocking bed consists of a mattress on a motorized platform that rocks in an arc of approximately 40°. The patient lies supine on the mattress with the head and knees raised slightly to prevent sliding. When the head rocks down, the abdominal viscera and diaphragm slide toward the head, assisting exhalation. As the head rocks up, the viscera and diaphragm slide toward the feet, assisting inhalation. The rocking rate is between 12 and 24 time/min, adjusted to optimize patient comfort and minute volume, as measured with a hand-held spirometer or magnetometer. The chief advantages of the rocking bed are ease of operation, lack of encumbrances, and patient comfort, although bulkiness, noisiness, and lack of portability and efficacy limit its appeal.

The pneumobelt consists of a corset wrapped around the patient s midsection, holding an inflatable rubber bladder firmly against the anterior abdomen. Intermittent inflation of the rubber bladder by a positive-pressure ventilator compresses the abdomen, forcing the diaphragm upward and actively assisting exhalation. With bladder deflation, gravity returns the diaphragm to its original position, assisting inhalation. Tidal volume is increased by raising bladder inflation pressure, usually between 35 and 50 cm H_2O. Desired minute volume can then be attained by adjusting ventilator rate, usually between 12 and 22/min. The pneumobelt is highly portable, can be mounted on a wheelchair to facilitate mobility, is easily hidden under clothing, and leaves the hands and face unencumbered, facilitating desk work. Because it requires gravity to pull the diaphragm down during bladder deflation, it is ineffective unless patients sit at angles of at least 30°. Hence, nocturnal use is limited to patients who can learn to sleep while sitting.

Because their main action is to assist diaphragm motion, both the rocking bed and the pneumobelt are well suited for patients with bilateral diaphragmatic paralysis. However, they are both relatively ineffective ventilators and are of limited use in patients with acute respiratory deterioration. Furthermore, efficacy of both depends on abdominal and chest wall compliance, so that patients with severe kyphoscoliosis, excessive thinness, or obesity may not be adequately ventilated.

Other Types of Ventilatory Assistance

Diaphragm pacing and glossopharyngeal breathing are ventilatory methods used in selected patients to enhance independence. Diaphragm pacing as currently applied was developed by Glenn and co-workers during the 1960s. It consists of a radiofrequency transmitter and antenna that signal a surgically implanted internal receiver and electrode to stimulate the phrenic nerve. Use of diaphragm pacing is limited to patients who have an intact diaphragm and phrenic nerve. Candidates include those with central hypoventilatory syndromes or quadriplegia from high spinal cord lesions. However, recent advances in noninvasive positive-pressure ventilation have virtually eliminated the need for diaphragm pacing in patients with central hypoventilation.

Diaphragm pacing has a number of limitations including high cost, the potential to fail abruptly despite a lack of built-in alarms, and the tendency to produce upper airway obstruction by the same mechanism as negative-pressure ventilators, necessitating tracheostomy placement in up to 90% of users. In addition, there are no controlled studies that demonstrate long-term efficacy. Nevertheless, diaphragm pacers are very easy to use once installed, highly portable, and patients are freed from positive-pressure ventilators. Thus, some patients with high cord lesions may still prefer diaphragm pacing over other types of ventilatory assistance. Its chief application at the present time is in children who have difficulty adapting to noninvasive forms of ventilation.

Glossopharyngeal or frog breathing utilizes intermittent motions of the tongue and pharyngeal muscles to force air into the trachea. When gulping, the patient lowers and then raises the tongue against the palate in piston-like fashion, injecting air into the trachea. With practice, each 0.5 sec gulp injects roughly 50 to 150 mL of air. The patient closes the glottis between gulps to prevent escape of air and rapidly repeats the gulping until a tidal volume of approximately 500 or 600 mL is achieved. The air is then exhaled, and the maneuver is repeated eight to ten times/min so that a normal minute volume can be achieved. The technique can be used to provide freedom from mechanical ventilation for periods of up to several hours, even in patients with severely weakened lower respiratory muscles. It can also be used to augment individual breaths in patients with low tidal volumes or to achieve inhaled volumes of 2 to 2½ L to assist in coughing. However, use is limited to patients who have intact upper airway musculature, more or less normal lungs and chest walls, and are capable of learning the technique. Good candidates include those with high spinal cord injuries, postpolio syndrome, and appropriate patients with other neuromuscular diseases.

EVIDENCE FOR EFFICACY OF NONINVASIVE VENTILATION IN THE TREATMENT OF CHRONIC RESPIRATORY FAILURE

"Body" Ventilators

Tank-type negative-pressure ventilators served as the main means of ventilatory support during the polio epidemics. Negative-pressure ventilation has also been used to provide intermittent ventilatory assistance to patients with symptomatic chronic respiratory failure secondary to slowly progressive neuromuscular diseases, chest wall deformities, or central hypoventilation. Uncontrolled studies during the early 1980s on patients with these diagnoses showed consistent improvements in gas exchange and symptoms of hypoventilation after several months of nocturnal ventilatory assistance using negative-pressure ventilation. Long-term follow-up of these patients, including those with Duchenne muscular dystrophy and postpolio syndrome, show that although the underlying illnesses steadily progress, survival rates are favorable.

The most controversial application of negative pressure ventilation has been its use in resting respiratory muscles in patients with severe stable COPD. Theorizing that these muscles are chronically fatigued and will benefit from intermittent rest, Braun and Marino showed that intermittent daytime sessions using the wrap ventilator improved daytime gas exchange and inspiratory and expiratory muscle strength in patients with severe COPD. However, this study was uncontrolled so that a beneficial effect of some other aspect of a rehabilitation program could not be excluded. Later, other controlled studies showed similar benefits, but they were very short-term (3–7d). Longer-term controlled studies have failed to demonstrate favorable effects of intermittent negative pressure ventilation in patients with severe COPD. Shapiro et al, in the largest study, randomized 184 patients to receive 3 mos of wrap or sham ventilation for 4-5 h daily, but found no improvements in gas exchange, muscle function or exercise capacity. In addition, like Zibrak et al in an earlier study, they found that patients tolerated the ventilators poorly, using them for less time daily than recommended, and having trouble sleeping during use.

The rocking bed and pneumobelt have also been reported to be effective in supporting ventilation in patients with neuromuscular disease, particularly those with weakened or paralyzed diaphragms. These patients are severely dyspneic in the supine position, frequently complain of restless sleep, and use of the rocking bed facilitates sleep and prevents nocturnal hypoventilation. Abd et al described use of the rocking bed in 10 patients who developed bilateral diaphragm paralysis following open heart surgery and were supported nocturnally until diaphragm function returned between 4 and 27 months later. The rocking bed may also be effective in other neuromuscular diseases with diaphragm involvement and a relatively normal body habitus.

Introduced as a daytime aid that frees the hands and face in patients with severe respiratory muscle weakness who use other ventilatory aids at night, the pneumobelt can be used as the sole means of respiratory support in occasional patients who can sleep in a sitting position. Like the rocking bed, it is been particularly useful in patients with diaphragm weakness or paralysis, and in recent years, it has been used as a daytime aid in patients with high cervical cord lesions.

Positive-Pressure Ventilation

Restrictive Thoracic Diseases

Since the first anecdotal series were published in 1987, numerous uncontrolled studies have shown efficacy of nasal NPPV in various neuromuscular and chest wall diseases. These studies consistently show improvements in gas exchange and symptoms after a few weeks of nocturnal nasal ventilation. They also demonstrate reversal of chronic hypoventilation in patients with severe kyphoscoliosis and obstructive sleep apnea who failed to improve with nasal CPAP alone. Although nasal NPPV appears to be better tolerated than mouthpiece NPPV, Bach et al. have reported that mouthpiece NPPV may be used for long-term ventilatory support in patients with severe neuromuscular diseases who have virtually no measurable vital capacity. However, no studies have compared nasal and mouthpiece NPPV directly.

Because no prospective, randomized studies on the use of NPPV in patients with restrictive thoracic diseases have been done, some might question whether efficacy has been proven. However, Hill et al. and others have shown that temporary withdrawal of NPPV from stable long-term users with restrictive thoracic diseases leads to a deterioration of nocturnal gas exchange, daytime symptoms, and sleep quality, offering strong evidence that NPPV is effective in reversing nocturnal hypoventilation and improving symptoms in patients with chronic respiratory failure from restrictive thoracic diseases.

Although the efficacy of NPPV appears to be well established, the optimal time for initiation is unclear. Some investigators have hypothesized that early initiation, before the onset of symptoms or daytime hypoventilation, may slow the progression of respiratory dysfunction in patients with neuromuscular diseases. In patients with Duchenne muscular dystrophy, Raphael et al. tested this hypothesis by randomizing patients to receive nasal NPPV or standard therapy. Contrary to their hypothesis, NPPV-treated patients had no slowing of disease progression. In addition, unexpectedly, the trial had to be stopped because of excess mortality in the NPPV group. Shortcomings of the study such as failure to document compliance with the device and an excess of patients with severe cardiac dysfunction in the NPPV group raise doubts about the significance of the mortality findings, but the study suggests that early initiation may not be beneficial. The present author recommends awaiting the onset of symptoms and daytime hypercarbia before initiation of NPPV, partly because patients are often reluctant to use NPPV unless motivated by the desire for symptom relief.

A recent French follow-up study by Leger et al. on several hundred patients treated with nasal NPPV found 5-year survival rates approximating 80% for postpolio and kyphoscoliosis patients. These survival rates compared favorably with those observed for similar patients treated with invasive mechanical ventilation reported earlier by Robert et al. (see Fig. 4). On the other hand, the likelihood of patients with Duchenne muscular dystrophy continuing NPPV (and surviving) was substantially lower than for the postpolio patients. This raises questions about the ability of NPPV to prolong survival in all groups of patients with restrictive thoracic disease, particularly when the mortality findings of Raphael et al. are considered. Larger randomized trials on patients with Duchenne muscular dystrophy, comparing noninvasive ventilation with earlier invasive ventilation, may be warranted.

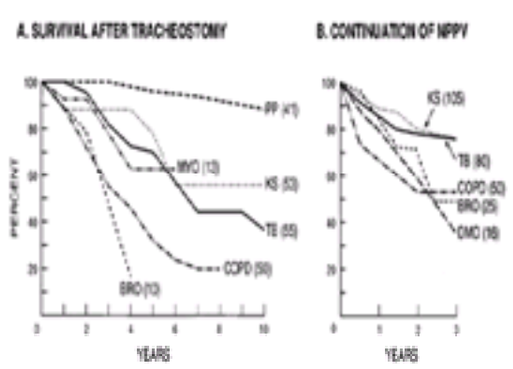

FIG. 4. (A) Survival over time of patients with chronic respiratory failure of various etiologies after placement of a tracheostomy. **(B)** The likelihood of continuing noninvasive positive-pressure ventilation (NPPV) over time in similar patients with chronic respiratory failure. BRO, bronchiectasis; COPD, chronic obstructive pulmonary disease; DMD, Duchenne muscular dystrophy; KS, kyphoscoliosis; MYO, myopathies; PP, postpolio syndrome; TB, old tuberculosis. Nasal intermittent positive pressure. Long-term follow-up in patients with severe chronic respiratory insufficiency. *Chest* 1994;105:100–105, with permission.)

Chronic Obstructive Pulmonary Disease

Studies on the use of NPPV in patients with severe obstructive lung diseases have yielded conflicting results. In a 3-month crossover trial on 19 patients with severe COPD, seven of whom completed the trial, Strumpf et al. found improvement only in tests of neuropsychological function but not nocturnal or daytime gas exchange, sleep quality, pulmonary functions, exercise tolerance, or symptoms. In contrast, Meecham-Jones et al. performed a study of nearly identical design on 18 patients with severe COPD, 14 of whom completed the trial, and found that NPPV use improved nocturnal and daytime gas exchange, total sleep time, and symptoms.

The substantial differences in baseline characteristics of entered patients may offer an explanation for the conflicting results. Patients entering the Meecham-Jones study had greater hypercarbia (P_aCO_2 57 mmHg versus 47 mmHg) and more nocturnal oxygen desaturations despite having less severe airway obstruction (FEV_1 0.81 liter versus 0.54 L) than patients in the Strumpf study. This suggests that the studies were examining different subsets of patients with COPD and that those with more

daytime CO_2 retention and nocturnal oxygen desaturations may be the group most likely to benefit from NPPV. Further support for this possibility is provided by anecdotal series of cystic fibrosis patients with severe CO_2 retention who have been successfully supported using NPPV while awaiting lung transplantation. Additional studies will be necessary to determine whether different ventilator modes or settings can improve the efficacy of NPPV in COPD patients and whether NPPV enhances quality of life or prolongs survival relative to oxygen therapy alone in appropriate subgroups.

Other Forms of Chronic Respiratory Failure

Noninvasive PPV improves daytime gas exchange and symptoms in patients with OSA who fail to improve after use of nasal CPAP alone. In addition, patients with central hypoventilation syndromes have been successfully supported using NPPV. Interest in NPPV has been increasing among pediatric practitioners, who report successful application in patients with bronchopulmonary dysplasia. Noninvasive PPV may also be used to speed extubation of patients who become chronically ventilator dependent after bouts of acute respiratory failure.

SELECTION GUIDELINES FOR PATIENTS TO RECEIVE NONINVASIVE VENTILATION

Based on the many uncontrolled trials, a number of characteristics can be identified that permit selection of appropriate candidates for noninvasive ventilation (Table 4). In general, there should be at least mild to moderate daytime CO_2 retention (usually an indication of more severe nocturnal CO_2 retention). Symptoms attributable to hypoventilation and associated poor sleep quality such as morning headache, daytime hypersomnolence, and energy loss should also be present. Patients with symptomatic nocturnal hypoventilation but no daytime CO_2 retention may also benefit. Unless motivated by the desire for symptom relief, patients have difficulty complying with noninvasive ventilation.

I. Chronic stable or slowly progressive respiratory failure
1. Significant CO_2 retention (P_aCO_2 > 50 mm/Hg)
2. Mild CO_2 retention with symptoms
a. Morning headache
b. Daytime hypersomnolence
3. Nocturnal hypoventilation or oxygen desaturation[b]
II. Inappropriate candidates excluded
1. Upper airway function adequate
2. No excessive airway secretions
3. Reversible underlying disorders (hypothyroidism, congestive heart failure, etc.) adequately treated
III. Appropriate condition
1. Slowly progressive neuromuscular disorder
2. Chest wall deformity
3. Obstructive sleep apnea unresponsive to CPAP
4. Control hypoventilation
5. Obstructive lung disease with:[b]
a. Significant CO_2 retention
b. Nocturnal desaturations

[b] Tentative indication.

TABLE 4. *Guideline for selection of patients with chronic respiratory failure for noninvasive ventilation*[a]

Patients should also have adequate airway defenses. Those with swallowing impairment or excessive secretions, particularly if combined with a weakened cough mechanism, are at risk for aspiration or mucus plugging. If such patients desire aggressive support, they are usually more safely managed with invasive ventilation.

The patient's diagnosis is also an important consideration. Those with stable or slowly progressive neuromuscular diseases or chest wall deformities are the best candidates, assuming that airway protection mechanisms are intact. Others, such as those with central hypoventilation or obstructive sleep apnea who have failed a trial of nasal CPAP, are also acceptable candidates. On the other hand, patients with rapidly progressive neuromuscular processes like Guillain-Barré syndrome, particularly if there is upper airway involvement, are poor candidates. Among patients with chronic airway obstruction, those with daytime CO_2 retention and nocturnal oxygen desaturations may warrant a trial of noninvasive ventilation, as may those with end-stage cystic fibrosis who are deteriorating while awaiting lung transplantation.

Mechanism of Action

Both invasive and noninvasive PPV work by intermittently raising airway and thereby transpulmonary pressure, inflating the lungs, and assisting alveolar ventilation. However, noninvasive ventilation differs in that it provides no direct access to the airway, rendering patient cooperation mandatory. If the patient closes his mouth or glottis or actively resists, ventilator air merely follows the path of least resistance and leaks out around the mask or through the mouth. In cooperative, awake patients, coordination with the ventilator can usually be achieved fairly quickly. During sleep, however, patients must learn to direct air into their lungs and relax their breathing muscles in order to receive optimal benefit. The process by which this nocturnal adaptation takes place is not fully understood, but patency of the glottis appears to be an important determinant of delivered tidal volume. Other poorly understood aspects of nasal NPPV include the role of nasal resistance in determining efficacy and mechanisms for controlling air leaking through the mouth. The latter is seen to a greater or lesser extent in virtually all patients using nasal NPPV, appears to contribute to sleep arousals, but only occasionally is severe enough to negate ventilatory benefits.

The mechanism responsible for sustained improvement of gas exchange and symptoms in patients with chronic respiratory failure receiving assisted ventilation for as little as 4 to 6 hrs nightly has also eluded delineation. Three main theories have been proposed to explain the sustained improvements. One postulates that noninvasive ventilation rests chronically fatigued respiratory muscles in patients with chronic respiratory failure, thereby improving daytime ventilatory muscle function. Supporting this theory are studies demonstrating that respiratory muscles do indeed rest during noninvasive ventilation and that indices of respiratory muscle strength and endurance may improve in patients with chronic respiratory failure after varying periods of noninvasive ventilatory assistance. However, chronic respiratory muscle fatigue has never been adequately defined or convincingly demonstrated, and a number of studies have failed to demonstrate improvement in respiratory muscle function despite amelioration of gas-exchange abnormalities and symptoms after periods of intermittent ventilatory assistance.

A second theory postulates that noninvasive ventilation improves respiratory system compliance by reversing microatelectasis of the lung, thereby diminishing daytime work of breathing. This theory derives from studies showing improvements in FVC without changes in indices of respiratory muscle strength after periods of positive-pressure ventilation. Once again, however, data are conflicting, with a number of studies showing no changes in vital capacity after periods of noninvasive ventilation.

A third theory proposes that noninvasive ventilation lowers the respiratory center set point for CO_2 by ameliorating nocturnal hypoventilation. In this context, the respiratory center is thought to adjust its output so that the work of respiratory muscles will not exceed the level that would precipitate muscle fatigue, a process sometimes referred to as “central” fatigue. Particularly at night, when upper respiratory muscle tone and activity of nondiaphragmatic inspiratory muscles diminish, progressive nocturnal hypoventilation may develop, permitting an upward resetting of the respiratory center and worsening daytime hypoventilation. Nocturnal ventilatory assistance ameliorates the hypoventilation and allows resetting of the respiratory center, thereby reducing daytime hypercarbia. Evidence for this theory derives from a study showing that when ventilatory assistance was discontinued for a night in patients with chronic respiratory failure who had been stabilized using noninvasive ventilation, the degree of nocturnal hypoventilation was less severe than before initiation, suggesting resetting of respiratory center sensitivity for CO_2. In a more recent study, worsening of nocturnal hypoventilation, oxygen desaturation, and daytime symptoms occurred without loss of respiratory muscle strength or vital capacity when nocturnal NPPV was discontinued for a week in patients whose chronic respiratory failure had previously been reversed by nocturnal NPPV. The worsening nocturnal hypoventilation and symptoms were promptly alleviated by resumption of NPPV. These studies suggest that prevention of nocturnal hypoventilation with resetting of respiratory center sensitivity for CO_2 may be an important mechanism for the efficacy of NPPV. However, the three theories are not mutually exclusive, and all could conceivably contribute to varying degrees depending on the patient.

Practical Considerations

Initiation

The process of initiating noninvasive ventilation is largely a trial-and-error process that must be modified for each individual patient. Unlike patients with acute respiratory failure, who have an urgent need for ventilatory assistance, most patients with chronic respiratory failure can begin noninvasive ventilation gradually, in a relaxed fashion, so that chances for success are optimized. After identification of an appropriate patient, a ventilator or combination of ventilators must be selected for the initial trial. Nasal NPPV should be considered the mode of first choice for most patients with chronic respiratory failure because of its greater convenience and portability compared to body ventilators and its ability to eliminate obstructive sleep apneas. On the other hand, body ventilators may be advantageous in patients who

have excessive air leaking through the mouth during NPPV or in the occasional patient who is unable to tolerate masks because of discomfort or claustrophobic reactions. In other situations, a combination of ventilators may work best, such as in a patient with a high spinal cord lesion who uses NPPV at night and a pneumobelt during the daytime.

The author advises performing the initial trial during the daytime in a relaxed setting, often on an outpatient basis. To establish continuity, the home respiratory therapist who will follow the patient is asked to assemble the necessary equipment and meet the patient in the physician's office or hospital room. Experienced practitioners then optimize fit and adjust initial settings, explaining each step to minimize patient anxiety. For fitting of nasal masks, the smallest standard mask that adequately covers the nose usually works best. Straps are tightened with the least tension necessary to avoid excessive air leakage. Some air leakage is acceptable because the strap tension necessary to eliminate leaking entirely often induces pressure sores, and the ventilator can be adjusted to compensate for leaks. With body ventilators, fitting may also be necessary. The tightness of the neck seal and body positioning are important with tank and wrap ventilators, and for the cuirass and pneumobelt ventilators, the proper size must be selected.

When the patient is fitted comfortably with the device, ventilation can be started. The author advises low initial pressures to facilitate patient acceptance, with gradual increases later as tolerated by the patient. Typical initial settings on pressure-limited ventilators are 8 to 12 cm H_2O for IPAP and 2 to 4 cm H_2O for EPAP (pressure support of 4 to 10 cm H_2O and PEEP of 2 to 4 cm H_2O). For volume ventilation, initial tidal volumes range from 10 to 15 mL/kg. The ventilator is usually set in the S/T or A/C mode to allow patient triggering. Ventilator back-up rate is set at spontaneous breathing rate if the aim is to entrain the patient's breathing and minimize respiratory muscle work, or slightly lower to encourage spontaneous breathing. If necessary, supplemental oxygen can be connected to ports in the mask or tubing, with liter flow titrated to maintain the desired oxygen saturation. Patient comfort should be a higher priority initially than improvement in gas exchange or tidal volume, which can be attained later as pressures are increased during the adaptation phase.

Initiation of body ventilation follows a similar approach, with initial adjustment of presures to optimize patient acceptance and later adjustments to achieve gas exchange goals. Measurement of assisted tidal volume is easier than with NPPV and should aim for increases of perhaps 30% to 50% over spontaneous. With both NPPV and body ventilators, end-tidal PCO_2 and oximetry monitoring or an arterial blood gas measurement obtained after the first hour or two of use may help in assessing the need for further adjustments. Typical pressure ranges and rates used for the various ventilators are listed in Table 5.

	Settings			Costs (US$/month)	
Ventilator	Rate (Breaths/min)	Pressure (cm H_2O)	Efficiency	Primary device	Pressure generator
Negative pressure					
Iron lung	12–24	−10 to −35	+++	378[b]	
Porta lung	12–24	−10 to −35	+++	562	380
Wrap	14–28	−15 to −45	++	159	380
Shell	14–28	−15 to −45	+	64	380
Pneumobelt	12–24	+15 to +50	++	50	310
Rocking bed	12–24	40°	+	250[b]	—
Positive pressure	12–24	+10 to +30	+++	453[c]	—

TABLE 5. *Typical settings, relative efficacy, and rental costs of body and positive-pressure ventilators*[a]

Adaptation and Monitoring

After the initial trial, the patient is encouraged to begin nocturnal use, but gradually, sometimes for only an hour or two at the start, and to extend the hours of use as tolerated. Comparing the process to that of mastering a musical instrument may be helpful. During this period, frequent visits from an experienced home respiratory therapist help to assure proper use of the device and allow adjustments in mask sizes and types, straps, and pressure settings that are often necessary. Some patients successfully sleep through the night within days of initiation, but others require several months. A trial should not be considered unsuccessful unless numerous adjustments have been tried over a period of at least several weeks. Perhaps 20% to 25% of patients are unable to tolerate NPPV, usually because of mask intolerance. In these patients, trials with alternative noninvasive ventilators such as negative-pressure or abdominal ventilators may still be successful, as long as the patient has no more than mild obstructive sleep apnea.

Patients should be seen every few weeks by a physician during the initial adaptation period. Once adaptation has been successful, physician visits may be scheduled much less often, as infrequently as twice or thrice yearly. At the time of office follow-up, symptoms and physical signs should be assessed for evidence of nocturnal hypoventilation or cor pulmonale. Spirography is indicated, particularly in patients with progressive neuromuscular syndromes, to assess loss of pulmonary function. Daytime arterial blood gases or pulse oximetry and end-tidal PCO_2 should be obtained at the time of physician visits or when symptoms worsen. Although there is no consensus on the ideal target level for daytime P_aCO_2 in patients receiving noninvasive ventilation, values ranging from the 40s to mid-50s mmHg are usually associated with good control of symptoms.

Nocturnal monitoring is also useful after adaptation to noninvasive ventilation to assure adequacy of oxygenation and ventilation. Nocturnal oximetry at home may help in screening but will not identify specific problems should desaturations occur. Thus, home monitoring of chest wall motion, mask pressure, and airflow in addition to oximetry, such as is possible with portable multichannel recorders (Edentrace II, Edentec, Eden Prairie, MN; Night Watch, Healthdyne), is useful to detect evidence of persistent apneas or excessive air leaking. Electroencephalographic recording may help to determine whether episodes of air leak though the mouth or sleep-disordered breathing during ventilator use are associated with desaturations, sleep arousals, and poor sleep quality. Monitoring of nocturnal PCO_2 is desirable, but neither transcutaneous nor end-tidal monitoring systems have proven reliable enough to be of much value in characterizing problems. The need for repeated nocturnal monitoring after succesful adaptation to noninvasive ventilation has not been evaluated. One approach is to initially establish adequacy of overnight gas exchange using a portable multichannel monitor in the home and then to repeat studies as dictated by changes in symptoms or daytime gas exchange. More sophisticated polysomnographic monitoring can be used when the portable monitor is insufficient to characterize problems.

Commonly Encountered Problems and Possible Solutions

Noninvasive ventilation is safe and well tolerated in most properly selected patients. With NPPV, the most commonly encountered problems occur during the adaptation phase and are interface-related (Table 6). Patients often complain of mask discomfort that can be alleviated by minimizing strap tension or trying different mask sizes or types. Excessive air pressure leading to sinus or ear pain is another common complaint and can be alleviated by lowering pressure temporarily and then gradually raising it again as tolerance improves. Patients may also complain of dryness or congestion of the nose or mouth. For dryness, nasal saline or efforts to reduce air leaking may help. Flow-by humidifiers may also be helpful, particularly in dry climates, but mask pressure should be verified when these are added to pressure-limited ventilators. For nasal congestion, inhaled steroids or decongestants or oral antihistamine–decongestant combinations may be used. Other commonly encountered problems include erythema, pain, or ulceration on the bridge of the nose related to nasal mask pressure. This can be ameliorated by minimizing strap tension, using artificial skin, or switching to alternative masks such as nasal “pillows.” Gastric insufflation is common but is usually not severe, probably because inflation pressures are low compared to those used with invasive ventilation.

Problem	Approximate rate of occurrence (%)	Possible remedy
Minor		
Interface-related		
Nasal dryness	40–60	Inhaled steroids, saline
Nasal congestion	40–60	Nasal saline or humidification
Skin reddening	25–40	Loosen straps, topical lotions
Mask intolerance	15–30	Different masks
Nasal ulceration	5–10	Loosen straps, artificial skin
Air-pressure-related		
Sinus, ear pain	5–30	Reduced pressure temporarily
Eye irritation	5–10	Reposition mask, straps
Gastric insufflation	5–10	Simethicone
Air leaking		
Around mask	50–100	Reposition mask, try different types
Through mouth	50–100	Chin straps
Through nose (with mouthpiece)	—	Nasal plugets
Major		
Aspiration	0–5	Careful patient selection, nasogastric tubes as indicated
Failure to improve ventilation	10–20	Increase pressure, V_T, or rate; reduce air leaks
Deterioration after prior stabilization	5–10	Alternative noninvasive ventilators, invasive ventilation

[a] Adapted from Hill, Noninvasive Mechanical Ventilation in *Pulmonary and Critical Care Medicine*, update 4, Chicago: Medby Year Book, 1997.

TABLE 6. *Problems encountered during noninvasive ventilation and possible remedies*[a]

Air leaking through the mouth (with nasal masks), through the nose (with mouthpieces), or around the mask (with all interfaces) is inevitable during NPPV. Pressure-limited devices compensate for air leaks by maintaining inspiratory airflow during leaking; tidal volumes on volume-limited ventilators may be increased by the practitioner to compensate. To reduce air leaking through the mouth, patients are coached to keep the mouth shut or use chin straps or oronasal masks. Air leaking occurs during the majority of sleep in many patients, but, fortunately, gas exchange is usually well maintained. Leaks may still contribute to arousals and poor sleep quality, however, and ventilatory assistance may occasionally be compromised. In this case, options include trials of alternative interfaces or ventilators or, if these fail, tracheostomy. Major complications of noninvasive ventilation, such as aspiration or pneumothorac, are unusual if patient selection guidelines are observed.

Failure of daytime gas exchange to improve is often related to the patient's inability to tolerate the device and use it for enough nocturnal hours. However, if the patient is using the device for most of the night, failure to improve may be related to inadequate inspiratory pressures or tidal volumes, ventilator rate, or excessive air leaking through the mouth. Further adjustments in settings and follow-up monitoring are indicated. When daytime gas exchange deteriorates after prior stabilization, the patient's underlying neuromuscular or respiratory disorder may have progressed and often responds to increases in inspiratory pressure, tidal volume, or ventilator rate. If gas exchange fails to respond to repeated adjustments, or the patient fails to tolerate NPPV, trials with alternative noninvasive ventilators may be successful. In patients who are intolerant of the devices or have persisting symptomatic hypoventilation despite prolonged trials of various noninvasive ventilators, tracheostomy placement may be necessary if the patient desires aggressive ventilatory support.

CONCLUSION

Chronic respiratory failure is most often caused by mechanical problems of the respiratory system, in particular, COPD. Patients also have secondary disturbances that may contribute to their CO_2 retention. These include insensitivity of the respiratory center to CO_2, hypothyroidism, and sleep-disordered breathing. It is important to seek these secondary contributing factors in formulating an effective therapy. The first therapeutic intervention should be to reverse these contributing factors, either by treating airway obstruction or by using a central stimulant. Nasal CPAP should be used as a next step if upper airway collapse is documented and CO_2 retention is mild. If this approach fails, nasal ventilation is the preferred alternative. Nasal NPPV enhances convenience, portability, and patient comfort, offering the advantages of simplified care, reduced complications, and lowered costs relative to invasive ventilation. Recent evidence strongly supports nasal NPPV as the ventilatory mode of first choice in patients with respiratory failure secondary to slowly progressive neuromuscular diseases, chest wall deformities, and central hypoventilatory disorders, but the use of noninvasive ventilation in patients with severe COPD remains controversial.

Initiation of noninvasive ventilation for chronic respiratory failure requires identification of an appropriate patient and selection of a ventilator. Patient intolerance for the device may limit reductions in P_aCO_2 or increases in minute volume initially, but these can be adjusted later, during the adaptation process. A minority of patients are unable to adapt despite prolonged efforts, and for these, alternative noninvasive ventilators, such as negative-pressure devices, pneumobelts, or rocking beds, may be successfully used as long as obstructive sleep apnea has been excluded. If these also fail to improve symptoms or gas exchange abnormalities, there is loss of the ability to adequately protect the upper airway, or a need for continuous ventilatory support, invasive ventilation may be necessary.

Complications of noninvasive ventilation are minimal if patients are selected according to established guidelines and are appropriately monitored. Most complications of NPPV are interface related, such as discomfort caused by air or mask pressure. Because NPPV is an open-circuit system, air leaks may compromise efficacy and interfere with sleep quality. Complications of other forms of noninvasive ventilation are also usually minor, such as musculoskeletal shoulder and back discomfort, but exacerbation of obstructive sleep apnea may occur. Follow-up nocturnal monitoring should be done with NPPV or alternative ventilators to assure adequacy of nocturnal gas exchange.

The role of noninvasive ventilation in respiratory care continues to evolve. Some indications are well established, such as use for patients with chronic respiratory failure from neuromuscular disease, but other indications, such as use for patients with severe COPD, await further study. Studies aimed at establishing the optimal applications for noninvasive ventilation and technologic advances in ventilators and interfaces should lead to wider use as indications are expanded and better defined.

Evaluation of intermittent long-term negative pressure ventilation in patients with severe chronic obstructive pulmonary disease. *Am Rev Respir Dis* 1988;138:1515–1518. *A 3-month crossover trial found no improvements in respiratory muscle strength, gas exchange, exercise capacity, or symptoms after daily wrap ventilation compared to standard therapy in a small group of patients with severe COPD. The authors also noted very poor tolerance of the wrap ventilator among their COPD patients.*

CHAPTER

51 Pulmonary Rehabilitation and Outcome Measurement

Barry Make

B. Make: Division of Pulmonary Sciences and Critical Care Medicine, National Jewish Center for Immunology and Respiratory Medicine, University of Colorado School of Medicine, Denver, Colorado 80206.

INTRODUCTION

The major goal of treatment of any chronic and irreversible disorder is to allay symptoms and minimize the impact of the illness by enhancing the individual's performance of desired activities. Pulmonary rehabilitation is an effective therapeutic intervention that can be employed to achieve these goals. Of the numerous respiratory conditions, patients with chronic obstructive pulmonary disease (COPD) frequently have the most chronic, debilitating symptoms, which are not completely eliminated or controlled by medications and other traditional medical treatments. Because of the severity of the dyspnea associated with increasing activity in patients with COPD, this disease frequently impairs the patient's ability to engage and participate constructively in daily activities. Comprehensive pulmonary rehabilitation has also been employed successfully in patients with cystic fibrosis and respiratory insufficiency associated with severe neuromuscular disorders. In addition, the approaches and comprehensive efforts, including disease-management programs, used with asthma to decrease utilization of health care resources, assure continued adherence with treatment programs and health-enhancing behaviors, and enhance collaborative self-management employ many of the principles of pulmonary rehabilitation.

This chapter defines pulmonary rehabilitation, describes the key components of a comprehensive pulmonary rehabilitation program, discusses the techniques and physiological basis for therapies employed during rehabilitation, and reviews the outcomes that can be achieved as a result of this therapy. Because COPD is the most common chronic respiratory disease, and because patients with COPD are the most common recipients of pulmonary rehabilitation, this chapter focuses on pulmonary rehabilitation as employed in these patients. However, all of the principles of pulmonary rehabilitation and many of the specific therapeutic modalities and approaches may also be applied to patients with other respiratory disorders.

DEFINITION AND CONCEPT OF PULMONARY REHABILITATION

Historically, rehabilitation has been the term applied to the therapeutic techniques used for patients with limitations as a result of physical impairments such as loss of function of an extremity through injury or birth defect or loss of function secondary to neurologic or muscular conditions such as polio. The principles of rehabilitation are based on the broad goal of restoring individuals to the fullest medical, mental, emotional, social, and vocational potential possible. This goal may also be applied to patients with chronic disorders of any organ system that impair ability to participate in functional activities. Pulmonary rehabilitation is the term used when the recipients of rehabilitation efforts are patients with disorders of the respiratory system and was originally defined by a committee of the American College of Chest Physicians (ACCP) and later revised by a National Institutes of Health (NIH) Workshop. A careful evaluation of the published definitions of pulmonary rehabilitation provides important insights into this form of therapy.

The ACCP Definition

The original definition of pulmonary rehabilitation was conceived in an era when there was little information about the efficacy of this form of therapy and limited information supporting the physiological basis for the therapeutic modalities employed. Pulmonary rehabilitation was defined as:

> an art of medical practice wherein an individually tailored, multidisciplinary program is formulated which through accurate diagnosis, therapy, emotional support, and education, stabilizes or reverses both the physio- and psychopathology of pulmonary diseases and attempts to return the patient to the highest possible functional capacity allowed by his pulmonary handicap and overall life situation.

There are several important implications of this definition.

Individually Tailored

The first implication of the definition of pulmonary rehabilitation is that, as in the practice of other types of rehabilitation, the efforts of the program are based on the individual needs of each patient. Not only is a carefully performed and complete assessment of the patient by the an experienced health care professional necessary to determine the medical needs, but the individual patient must also provide input to determine his or her individual needs and goals. Because rehabilitation requires the active participation of the recipient, patients must be involved in setting the goals of their efforts.

Multidisciplinary

Second, rehabilitation is not usually considered to be a single therapy but rather is a coordinated program of a number of therapies, most often applied by health care professionals with a variety of backgrounds and with different areas of expertise. Indeed, results and outcomes have most commonly been assessed in response to comprehensive multimodality pulmonary rehabilitation programs. As noted in the rest of this chapter, the various multifaceted components of pulmonary rehabilitation are not usually within the expertise of a single member of the health care team and often require personnel with knowledge and experience in exercise training, psychosocial evaluation and counseling, use of the unique respiratory medications and breathing exercises used in patients with lung disease, education of adults with chronic lung disease, energy conservation and management techniques, nutritional issues, and medical issues of patients with respiratory disorders.

Improvement in Function

Although individual goals may vary from one patient to another, the objective of pulmonary rehabilitation is to improve the ability of the patient to function to the maximal extent possible given the limitations imposed by the underlying respiratory disorder. Although it may not be possible to reverse the pathologic effects of the disease, the physiological and psychological responses to the disease may be amenable to treatment. For example, although pulmonary rehabilitation does not improve oxygenation, limitations in activity by hypoxemia-induced dyspnea may be partially reversed with supplemental oxygen therapy used during periods of increased daily activities such as grocery shopping and thereby improve overall patient function. The measurement of patient function as an outcome of pulmonary rehabilitation is thus important to determine the effectiveness of this therapy.

The NIH Definition

Although the earlier definition of pulmonary rehabilitation noted the importance of the art of medical practice, the National Institutes of Health later reviewed the scientific basis for pulmonary rehabilitation. The NIH Workshop convened to assess research needs in pulmonary rehabilitation formulated another definition of pulmonary rehabilitation:

> a multidimensional continuum of services directed to persons with pulmonary disease and their families, usually by an interdisciplinary team of specialists, with a goal of achieving and maintaining the individual's maximum level of independence and functioning in the community.

Rather than providing a completely new definition, the NIH Workshop expanded on the earlier effort and attempted to integrate the concept of pulmonary rehabilitation into the evolving health care environment in several ways. First, the Workshop recognized the evolution of health care delivery, which has increasingly focused on providing care at multiple sites ranging from the acute care hospital to the home and to patients at all life stages—a concept referred to as the continuum of health care delivery. Second, pulmonary rehabilitation is now seen not as a time-limited therapy employed within a defined period to achieve a particular end result but rather as requiring an ongoing program of organized and integrated services provided to the patient to maintain function over the long term. Although this is a laudable goal that will likely improve long-term outcomes, the current practice of pulmonary rehabilitation does not usually fulfill this definition but is still traditionally implemented as a defined program over a limited period of time. Third, the NIH definition takes a broader view of pulmonary rehabilitation by recognizing the importance of family members and viewing the patient as functioning and participating within the larger community outside of the boundaries of the home. Last, this newer concept of rehabilitation recognizes that, although usually implemented by a multidisciplinary team, some of the individual elements of pulmonary rehabilitation may more commonly be applied in a limited fashion to patients not enrolled in a comprehensive rehabilitation program. For example, prescription of medications always requires education of the patient in proper medication use. Although education is one of the components of pulmonary rehabilitation, patients should be educated about their medications even when they are not enrolled in a rehabilitation program. In recognition of the NIH definition, this chapter describes pulmonary rehabilitation as a long-term continuum of a set of comprehensive services provided in an organized manner.

KEY COMPONENTS OF COMPREHENSIVE PULMONARY REHABILITATION

It is generally accepted that there are several key elements of a state-of-the-art comprehensive pulmonary rehabilitation program (Table 1). These components may be categorized into five areas: (1) medical evaluation and management, (2) initial assessment and goal setting, (3) therapeutic modalities of exercise training, psychosocial counseling, nutritional counseling, daily living training and energy management, and education, (4) evaluation of outcomes, and (5) a maintenance program. Each component is discussed individually.

Medical evaluation and management
Initial assessment and goal setting
Therapeutic modalities
Smoking cessation
Exercise training
Psychosocial counseling
Breathing retraining
Daily activity performance and energy management
Nutritional counseling
Outcome evaluation
Maintenance program

TABLE 1. *Components of a comprehensive pulmonary rehabilitation program*

MEDICAL EVALUATION AND MANAGEMENT

The physician (whether a general practitioner, internist, or pulmonary specialist) who provides primary and ongoing care of the patient with respiratory disease plays an integral role in pulmonary rehabilitation. The physician not only refers the patient for rehabilitation but also helps to assure the patient's participation by explaining the rationale and benefits of rehabilitation, integrating rehabilitation into the patient's continuing medical care, and monitoring the patient's ongoing adherence with the components of rehabilitation.

An appropriate diagnosis and optimal medical treatment of the patient with respiratory disease are prerequisites for initiation of pulmonary rehabilitation. The goal of evaluation and management by the physician is to minimize the medical impact of the disease on the patient and thereby maximize the patient's ability to benefit from the pulmonary rehabilitation program. The results of the medical evaluation should be available and communicated to the rehabilitation team. Because patients referred for pulmonary rehabilitation usually have at least moderately severe airflow limitation and significant functional limitations as a result of their illness, it is appropriate for a physician with specialized training in pulmonary medicine to play a major role in confirming the diagnosis and reviewing the medical plan.

As outlined in Table 2, medical evaluation and management have multiple components. One of the most important elements of the evaluation is the diagnosis of conditions of other organ systems that might potentially limit the patient's ability to participate in and obtain maximal benefit from rehabilitation. For example, COPD patients referred for rehabilitation are usually older and may have concomitant osteoarthritis of the knees, which may impair their ability to perform walking exercise. Establishing and communicating the diagnosis will allow the rehabilitation team to choose exercise programs that minimize stress on the knees. Providing appropriate medications to reduce inflammation and pain will not only ensure that the patient is comfortable but also maximize participation in the exercise program. The physician should also consider the diagnosis of osteoporosis, particularly in older postmenopausal women and individuals with a history of corticosteroid administration. Because patients are older, commonly have a history of cigarette use, and because the cardiovascular system will be stressed during exercise training, cardiac disease should be excluded. A maximal exercise test may not only be used to screen for ischemic cardiac disease but is also useful to evaluate the presence of oxygen desaturation with exercise and to determine the appropriate dose of oxygen to prevent desaturation.

Evaluation
Respiratory diagnosis
Severity of respiratory disease
Other conditions potentially interfering with pulmonary rehabilitation
Arthritis
Osteoporosis
Cardiac disorders
Oxygenation at rest and during activity
Management
Reduce airflow limitation
Minimize pulmonary secretions
Eliminate/reduce medication adverse effects
Promote collaborative self-management
Provide plan to address changes in symptoms
Reduce impact of other conditions on participation in rehabilitation program
Provide plan for maintaining continuity of medical care

TABLE 2. *Medical evaluation and management component of pulmonary rehabilitation*

The medical treatment plan should include prescriptions and specific instructions on the dose, frequency, and route of administration of all medications, particularly those required to reduce airflow limitation. Some patients with COPD have notable difficulty clearing secretions, leading to dyspnea and increased work of breathing. Although the rehabilitation team can provide assistance in secretion management, the physician should prescribe antibiotics when necessary to control infection. Finally, the physician must provide a referral and an order for pulmonary rehabilitation. Because the team providing comprehensive pulmonary rehabilitation will be skilled and experienced in patient assessment in order to individualize the program for each patient, determine the goals and duration of therapy, and apply each component of rehabilitation, in most cases the physician's order may be very general.

Selection of Patients for Rehabilitation

Based on the definitions, goals, and outcomes of pulmonary rehabilitation, a comprehensive rehabilitation program is recommended for patients with disorders of the respiratory system who, despite optimal medical management, have functional limitations preventing them for participating fully in daily activities or vocational activities. As noted in Table 3, patients with a variety of respiratory conditions may be candidates for pulmonary rehabilitation. Because of the varied nature of the underlying disorders of patients suitable for rehabilitation and the imprecise relationship between pulmonary function and functional capacity, there are no specific physiological indices to assist in selecting patients for pulmonary rehabilitation. Unfortunately, tools assessing functional capacity and quality of life are not useful in this task. The patient and the physician providing ongoing care, often in conjunction with the physician specialist in pulmonary medicine, are in the best position to evaluate the need for pulmonary rehabilitation. It is important to note that third-party payers typically require documentation not only of functional limitations but also of a treatment plan incorporating short- and long-term goals before providing reimbursement for rehabilitation.

Obstructive lung disease
Chronic obstructive pulmonary disease
Asthma
Cystic fibrosis
Bronchiectasis
Restrictive lung disease
Interstitial lung diseases
Tuberculosis and other mycobacterial diseases
Restrictive respiratory system disorders
Neuromuscular
Postpolio
Muscular dystrophy
Guillain-Barré syndrome
Chest wall
Kyphoscoliosis
Thoracoplasty
Other
Pre and post lung surgery lung volume reduction
Lung transplant
Lung cancer
Ventilatory dependency
Sleep apnea

TABLE 3. *Respiratory disorders suitable for pulmonary rehabilitation*

Although pulmonary rehabilitation should not be delayed until the patient has a very severe degree of physiological impairment, some general guidelines for patient selection based on the severity of the respiratory impairment may be outlined. In general, patients requiring chronic ambulatory oxygen therapy and patients with frequent emergency room visits or hospitalizations are candidates for pulmonary rehabilitation.

Oxygen Therapy

Assessment of the patient's oxygenation and need for oxygen therapy should be performed either before rehabilitation or during the initial assessment for pulmonary rehabilitation. In order to determine the need for supplemental oxygen administration during activity, it is recommended that oxygen saturation (S_aO_2) be assessed with pulse oximetry during activity in all patients participating in pulmonary rehabilitation. Although any type of activity performed by the patient on a regular basis may be used for this evaluation, many centers assess pulse oximetry while the patient is walking at his or her normal pace for a defined period of time such as 6 min. The medical aspects of oxygen therapy are covered in more detail elsewhere in this text.

One of the goals of pulmonary rehabilitation is to enhance health-promoting behaviors, and this goal should be applied to the use of oxygen therapy. Whenever oxygen therapy is prescribed, the patient should receive sufficient education to assure safe and effective use of this important therapeutic modality. Education should include not only the benefits and safe use of oxygen therapy but also details of the specific prescription for oxygen for the individual patient including the flow rate to be used at rest, with activity, and during sleep. Such education is routinely provided during pulmonary rehabilitation and should include efforts to enhance use of oxygen as prescribed by the physician. Barriers to use, such as patient fears about the safety of oxygen and the visibility and unsightly nature of the nasal canula, should be addressed. Patients should be instructed on how to use the specific oxygen system supplied for them including how to turn the oxygen on and off, how to fill the portable system or obtain additional portable oxygen supplies, and the name and phone number of the vendor supplying the oxygen.

Providing chronic outpatient supplemental oxygen therapy to patients with respiratory disorders may impair patient mobility and thus quality of life. Despite the benefits of improved exercise capacity and lessened dyspnea with the use of ambulatory oxygen, the size, weight, and limited duration of the portable oxygen supply usually appear to the patient to present a barrier to achieving the benefits of greater and more comfortable capacity for activity. Pulmonary rehabilitation can assist in reducing this barrier to the use of oxygen. For example, patients often feel that oxygen use during activity does not lessen dyspnea. During rehabilitation, it may be helpful to assist the patient to objectively assess the benefits of oxygen; one method is having the patient walk with and then without oxygen while a health care professional measures the distance walked and the patient quantifies the degree of shortness of breath. In this manner, patients can determine for themselves whether oxygen is beneficial.

During pulmonary rehabilitation, patients should be informed of the different types of portable supply systems available to allow the choice of a system that best meets their needs. One method of overcoming the difficulties with the size and weight of the portable oxygen system is to employ oxygen conservation devices, i.e., oxygen reservoirs, inspiratory demand delivery devices, and transtracheal oxygen. The lightest portable oxygen systems utilize demand delivery oxygen conservers and include cylinders of compressed gas with a device that delivers oxygen only during inspiration and small liquid systems that incorporate a similar conserver.

The physician can initiate discussions with the patient about the types of available oxygen systems and refer the patient to the pulmonary rehabilitation team for incorporation of oxygen therapy into the patient's daily routine. The physician also serves an important role in writing the prescription for the type of oxygen system that best meets patient needs and helps to ensure not only patient adherence with the oxygen prescription but also enhanced mobility and quality of life.

INITIAL ASSESSMENT

Probably the most important element of pulmonary rehabilitation is the performance of an initial assessment that culminates in the development of goals to guide the rehabilitation process and coordinate the actions of all team members. This element deserves special mention because it is not universally considered a separate component of pulmonary rehabilitation.

The goal of the assessment is to (1) determine the individual needs of the patient, (2) develop short-term goals for the patient to achieve during the initial rehabilitation program, (3) provide a baseline in order to assess changes that result from rehabilitation, and (4) develop long-term goals that may be incorporated into the continuing management of the patient. This assessment is separate and distinct from the physician's medical evaluation and management and may be performed by a single pulmonary rehabilitation team member such as the program coordinator; alternatively, portions of the assessment may be performed by multiple team members. The importance of this process lies in the communication and interactions between practitioners and patients with development of mutual trust and respect and the subsequent incorporation of the health professional's assessments with the patient's needs and desires. From this mutual process flows a therapeutic plan and a set of patient-centered goals. The initial goals must be mutually agreed on by the patient and the rehabilitation team. In addition, short-term goals should also be readily achievable within a limited period of time in order to enhance patient motivation and thus help assure adherence with continued rehabilitation efforts. Longer-term goals should also be developed and revised as the patient progresses through rehabilitation.

One of the major goals of pulmonary rehabilitation is to improve the individual's level of function. This process should begin with a careful assessment of all the activities the patient does every day and what perceived and observed difficulties are encountered in accomplishing these tasks. Activities that are important to the patient include not simply the basic activities of daily living (ADL) such as bathing, toileting, and dressing but also vocational, social, and recreational pursuits both in the home and in the community. Physical and occupational therapy team members may be very useful in assessing these aspects and in developing goals based on the patient's functional ability. Functional assessments may include a history and exam along with use of appropriate questionnaires and observation of the performance of functional tasks. Functional goals are important guides for the interventions provided by all pulmonary rehabilitation team members, and most third-party payers require that therapy be based on written functional goals with defined short- and long-term outcomes including the time frame expected for patients to achieve those goals.

SMOKING CESSATION

Although many physicians have an aversion to refer patients who continue to smoke for pulmonary rehabilitation, there is no reason to withhold pulmonary rehabilitation from such patients. Rather, smoking cessation should be considered as a part of comprehensive pulmonary rehabilitation, and smoking cessation may be the primary goal for some patients enrolled in pulmonary rehabilitation. When conducted during a comprehensive rehabilitation program, other positive health-enhancing behaviors such as exercise may be substituted for smoking. Additional support and encouragement during the smoking cessation effort can be provided by all rehabilitation team members as well as by other patients.

The physician has a key role in promoting, encouraging, and implementing a smoking cessation program. The approach and consequences of smoking cessation are discussed in the chapter on COPD (Chapter 43).

As an aid to routinely determining patient smoking habits, it has been suggested that office staff record the patient's smoking status at every office visit in a manner similar to routine reporting of other significant vital signs such as heart rate, blood pressure, respiratory rate, and temperature. When recorded in this manner, smoking becomes the “fifth vital sign,” and this record can serve as a reminder to the physician and office staff to discuss smoking cessation during the visit. Further smoking cessation assistance should include recommendations on the use of nicotine replacement therapy such as nicotine gums or patches; such recommendations should include information about the appropriate method of administration including dose and frequency of use. This is particularly important with the use of nicotine gum, which should be chewed whenever patients note a craving for a cigarette and then for only a very brief period until tingling of the mouth is noticed; this should be subsequently followed by “parking” the gum between the inside of the cheek and teeth. Because the use of nicotine replacement alone can not assure smoking cessation, a program of counseling should accompany all smoking cessation efforts. Written self-help materials are available from many sources including the National Institutes of Health, American Lung Association, American Cancer Society, and American Heart Association. Patients may be referred to group programs conducted by local hospitals or nonprofit health organizations to assist in providing social supports for the patient. Family members should also be encouraged to assist the patient in smoking cessation. A follow-up visit with the physician should be scheduled to assess the patient's progress and provide ongoing encouragement and support for long-term smoking cessation. The physician should recognize that relapse is common and that many patients require multiple cessation efforts to achieve long-term abstinence from smoking.

EXERCISE TRAINING

The most important aspect of pulmonary rehabilitation is exercise training, and the most important training method is endurance training of the lower extremities. However, in order to understand the effects of training, a brief overview of the effects of chronic airflow limitation (CAL) on exercise capacity is necessary.

Exercise Capacity in COPD

Whereas in normal individuals exercise is limited by the cardiovascular system, in patients with severe CAL exercise is usually limited by the respiratory system. This limitation may be caused by one or more of several factors including abnormal lung mechanics, impaired oxygenation, respiratory muscle dysfunction, and impaired cardiac function.

It is also likely that exercise limitation in COPD is related at least in part to deconditioning, which may be related to inactivity resulting from the fear of dyspnea and associated anxiety. It is generally acknowledged that patients terminate activities performed in the course of their daily lives because of the uncomfortable and fear-provoking symptom of dyspnea. According to the model of COPD shown in Fig. 1, patients with COPD consciously and unconsciously learn to recognize not only that activity leads to dyspnea but also that avoidance of activity will prevent dyspnea. Thus, patients become inactive, which leads to deconditioning and decreased cardiovascular and peripheral muscle strength and endurance. This sequence has also been termed the downward spiral of disease leading to disability, inactivity, and resultant deconditioning. Moreover, anxiety can lead to dyspnea even without an increase in physical activity. In addition, the anticipatory anxiety associated with the thought of increasing activity, even in the absence of the actual stimulus of the activity, can cause shortness of breath.

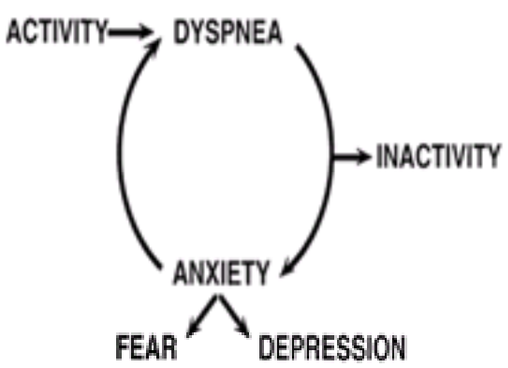

FIG. 1. The vicious circle of dyspnea. Because increased activity leads to dyspnea in patients with COPD, patients learn to prevent dyspnea by reducing their level of activity. Dyspnea not only is provoked by anxiety but also dyspnea causes anxiety. (Modified with permission from Make B. COPD: Management and rehabilitation. *Am Fam Physician* 1991;43:1315–1324.)

Training

Pulmonary rehabilitation does not improve lung mechanics, and the mechanical limitations to exercise noted above should not be expected to improve following exercise training. However, there are multiple potential mechanisms to explain the beneficial effects of exercise training in patients with respiratory disease including increased efficiency in activity performance, enhanced motivation, desensitization to the sensation of dyspnea, improved cardiovascular function, improved muscle function, and increased aerobic capacity. Although one or more of these mechanisms may occur in a given individual, published evidence indicates that patients with severe COPD can obtain a physiological benefit from exercise training. It has been demonstrated, for example, that improved aerobic capacity can be achieved in these patients. After training, reduced levels of lactate are seen at a given level of exercise; the reduced lactate production is associated with a reduced minute ventilation, which in turn is associated with a reduced level of dyspnea (Fig. 2). It has also been demonstrated that high-intensity exercise is more effective than low-intensity training. Although the most effective exercise prescription has not been precisely determined, pulmonary rehabilitation programs uniformly incorporate lower extremity aerobic endurance exercise. Following the principles of exercise training for healthy individuals, the mode, intensity, duration, and frequency of exercise

training should be precisely prescribed for the individual patient and based on the baseline exercise capacity of the individual.

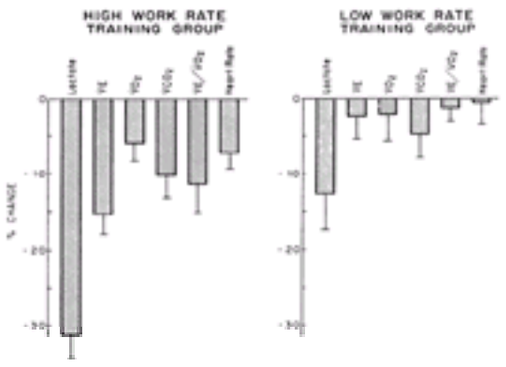

FIG. 2. Changes in physiological responses to exercise produced by two training strategies in patients with COPD (FEV_1 56% predicted). The *left panel* shows results in 11 patients trained at a high work rate (60% of the difference between the anaerobic threshold work rate and maximal work rate) for 45 min a day five times a week for 8 weeks. The *right panel* shows results in eight patients who trained at a lower work rate (90% of the anaerobic threshold work rate). Reductions in lactate and minute ventilation (VE) were greater with high-work than with low-work training. (Reproduced by permission from Casaburi R, Patessio A, Ioli F, Silvio Z, Conner CF, Wasserman K. Reductions in exercise lactic acidosis and ventilation as a result of exercise training in pa-tients with obstructive lung disease. *Am Rev Respir Dis* 1991;143:9–18.)

Mode of Exercise Training

Lower extremity aerobic exercise training is the cornerstone of exercise training during pulmonary rehabilitation. In healthy individuals, the effects of exercise training are specific to the muscles that are trained. This concept of the specificity of training implies that leg exercises will improve the performance of leg muscles and arm exercise will improve performance of the arms. Because most daily activities require walking and use of the legs, leg exercise is beneficial in improving a patient's functional performance during activities of daily living. Nevertheless, lower extremity exercise performed by using a stationary bicycle also improves exercise capacity and may be used in training programs. There is less information available concerning the efficacy of other training modalities such as swimming.

Exercise Intensity

Although there are few guidelines for the optimal intensity of training, it is generally felt that there is a minimum intensity that is required to achieve benefits. Lactate production, heart rate, and oxygen uptake have been proposed as indicators of the appropriate level of training. Although in healthy individuals it has been suggested that patients need to exercise above 60% of their predicted maximal heart rate, this may not be appropriate in patients with lung disease whose heart rate is limited by their lung disease. Nevertheless, patients who can achieve this level of heart rate during training are likely to achieve benefits from exercise. Alternatively, it has also been suggested that patients should exercise above their anaerobic threshold; however, such an exercise prescription requires a more formal exercise test before training to determine the anaerobic threshold. Last, some investigators recommend training at a predefined level of maximum exercise capacity and have utilized intensities of between 50% and 80% of the patient's maximal exercise capacity. Whichever intensity is chosen, the patient's level of dyspnea must be considered. Some training programs simply employ continuous walking as long as tolerated and limited by the patient's sensation of dyspnea. Nevertheless, with continued encouragement and training, most patients with COPD should be able to reach the higher intensities of exercise required to achieve benefits.

Training Session Duration

Although there is limited information to recommend a precise duration, the exercise sessions should probably be 30 to 45 min in length. Longer sessions may predispose to injury, and, based on information in healthy individuals, sessions of less than 20 min will likely be ineffective. The training duration should be based on the goals to be achieved. If weight loss is the major goal, longer periods (45 to 60 min in duration) of activity are likely to be more beneficial than shorter periods. It is generally accepted that aerobic activity should be preceded by a short warm-up period and that stretching exercises should follow the training.

Most programs incorporate a single exercise session each day. Although the efficacy of more frequent daily sessions has not been studied, some patients cannot tolerate continuous exercise. Patients with severe interstitial lung disease may have severe exercise-induced hypoxemia that is not correctable with supplemental oxygen therapy. In such individuals, interval training (brief periods of exercise initially for as little as 1 min followed by rest periods of equal or longer time periods) may be necessary not only to prevent desaturation but also to limit severe dyspnea.

Training Frequency

Although benefits may accrue from as little as twice-weekly training sessions, it is generally agreed that training should take place three to five times each week to obtain maximal benefits. This recommended frequency is applicable both to initial training and also to maintenance exercise regimens. Daily training is impractical in most cases and probably accrues little additional benefit. Although many rehabilitation programs offer formal supervised training twice each week, patients should be expected to exercise on their own as well.

Training Program Duration

The optimal duration of the initial training is unknown. In healthy individuals using a constant intensity exercise program, maximal physiological benefits are achieved in about 3 to 4 weeks. Thus, an initial exercise program could be conducted in as little as 3 weeks. Nevertheless, most rehabilitation programs offer structured training sessions for 6 to 12 weeks in an attempt to achieve maximal benefit from the initial program.

After the initial training component, a maintenance exercise program is necessary to retain the benefits of the initial training. Patients may need to restart their exercise program at a lower level following exacerbations of their underlying lung disease or intercurrent illness that reduce their activity level. Although lifelong exercise is recommended, there are few studies outlining methods of assuring continued patient adherence with exercise. Because it is likely that most patients do not continue to exercise following the initial training, education about continued exercise and behavioral approaches to assured continued patient adherence should be incorporated into the rehabilitation program.

Upper Extremity Training

Although many daily functional tasks require the use of the arms, until recently little emphasis has been placed on training of the upper extremities during pulmonary rehabilitation. In healthy individuals, arm work results in a higher metabolic demand than leg work. Thus, for a given workload, upper extremity activity is associated with a higher oxygen uptake, minute ventilation, heart rate, blood pressure, and lactate production than leg exercise. In addition, as individuals age, they tend to lose muscle mass and strength in the arms, which are used to a lesser extent in daily activities than the legs. These factors suggest that upper extremity training may be beneficial in patients with COPD.

In patients with COPD, arm exercise is terminated at a lower oxygen consumption than leg exercise. During arm exercise, patients with severe airflow limitation may develop irregular and dyssynchronous movements of the thorax and abdomen and even abdominal paradox accompanied by severe dyspnea. It has been suggested that upper extremity exercise places a dual burden on the muscles of the shoulder girdle, requiring them to participate simultaneously in arm activity and ventilatory activity. As a result, demand is placed on the diaphragm to increase its contribution to ventilation, leading to an increase in shortness of breath.

The simple act of raising the arms without support increases the ventilatory and metabolic demands of patients with COPD. Furthermore, it has been shown that following pulmonary rehabilitation including unsupported arm exercise, there is a reduction in work required for simple arm elevation.

Based on the available evidence, it appears prudent to include upper extremity exercise during pulmonary rehabilitation, and it has been suggested that both supported and unsupported training may be beneficial. Unsupported exercises usually require the patient to lift a dowel to the level of the shoulders, inhaling during dowel raises and exhaling as the dowel is lowered, and pacing that activity with a comfortable respiratory rate. Because dyspnea occurs rapidly during such exercise, interval training has been recommended, initially with a very brief periods of 1 min of exercise followed by 2 min of rest. The exercise intervals may be increased as tolerated,

weights may be added to the dowel, and the session duration may be increased to a total of 20 to 30 min. Supported arm training, such as with an arm rest, may also be employed.

Strength Training

In order for patients to participate in an aerobic training program, they must have sufficient strength to perform the exercise. In patients who have muscle weakness from age, disuse, deconditioning, or from the effects of medications such as oral corticosteroids, strength training may be necessary before embarking on an intensive aerobic conditioning program. An evaluation by a trained physical therapist employing a manual muscle test can be helpful in identifying muscle groups that are weak and may benefit from strength training. Alternatively, isokinetic muscle testing equipment may provide similar objective information about muscle strength.

Even in patients who demonstrate relatively normal strength, strength training is routinely employed by most pulmonary rehabilitation programs in order to preserve and enhance strength and as an adjunct to aerobic conditioning. Strength training is usually recommended for 3 to 5 days each week in addition to lower and upper extremity training. Training may employ use of free weights or even weight-training equipment when such is readily available to the patient.

Ventilatory Muscle Training

Patients with severe COPD commonly have reduced inspiratory muscle strength as measured by maximum inspiratory pressure at the mouth. There are likely several mechanisms for this effect including reduced diaphragm curvature associated with hyperinflation and associated reduced force-generating capacity, alterations in the orientation of other respiratory muscles associated with hyperinflation, and possible diaphragm weakness associated with increased demands imparted by increased work of breathing. Further speculation suggests that diaphragm weakness or fatigue may impair ventilation and increase dyspnea in COPD. It is therefore attractive to hypothesize that specific training of the inspiratory muscles may improve not only ventilatory muscle strength but also endurance and ventilatory capacity and reduce dyspnea.

If ventilatory muscle training is used, it should follow the principles of intensity, frequency, mode, and duration suggested for other forms of muscle training. In particular, training load should be carefully monitored. Training devices with a linear resistance pattern should be used that permit the specified work load to be maintained over a wide range of inspiratory flow rates. With alinear resistors, patients may alter their breathing pattern to minimize inspiratory resistance and thus not achieve the desired training load. An initial training resistance that assures a mouth pressure of ³30% of maximal inspiratory pressure (P_{Imax}) should be used.

PSYCHOSOCIAL COUNSELING

Psychological Issues in COPD

Patients with chronic lung disease frequently exhibit emotional and psychological concerns related to their illness. Anxiety is a common complaint, particularly in patients with more severe degrees of COPD. As noted in Fig. 1, anxiety may in part be caused by the disabling symptom of dyspnea and may be severe enough to be considered panic and to limit patient activities. The consequence of expressions of patient emotional response is often increasing shortness of breath. To avoid this fear-provoking symptom, patients may repress their emotions, a situation described as placing these patients in an “emotional strait-jacket.”

Depressive symptoms are frequently present in patients with COPD and may in part be caused by reduced functional capacity and resultant impairment in vocational pursuits, recreational interests, and activities of daily living. These changes in life style have been documented to impair quality of life and consequently diminish the patient's role within the family and community. Patients may express feelings of worthlessness and despair because of their inability to provide financial or emotional support to family members. Depression is the most common emotional consequence of COPD and is more common in this illness than in patients with other chronic medical disorders.

Sexual functioning may also be altered in patients with COPD and may be more impaired in patients with more severe lung disease. Dyspnea may limit intercourse, lead to impotence, alter relationships with spouses or significant others, and lead to reduced sexual self-image. Physicians should recognize that impotence and reduced sexual activity seen in these patients may not be associated with advancing age but may rather be caused by the impact of the lung disease. Educational programs and counseling to address sexual issues are routinely included in most pulmonary rehabilitation programs.

Neuropsychological deficits may also be seen in patients with COPD. Decreased fine motor speed and coordination, impaired perceptual motor skills, and difficulty with abstracting have been documented. However, memory is usually spared. More severe neuropsychological dysfunction is seen in patients with more severe degrees of hypoxemia.

Psychosocial Interventions

Exercise Training

Based on the theory depicted in Fig. 1, depressive symptoms and anxiety may improve with pulmonary rehabilitation as exercise capacity is improved. The importance of the emotional support and encouragement provided by health professionals during exercise training should not be underestimated. Exercising under the supervision and direct observation of a physical therapist, respiratory therapist, or nurse experienced in the management of patients with respiratory disease and in whom the patient has confidence is an important factor in allaying anxiety and fear and reducing panic associated with activity.

Antidepressant Medications

If significant clinical depression is confirmed, consideration should be given to therapy with antidepressant medications. Careful consideration should be given to the side effects of antidepressants in patients with COPD, who tend to be older, may have excessive respiratory secretions, and have a tendency to prostatic hypertrophy. Some antidepressants produce sedation, and others are associated with activation, and these drugs should be tailored to the needs of individual patients. In patients with hypercapnia, drugs that act centrally and reduce respiratory drive should be avoided. Agents with cholinergic properties are not appropriate for patients with prostatic hypertrophy. Anxiolytic agents may be effective in selected patients with severe agitation and anxiety that is unresponsive to counseling, relaxation, and the other components of pulmonary rehabilitation.

Psychosocial Support

Psychosocial clinicians including licensed clinical social workers, clinical psychologists, and psychiatrists may be helpful in structuring the psychosocial component of the rehabilitation program and providing psychosocial evaluation and support services. Psychosocial support techniques include group and individual counseling, stress management, relaxation, and use of support groups. Group sessions with the patient and family that incorporate counseling and peer group support are used in many rehabilitation programs. Groups of patients with the same disease may be useful to allow patients to see that their expressed feelings are also shared by others; the group may provide insights into methods of coping that have proved effective. The anxiety noted by patients with lung disease may be lessened by giving patients stress management and relaxation techniques to allow them to gain control over their symptoms.

BREATHING RETRAINING

Breathing retraining includes pursed-lip breathing, diaphragmatic breathing, and paced breathing. The goal of these controlled-breathing techniques is to reduce dyspnea, and they have the additional benefit of improving respiratory physiological parameters. Controlled breathing may be practiced during exercise and with daily activities to lessen dyspnea or whenever patients experience increased shortness of breath. These methods may improve oxygenation, slow the respiratory rate, increase tidal volume, decrease air trapping, and reduce work of breathing.

Pursed-Lip Breathing

This is the most commonly used technique and is often learned and adopted by patients without instruction from health care professionals. Patients breath in slowly through the nose and then exhale slowly over 4 to 6 sec or longer through lightly pursed lips. Pursed-lip breathing (PLB) may be used with diaphragmatic breathing during inspiration. One explanation for the physiological benefits of PLB is that airway pressure is increased during exhalation, thereby preventing airway collapse in patients with reduced elastic recoil resulting in decreased hyperinflation and improved oxygenation. However, PLB has also been shown to improve oxygenation in patients with interstitial lung disease who have increased elastic recoil. In some studies, work of breathing has been shown to increase with the use of PLB, an effect

that might be exaggerated if the lips are pursed too tightly, resulting in a significantly higher expiratory resistance.

Diaphragmatic Breathing

With this technique, patients are encouraged to use their diaphragm by attempting to push the abdomen outward during inspiration. The technique was originally described for use while the patient is supine with the hands placed on the abdomen to facilitate the patient's ability to assess outward abdominal motion. The physiological and clinical benefits of diaphragmatic breathing have been less well studied, and patients often report greater relief of dyspnea using PLB.

Controlled Breathing

During periods of greatly increased effort, most healthy individuals have a tendency to hold their breath. During activity, patients with lung disease often develop breathing patterns that are irregular and not coordinated with their activity. Controlled or paced breathing is the use of a regular breathing pattern and coordination of regular breathing with activity. For example, during arm activities, inhalation might be coordinated with raising of the arms and exhalation with lowering of the arms. During stair climbing, exhalation might be coordinated with raising the body up to the next higher stair. Controlled breathing during exercise training may also increase exercise endurance and delay the onset of shortness of breath.

DAILY ACTIVITY PERFORMANCE AND ENERGY MANAGEMENT

Based on the initial patient assessment, appropriate treatment goals for improving performance of daily activities may include (1) reducing shortness of breath with basic ADL, (2) applying regular coordinated breathing patterns, (3) increasing functional endurance, (4) using energy and time management methods, (5) using adaptive equipment, (6) obtaining assistance from others including family members, and (7) enhancing performance at work. These potential treatment goals are in addition to the goals of reducing stress and providing relaxation, which will also decrease the energy required during the day.

In patients with limited functional capacity, energy management techniques can allow greater achievement of desired tasks. Energy management includes employing energy conservation techniques, improving work efficiency, using proper body mechanics, incorporating time management, pacing, and careful planning. These techniques are not tools that need to be practiced routinely by healthy individuals, and so they are not usually self-evident to patients. However, incorporation of these principles into daily life can enhance functional performance. For example, it may be impossible for a patient to run up a flight of stairs to a restaurant after walking from a parked car. The stairs to the restaurant may be more easily attainable by leaving the home with sufficient time to avoid rushing (planning), leaving the patient off at the door to the building (planning and energy conservation), resting before climbing the stairs (energy management), walking up the stairs more slowly (pacing), resting on the stairs when needed (energy management), and using a regular breathing pattern incorporating pursed-lip breathing.

An important part of one's daily life is recreation and leisure pursuits. Evaluation of leisure function includes assessment of barriers limiting participation in such activities. Such barriers potentially relate to financial issues such as limited income, physical concerns secondary to the patient's dyspnea, and emotional factors such as the fear of dyspnea associated with increased activity. Addressing these barriers and discussion of the methods of successfully participating in leisure activities may enhance patient quality of life.

EDUCATION

The traditional goal of education has been to increase cognitive knowledge, i.e., to inform patients about their disease. Such education requires teaching an understanding of the lungs and how they work, the nature of the lung disease and its signs and symptoms, and the names, actions, and side effects of medications. However, a more appropriate and effective role of education for individuals with chronic illness is to effect a positive behavioral change. For example, the goal of education about inhaled medications is to assure patient use of the medications to achieve the desired benefits, i.e., reduction of dyspnea and increases in daily activities. Patient knowledge about the mechanism of action of the inhaled bronchodilator is likely to be less important in achieving this goal than information about the benefits to be achieved by the individual patient. In addition, important dosing information including time and frequency of medication administration and technique of administration for the individual may help assure adherence with use of the medication.

Based on the health belief model, patients and families should be queried about their perceptions of the seriousness of their disease, susceptibility to further illness and complications, threat of their disorder, benefits of treatment, and barriers to therapy. An understanding of the health beliefs of the patient and family will assist the educational efforts of the rehabilitation team to change the health beliefs so the treatment plan will be more readily accepted and result in improved adherence with the prescribed therapies.

An initial educational evaluation is useful in all patients enrolled in pulmonary rehabilitation. Because learning styles differ, it is useful to determine if the patient will learn best by using verbal or visual methods and to provide the educational material in a manner that is most appropriate for the patient's learning style. The patient's educational level, native language, and reading level are also important to assess, along with any difficulty in vision and hearing. Written information should be provided to all patients, particularly when memory problems are evident.

Education may be conducted both formally and informally throughout comprehensive pulmonary rehabilitation and should be guided by learning objectives based on the needs of the individual patient. Education begins before patient enrollment in rehabilitation by explanations of the purpose, goals, expected results, and nature of the rehabilitation program. Formal education may be provided through group classes, one-on-one teaching with a health care professional, or using written or audiovisual materials. Informal education should occur with every member of the pulmonary rehabilitation team such as when a physician prescribes a new medication, a respiratory therapist performs a pulmonary function test, a physical therapist performs chest physiotherapy, an occupational therapist evaluates activities of daily living, and a social worker implements a relaxation program. Patient learning should be assessed both formally and informally to determine whether the learning objectives have been met.

NUTRITIONAL COUNSELING

It is reasonable to assume that in order for patients to participate in pulmonary rehabilitation that incorporates exercise training program adequate nutritional intake must be assured, weight excess should be treated, and weight loss should be avoided. Even though there is limited scientific information on the best approaches to nutritional counseling in patients with respiratory disease, recommendations for counseling patients about the common problems of weight loss and dyspnea during meals are outlined in Table 4.

Problem	Recommendations
Anorexia, weight loss	Eat high-calorie foods first Have favorite foods available Try more frequent small meals and snacks throughout the day Add butter, mayonnaise, sauces, and gravies to add calories Limit liquids in meals; sip liquids an hour after meals Cold foods can give less of a sense of fullness than hot foods Instruct patients to push themselves
Dyspnea	Rest before meals Use bronchodilators before meals Use secretion clearance strategies if indicated Eat more slowly Use pursed-lip breathing between bites Use tripod position for meals Have readily prepared meals available Evaluate for oxygen desaturation during meals

[a] Modified from Rogers RM, Donahoe M. Nutrition in pulmonary rehabilitation. In: Fishman AP, ed. Pulmonary Rehabilitation. New York: Marcel Dekker, 1996:555.

TABLE 4. *Symptoms and counseling strategies for nutritional therapy in chronic obstructive pulmonary disease*[a]

A nutritional evaluation should be performed on all patients involved in pulmonary rehabilitation. A dietary history including what the patient actually consumes and a history of any weight loss or weight gain are important to elicit. The patient may be asked to recall his or her diet for the last 24 hrs or maintain a diary of foods eaten to determine the amount and types of food consumed. From the patient's height and body weight, tables can be used to identify ideal body weight. However, it is also important to determine lean body mass (LBM) and fat mass to develop an optimal nutritional program for each individual patient. A relatively simple way to assess lean body mass involves measurement of skinfold thickness and skeletal circumference at established sites. One of the goals of nutritional counseling should be to ensure

optimal lean body mass, which includes muscle mass, and minimize excessive fat mass.

In part because of reduced activity levels associated with severe respiratory disease and decreased caloric needs associated with advancing age, patients with COPD may be overweight and have excess fat mass. Individuals who are overweight, particularly those who are obese (>120% of ideal body weight), may be expected to have more limited exercise capacity for weight-bearing activity than normal-weight patients. Thus, weight loss in this group of patients is theoretically desirable to reduce the metabolic and thus the ventilatory demands of daily activities. Weight loss should be associated with decreased dyspnea and improved exercise capacity and is an important adjunct to the other elements of pulmonary rehabilitation.

Patients with severe COPD may be underweight (<90% of ideal body weight). Weight loss has several potential implications for the patient with respiratory disease and may be associated with decreased diaphragm and respiratory muscle function, decreased hypoxic and hypercapnic ventilatory responses, and decreased respiratory clearance and defense mechanisms. It has also been demonstrated that weight loss in patients with COPD is associated with increased mortality. Whether the weight loss in some undefined manner directly causes early mortality or whether weight loss is simply a marker for more severe lung disease has not been determined. Although some carefully controlled investigations that allow patients access to adequate caloric intake have been associated with weight gain, improved mortality has not been documented. Nevertheless, adequate caloric intake can be expected to be helpful in improving muscle strength and endurance in underweight patients.

MAINTENANCE PROGRAM

It is understandably difficult for older individuals who have developed life-long habits of not exercising as well as acting independently without advice from others to incorporate changes into their daily lives. Based on the techniques learned during the initial phase of pulmonary rehabilitation, patients with chronic lung disease are nonetheless expected to permanently change their life style by incorporating regular exercise training and adhere to advice from health care professionals.

Although the degree of patient adherence and nonadherence to continued exercise and pulmonary rehabilitation is unknown, it is likely that adherence is less than optimal. In studies of patients with chronic illness, non-adherence rates vary greatly and are frequently greater than 50%.

There is little available literature to guide clinicians and suggest the best methods of assuring long-term adherence with the key elements of pulmonary rehabilitation. However, it is prudent to incorporate as many techniques as possible to assist the patient to adhere to a long-term maintenance program. It is the responsibility of every pulmonary rehabilitation program not only to provide long-term goals for the patient but also to assist the patient in developing daily routines that incorporate methods of achieving those goals. In addition, barriers to long-term maintenance, such as the site and costs of regular ongoing exercise training, should be addressed and resolved in a cooperative manner by the patient and the rehabilitation team. Collaborative self-management has been the term applied to a long-term cooperative effort by the patient and physician to emphasize the importance of the patient's central role in making decisions and choices regarding disease management and the physician's role as educator and facilitator. The role of education in allowing patients to become active participants in their care and responsible for their own health can not be overemphasized.

POTENTIAL OUTCOMES OF PULMONARY REHABILITATION

Many of the 13 potential outcomes listed in Table 5 may be affected by multidimensional pulmonary rehabilitation programs. Determination of the results, or outcomes, of pulmonary rehabilitation is important for three major reasons. First, a clear and concise description of the expected outcomes of pulmonary rehabilitation can be used to convey the benefits of pulmonary rehabilitation to patients who are considering participation in rehabilitation, physicians who refer patients for rehabilitation, and medical benefits providers paying for such services. Information about outcomes that have been documented by other programs may be gleaned from studies published in the medical literature and provide a basis for the medical necessity for rehabilitation services. Second, assessment of outcomes of programs within the local community must be used to evaluate the results in individual patients to assure that desired results are actually achieved. Third, outcomes assessment should be used to guide the development and ongoing evaluation of comprehensive programs. Each pulmonary rehabilitation program should assess outcomes and should decide which outcomes are important to measure.

[a] Modified with permission from Make B, Glenn K. Outcomes of pulmonary rehabilitation. In: Baum JH, ed. *Pulmonary Rehabilitation: The Obstructive and Paralytic Conditions*. 1985.

TABLE 5. *Potential outcomes of pulmonary rehabilitation*[a]

Medical issues are addressed by the first four outcomes listed in Table 5. Traditionally, *mortality,* or survival, is the most important outcome of medical care. However, patients with chronic disease frequently indicate that quality of life is much more important than the quantity of life. Medical *morbidity* in patients with respiratory disease includes complications of the primary respiratory process. In patients with COPD pulmonary hypertension with subsequent cor pulmonale (right-sided heart failure from chronic hypoxemia), acute exacerbations of COPD, and respiratory tract infections increase the morbidity of the illness. In addition, morbidity also includes hospitalizations for acute exacerbations and the need for emergency or urgent medical care related to the respiratory disorder, although these may also be considered as costs.

Respiratory symptoms are prominent complaints in patients with respiratory disorders. The primary symptom of respiratory disease is shortness of breath (dyspnea), which may be disabling for patients with severe airflow limitation. Secondary symptoms related to the effects of respiratory disease, such as headaches related to hypoxemia and fatigue, should also be considered.

Physiological indices in individuals with respiratory disorders may be measured by simple spirometry and include the forced vital capacity (FVC) and forced expired volume in 1 sec (FEV_1). However, in patients with COPD, these physiological indices as well as measures of oxygenation are not expected to change because the underlying respiratory disorder is not altered by pulmonary rehabilitation. On the other hand, improved adherence to medications may improve airflow limitation in patients with reversible disorders such as asthma. One of the more important physiological indices is direct assessment of exercise capacity, which may be most objectively evaluated with a cardiopulmonary exercise tolerance test performed in a controlled laboratory setting. Workload, oxygen consumption, heart rate, and minute ventilation are relatively easy to measure with commercially available equipment while the patient exercises on a treadmill or bicycle ergometer using steady-state or incremental exercise protocols.

The remainder of the potential outcomes of pulmonary rehabilitation listed in Table 5 address “nonmedical issues,” which are not considered as important as the “medical” factors. The nonmedical issues are frequently identified as goals of patients and thus incorporated into rehabilitation programs. Functional capacity refers to the ability to perform tasks required during the course of an individual's daily life. Because walking is an important daily activity, functional capacity may be measured in patients with pulmonary disease as the distance walked in 6 or 12 min. This walk test is an outgrowth of the 12-min run developed to evaluate the fitness of army recruits. Although the run has been shown to correlate with maximum exercise capacity, the walk test is more appropriately considered as a functional evaluation tool in patients with respiratory disease. Because encouragement by the tester can increase the distance walked, the walk test should be performed according to a rigid protocol defining the number of walks and methodology to be used by the tester.

Patients with COPD are often hypoxemic and demonstrate associated reductions in neuropsychological function, which may also be affected by advancing age. Patient adherence to health-related behaviors should be stressed during pulmonary rehabilitation. Cigarette smoking is the major cause of chronic obstructive pulmonary disease, and smoking cessation efforts are often incorporated into pulmonary rehabilitation programs. Adherence to medication, oxygen, and exercise prescriptions are other behavioral outcomes that foster continued health and thus should be assessed following pulmonary rehabilitation.

Physical function, mental/emotional function, social function, role function, and perception of well-being are often considered together as “health-related quality of life.” Although a perception by the patient of his or her own condition, quality of life can nevertheless be objectively measured. *Physical health* is the ability to perform

everyday activities including self-care and mobility. *Mental/emotional health* incorporates patients' feelings such as anxiety, nervousness, and depression; control over behaviors, feelings, and thoughts; and cognitive functions such as memory, orientation, and alertness. *Social health* incorporates interactions with other individuals in the community. *Role function* refers to the performance of activities such as employment, school, and housework. A global perception of *general well-being* can also be evaluated.

The *ability to work* may be important for younger individuals but may not be as critical for elderly, retired patients. The ability of children to attend school and participate in the full range of school activities should be considered. Lost time from work or school because of illness may also be an important outcome. *Caregiver burden* refers to the effects of the patient's illness on family, friends, and others who may assist with the patient's care. This includes financial issues such as time lost from work for family members as well as psychological stressors on family caring for chronically ill patients. Patients with limited function may benefit from the use of assistive technology such as wheelchairs and vans for people with neuromuscular disorders, which may be lessened by rehabilitation. As health care expenditures are being more tightly controlled, costs are increasingly of concern. Direct costs of medical care include not only the cost of rehabilitation but also of hospitalizations, emergency medical care, and prescription medications. Indirect costs include lost wages for patients and families and the psychosocial impact of illness on both patients and their families.

TOOLS TO ASSESS QUALITY-OF-LIFE OUTCOMES

Because enhancement in quality of life is one of the major goals of pulmonary rehabilitation, and because assessment of quality of life is a relatively new field, this section reviews the use of questionnaires to assess health-related quality of life.

Criteria for Quality-of-Life Questionnaires

Before a measurement tool is selected, the intent of the measurement must be defined in order to ensure that the measurement instrument can adequately assess the desired outcome. Measurement tools can be classified into three types (discriminative, predictive, and evaluative), based on the purpose for which they are used. The measurement of outcomes that result from pulmonary rehabilitation requires use of evaluative tools, which are designed to detect a difference over time in a group, such as before and after pulmonary rehabilitation in patients with COPD. An established evaluative measurement tool must meet three fundamental psychometric criteria: reliability, validity, and sensitivity.

The reliability of a measurement tool refers to its accuracy and its lack of change over time. Using a scale as an example of a reliable measurement tool for weight, repeated measurements of the same object with the same scale should yield the same results. To assess the reliability of a questionnaire, the tool may be administered twice to a group of people who are thought to be stable and then the results of the two tests are compared, a process known as test–retest reproducibility. Interobserver reliability assesses differences related to results obtained by different observers administering the same instrument to the same subject and is important when questionnaires cannot be completed without a trained administrator.

Demonstration of the validity of a quality-of-life instrument is a process of accumulating sufficient evidence to document that the tool actually measures the desired attribute. Because there is no universally agreed-on “gold standard” measure of quality of life, the validity of quality-of-life measurement instruments is difficult to assess. Development of quality-of-life questionnaires is usually based on expert knowledge and experience of the disease, and the tool is derived from such evidence combined with theories and postulations. However, both the instrument and its underlying theories must be assessed for accuracy.

Pulmonary rehabilitation programs are interested in changes that occur in response to the program intervention and thus must assure that they utilize tools that are able to measure change. When evaluative tools are readministered after rehabilitation, such tools should have the ability to reflect a clinically relevant difference, referred to as sensitivity or responsiveness.

General Quality-of-Life Tools

Quality-of-life instruments are structured as either general or disease-specific tools. General health or generic tools are intended to comprehensively profile the areas believed to be impacted by any disease or treatment and include physical and emotional function and general well-being. These instruments can be used across cultures, genders, populations, and diseases. General health profiles have the advantage of measuring the global impact of a disease or a medical intervention. Three general quality-of-life tools have been used in patients with COPD.

SF-36 Health Survey

This instrument (SF-36) contains 36 written questions that can be answered independently by the patient in 5 to 10 min. Eight subscale scores are generated: physical functioning, social functioning, role-physical, role-emotional, bodily pain, general health, vitality, and mental health. Each subscale score ranges from 0 to 100, with 100 representing the most desirable score. Two summary scores (physical and mental) have also been described.

Quality of Well-Being Scale

This (QWB) is a somewhat complex tool requiring administration by a trained interviewer, and a response-coding procedure must be applied before the questionnaire can be scored. The interviewer must keep an elaborate record of the subject's verbal and bodily responses. The QWB contains 50 items and can be administered in about 10 to 15 min. Components include mobility, physical activity, social activity, and symptoms, and the results are weighted by general population preferences. The measured general health status can be reported as a continuum between optimal functioning (represented as a score of 1) and death (represented by a score of 0). Subjects can be classified into one of 43 states of functioning ranging between 1 and 0; the weight of each state is derived from community surveys to reflect social preference. The QWB can be used to profile a single day or a span of several days, with the interviewer probing health, symptoms, and performance. In addition, the effects of a treatment can be expressed as well-years.

Sickness Impact Profile

This tool (SIP) is designed to assess the impact of illness on behaviors and activities. This questionnaire contains 136 questions, which are grouped into 12 subscales and further summarized into two broad scores and an overall summary score. The general scale of physical activity includes subscales of ambulation, mobility, and body care and movement. The psychosocial score includes subscales of social interaction, communication, alertness, and emotional behavior. The remaining subscales include sleep and rest, eating, work, home management, and recreation and pastimes. Although this questionnaire is long, it has been widely used and can be completed independently by the patient.

Respiratory Disease-Specific Quality-of-Life Tools

Although general health surveys can provide useful information, there is the potential for limited sensitivity in patients with severe disease and with specific symptom complexes such as COPD. One dimension of health where this issue is likely to arise is physical activities. For example, a physical functioning scale with questions that include running, lawn mowing, or other strenuous activities lack the sensitivity to differentiate among individuals with extremely limited abilities who are recipients of pulmonary rehabilitation. Moreover, a scale can inhibit detection of differences if it contains a significant proportion of items to which most COPD patients would typically respond in a similar manner, either with or without therapeutic interventions. Some disease-specific tools allow patients to identify individual areas or activities that they feel are most impacted and allow these patient-selected areas to be reassessed over time. This process allows individuals to determine the impact of disease on their own lives. Although this individualization increases the sensitivity to detect change for an individual, comparisons across disease groups or populations are difficult.

Chronic Respiratory Disease Questionnaire

The most widely used tool to evaluate patients with respiratory disease is the CRDQ, which was designed to measure the impact of chronic airflow limitation on quality of life. Because different individuals with chronic lung disease often identify different physical tasks that have been affected by their lung disease, this questionnaire allows each patient to choose activities in which their performance has been most altered. The interviewer asks each subject to identify five activities most impacted by dyspnea, and these same activities are queried on each subsequent questionnaire administration, at which time it is suggested that patients be informed about their response to the prior questionnaire. Responses are recorded using a seven-point Likert scale ranging from 1, indicating extreme disability, to 7, indicating no disability. This questionnaire includes 15 items measuring dyspnea and fatigue (physical functioning scale), anxiety and depression (emotional functioning scale), and the sense of control over respiratory disease (mastery scale). After the initial interviewer administration, the patient may complete the questionnaire independently.

St. George's Respiratory Questionnaire

This self-administered questionnaire incorporates 76 items for use in patients with respiratory disease including COPD and asthma. The questions are weighted as to their importance, and a computerized scoring system is required to obtain a total score and three component scores: respiratory symptoms, performance of activities, and impact of the illness. Normal ranges have been determined, and the instrument appears sensitive to change. This instrument is unique in that clinically significant changes in the scores have been determined.

OUTCOMES OF PULMONARY REHABILITATION

Improvements in many of the important outcome domains have been demonstrated following pulmonary rehabilitation in patients with chronic obstructive pulmonary disease (Table 6). Although it is not always clear which component of pulmonary rehabilitation is most responsible for a specific outcome, most of the results noted below have been demonstrated in response to comprehensive multidisciplinary programs. The reader is referred to several evidence-based reviews of pulmonary rehabilitation included in the References, which provide documentation of the outcomes of pulmonary rehabilitation.

Component/symptom	Outcome	Grade*	Recommendation
Survival	Survival may be improved	C	
Health care utilization	Reduced number and days of hospitalizations	B	
Dyspnea	Reduced dyspnea	A	Dyspnea outcomes should be routinely measured
Quality of life	Improved quality of life	B	
Lower extremity exercise training	Improved exercise tolerance without appreciable adverse outcome	A	Exercise training of muscles of ambulation is recommended
Upper extremity exercise training	Improved arm function with strength and endurance	B	Arm exercise is recommended
Ventilatory muscle training	Improved dyspnea and exercise tolerance in some studies	B	Not an essential component of pulmonary rehabilitation, may be considered in selected patients with decreased respiratory muscle strength and dyspnea who remain symptomatic despite optimal therapy
Psychosocial and education	Decreased affective distress Cognitive and behavioral intervention enhance exercise adherence	C	Recommended based on expert opinion

*Grade, grade of evidence supporting recommendation: A, evidence provided by controlled trials with statistically significant consistent results; B, evidence provided by observational studies or controlled trials with less consistent results; C, supporting expert opinion because of results or lack of controlled trials.

TABLE 6. *Summary of demonstrated outcomes of pulmonary rehabilitation*

Survival

Mortality is most closely related to the degree of airflow limitation as measured by the FEV_1 but is also related to age and possibly exercise tolerance and perceived physical disability. Because pulmonary rehabilitation does not change the underlying pulmonary disease and FEV_1 in patients with COPD, it might be anticipated that survival would be unchanged following rehabilitation in patients with very severe airflow limitation. On the other hand, in selected groups of patients with COPD who have decreased exercise capacity and increasingly frequent exacerbations with resulting deconditioning, pulmonary rehabilitation may decrease the frequency of exacerbations, lessen physical disability, and improve exercise tolerance and thus might improve survival.

Oxygen therapy in patients with COPD and severe hypoxemia has been clearly shown to improve survival. However, conclusive evidence that comprehensive pulmonary rehabilitation decreases mortality is lacking. Using historical control groups and observational studies, several publications have suggested that pulmonary rehabilitation may improve 5-year survival by 13% to 28%, and randomized studies have demonstrated a trend to improved survival. Nevertheless, further controlled randomized studies are required to more completely address the effects of rehabilitation on survival. The investigations evaluating survival have frequently not incorporated a concurrent control population that did not receive pulmonary rehabilitation. In addition, the available studies include patients with differing severity of underlying pulmonary disease as measured by the FEV_1 and report divergent survival rates, making comparisons between studies difficult.

Morbidity

Several studies have demonstrated a reduction in hospital days in COPD patients following pulmonary rehabilitation including programs based in the home, utilizing the services of a nurse and other ancillary health care personnel when necessary, and in other outpatient settings. It is most likely that decreased hospitalizations might occur in those patients with frequent hospital admissions and moderately severe pulmonary disease who were enrolled in a home care program. In the current health environment, with its focus on cost reductions and reduction in hospitalizations, the role of pulmonary rehabilitation in reducing morbidity and the utilization of expensive health care resources in the hospital and emergency room is of critical importance.

Because of a reduction in hospital days, pulmonary rehabilitation can decrease the costs of medical care in patients with COPD. The cost savings associated with reduced hospitalizations following pulmonary rehabilitation is in the range of $2,000 per patient per year. The cost-effectiveness of rehabilitation in patients with COPD has also been evaluated by using the Quality of Well-Being scale to measure years of quality life (well-years) as an outcome measure. The cost per additional year of well-being was $24,256, considered cost-effective by current standards when compared to other therapeutic modalities for other diseases.

Respiratory Symptoms

The major respiratory symptom of interest to patients with COPD is breathlessness. Randomized controlled clinical trials have shown that dyspnea decreases as a result of pulmonary rehabilitation, both when measured by the specific questionnaires assessing breathlessness and when measured by disease-specific quality-of-life questionnaires such as the CRDQ (Fig. 3). Reduction in dyspnea as measured during formal exercise tests has also been documented following rehabilitation. Improved breathlessness has been noted with rehabilitation when applied in different sites including the home outpatient setting and the inpatient setting. The major rehabilitation component leading to reduced breathlessness is lower extremity exercise training. Breathing retraining including pursed lips and diaphragm breathing are also known to decrease dyspnea. Because of the importance of this cardinal symptom and the frequency with which reduction in dyspnea is a stated goal of the patient, dyspnea is an important symptom to monitor and assess in response to pulmonary rehabilitation. The respiratory disease-specific questionnaires (such as the CRDQ and St. George's Respiratory Questionnaire) incorporate measures of dyspnea. Specific dyspnea questionnaires are also available (such as the Baseline and Transitional Dyspnea Indices), and other tools are designed to assess dyspnea during exercise (such as the Borg Dyspnea Scale and Visual Analog Scale).

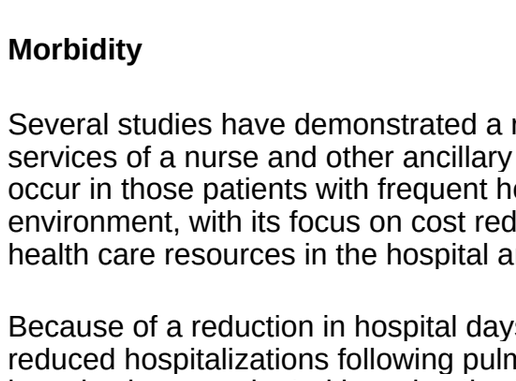

FIG. 3. Treadmill endurance is improved at 2, 6, and 12 months in patients with COPD randomized to receive comprehensive pulmonary rehabilitation compared to patients receiving education only. (Reproduced by permission from Ries AL, Kaplan RM, Limberg TM, Prewitt LM. Effects of pulmonary rehabilitation on physiological and psychosocial outcomes in patients with chronic obstructive pulmonary disease. *Ann Intern Med* 1995;122:823–832.)

Functional Capacity

Pulmonary rehabilitation improves objectively assessed functional capacity as well as patient-perceived functional status. Some studies have classified patients by their functional ability and demonstrate improved functional classification following rehabilitation. The 6- or 12-min walk test can also be used to assess functional capacity; walk distance improves about 20% to 25% following rehabilitation in patients with COPD.

Exercise Capacity

It has been repeatedly demonstrated that pulmonary rehabilitation including aerobic exercise training of the lower extremities improves exercise tolerance (Fig. 4). Exercise capacity can be measured objectively in the laboratory on a bicycle or treadmill with an incremental maximal test or a steady-state endurance test. During steady-state exercise, declines in oxygen consumption, heart rate, respiratory rate, and minute ventilation and an increase in exercise duration are noted following rehabilitation. Improvement in peak exercise capacity (peak work and oxygen consumption) has also been demonstrated.

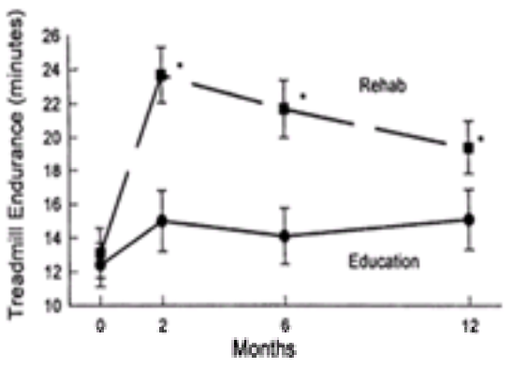

FIG. 4. Self-reported shortness of breath with activities of daily living is improved at 2, 6, and 12 months in patients with COPD randomized to receive comprehensive pulmonary rehabilitation compared to patients receiving education only. (Reproduced by permission from Ries AL, Kaplan RM, Limberg TM, Prewitt LM. Effects of pulmonary rehabilitation on physiological and psychosocial outcomes in patients with chronic obstructive pulmonary disease. *Ann Intern Med* 1995;122:823–832.)

Strength Training

Other forms of exercise, including strength training, have also been employed, but to a lesser extent. Strength training of the upper and lower extremities has been shown to improve dyspnea, mastery, and bicycle exercise endurance time in COPD.

Upper Extremity Training

Training of the upper extremities in COPD is specific for arm function and reduces the increased metabolic demand and ventilation associated with arm elevation and arm work. Upper extremity training does not appear to improve performance in other tests not related to the training such as lower extremity walking or treadmill exercise. In addition, although upper extremity training increases endurance for arm exercise, there is no documented improvement with arm exercise as the sole intervention in activities of daily living. A reduction in perceived dyspnea during upper extremity performance has also been noted. Current recommendations indicate that supported and unsupported upper extremity training should be incorporated into comprehensive pulmonary rehabilitation programs.

Ventilatory Muscle Training

The only modes of respiratory muscle training that increase strength and endurance of the ventilatory muscles are those that achieve an adequate training load, thus emphasizing the importance of the linear resistance characteristics of the training device. With adequate training loads, it appears that endurance and function of the inspiratory muscles are improved when resistance training is performed with controlled flow breathing patterns. However, published studies indicate inconsistent results in other outcomes of inspiratory muscle training. For example, exercise capacity and quality of life are not uniformly improved following inspiratory muscle training in patients with COPD, in part because of the lack of an adequate training stimulus. Ventilatory muscle training may be considered as an adjunctive form of therapy to improve exercise and quality of life in selected patients if an adequate training load can be assured.

Quality of Life

Based on published studies, comprehensive pulmonary rehabilitation should be considered as a therapeutic intervention that improves quality of life (QoL) in patients with chronic obstructive pulmonary disease. Although most studies that have evaluated quality of life have demonstrated improvements following comprehensive pulmonary rehabilitation, not all studies have used standard quality-of-life tools nor controlled randomized study designs. Nevertheless, recent randomized controlled studies employing respiratory disease-specific quality-of-life instruments have documented improved quality of life. However, some studies using general-health quality-of-life measures have not shown improvement in QoL, emphasizing the importance of choosing QoL instruments that are sensitive to change. Improved QoL has been noted for rehabilitation conducted in an outpatient setting, inpatient setting, and in the home.

The precise components of comprehensive rehabilitation that are most responsible for improvement in quality of life are unclear. However, it appears that comprehensive programs that include exercise training may be necessary to achieve improved QoL. Education alone has not been shown to result in significant quality-of-life benefits.

Ability to Work

It is unclear whether pulmonary rehabilitation can assist patients in returning to gainful employment. It is important to emphasize that this is not generally a goal of pulmonary rehabilitation, particularly in patients with more advanced COPD who are generally older and retired because of a combination of age and respiratory symptoms. Pulmonary rehabilitation is generally considered more effective in maintaining employment in younger patients with less advanced disease and thus should be started earlier in the course of COPD. Some investigators have noted a poor compliance with vocational rehabilitation, and others have suggested that vocational rehabilitation success was related to intelligence test scores. Patients with higher IQ levels might have decreased energy requirements in their jobs because of decreased physical demands of employment, thus allowing better vocational outcomes.

Other Outcomes

Little information is available concerning caregiver burden and use of assistive technology outcomes in COPD. Improved self-care ability and decreased need for nursing home care have been reported.

Prediction of Beneficial Outcomes

Although it is tempting to evaluate which patients are most likely to benefit from pulmonary rehabilitation, previous investigations have not consistently been able to identify such individuals. Age and sex do not appear to be predictors of outcome. The ability of baseline functional capacity and airflow limitation to predict outcome are questionable. It has been suggested that patients with less airflow limitation (i.e., a higher FEV_1) are more likely to show improvement with rehabilitation, and thus, rehabilitation should be started earlier in the course of COPD to achieve greater cumulative benefits. However, some studies have demonstrated a greater degree of improvement in walk distance (as measured by percentage increase in walk distance) in patients with the lowest baseline walk distance. Whether these benefits in more functionally limited patients represents the effect of deconditioning or the degree of airflow limitation before rehabilitation was not evaluated.

In the absence of the ability to identify patients most likely to benefit from rehabilitation, and because pulmonary rehabilitation improves dyspnea, exercise capacity, quality of life, and hospitalizations, it is reasonable to enroll patients with dyspnea, reduced exercise capacity, impaired quality of life, and frequent hospitalizations in comprehensive pulmonary rehabilitation.

CONCLUSION

Comprehensive pulmonary rehabilitation programs can improve physiological measures of exercise capacity, functional capacity and health-related quality of life. The variety, diversity, and number of potential outcomes of pulmonary rehabilitation suggest that not all outcomes will be of equal importance for all patients with chronic obstructive pulmonary disease. Based on the nature and needs of the populations and individuals being served, pulmonary rehabilitation programs should determine which outcomes should be the focus for their rehabilitative efforts. Periodic assessment of the outcomes achieved by rehabilitation can be used to modify the rehabilitation program with the goals of improving outcomes and thus enhancing patient care.

INTRODUCTION

Lung and heart-lung transplantation have become viable options for end-stage pulmonary parenchymal and vascular diseases over the last decade. Lung transplantation has lagged behind other solid-organ transplantation primarily because of surgical difficulties and inadequacy of immunosuppressive agents. Many of the immediate and short-term postoperative complications have been solved, with many centers reporting 1-year actuarial survival in excess of 70%. This chapter covers important aspects of lung transplantation and includes lessons from the early years as well as current and future challenges facing the transplant community.

HISTORICAL BACKGROUND

The first human lung transplant was reported in 1963 by Hardy in a patient with advanced bronchogenic carcinoma. The recipient died with renal failure 18 days after transplantation. At autopsy there was no evidence of rejection. This case demonstrated the feasibility of the operation and the capability of the allograft to function. After Hardy's experience, approximately 40 lung or lobar transplantations were performed during the next two decades. The longest survivor during this period was a 23-year-old Belgian man with acute silicosis who survived 10 months after one lung was transplanted but spent almost 9 months in the hospital. Bronchial dehiscence and pulmonary sepsis were major causes of mortality in these early cases because of the use of high-dose (1 to 2 mg/kg) corticosteroids. The introduction of cyclosporine A in the early 1980s as an immunosuppressive agent allowed for a reduction in the corticosteroid dose after transplantation. This, together with improvement in surgical technique (by using omental wraps), reduced the incidence of airway complications and resulted in improved early survival after transplantation.

PATIENT SELECTION

One of the most important aspects of lung transplantation is the selection of appropriate patients for the procedure. Basic criteria have been developed enabling the selection of optimal candidates to ensure the best possible chance for survival (Table 1). The criteria cited continue to evolve as experience in this field continues to accrue.

End-stage lung disease (life expectancy <12 to 24 months)
Age <65 for SLT, <55 for BLT[a]
No other significant systemic disease[b]
Medical compliance
Psychological stability, no substance abuse
Ambulatory with oxygen (if required)
No history of malignancy[c]
Adequate social support
Adequate nutrition
Systemic steroids <15 mg prednisone/day

[a] Patients older than 60 must be in exceptional condition.
[b] Patients should not have renal or significant hepatic dysfunction.
[c] If there is a prior malignancy, it must be remote and cured.

TABLE 1. *Selection criteria for transplantation*

Age

Most centers accept patients up to 60 to 65 years of age as candidates for single lung transplantation (SLT). The upper age limit for heart–lung (HLT) and bilateral lung

transplantation (BLT) is 50 to 55 years of age, although these limits are somewhat arbitrary. In general, older patients are more likely to have complicating medical conditions and postoperative complications.

Single Organ Failure

The ideal candidate would have end-stage lung disease as the only medical condition. End-stage liver or renal disease is considered an absolute contraindication to lung transplantation, as these organs are subject to the toxicity of the immunosuppressive agents. Even a mildly elevated creatinine is a concern. More recently, patients with systemic hypertension and diabetes mellitus have been successfully transplanted. These patients should be well controlled with medical management and without any evidence of end-organ damage.

Cancer

A recent history of primary or metastatic pulmonary neoplasm is considered an absolute contraindication to transplantation. This is mainly because of the poor prognosis associated with such malignancies and because of the potential for such malignancies to recur with the use of heavy immunosuppression after transplantation. Patients with a remote history (in excess of 5 years) of extrapulmonary malignancy have successfully undergone lung transplantation.

Corticosteroid Therapy

Most transplant centers accept recipients on low doses of corticosteroids (prednisone 10 to 20 mg/day), as such doses have no significant deleterious effect on short-term survival. However, potential candidates on chronic steroid therapy should be carefully screened for osteoporosis. Evidence of osteoporosis is considered a relative contraindication to transplantation, and most centers exclude patients with severe osteoporosis. The adverse impact of complications associated with osteoporosis on the quality of life after transplantation should not be underestimated.

Functional Status

Most centers require that their recipients be ambulatory and able to undergo rehabilitation in a comprehensive program both preoperatively and postoperatively. Pulmonary rehabilitation programs increase endurance levels as measured by the 6-min walk test. This improvement in endurance may translate to more rapid extubation after transplantation, especially in cases of severe reperfusion injury requiring prolonged mechanical ventilation. However, there are inadequate objective data addressing the results of preoperative rehabilitation on the immediate outcome after transplantation. Successful transplantation of ventilator-dependent patients has been performed by many centers, but this should be performed by experienced teams and in patients who are relatively well nourished and ambulatory.

Chronic Infection

Patients with chronic respiratory tract infections should be carefully screened. High rates of reinfection (after transplantation) with poor survival have been reported when the upper airways of the recipient are colonized with highly resistant bacteria. A common clinical scenario is colonization of a cystic fibrosis patient with highly resistant pseudomonas aeruginosa. Many centers will not list patients if they have resistant pseudomonas, especially if synergy studies do not reveal any potentially useful antibiotic combination. The colonization of recipient airways with *Aspergillus* species is generally not considered a contraindication to transplantation. However, patients with aspergillomas are probably not ideal candidates because of the potential for recurrence after transplantation. Prophylaxis with inhaled amphotericin B or oral itraconazole may have a role in these settings. Uncontrolled extrapulmonary infection is an absolute contraindication to transplantation.

Psychosocial Factors

Active psychosis or drug abuse is a contraindication to transplantation because it would interfere with the recipient's ability to adhere to strict and complicated medication regimens after transplantation. Most programs require strict smoking cessation for 6 to 12 months before consideration for transplantation. Good social support is essential.

Nutritional Factors

Most centers avoid transplanting severely cachectic or obese individuals because of their relatively poor potential for physical rehabilitation after transplantation. Malnourished cystic fibrosis patients may be able to achieve weight gain with percutaneous feeding tubes. However, it is not clear if such a response will result in a significant survival advantage after transplantation.

Previous Chest Surgery

Previous lung biopsy, resection, or violation of the pleural space by pleurodesis is not considered an absolute contraindication to transplantation. These may place the recipients at a slightly increased risk of perioperative bleeding, but this risk is generally not prohibitive. Parietal pleurectomy precludes transplantation on the operated side.

INDICATIONS

The most common indication for SLT is chronic obstructive pulmonary disease (COPD), and cystic fibrosis is the leading indication for BLT (Table 2). Approximately 1500 patients were listed for lung transplantation by 90 centers in the United States in 1994. The median waiting time was 553 days. This compares with 125 patients listed in 1988 with a median waiting time of 386 days (United Network for Organ Sharing, *personal communication*). The waiting time for HLT is usually longer because heart transplant centers compete for organs. Approximately 500 SLT, 300 BLT, and 100 HLT were performed worldwide in 1994.

Chronic obstructive pulmonary disease
Idiopathic pulmonary fibrosis
Cystic fibrosis[a]
Diffuse bronchiectasis
Sarcoidosis
Eosinophilic granuloma
Extrinsic allergic alveolitis
Drug-induced lung disease
Primary pulmonary hypertension[b]
Secondary pulmonary hypertension[b]
Lymphangiomyomatosis

[a] Cystic fibrosis and bronchiectasis ("septic lung disease") require bilateral transplantation to avoid contamination of a new lung by severe infection.
[b] Bilateral sequential transplantation is preferred by many centers for pulmonary hypertension.

TABLE 2. *Examples of end-stage lung disease treated with lung transplantation*

Single lung transplantation is generally applied for emphysema and pulmonary fibrosis. It is also applied, with good results by some centers, for pulmonary vascular disease. A single lung allograft with normal vasculature can accommodate the entire cardiac output without a rise in pulmonary artery (PA) pressure. Most enlarged right ventricles will recover significant function after SLT, mirroring the phenomenon of right ventricular recovery after pulmonary thromboendarterectomy.

The only absolute indication for BLT is bilateral pulmonary sepsis. The presence of severe infection in the remaining native lung precludes SLT. Some centers also perform BLT for severe bilateral bullous emphysema. Bilateral lung transplant is also performed routinely for patients with pulmonary hypertension at many institutions. Either BLT or SLT (with repair of cardiac anomalies) can be applied in patients with Eisenmenger's syndrome unless left ventricular dysfunction is present or the congenital anomaly is not amenable to repair.

Heart-lung transplantation is indicated in a subset of patients with Eisenmenger's syndrome. These patients usually have a surgically irreparable congenital anomaly or

severe left ventricular dysfunction. The HLT allows the transplantation of patients with combined cardiac and pulmonary diseases (Table 3).

Pulmonary vascular or parenchymal disease with associated left ventricular dysfunction[#]
Pulmonary hypertension with irreparable congenital cardiac defect

[#]Even extreme right ventricular dysfunction appears to recover isolated lung transplantation in the vast majority of cases.

TABLE 3. *Indications for heart–lung transplantation*

PATIENT EVALUATION

General Concerns

Lung transplantation is appropriate in patients with irreversible, progressive end-stage pulmonary disease and an estimated life expectancy of 12 to 24 months despite the use of appropriate medical therapy. Certain parameters have been used to predict survival in end-stage lung disease. Such predictors are not necessarily reliable in estimating survival in an individual patient, and clinical judgment is necessary to determine when transplantation is appropriate. In general, patients should be considered for transplantation when they are oxygen dependent, have failed medical therapy, and demonstrate progressive deterioration in their functional status. Because patients are listed according to size and blood type, patients with common blood types such as O may merit earlier listing; many similar patients may precede them on the list.

A typical transplant evaluation appears in Table 4. The general evaluation for potential lung transplant recipients includes a detailed laboratory, radiographic, and consultative evaluation. Computerized tomographic (CT) scanning of the chest is routinely performed to evaluate for evidence of bronchiectasis, extent of bullous disease, and for mediastinal and pleural abnormalities. Measurement of serum creatinine (some centers include creatinine clearance), liver enzyme studies, and serologic tests to determine previous exposure to opportunistic microbes (HIV, CMV, HSV) are routinely performed. Echocardiography is included to detect cardiac anomalies and ventricular dysfunction. Cardiac catheterization is performed in patients over 40 years of age and in those with significant risk factors for coronary artery disease. Nutritional, psychosocial, and physical therapy assessments are also routinely performed.

Testing
Detailed history and physical exam
Chest x-ray, ECG
Pulmonary function with ABG
Differential ventilation–perfusion scan
Radionuclide ventriculography
Two-dimensional echocardiogram
24-hr Holter monitor
Chest CT scan
Bronchoscopy (if indicated)
Right/left heart catheterization (as indicated)
Laboratory testing: Serologies (hepatitis, HIV, EBV, and CMV), ABO blood group, HLA typing, panel reactive antibodies
Consults
Physical therapy
a. 6-min walk test
b. Musculoskeletal assessment
c. Rest/exercise oxygen saturation
Social work
Psychology[#]
Nutrition
Anesthesiology
Pulmonary

[#]Psychiatry evaluation if indicated.

TABLE 4. *Transplant evaluation*

Chronic Obstructive Pulmonary Disease

Postbronchodilator forced expiratory volume in 1 sec (FEV_1) and mean pulmonary artery pressure (PAP) are among the most important parameters used to assess prognosis in patients with COPD who are less than 65 years of age. Patients with a postbronchodilator FEV_1 < 30% of predicted or a mean PAP > 25 mmHg have an estimated 2-year survival of 50% to 60%. However, this survival may be variable; as stated by Burrows in his 1979 report, “The variability in survival should cause clinicians to be cautious when discussing longevity with their patients.” Usually patients who are transplanted have an FEV_1 less than 20% of predicted.

Pulmonary Fibrosis

Patients with idiopathic pulmonary fibrosis (IPF) generally have a median survival of 5 years from the time of diagnosis. However, their rate of progression may be variable. These patients tend to have the highest mortality while awaiting transplantation. Patients with lung volumes < 50% of predicted and diffusing capacity values < 40% are unlikely to survive more than 2 years. These patients should be referred for lung transplantation evaluation as soon as medical therapy fails, particularly when the oxygen requirement begins to increase.

Cystic Fibrosis

The mean survival of patients with cystic fibrosis is approximately 30 years of age. The FEV_1 is probably the most reliable parameter in predicting 2-year survival. Patients with FEV_1 < 30% of predicted have an average 2-year survival of 50%. Other ominous features in patients with cystic fibrosis are hypercapnia and increasing hospitalizations in the previous 1 to 2 years. Once on the transplant list, they should be encouraged to remain ambulatory and to emphasize nutrition. Patients with panresistant *Pseudomonas aeruginosa* or *Burkholderia cepacia* tend to have a poor outcome after transplantation because of the increased mortality associated with the recurrence of these organisms.

Pulmonary Hypertension

Patients with pulmonary vascular disease include those with primary pulmonary hypertension (PPH), those with congenital heart disease and associated secondary pulmonary hypertension, and certain patients with severe parenchymal lung disease such as COPD, sarcoidosis, and IPF. This feature needs to be considered when patients are listed and transplanted. Patients with PPH have a mean survival of 2.7 years from the time of diagnosis. Right atrial pressure, cardiac index, and mean PAP have been used to predict survival in this population. Patients with right atrial pressures > 16 mmHg, cardiac index < 2 L/min per m^2, and mean PA pressures > 80 mmHg have an estimated 2-year survival of 30%. Patients with such indices should be promptly referred for transplantation because of their poor prognosis without transplantation. Patients with right atrial pressure < 12 mmHg, cardiac index > 2 L/min per m^2, and mean PAP < 60 mmHg have an estimated 2-year survival of approximately 70%, comparable to the 2-year actuarial survival after lung transplantation. These patients should be followed closely and referred for transplantation at the earliest signs of progressive right ventricular failure. Calcium channel blocker therapy is generally utilized early. Prostacyclin therapy is now much more commonly used for PPH and has been shown to improve exercise tolerance and survival. Patients on prostacyclin therapy may be observed very carefully, with listing and transplantation occurring when survival is deemed limited. Unlike PPH, there are no clear predictors of survival in secondary pulmonary hypertension. In this subgroup, the level of debility may be the most important factor when considering referral.

SURGICAL TECHNIQUE AND INTRAOPERATIVE CONSIDERATIONS

The surgical technique for SLT and BLT has evolved substantially, as have intraoperative and postoperative management. The patient undergoing lung transplantation requires rigorous intraoperative hemodynamic monitoring because of the substantial alterations in ventilation, perfusion, ventricular filling pressures, and pulmonary function that take place during the operation. Monitoring via a pulmonary artery catheter and peripheral arterial line together with pulse oximetry and end-tidal CO_2 monitoring facilitate management. Transesophageal echocardiography permits continuous assessment of right ventricular function which is useful in determining the need for cardiopulmonary bypass. A double-lumen endotracheal tube is generally in place during transplantation and removed prior to transfer to the surgical intensive care unit.

Single Lung Transplantation

The Toronto group was the first to perform SLT in humans with successful short-term results. This procedure was accomplished through a standard lateral thoracotomy incision and did not require cardiopulmonary bypass. An end-to-end bronchial anastomosis was wrapped with omentum tunneled up through the diaphragm. The pulmonary artery was directly reanastomosed, and a cuff of the donor's left atrium (containing the pulmonary veins) was connected to the recipient's left atrium. Veith demonstrated in dogs that a telescoping bronchial anastomotic connection was associated with a lower incidence of bronchial dehiscence. This procedure is accomplished by pulling either the donor or recipient bronchus inside the other and suturing them together. Since first being performed by the San Antonio group, it has been widely adopted. With this technique, omentopexy became unnecessary for bronchial healing. The SLT procedure is performed via a posterolateral thoracotomy and is considered acceptable for all pulmonary disease requiring transplantation except cystic fibrosis and other septic lung disease. Many centers also prefer bilateral lung transplantation for pulmonary hypertension.

Bilateral Lung Transplantation

Double lung tranplantation was developed for patients with chronic pulmonary sepsis or emphysema associated with severe bilateral bullous disease. The procedure was perfected in dogs via median sternotomy. The donor lungs were transected at the level of the distal trachea and were removed en bloc with the main pulmonary artery and a large left atrial cuff. Because of the high incidence of tracheal anastomotic complications as well as bleeding complications and poor exposure to the posterior mediastinum, bilateral sequential SLT was performed by the Washington University group. The incision was changed from median sternotomy to anterior thoracosternotomy (the “clam shell” incision). The lungs were thus implanted as two single lungs with separate vascular and bronchial anastomoses. This procedure generally eliminates the need for cardiopulmonary bypass.

Heart–Lung Transplantation

The technique of HLT was first described by the Stanford group. The airway anastomosis is at the distal level of the trachea, and the vascular anastomoses are at the right atrium and aorta. Some transplant centers wrap the distal trachea with omentum. The domino procedure allows the heart of the intended heart–lung recipient to be removed and used as a donor heart, which may improve the donor heart supply.

Living-Related Lobar Transplantation

This technique has been applied primarily in children because of the small donor pool. Donation of a lobe from a living relative has been proposed as a life-saving procedure, with minimal risk to an otherwise healthy donor. Despite the potential immunologic advantage of a related donor, the complication rate has not been shown to be significantly less than with unrelated donors. Bilateral lower lobe living-related implantation has been performed predominantly in CF patients by Starnes and colleagues at the University of Southern California. Potential cases are carefully reviewed with ethical considerations a prime concern.

DONOR SELECTION

In the setting of brain death, the lung is particularly susceptible to injury from hemodynamic instability, noncardiogenic pulmonary edema, or aspiration. Thus, procurement of acceptable lungs for transplantation is more difficult than for other solid organs. At the present time, cold ischemic times of up to 6 hr appear to be well tolerated. Ideal donor characteristics include an insignificant smoking history, ABO compatibility, a PO_2 > 300 mmHg on 100% inspired oxygen and 5 mmHg of positive end-expiratory pressure (PEEP), a clear chest radiograph, and absence of purulent secretions at bronchoscopy. Size matching is estimated from the chest radiograph using vertical (apex to diaphragm at midclavicular line) and horizontal (level of dome of diaphragm) measurements. Oversizing is better tolerated in SLT than in BLT. The increased demand for donor lungs together with increased experience has led to the use of donor lungs previously judged unsuitable. Minimal pulmonary infiltrates, borderline oxygenation, or secretions that can be easily cleared by bronchoscopy may not contraindicate donation. Such cases need to be individualized.

POSTOPERATIVE CONSIDERATIONS

The postoperative course in the lung transplant patient is often determined by the operative procedure, the need for cardiopulmonary bypass, and the underlying pulmonary disease. Patients without pulmonary hypertension undergoing SLT tend to require minimal hemodynamic and ventilatory support, which can often minimize the intensive care unit length of stay and allow discharge from the hospital within 7 to 10 days. A number of events may complicate the postoperative course. Routine postoperative care as well as issues specific to the lung transplant patient are important to address.

After transfer from the operating room to the surgical intensive care unit, the lung transplant recipient is managed by a multidisciplinary team including the transplant surgeons, the critical care nursing staff, the transplant coordinators, the transplant pulmonologist, physical and respiratory therapists, and nutritionists. Infectious disease specialists are often involved. Routine early postoperative care includes careful monitoring of vital signs, accurate documentation of intake and output, daily chest radiographs, and laboratory analysis including cyclosporine or tacrolimus levels. The serum creatinine must be monitored particularly closely because attempts at keeping the patient relatively intravascularly volume depleted together with the use of nephrotoxic immunosuppressive agents and antibiotics may have adverse effects on renal function. Patients always have a pulmonary artery catheter and arterial line in place on arrival from the operating room. A postoperative perfusion scan is performed to detect pulmonary artery anastomotic abnormalities and thrombosis. Venous thromboembolism and gastrointestinal prophylaxis as well as adequate pain management are crucial. Placement of an epidural catheter for analgesia is frequently beneficial and facilitates early postoperative ambulation and physical therapy. Nutrition should be addressed early, particularly in patients with cystic fibrosis. Enteral tube feeding should be initiated early if a patient is unable to be fed orally within a few days. If postoperative ileus prevents this, then total parenteral nutrition should be administered.

Hemodynamic Management

Optimal hemodynamic management is essential after lung or heart–lung transplantation. Because the lymphatic drainage of the lung has been interrupted during transplantation, and because of capillary damage from ischemia and preservation injury of the transplanted lung(s), there is susceptibility to pulmonary edema formation. Early rejection or infection may also contribute. The reimplantation response may result in severe noncardiogenic pulmonary edema and requires aggressive diuresis, cautious use of PEEP, and, in the SLT patient, positioning the affected lung up. Independent lung ventilation has been used when pulmonary edema is severe and the lungs have markedly differing compliances.

Patients with pulmonary hypertension undergoing SLT present particular difficulties, and cardiopulmonary bypass is usually required. These individuals often develop reperfusion edema from the tremendous diversion of blood flow to the new lung. This may result in extreme hemodynamic instability. Discontinuing chronic continuous prostacyclin therapy may result in an acute increase in right ventricular afterload. Weaning of this medication is often delayed until the patient is more stable in the intensive care unit. The early postoperative course is generally notable for labile pulmonary arterial and systemic pressures requiring vasopressor and inotropic agents, and paralysis is often required in addition to heavy sedation. Prostaglandin E may also contribute to hemodynamic stability. Thus, patients are kept relatively intravascularly volume depleted, and diuretic and vasoactive medications are used liberally, but with careful monitoring. Extreme volume depletion is avoided to protect renal function and to minimize bronchial anastomotic ischemia. When BLT is performed in patients with pulmonary hypertension, hemodynamic management is less difficult.

Mechanical Ventilation

Management of the ventilator after transplantation depends on the underlying disease, the operative procedure, and the stability of the patient. In COPD patients undergoing SLT, minimal or no PEEP and lower tidal volumes are utilized to minimize overdistention of the more compliant native lung. The latter phenomenon can result in lung herniation with mediastinal shift. Occasionally, replacing the double-lumen tube to permit separate lung ventilation or even volume reduction surgery on the native lung may be helpful. In SLT recipients with underlying pulmonary fibrosis, low tidal volumes and flow rates may help to avoid barotrauma in the stiff native lung.

Bronchoscopy

Examination of the airways is performed in the operating room and again before extubation to evaluate the anastomoses. In patients requiring prolonged mechanical ventilation after transplantation, frequent bronchoscopy may be required for clearance of secretions and to obtain microbiological specimens. Impairment of the cough reflex may suggest the need for bronchoscopy as often as daily in some patients during the intensive care unit stay. Aggressive physical therapy is crucial after transplantation. Incentive spirometry, chest physical therapy, frequent turning, and early ambulation are emphasized.

Infection Prophylaxis

Protocols for infection prophylaxis are routinely utilized for bacterial, CMV, *Pneumocystis,* and *Toxoplasma* infections. Certain patients may benefit from fungal prophylaxis as well. Patients with cystic fibrosis undergo periodic preoperative sputum culture analysis to allow appropriate postoperative antibiotic administration. Synergy studies are often useful in determining appropriate antibiotic combinations. Because CMV is such a frequent pathogen after transplantation, most programs utilize prolonged prophylaxis, particularly in CMV-seronegative recipients receiving CMV-positive lung grafts. Such prophylaxis will delay but not necessarily prevent the development of CMV infection.

IMMUNOSUPPRESSION

Cyclosporine A has served as the cornerstone for immunosuppression after lung transplantation. An oral dose may be administered 4 hr before surgery, followed by a postoperative intravenous infusion at 3 to 4 mg/hr and adjustment to 250 to 300 ng/ml using the high-pressure liquid chromatography assay. When adequate blood levels are achieved and the gastrointestinal tract is functional, oral cyclosporine is initiated every 12 hr. A number of agents can affect cyclosporine levels and need to be considered. This drug is metabolized by cytochrome P_{450} IIIA, and inhibitors of this enzyme such as fluconazole and itraconazole may significantly increase cyclosporine levels. Diltiazem may be useful in treating posttransplant hypertension as well as lowering the required dose of cyclosporine. Erythromycin also increases cyclosporine levels. Adverse effects of this immunosuppressive agent include nephrotoxicity, hypertension, hypertrichosis, gastrointestinal disturbances, neurotoxicity, gingival hypertrophy, hyperglycemia, and hyperkalemia. Tacrolimus is being used increasingly instead of cyclosporine after lung transplantation. Less data is available for lung allografts than in liver or kidney transplantation. This immunosuppressive agent bears no chemical resemblance to cyclosporine but exhibits similar activity. It is also metabolized by cytochrome P_{450} IIIA, and, as with cyclosporine, certain drug interactions can be expected. Nonsteroidal antiinflammatory drugs should be avoided in patients on either agent in view of nephrotoxicity. The principal adverse effects include nephrotoxicity, neurotoxicity (including headache, insomnia, and tremor), gastrointestinal disturbances, hyperglycemia, hyperkalemia, and hair loss. Anaphylaxis has been reported with this drug as well as with cyclosporine.

Azathioprine is initiated preoperatively at a dose of 2 mg/kg and is adjusted downward for a white blood cell count of 5000 or less. We administer methylprednisolone as 500 mg intravenously before reperfusion of the transplanted lung followed by 125 mg every 12 hr for 48 hrs. It is then given as 20 mg/day until oral prednisone can be taken. The latter is tapered to 10 mg/day over the first 6 months. Mycophenolate, a morpholinoethylester of mycophenolic acid, has been used to replace azathioprine. More data in the setting of lung transplantation will more clearly define the role of this drug. Induction immunosuppression with T-cell-lytic therapy such as OKT-3, ATGAM, or RATG is utilized by some groups. Although there may be the potential benefit of a reduced incidence of graft rejection, these agents increase the incidence of infections and lymphoproliferative disorders.

POSTOPERATIVE COMPLICATIONS

Acute Rejection and Graft Dysfunction

Rejection may be manifested by such nonspecific findings as low-grade fever, worsening oxygenation, reduction in the FEV_1, and by the presence of pulmonary infiltrates. Reduced air flow may be the only manifestation. Early after transplantation, infection is excluded and treatment is instituted with intravenous methylprednisolone (bolus of approximately 500 mg daily for 3 days). A clinical response suggests a correct diagnosis, but continued observation for infection is prudent. Possible rejection after the first few weeks is determined by more objective parameters (see “Long-Term Follow-Up”).

Early graft dysfunction appears to be related to ischemia/reperfusion injury and presents as abnormal gas exchange in the absence of infection or rejection. This is addressed with supportive therapy and exclusion of the latter complications.

Infectious Complications

Infections remain the most frequent complication after lung transplantation. The incidence of bacterial pneumonia is highest within the first 4 weeks, and many centers practice routine bacterial prophylaxis for the first 5 to 7 days after transplantation. The organisms frequently involved include *Staphylococcus aureus* and gram-negative bacilli. *Pseudomonas* infections commonly occur after BLT for cystic fibrosis. In SLT recipients, pneumonias generally arise in the transplanted lung. Bronchoscopy is frequently used in the setting of pneumonia after transplantation unless clearly adequate sputum samples are obtained.

Fungal infections account for substantial morbidity and mortality after lung transplantation. *Candida* and *Aspergillus* species account for the majority of these infections, but nearly all other common and many unusual pathogens have been described. The respiratory tract, gastrointestinal tract, intravascular catheters, and donor organ may all serve as potential sources of infection. Treatment should be aggressive, particularly early after transplantation. Fluconazole, itraconazole, and amphotericin B (inhaled and intravenous) are often utilized, and continued efforts are necessary to determine appropriate prophylactic and therapeutic protocols.

Cytomegalovirus infections occur commonly in the posttransplant setting and may range from asymptomatic presence on immunostained surveillance biopsies or bronchoalveolar lavage specimens or cultures to severe pneumonitis resulting in death. Less severe infections are far more common. A common scenario includes malaise, myalgias, low-grade fever, and leukopenia. Infections with CMV generally do not appear before 30 days and are further delayed with appropriate prophylaxis. More frequent and severe CMV disease occurs in CMV-negative recipients receiving CMV-positive lungs. Ganciclovir is administered at 5 mg/kg twice daily (adjusted for renal function), and outcome is generally good. Intravenous immunoglobulin for CMV has been recommended in high-risk patients by some centers. Other viral infections such as adenovirus and respiratory syncytial virus may occur and may be severe.

Airway complications are relatively common after lung transplantation. Early success in lung transplantation was marred by frequent anastomotic complications, generally related to ischemia. Immediately postoperatively, the donor bronchus is relatively ischemic and relies on retrograde flow from the pulmonary artery. Collateral flow from the bronchial circulation develops over the first several weeks. Significant ischemia can lead to bronchial necrosis with airway collapse and/or stricture formation. Bronchomalacia or stenosis may require stent placement. Silicone and metal stents have been used with success, with an increasing trend toward the use of expanding metal stents. Balloon dilation may be utilized before stent placement. In the absence of bronchomalacia, dilation alone may be sufficient. Fungal infections frequently involve the anastomotic site and are aggressively treated with systemic antifungal agents. Nebulized amphotericin B has been used as adjuvant therapy in this setting to provide direct administration to the airway.

Gastrointestinal complications occur frequently after lung transplantation. An extremely frequent syndrome consists of nausea and bloating with gastroparesis occurring over the first month after surgery. The necessary polypharmacy in transplant patients (particularly cyclosporine and tacrolimus) may contribute significantly, and the syndrome is clearly not caused solely by vagotomy. Treatment with metoclopramide, cisapride, or domperidone may help but often does not lead to complete resolution. Feeding tubes are often temporarily required. Patients with cystic fibrosis may develop distal intestinal obstruction syndrome leading to constipation and abdominal distention. Gastrointestinal bleeding of various causes and diverticulitis may occur after lung transplantation. Diarrhea may develop from infection (commonly with *Clostridium difficile*) or as a result of tube feeding or antibiotics.

Other complications occurring after transplantation include cardiac arrhythmias, venous thromboembolism, steroid-induced osteoporosis, mild anemia, hyperlipidemia, and hyperglycemia. Hypertension is an extremely common result of cyclosporine use and should be treated aggressively. Recurrence of native lung disease has been reported in sarcoidosis, lymphangiomyomatosis, and diffuse panbronchiolitis. Recurrence of other underlying pulmonary disease has not been described.

LONG-TERM FOLLOW-UP AND LATE COMPLICATIONS

Before discharge, extensive postoperative teaching takes place, and at discharge patients are immediately enrolled in pulmonary rehabilitation for 1 month and are followed closely. They are encouraged to continue a regular exercise program. Daily incentive spirometry is recommended by many programs as well as daily diagnostic microspirometry. A persistent decrease in the FEV_1 by more than 10% over several days, although not specific, should arouse suspicion for acute rejection. Standard pulmonary function testing is performed frequently, and a decrease in the forced expiratory flow over the midportion of the vital capacity maneuver ($FEF_{25–75}$) may be even more sensitive than the FEV_1 for acute rejection, although less specific. After the first month, acute rejection is less likely to be radiographically apparent

than it is earlier in the course. Transbronchial biopsies together with bronchoalveolar lavage are performed routinely at Duke University Medical Center at 1, 3, 6, and 9 months after transplantation. Thereafter, patients without previous rejection or CMV infection do not appear to benefit. It remains to be definitively proven whether or not even the early surveillance bronchoscopies are advantageous over close clinical follow-up. When rejection is diagnosed, episodes of grade 2 (mild) or higher are treated with bolus steroid therapy, which is often followed by a tapering oral regimen over 10 to 14 days. Continued frequent monitoring of cyclosporine or acrolimus levels is crucial. Serum CMV antigen samples may be sent for analysis at periodic intervals, but the specificity and sensitivity remain to be determined.

Obliterative Bronchiolitis

The major impediment to long-term survival after lung transplantation is obliterative bronchiolitis (OB). The OB syndrome is defined clinically by graft deterioration characterized by progressive obstructive airways dysfunction for which there is no other proven cause. Entities to be excluded include bronchial stenosis or other airway complications, infection, reversible airway reactivity, congestive heart failure, and other pleural or pulmonary parenchymal disease. The condition initially appeared to be confined to HLT patients but clearly occurs in SLT and BLT patients. It may occur in as many as 50% of patients with a mortality of between 29% and 50%.

The pathogenesis of OB is unknown, but the data available suggest that it is an immunologically mediated process directed against the airway epithelial cells and is presumably a manifestation of chronic rejection. Patients with an unexplained FEV_1 decline of 20% or more compared with previous baseline studies are considered to have OB. The $FEF_{25–75}$ may be a more sensitive marker for OB but is a less specific parameter. Chest CT scanning with expiratory views to evaluate for air trapping may be useful, but the precise sensitivity and specificity remain to be defined. Bronchiectasis may also be detected by chest CT suggesting OB. Because the yield of transbronchial biopsy is generally low for OB, and because open lung or thoracoscopic biopsy procedures are invasive, pulmonary function testing together with exclusion of other diagnoses remains the accepted diagnostic approach. This disorder has been reported as early as the second month after transplantation but generally appears between 6 months and 2 years after the procedure. The clinical course may be rapidly progressive or insidious. Some patients may deteriorate rapidly with a subsequent stabilization of lung function. Therapy for this disorder has proven frustrating, with augmentation of immunosuppression and retransplantation the primary modalities. Augmentation of steroid therapy or changing from cyclosporine to tacrolimus and/or from azathioprine to mycophenolate are generally considered, but prospective, randomized trials remain to be completed.

A recent multicenter study of retransplantation for OB has documented a 1-year survival of approximately 43% and 2-year survival of 35% in 72 patients in whom a second transplant has been performed.

Posttransplant Lymphoproliferative Disease

This entity develops in fewer than 10% of recipients and often presents as low-grade fever with fatigue and weight loss with radiographic changes involving the transplanted lung. The syndrome results from proliferation of Epstein-Barr-infected donor B lymphocytes. It develops more commonly in the setting of intense immunosuppression, with Epstein-Barr virus donor seropositivity and in seronegative recipients. Patients may respond transiently to a reduction in immunosuppression, but allograft rejection may then increase in incidence. Conventional chemotherapy has been utilized. The incidence of other malignancies is probably increased, as has been shown in other solid-organ transplants. The skin should be regularly inspected.

OUTCOME AND SURVIVAL

Exercise tolerance is generally markedly improved after SLT, BLT, and HLT. Objective measurements, such as the 6-min walk test, are slightly better after BLT than after SLT. Pulmonary function testing reveals marked improvement, with BLT recipients improving more than SLT patients and attaining essentially normal spirometric values. The arterial oxygenation generally returns to normal or near normal after transplantation. Maximum oxygen consumption increases substantially after the procedure but remains below normal in most cases. Pulmonary artery pressure decreases dramatically, and right ventricular function improves substantially, after transplantation for pulmonary hypertension.

The average 1-year actuarial survival after SLT is approximately 70%, with a 4-year actuarial survival of 42%. This statistic includes all lung transplants performed worldwide. However, many centers are reporting a 1-year actuarial survival in excess of 80%. The average 1-year actuarial survival after BLT is 67%, with the 4-year survival being 47%. HLT has a 1-year actuarial survival of 56% and a 10-year survival of 20%. Obliterative bronchiolitis is a major determinant of long-term survival.

THE FUTURE

Lung transplantation offers an option for patients with end-stage lung disease meeting certain rigid criteria. It should be performed at centers with considerable expertise. The major factor preventing lung transplantation is the limited supply of adequate donors. Extensive efforts are being made to research preservation methods to allow more prolonged donor ischemic times. New immunosuppressive medications are on the horizon, as are new methods to diagnose and treat common infections such as CMV.

Lung volume reduction surgery is an alternative in carefully selected patients with COPD and severe hyperinflation particularly older patients in whom lung transplantation is not an option. The donor cell chimerism occurring naturally after lung transplantation has been suggested to reduce the incidence of obliterative bronchiolitis. In view of this, donor bone marrow cell infusions have been administered during lung transplantation with demonstration of donor cell chimerism in the peripheral blood of the majority of recipients. Such efforts may lead to better understanding of graft acceptance. Xenotransplantation offers another alternative, with perhaps pig-to-human transplantation being the most realistic option. There is some evidence that the lung xenograft may be less susceptible to hyperacute rejection (a significant barrier to xenotransplantation) than the heart or kidney.

It is our hope that future efforts will lead to more efficient use of donor organs, improved graft acceptance with lower toxicity, and a reduction in infectious complications. Lung transplantation remains an exciting and evolving realm of medicine.

CHAPTER

53 Rheumatologic Diseases

Udaya B.S. Prakash

U.B.S. Prakash: Pulmonary and Critical Care Medicine, Mayo Medical School, Mayo Clinic, Rochester, Minnesota 55905.

INTRODUCTION

The rheumatologic diseases encompass a variety of connective tissue disorders, collagenoses, autoimmune diseases, and vasculitic syndromes. Respiratory complications in vasculitic syndromes are discussed in Chapter 54. The majority of rheumatologic diseases have no known etiologic factors even though the inflammatory processes in most of these diseases are immunologically mediated and manifested by the presence of various autoantibodies, rheumatoid factor, immune complexes, elevated erythrocyte sedimentation rate, and certain clinical characteristics. Genetic predisposition, environmental factors, and exposure to chemicals may play significant roles in the etiology of many of these diseases. As a general rule, the histologic changes are nonspecific in the majority of rheumatologic diseases. Clinical features are as diverse as are the organ systems involved by these disorders. In disorders such as systemic lupus erythematosus, multiple criteria are necessary to establish the diagnosis. Although secondary vasculitis is present in the pathologic specimens obtained from patients with these disorders, they are not usually considered primary vasculitides. At times, however, it becomes difficult to separate the vasculitides from rheumatologic diseases.

In each of the rheumatologic disorders discussed below, it is common for one major organ system to be affected to a greater extent than others. Not infrequently, pulmonary manifestations are the major complications. Indeed, it is common to see the pulmonary manifestation as the presenting symptom or sign of many rheumatologic diseases. Herein are described the pulmonary manifestations in rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), scleroderma or systemic sclerosis (SSc), polymyositis-dermatomyositis (PM-DM), mixed connective tissue disease (MCTD), Sjögren's syndrome, and relapsing polychondritis (RPC). For detailed definitions, criteria for classification, and nonpulmonary manifestations of various rheumatologic diseases, the reader is referred to a standard textbook of rheumatology or the *Primer on Rheumatic Diseases* published by the Arthritis Foundation.

SYSTEMIC LUPUS ERYTHEMATOSUS

Lupus is a disorder of unknown etiology characterized by immunologically mediated inflammation that affects multiple organs, including the skin, musculoskeletal, renal, and central nervous systems, and by the presence of multiple autoantibodies in the serum. Clinical criteria necessary to establish the diagnosis of SLE have been published by the American Rheumatologic Association. Almost any organ system can be affected by the disease. Pleuropulmonary complications occur in 50% to 60% of patients with SLE, a higher percentage than in any other rheumatologic disease. Intrathoracic complications described in SLE are listed in Table 1. Histopathologic abnormalities in pleuropulmonary tissues are nonspecific. Many of the pathologic lesions are not caused by SLE itself but by secondary factors such as secondary vasculitis, congestive cardiac failure, infection, aspiration, and drug-induced pulmonary complications.

Pleurisy with or without pleural effusion
Lupus pneumonitis
Shrinking lung syndrome (atelectasizing pneumonitis)
Interstitial pneumonitis and fibrosis
Lymphocytic interstitial pneumonitis
Pulmonary alveolar hemorrhage
Diaphragmatic dysfunction
Respiratory infections
Pulmonary edema
Obstructive lung disease
Bronchiolitis obliterans with organizing pneumonia (BOOP)
Pulmonary vasculitis including capillaritis
Pulmonary thromboembolism
Pulmonary venoocclusive disease
Pulmonary hypertension
Acute reversible hypoxemia
Upper airway disease (epiglottitis, subglottic stenosis, laryngeal edema, vocal cord paralysis, and cricoarytenoid arthritis)

TABLE 1. *Pulmonary complications in systemic lupus erythematosus*

Pleural Involvement

Pleurisy is the most common and often the presenting manifestation of SLE. Pleural abnormalities have been found in 50% to 83% of autopsies in patients with SLE. However, a prospective study of 34 patients with SLE who underwent high-resolution chest CT concluded that pleural abnormalities are less common than previously suggested. Pleural effusions are more frequent in older patients and in patients with drug-induced SLE. Histopathologic changes in the pleura are nonspecific and include infiltration by lymphocytes, mononuclear cells, and plasma cells along with various degrees of fibrosis. Pleuritic pain caused by pleurisy may be the first symptom in up to 50% of patients. Patients, particularly young women, who present with pleurisy or pleural effusion should be evaluated for SLE. An important differential diagnosis in such patients is pulmonary embolism because patients with SLE have a higher incidence of pulmonary thromboembolism (see below). Pleuritic pain may be unilateral or bilateral and is usually located at the costophrenic margins. Pleural effusions are small to moderate, bilateral in 50% of patients, occasionally associated with small pericardial effusion, and frequently accompanied by dyspnea, cough, and fever (Fig. 1). Large pleural effusions are rare. Other reasons for the development of pleural effusions in a patient with SLE include pulmonary embolism and infarction, lupus-induced nephrotic syndrome, or pleuropulmonary infection.

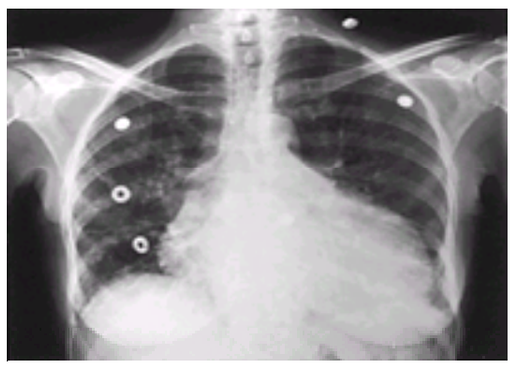

FIG. 1. Chest roentgenogram demonstrates a large pericardial effusion, blunting of the left costophrenic angle, and patchy pulmonary infiltrates in a patient with systemic lupus erythematosus.

Thoracentesis is not indicated in all SLE-induced pleural effusions unless the cause of effusion is in doubt. The pleural fluid is clear or serosanguineous. Grossly bloody effusions are uncommon. The fluid is usually an exudate with a mild to moderate increase in leukocytes. The total and differential leukocyte counts in SLE-associated pleural effusion are nonspecific. The glucose level is usually normal (greater than 60 mg/dl). Decreased levels of total hemolytic complement as well as of C3 and C4 components of the complement and increased immune complexes in the pleural fluid are useful diagnostic tests of SLE-induced pleurisy. Decreased levels and, occasionally, undetectable levels of complement components, observed in nearly 80% of lupus effusions, have been used to corroborate the diagnosis of lupus pleuritis, although similar findings can be found in pleural effusion caused by rheumatoid arthritis and other disorders. The presence of antinuclear antibody in the pleural fluid is nondiagnostic. Likewise, the diagnostic role of immune complexes in SLE-induced pleural effusion is unclear. Lupus erythematosus cells (LE cells) have been found in zero to more than 85% of lupus effusions. The presence of LE cells in pleural effusion is characteristic of SLE-induced effusion and has not been described in other conditions except in pleural effusion caused by drug-induced SLE. Pleural biopsy is rarely required because histologic findings are nonspecific.

Acute Lupus Pneumonitis

Acute lupus pneumonitis has been described in several publications. The syndrome, however, is distinctly uncommon and is usually accompanied by other manifestations of SLE. In two large series of 150 and 207 patients, the incidence of acute lupus pneumonia was 9.3% and 1.4%, respectively. The immediate postpartum period is reported to increase the risk for the development of acute lupus pneumonitis. The pathophysiology of acute lupus pneumonitis involves deposition of immune complexes in blood vessels and alveolar walls with or without associated vasculitis. Acute lupus pneumonitis mimics acute lung infection. Clinical features of acute lupus pneumonitis include acute onset of dyspnea, high fever, and cough with occasional hemoptysis. Physical findings are minimal unless hypoxia leads to cyanosis. Mild to moderate leukocytosis, an elevated erythrocyte sedimentation rate, and significant hypoxemia are noted. Chest roentgenogram may reveal unilateral or bilateral localized, diffuse, or patchy lung infiltrates, predominantly in the lower-lung zones, with small pleural effusions (Fig. 2). Morphologic features of lupus pneumonitis consist of nonspecific changes such as interstitial pneumonia, edema, and arteriolar thrombi. Vasculitis of major vessels is distinctly uncommon. Lung tissue culture for pathogenic organisms is negative. Because respiratory infections and other nonspecific pulmonary parenchymal abnormalities are common in these patients, a diagnostic bronchoalveolar lavage is recommended to exclude an infectious process. The diagnosis of lupus pneumonitis is one of exclusion. The chronic form of lupus pneumonitis produces patchy interstitial processes leading to dyspnea on exertion and nonproductive cough. Lung biopsy is seldom necessary.

FIG. 2. Lupus pneumonitis involving left upper-lobe segment. This entity is very rare.

Pulmonary Hemorrhage

Pulmonary hemorrhage is a serious and frequently fatal complication of SLE. Pulmonary hemorrhage was observed in 1.6% of 750 patients with SLE and was the primary cause of death in 14.4% of 76 autopsy cases of SLE collected over a period of 20 years. In another series of 57 patients with SLE, pulmonary hemorrhage was the cause of death in 10.5%. It is clear that acute pulmonary alveolar hemorrhage is a common cause of mortality in patients with SLE. Pulmonary hemorrhage is likely mediated by activation of the complement system and leukocytes, the latter attracted by immune complex deposits in the lungs. Disruption in the integrity of alveolocapillary basement membrane leads to hemorrhage. Presence of uremia, bleeding diathesis, oxygen toxicity, and infection increase the risk of pulmonary

hemorrhage. Pathologic features in SLE-induced lung hemorrhage are similar to those in lupus pneumonitis. Vasculitis of small vessels can be seen.

Pulmonary hemorrhage is more common in patients with active and progressive SLE. Pulmonary hemorrhage can be the presenting feature of SLE. Pulmonary hemorrhage can be subclinical or massive. Renal failure caused by SLE enhances the risk of lung hemorrhage. Significant hemoptysis is noted in 8% to 15% of patients. The onset of hemoptysis and progressive respiratory distress can be abrupt, and the clinical presentation frequently resembles that of acute lupus pneumonitis. Chest roentgenograms usually reveal bibasal, patchy, alveolar infiltrates (Fig. 3). Bronchoscopy may help visualize diffuse bleeding from segmental bronchi, and the effluent from bronchoalveolar lavage will be bloody throughout the procedure. A diagnostic bronchoalveolar lavage is likely to show a large number of hemosiderin-laden macrophages, although this finding by itself is not diagnostic. Chronic subclinical pulmonary alveolar hemorrhage occurs less commonly than the acute variety and may occur intermittently. Chronic subclinical pulmonary alveolar hemorrhage may lead to a clinical and pathologic picture of pulmonary hemosiderosis.

FIG. 3. Pulmonary alveolar hemorrhage in a patient with systemic lupus erythematosus and severe renal involvement. Alveolar infiltrates are basal and patchy in distribution.

Death frequently occurs within the first several days of SLE-induced pulmonary hemorrhage. Massive lung hemorrhage requires emergent treatment to prevent respiratory failure. The initial therapy may require supplemental oxygen, endotracheal intubation and ventilation, and bronchoscopy. The medical treatment consists of high-dose (1.5 to 2.0 mg/kg/day) corticosteroid therapy supplemented by a cytotoxic agent such as cyclophosphamide (2 mg/kg/day). However, this treatment protocol has been of only limited value. Plasmapheresis should be strongly considered in SLE patients with severe or life-threatening pulmonary hemorrhage.

Interstitial Pneumonitis

Extensive interstitial fibrosis, as encountered in patients with RA and SSc, is rarely observed in patients with SLE. The prevalence of a diffuse interstitial process in SLE is about 3%. Patchy and irregular areas of nonspecific interstitial pneumonitis and fibrosis develop in 15% to 45% of patients (Fig. 4). Lung biopsy specimens subjected to immunofluorescent stains for IgG may show patchy and lumpy staining of the alveolar basement membrane (Fig. 5). Clinically, patients commonly pre sent with insidious onset of chronic nonproductive cough, dyspnea on exertion, and recurrent pleuritic pain. Less commonly, the diffuse process may develop after a bout of acute lupus pneumonitis. Clinical features of diffuse interstitial processes are similar to those in RA and SSc. In a study of 18 patients with SLE-induced diffuse lung disease, the mean age was 45.7 years, and the mean duration of the disease was 10.3 years; respiratory symptoms were present for a mean of 6 years. Restrictive types of pulmonary dysfunction along with diminished diffusing capacity for carbon monoxide are noted. The clinical course is similar to that of diffuse lung disease associated with RA or SSc.

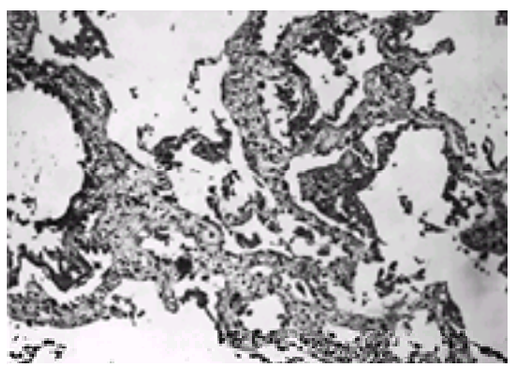

FIG. 4. Lung changes in systemic lupus erythematosus showing edema and thickening of alveolar septa, fibrinous exudate, and hyaline membrane formation in the alveoli.

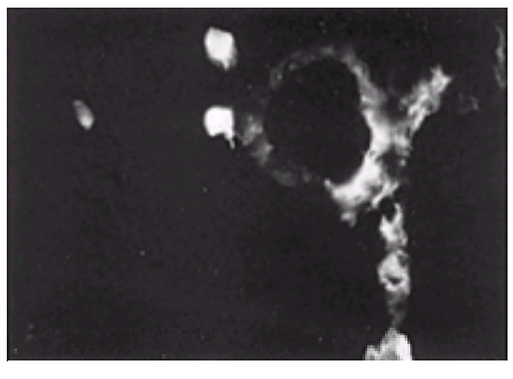

FIG. 5. Immunofluorescence of lung specimen for IgG in systemic lupus erythematosus shows patchy staining of alveolar wall as well as a few intraalveolar cells.

Plate-like or discoid atelectatic areas are more common and usually occur in the lower two-thirds of lung fields (Fig. 6). Infectious processes, particularly in patients who are on immunosuppressive therapy, are the most common cause of lung infiltrates. Sepsis and renal disease are more frequent causes of mortality than are pulmonary complications.

FIG. 6. Discoid or plate-like atelectasis, also called atelectatic pneumonitis, is perhaps the most common chest roentgenographic finding in patients with chronic systemic lu pus erythematosus. Diffuse interstitial process is distinctly uncommon.

Pulmonary Thromboembolism

Thrombophlebitis occurs in up to 10% of patients with SLE. The factors that predispose patients with SLE to thrombophlebitis and pulmonary embolism include chronic low-grade disseminated intravascular coagulation, small-vessel angiitis, prolonged bed rest, and increased thromboplastin generation.

An important factor responsible for the thromboembolic complications in SLE is the antiphospholipid antibody syndrome.

Antiphospholipid Antibody Syndrome

Also known as lupus anticoagulant syndrome, anti-cardiolipin antibody syndrome, the antiphospholipid antibody syndrome is characterized by the presence of antiphospholipid antibodies in serum. The term antiphospholipid antibody refers to a spectrum of autoantibodies, including lupus anticoagulant antibodies and anticardiolipin antibodies, that bind to negatively charged phospholipids. The antiphospholipid antibody syndrome is responsible for the majority of thromboembolic phenomena involving extremities and pulmonary vasculature. In addition to the presence of these antibodies, laboratory abnormalities include a prolonged activated partial thromboplastin time in association with otherwise normal clotting and platelet counts and a false-positive VDRL test. Secondary pulmonary hypertension caused by recurrent pulmonary thromboembolism is a serious consequence of this syndrome. Therapy for these complications consists of inferior vena caval filter insertion and life-long anticoagulant therapy. Adult respiratory distress syndrome caused by extensive small vessel thrombosis of multiple organs including the lungs has been described.

Pulmonary Hypertension

Pulmonary hypertension has been described in up to 15% of patients with systemic lupus erythematosus. It is not usually clinically significant. The pathology of pulmonary hypertension in systemic lupus erythematosus is not well understood. Vasculitis of pulmonary vasculature is rarely seen. As discussed above, the role of recurrent pulmonary thromboembolism and antiphospholipid antibody syndrome should be considered among the major etiologies of pulmonary hypertension. Other potential mechanisms include chronic hypoxic state from interstitial fibrosis and chronic alveolar hemorrhage syndrome. Clinically, pulmonary hypertension in systemic lupus erythematosus is analogous to primary (idiopathic) pulmonary hypertension. Raynaud's phenomenon is common. The secondary form of pulmonary hypertension caused by chronic and recurrent pulmonary emboli can be treated by pulmonary thromboembolectomy. The prognosis in those with persistent pulmonary hypertension is grave. Response to vasodilator therapy is unsatisfactory.

Diaphragmatic Dysfunction

Diaphragmatic elevation and decreased diaphragmatic function have been observed in patients with SLE. Unexplained dyspnea in some patients with SLE may be the result of this phenomenon. The term *shrinking lung syndrome* has been used to describe this. Diaphragmatic weakness may be the result of recurrent diaphragmatic pleurisy, basal atelectasis, and steroid myopathy. Maximal inspiratory expiratory pressures may be diminished. Diaphragm dysfunction does not appear to respond to corticosteroid therapy.

Other Complications

Obstructive airway disease is rare in SLE. Anecdotal reports of severe airway obstruction have been published. The airflow obstruction may be attributable to bronchiolitis, a known complication of SLE. Several cases of upper airway involvement from laryngeal inflammation have been observed. Epiglottitis, subglottic stenosis, laryngeal edema or ulceration, inflammatory mass lesions or nodules, vocal cord paralysis, and cricoarytenoid arthritis have been reported.

Acute reversible hypoxemia is a syndrome reported in a small group of acutely ill patients with SLE. This phenomenon is postulated to be the result of aggregation of circulating leukocytes within the pulmonary vasculature because of complement-mediated phenomena. Corticosteroid therapy leads to decreased levels of complement components and reversal of leukocyte aggregation and hypoxemia. Other thoracic complications reported in patients with SLE include bronchiolitis obliterans with organizing pneumonitis (BOOP), bilateral hilar adenopathy, lymphocytic interstitial pneumonitis, and pulmonary amyloidosis.

A prospective study of 34 patients with SLE who underwent high-resolution CT of the chest showed abnormalities in 24 patients (70%), although pulmonary function abnormalities were present in only 14 patients (41%), and the plain chest roentgenograph was abnormal in only eight (24%). The most common HRCT findings included interstitial lung disease, bronchiectasis, mediastinal or axillary lymphadenopathy, and pleuropericardial abnormalities.

Lung biopsies from patients with SLE may demonstrate areas of vasculitis. However, vasculitis is not characteristic of all lupus-induced pleuropulmonary processes. Nevertheless, vasculitic lesions of large pulmonary vessels as well as capillaritis have been observed in up to 50% of patients.

Drug-Induced SLE and the Lung

Drug-induced SLE is an important clinical syndrome because of the large number of drugs known to cause SLE (see Chapter 22). Pleuropulmonary complications are common in drug-induced SLE. Pleural disease is more common with certain drugs such as procainamide and hydralazine. The pleural fluid shows biochemical characteristics similar to the classic form of SLE. Withdrawal of the drug usually results in resolution of symptoms and signs within days or weeks.

Treatment and Prognosis

Pleural effusion responds favorably to systemic corticosteroid therapy, with an occasional large effusion being refractory. Lupus pneumonitis and alveolar hemorrhage syndrome may respond to high-dose corticosteroid therapy. Cytotoxic agents have been used in patients refractory to corticosteroid therapy. Sepsis and progressive renal dysfunction are the most frequent causes of mortality in patients with SLE, but acute pulmonary alveolar hemorrhage is also important. In patients with lupus pneumonitis, dramatic response can be expected following systemic corticosteroid therapy, although a review of 12 cases of lupus pneumonitis noted a mortality of approximately 50%.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is a chronic systemic inflammatory process characterized by nonsuppurative arthritis involving the diarthrodial joints, with frequent involvement of tendons, ligaments, fascia, muscle, and bone. The American Rheumatism Association has established the diagnostic criteria for RA. Extraskeletal organ systems are frequently involved in RA. Indeed, the nonarthritic symptoms may be the presenting features of RA. The pulmonary system is among the most commonly affected organs. Pleuropulmonary manifestations are encountered in 2% to 45% of patients, depending on whether chest roentgenographs or diffusing capacity for carbon monoxide is used to assess the prevalence of lung involvement. The involvement of the lungs is peculiar in that although RA occurs more frequently in women, respiratory complications are more common in middle-aged men with RA. Furthermore, pleuropulmonary complications may precede the onset of arthritic symptoms. Many of the intrathoracic manifestations have the potential to cause critical illness and respiratory distress (Table 2).

Pleurisy and pleural effusion
Interstitial pneumonitis and fibrosis
Lymphocytic interstitial pneumonitis
Obstructive airway disease
Bronchiolitis obliterans with organizing pneumonia (BOOP)
Necrobiotic nodules (rheumatoid nodules)
Rheumatoid pneumoconiosis (Caplan's syndrome)
Cricoarytenoid arthritis
Laryngeal rheumatoid nodules
Pulmonary hypertension
Bronchiectasis
Pulmonary vasculitis

TABLE 2. *Pulmonary complications in rheumatoid arthritis*

Pleural Involvement

Pleural involvement is the most common intrathoracic manifestation of RA (Fig. 7). In a study of 309 patients with RA, chest roentgenographic evidence of pleural involvement was observed in 24% of men and 16% of women. Autopsy studies have demonstrated pleural involvement in nearly 50%. In contrast to the common occurrence of painful pleurisy encountered in patients with SLE, one-third of patients with rheumatoid pleurisy are asymptomatic. Patients with active (seropositive) RA are more likely to develop pleurisy with effusion than those with inactive disease. Pleural effusion may precede the onset of arthritic symptoms by months. The effusions are usually unilateral, small, persistent, or recurrent. Occasionally, effusions become chronic and persist for months to years. Other pulmonary complications (Table 2) may occur along with pleural involvement. One-third of rheumatoid pleural effusions are associated with other lung processes.

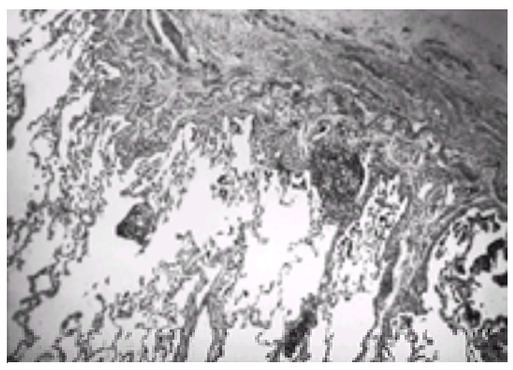

FIG. 7. Pleuropulmonary interphase (upper right) in rheumatoid arthritis. Virtually all patients with rheumatoid arthritis show evidence of pleural thickening at autopsy.

Pleural fluid in RA is typically an exudate, usually yellow and occasionally bloody. Chronic effusions may appear opalescent green because of high cholesterol content (pseudochylothorax). The glucose content in the fluid is very low (<30 mg/dl) in more than 80% of patients; the very low level of glucose is the result of selective blockage of glucose transport into the pleural space as well as from increased utilization of glucose by the inflamed and metabolically active pleural mesothelial cells. Pleural fluid hypoglycemia is not diagnostic of RA-induced pleurisy because pleural fluid glucose levels are also diminished in effusions secondary to empyema, malignant mesothelioma, and tuberculosis. In some patients, the low pH of pleural fluid is the result of localized acidosis caused by blockage to the efflux of end products of glucose metabolism (lactate and CO_2) in the pleural space. Total complement levels in pleural fluid are low in 40% of patients. The presence of rheumatoid factor and the so-called RA cell (monocytes containing cytoplasmic inclusions representing phagocytized IgM in immune-complex form) are not specific in the diagnosis of rheumatoid pleural effusion. High cholesterol levels, including some of the highest ever recorded, are common in chronic pleural effusions associated with RA. High pleural fluid:serum neuron-specific enolase (NSE), found in small-cell lung cancer, has been found consistently in pleural effusions from patients with RA. Pleural fluid concentrations of NSE correlate inversely with pleural fluid glucose concentrations and the pH of the pleural fluid. High levels of soluble interleukin 2 receptor associated with local T-cell-mediated reaction have been found in pleural fluid of patients with RA.

Rheumatoid Lung

Rheumatoid lung is defined as diffuse interstitial pneumonitis or fibrosis associated with RA (Fig. 8 and Fig. 9), and it is perhaps the most serious pulmonary complication of RA. A diffuse pulmonary process is observed in up to 5% of chest roentgenograms in patients with RA. Restrictive pulmonary dysfunction can be demonstrated in more than one-third of patients with rheumatoid lung disease. Clinically, physiologically, and morphologically, the respiratory involvement in RA is identical to that in idiopathic pulmonary fibrosis. It appears that smoking and the presence of secondary Sjögren's syndrome might be important in predisposing the patient with RA to the development of lung disease. Cough and dyspnea are common symptoms, and clubbing has been observed in up to 70%. Chest roentgenograms generally demonstrate a bibasilar interstitial process or micronodules. Honeycombing occurs in late stages of the disease. High-resolution computed tomographic scan of lungs is superior to plain chest roentgenography in the detection of rheumatoid lung disease. In one study of 91 patients with RA, HRCT detected subclinical interstitial lung disease in approximately 50% of patients. High-resolution CT of chest in early stages of the disease may show the ground-glass infiltrates, and as the disease progresses, interstitial processes and honeycombing appear. Fewer than 6% of patients with RA have been shown to develop a bilateral upper-lobe process similar to the pulmonary abnormalities in ankylosing spondylitis. Physiologically, restrictive dysfunction is noted. The earliest physiological abnormality is diminished D_LCO. Exercise-induced hypoxia is common in patients with advanced disease.

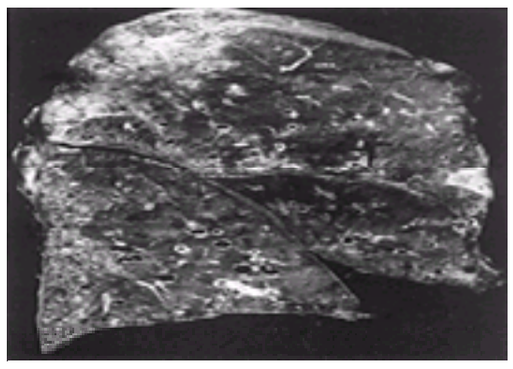

FIG. 8. Gross photograph of chronic interstitial pneumonia in rheumatoid arthritis. Zones of honeycombing can be seen in the posterior subpleural regions. Some contraction and thickening of the lung also is noted along with pleural thickening.

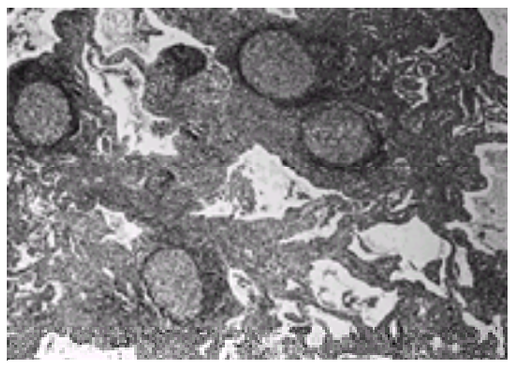

FIG. 9. Chronic fibrosing interstitial pneumonia with associated lymphoid hyperplasia and germinal centers in rheumatoid arthritis. Alveolar architecture is somewhat preserved.

Diagnostic bronchoalveolar lavage has demonstrated abnormalities similar to those in idiopathic pulmonary fibrosis, namely increased neutrophils as well as lymphocytes. Even though it has been suggested that increased lymphocytosis of bronchoalveolar lavage fluid is associated with a good pulmonary prognosis, the supporting data for this assertion are scanty. One study of 40 patients with RA and active pulmonary process described five histologic patterns of pulmonary disease: rheumatoid nodules, nonspecific interstitial pneumonitis, bronchiolitis obliterans with patchy organizing pneumonia, lymphoid hyperplasia, and cellular interstitial infiltrates (Fig. 9 and Fig. 10), In the majority of patients with rheumatoid lung, the morphologic features are nonspecific, without clinical correlates, because the observed abnormalities are dependent on the stage of the disease. Therefore, bronchoscopy, bronchoalveolar lavage, and lung biopsy are rarely indicated. However, diagnostic bronchoalveolar lavage and lung biopsy may be indicated in complicated situations, particularly in patients with immunocompromised status as a result of therapy.

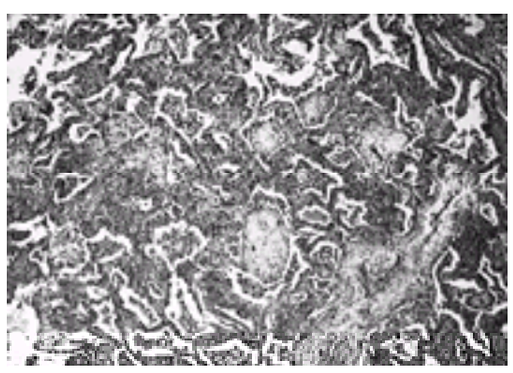

FIG. 10. Bronchiolitis obliterans with patchy organizing pneumonia in rheumatoid arthritis. Several pale rounded polyps of edematous granulation tissue are seen within the air space, between which mildly thickened alveolar septa with a mild chronic inflammatory infiltrate can be seen.

Systemic corticosteroid therapy in early stages may reverse the lung process. It is important to recognize that several drugs used to treat RA can by themselves cause pulmonary disease. These include methotrexate, gold, and penicillamine.

Necrobiotic Rheumatoid Nodules

Necrobiotic rheumatoid pulmonary nodules are different from the nodules observed in Caplan's syndrome. Necrobiotic nodules occur within the lung parenchyma and are histologically similar to subcutaneous rheumatoid nodules. They are more common in men than in women and in those with seropositive RA. Necrobiotic nodules are known to precede the arthritic symptoms. The pulmonary nodules produce minimal symptoms and often are discovered incidentally. They measure from a few millimeters to several centimeters in diameter and are usually bilateral (Fig. 11), occur near pleural surfaces, cavitate in two-thirds, and may rupture into the pleural space to produce pneumothorax or empyema. Aspergilloma is a complication of rheumatoid nodules. The necrobiotic nodules usually wax and wane with activity of the RA, although they may resolve spontaneously despite continuously active RA.

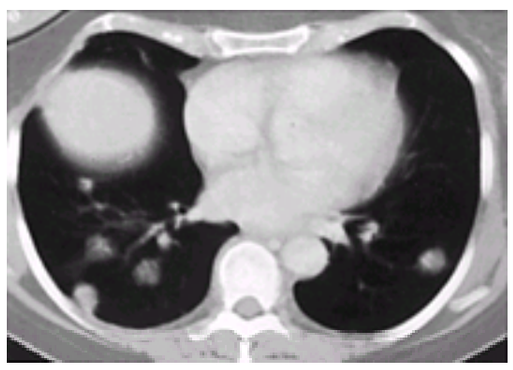

FIG. 11. Multiple bilateral rheumatoid nodules in the lower lung zones. Cavitation is not seen clearly in this computed tomographic image, even though one-third of the nodules cavitate.

Rheumatoid Pneumoconiosis (Caplan's Syndrome)

Caplan's syndrome denotes the presence of rheumatoid nodules in association with pneumoconiosis. Originally described in coal workers with RA, Caplan's syndrome now encompasses persons with silicosis, asbestosis, aluminosis, and the like. The syndrome is uncommon in North America, and most reports have been from Europe. Pulmonary parenchymal nodules in Caplan's syndrome measure 1 to 5 cm in diameter, evolve rapidly, undergo cavitation, appear in crops, and are frequently associated with other lung lesions. Histologically, features are identical to those of rheumatoid nodules except for the presence as well of pneumoconiotic material in the center. Occasionally, the nodules remain quiescent and heal by fibrosis.

Obstructive Airways Disease

Obstructive airways disease occurs in nearly one-third of patients (nonsmokers) with RA. In one study of patients with active rheumatoid lung disease, 23% were found to have obstructive dysfunction secondary to rheumatoid bronchiolitis; others had follicular bronchiolitis and bronchitis. In a study of 100 patients with unselected RA, both airflow obstruction and bronchial reactivity measured by methacholine inhalation challenge were significantly increased relative to controls. The combination of RA and smoking is associated with a much higher prevalence of obstructive lung disease than is either of these factors alone. Mucociliary clearance may be diminished in some patients with RA. Genetic predisposition to obstructive lung disease appears to be a contributing factor. Congenital deficiency of a_1-antitrypsin causes panlobular emphysema and obstructive airway disease. Patients with RA and airway disease have been found to exhibit a 50% incidence of non-PiM (that is, PiMZ and PiMS) phenotypes for a_1-antitrypsin. Penicillamine and gold salts are used to treat RA, and because these drugs are known to cause bronchiolitis obliterans, this complication should be considered in patients with RA who present with obstructive airway symptoms. High-resolution computed chest tomography may show pulmonary parenchymal ground-glass-type alveolar infiltrates (Fig. 12). Progressive rheumatoid airway disease with rapid progression may lead to respiratory distress. Although

unusual, anecdotal reports of life-threatening obstructive airway disease associated with RA have been published.

FIG. 12. High-resolution computed tomographic image of basal regions of lungs in bronchiolitis obliterans associated with rheumatoid arthritis. Diffuse but patchy "ground-glass"-type infiltrates are well seen.

Upper Airway Disease

Cricoarytenoid arthritis caused by RA is clinically recognized in 25% to 35% of cases, although it is present in a significant number of autopsies. Clinically, manifestations consist of chronic persistent sore throat and hoarseness. Both inspiratory and expiratory difficulty may result from a fixed obstruction at the laryngeal level. Laryngoscopy reveals edema and erythema of the vocal apparatus, abnormal motion of vocal cords, and dysfunction of the arytenoids. Rheumatoid nodules occur in the laryngeal region and produce hoarseness, cough, and dyspnea. It is important for specialists in critical care and anesthesia to recognize that laryngeal nodules may remain asymptomatic and pose problems at the time of tracheal intubation.

Bronchiectasis

Bronchiectasis is a late complication of RA. In many published cases, bronchiectasis has been documented in patients with advanced and severe RA. Rheumatoid bronchiolitis appears to predispose to this complication. Patients with rheumatoid bronchiolitis have been shown to have a significantly higher incidence of positive bacterial cultures in their sputum specimens. Bronchiectasis occurs with greater frequency in patients with Felty's syndrome; rheumatoid arthritis associated with hypersplenism and pancytopenia.

Other Complications

Pulmonary hypertension is an uncommon complication of RA. Pulmonary vasculitis, also an uncommon complication, may play a role in the development of pulmonary hypertension. Vasculitis may also cause alveolar hemorrhage, another rare complication of RA. Goodpasture's syndrome has also been reported in association with RA.

Rheumatoid arthritis involving cervical spines may lead to instability of the cervical spinal column. This can preclude extension of the neck for purposes of laryngoscopic tracheal intubation. The tracheal intubation in such patients should be accomplished with a flexible bronchoscope.

Treatment and Prognosis

Nonsteroidal antiinflammatory agents, if successful in controlling RA, may subdue many of the acute respiratory manifestations. Specific complications such as large pleural effusion and obstructive airway disease may require individualized therapy. Systemic corticosteroid therapy in the earlier stages of rheumatoid interstitial lung disease may reverse the acute inflammatory process and slow or stop progression to irreversible fibrotic lung disease. As the lung disease becomes chronic, the ability to reverse it with corticosteroid and other pharmacologic agents diminishes. A poor prognosis results when the interstitial process is advanced. In one large series, such patients had a median survival of 3.5 years and a 5-year survival rate of 39%. Poor prognosis follows rheumatoid bronchiolitis. It is important to recognize that certain cytotoxic agents used in the treatment of rheumatoid arthritis can produce pulmonary toxicity. The agents with known pulmonary toxicity include gold, methotrexate, and penicillamine. Methotrexate, however, has no significant effect on pulmonary function in the majority of patients with RA. Also, there is no evidence that patients with preexisting pulmonary disease are at increased risk for further deterioration in lung function following methotrexate therapy. It should be noted, however, that fatal pulmonary fibrosis following short courses of low-dose methotrexate therapy for RA has been reported.

SYSTEMIC SCLEROSIS OR SCLERODERMA

Systemic sclerosis (SSc) is a systemic connective tissue disease of unknown etiology characterized by a fibrosis of the skin and visceral organs, vasculitis, and presence of relatively specific antinuclear antibodies. The major pathologic attributes of SSc include vascular changes, immune dysfunction, and increased collagen synthesis. It has been suggested that the neutrophil participates in the pathogenesis of lung disease through the release of elastase and that alveolar macrophage, through the release of interleukin-8, recruits neutrophils into the alveoli. Spontaneous and stimulated interleukin-6 secretion by blood monocytes is also increased. Pulmonary involvement is common in patients with SSc. The majority of patients are minimally symptomatic during life, but postmortem examinations have shown abnormal lung histology in up to 80%. Risk factors for developing severe restrictive lung disease include black race, male sex, early onset of SSc, and primary cardiac involvement secondary to SSc. Antihistone antibodies (AHA) in the serum are suspected to indicate more severe lung disease. Several of the pulmonary complications in SSc are listed in Table 3.

Pulmonary interstitial fibrosis
Organizing pneumonitis
Pulmonary hypertension
Aspiration pneumonia
Bronchiolitis obliterans
Chest wall restriction
Bronchiectasis (traction bronchiectasis)
Pleural effusion and fibrosis
Calcification of lung and soft tissues of chest cage (especially in patients with CREST syndrome)
Resorption of ribs
Alveolar hemorrhage
Spontaneous pneumothorax
Pulmonary hemosiderosis-like syndrome
Diaphragmatic dysfunction
Telangiectasia of the airways leading to hemoptysis
Cancer of lung (scar cancer?)

TABLE 3. *Pulmonary complications in scleroderma*

Pulmonary Fibrosis

Progressive interstitial pulmonary fibrosis is the most common pulmonary complication of SSc and develops in up to two-thirds of patients. The frequency of roentgenographic interstitial fibrosis is increased in patients with serum anti-Scl-70 antibody and decreased in those with anticentromere antibody. Histologic features are analogous to those of idiopathic pulmonary fibrosis. Alveolar inflammation has been recognized as a primary event in the pulmonary manifestation of SSc. In early stages, alveolar edema with lymphocytic and monocytic infiltrates occurs. Later, severe fibrosis with honeycombing and cyst formation is noted (Fig. 13). The incidence of pneumothorax in late stage is a complication. Although only one-third of patients have abnormal chest roentgenographs, more than 50% complain of dyspnea on exertion and exhibit diminished D_LCO. Subclinical alveolitis diagnosed by bronchoalveolar lavage occurs in asymptomatic patients. Studies have shown that increased pulmonary vascular leakage and neutrophilic alveolitis are perhaps the earliest features of interstitial lung disease in SSc and that these changes are associated with enhanced type II collagen synthesis. Bronchoalveolar lavage and pulmonary functions in patients with SSc-induced lung disease have shown both neutrophilic and

lymphocytic alveolitis; bronchoalveolar lavage that shows active alveolitis is associated with more severe impairment of lung function than is bronchoalveolar lavage that shows inactive alveolitis. Neutrophilic alveolitis is generally associated with extensive fibrotic lung disease, whereas eosinophilic alveolitis is often seen in less advanced disease, particularly when computed tomographic appearances suggest lung inflammation. Pulmonary in volvement is more severe in patients with the CREST (calcinosis, Raynaud's phenomenon, esophageal involvement, sclerodactyly, and telangiectasia) variant of SSc.

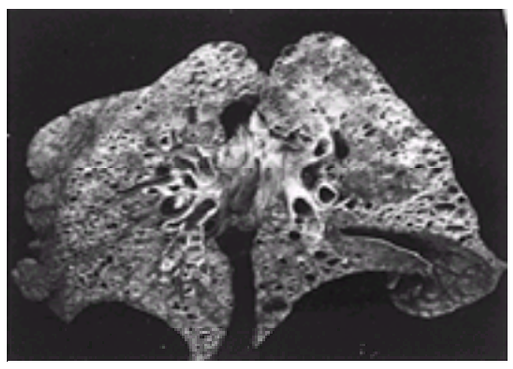

FIG. 13. Gross appearance of lungs in a patient with severe scleroderma. Lungs show extensive honeycombing.

Chest roentgenograph in SSc-induced lung disease shows changes similar to those in idiopathic pulmonary fibrosis. Thoracic (mediastinal) lymphadenopathy is prevalent in patients with SSc and lung disease regardless of clinical subtype or interstitial pattern, and the lymphadenopathy increases as a function of the profusion of the lung infiltrates rather than the morphology of lung disease. Pulmonary function tests in patients with SSc most commonly reveal restrictive dysfunction with diminished D_LCO, the latter being the earliest to occur. The D_LCO is also an important predictor of mortality. Pulmonary dysfunction appears to be related to involvement of the right side of the heart but not to involvement of other extrapulmonary systems. Patients with SSc and Raynaud's phenomenon tend to have lower D_LCO than those with SSc alone.

Pulmonary Hypertension

Pulmonary hypertension is a serious complication that occurs in up to 60% of patients with SSc. This complication is the result of medial hypertrophy of the pulmonary arteries (Fig. 14) and is a major cause of morbidity and mortality. Pulmonary hypertension occurs with greater frequency in patients with the CREST variant of SSc. Chronic hypoxia induced by pulmonary fibrosis also may contribute to the development of pulmonary hypertension. Progressive decrease in D_LCO is an early sign of pulmonary hypertension. The results of treatment, using vas odilators, have been discouraging. The incidence of renovascular pathology is high among patients with pulmonary vascular involvement.

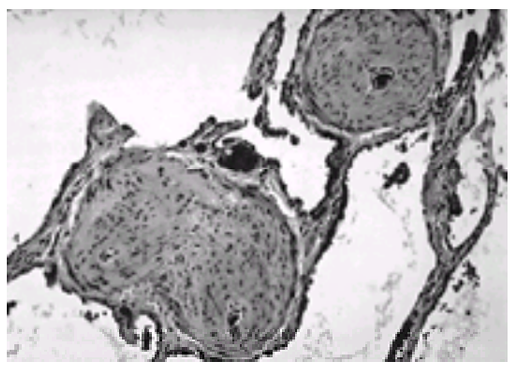

FIG. 14. Pulmonary hypertension in scleroderma, with marked thickening of the muscular wall of small pulmonary arteries.

Aspiration Pneumonia

Esophageal involvement in the form of motor dysfunction occurs in more than 90% of patients with SSc. Acid reflux caused by esophageal dysfunction may lead to aspiration pneumonia. Although chronic aspiration has been considered to play a role in the etiology of pulmonary fibrosis, one study of 39 patients with SSc reported that changes in total lung capacity and forced vital capacity do not appear to be related to abnormal gastroesophageal acid reflux.

Other Complications

Diffuse pulmonary calcification, (especially in patients with CREST syndrome), resorption of ribs, alveolar hemorrhage, a syndrome resembling pulmonary hemosiderosis, diaphragmatic dysfunction, hemoptysis caused by telangiectasia of the airways, and rare instances of pleural thickening have been described.

Chronic SSc is associated with an increased risk of lung cancer. Some have reported that the risk for developing bronchoalveolar carcinoma is increased, but other histologic types of lung carcinoma have also been described. Among 248 patients with SSc who were followed up, cancers developed in 18 patients (7.3%) during 2001 patient-years at risk. The most frequent types were cancers of the lung (seven patients) and breast (five patients). Lung cancer was associated with the presence of pulmonary fibrosis. It is not clear whether such cancers represent the so-called scar cancers.

Treatment and Prognosis

Systemic corticosteroid therapy has had no effect on prognosis in patients with SSc. However, some studies have indicated that active alveolitis, as determined by the results of bronchoalveolar lavage, may respond favorably to immunosuppressive agents. In one study of patients with scleroderma lung disease and an FVC less than 70% predicted, the group treated with cyclophosphamide showed significantly more improvement in FVC over time than did the patients treated with other drugs. D-Penicillamine has been used to prevent progression of pulmonary complications. Fibrosing alveolitis associated with SSc is reported to have a better prognosis than idiopathic fibrosing alveolitis. When patients with SSc develop hypoxemia, supplemental oxygen therapy may relieve dyspnea. Single lung transplantation has been performed in selected cases.

POLYMYOSITIS-DERMATOMYOSITIS

Polymyositis and dermatomyositis are idiopathic myopathies characterized by inflammation of skeletal muscles with resultant weakness of proximal muscles and a characteristic skin rash (heliotrope hue). The autoimmune type of PM-DM (types I, II, and V) discussed here is different from the paraneoplastic type of PM-DM associated in up to 10% of cases with carcinoma of lung and other organs. Underlying malignancy, however, must be excluded before the diagnosis of autoimmune PM-DM is considered. The disease is more common in women. The diagnosis is based on clinical features, elevation of creatine phosphokinase and aldolase, electromyographic studies, and muscle biopsy. The clinical hallmark of PM-DM is proximal limb and neck weakness, sometimes associated with muscle pain. Lung involvement has been described in up to 5% of patients. In one-third of patients, respiratory manifestations may precede musculocutaneous signs and symptoms. A relationship between the severity and progression of the myositis and the severity of respiratory disease is lacking.

Interstitial Pneumonitis and Fibrosis

Interstitial pneumonitis and fibrosis is the most common pulmonary complication and occurs in 5% to 10% of patients. Pulmonary disease precedes the dermatologic or myopathic manifestations by 1 to 24 months in nearly one-third of patients. Respiratory features include dyspnea, cough, and hypoxemia. Symptoms related to

gastroesophageal reflux may be the initial manifestation in some. The process starts in the lung bases and may extend upward. It may present as acute pneumonitis with alveolar or mixed alveolar–interstitial infiltrates. Hypersensitivity to autoantibodies is considered responsible for the lung disease. The anti-Jo-1 antibody in the serum is associated with lung disease; over 50% of patients with anti-Jo-1 antibody exhibit interstitial pulmonary disease. There are reports of patients with anti-Jo-1 syndrome presenting as cryptogenic organizing pneumonia and developing adult respiratory distress syndrome. Pulmonary capillaritis with diffuse alveolar hemorrhage has been described as the primary manifestation of PM-DM. Anti-EJ antibodies have been demonstrated in the sera of some patients with inflammatory myopathy, rash typical of DM, arthritis, Raynaud's phenomenon, and interstitial lung disease. Morphologically, the lung exhibits nonspecific fibrosis and bronchiolitis obliterans with organizing pneumonitis (BOOP) and desquamation of alveolar lining cells (Fig. 15). Pulmonary dysfunction is present in over 50% of patients and consists of decreased lung volumes, $D_L CO$, and arterial oxygenation. Results of bronchoalveolar lavage do not provide diagnostic characteristics.

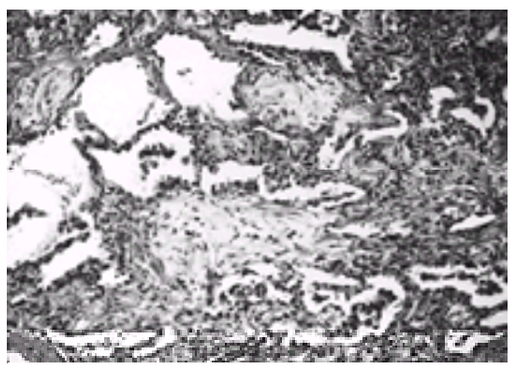

FIG. 15. Bronchiolitis obliterans with patchy organizing pneumonia in polymyositis-dermatomyositis. Two rounded edematous masses of intraalveolar fibrous connective tissue can be seen in the center of the figure.

Hypoventilation

Hypoventilation and respiratory failure are caused by weakness of the respiratory muscles because of the myopathy. Progressive hypercapnia is a poor prognostic sign. Muscle weakness may severely compromise the respiratory bellows mechanism, thereby worsening the basal atelectasis. An ineffective cough increases the risk of bacterial pneumonia.

Aspiration Pneumonitis

Esophageal involvement is common in patients with PM-DM. Uncoordinated peristalsis, esophageal reflux, odynophagia, and delayed gastric emptying are noted. Bulbar involvement and deranged deglutition often lead to recurrent aspiration and pneumonia. Poor cough as a result of respiratory muscle weakness contributes to the development and progression of aspiration pneumonia. Aspiration pneumonia is often the cause of death.

Treatment and Prognosis

Corticosteroids, azathioprine, methotrexate, total body irradiation, and thymectomy have been tried, with varying rates of success. The pulmonary involvement in PM-DM is usually progressive, and long-term response to corticosteroid therapy is poor even though the initial response may be good. Patients receiving high-dose therapy (prednisolone, 1 to 2 mg/kg per day) have shown less morbidity.

MIXED CONNECTIVE TISSUE DISEASE

The terms *overlap syndrome, undifferentiated connective tissue disease, sclerodermatomyositis, RUPUS* (RA and SLE), and *lupoderma* (SLE and SSc) have been used to describe patients who exhibit clinical features of more than one rheumatologic disease. The term *mixed connective tissue disease* (MCTD) refers to patients with clinical features of SLE, SSc, and PM-DM and high titers of a specific circulating antibody to an extractable nuclear ribonucleoprotein antigen (ENA). The presence of high titers of antibody to ENA and the absence of antibodies to Sm antigen are believed to be specific for MCTD. The prevalence of MCTD is more common than PM-DM and less common than SLE. The majority of patients are women, and the average age at diagnosis is 37 years. Renal disease occurs in 10% to 20%, and some patients may require aggressive or prolonged therapy. Pleuropulmonary involvement occurs in 20% to 80% of patients. Many of these manifestations, both clinical and pathophysiological, are similar to those observed in SLE, SSc, and PM-DM.

Interstitial Fibrosis

Interstitial lung disease in patients with MCTD exhibits morphologic features similar to those of idiopathic pulmonary fibrosis. Alveolar septal infiltration by lymphocytes, plasma cells, and type III collagen has been demonstrated. The degree of fibrosis tends to be severe if the predominant clinical feature is that of SSc. Abnormal pulmonary function tests and chest roentgenograms have been noted in 69% of patients without respiratory symptoms. In a multicenter study of 100 patients with MCTD, impaired $D_L CO$ and restrictive lung volumes were noted in 67% and 50%, respectively.

Chest roentgenographic findings are akin to idiopathic pulmonary fibrosis if the clinical profile is predominantly scleroderma-like. Mixed infiltrates can be seen in those with primarily PM-DM-like features. In a study of 81 patients, respiratory symptoms included dyspnea (16%), chest pain and tightness (7%), and cough (5%). Chest roentgenograms revealed abnormalities in 21%, the most common being an interstitial process in both lower lung fields. Pulmonary function testing demonstrated a restrictive type of defect in 69%. $D_L CO$ is the most sensitive single parameter in evaluating pulmonary dysfunction in MCTD.

Pleural Effusion

Pleurisy is a common manifestation of MCTD. Nearly 40% of patients in a prospective study were noted to have pleuritic pain. Pleural fluid shows the same characteristics as that in SLE. The effusions are usually small and resolve spontaneously.

Pulmonary Hypertension

Progressive pulmonary hypertension is the most severe pulmonary complication of MCTD and may be accompanied by severe vasculitic lesions. In an evaluation of 34 patients, significant pulmonary hypertension was noted in 67% of the 15 patients studied. Examination of lung biopsy tissue has revealed muscular hypertrophy of small pulmonary arteries. Plexogenic angiopathy and chronic intimal thickening of medium-size pulmonary arteries have been observed. Fatal pulmonary hypertension has been reported.

Aspiration Pneumonitis

Abnormal esophagograms and esophageal manometry are common in MCTD. Hypotonicity and dilation of the esophagus, similar to that in SSc, are responsible for the reflux and aspiration pneumonia.

Other Complications

Circulating lupus anticoagulant, recurrent thromboemboli complicated by pulmonary embolism and pulmonary hypertension, pulmonary hemorrhage, cavitated pulmonary nodules, and mediastinal lymphadenopathy have been described in patients with MCTD.

If the characteristics of PM-DM are prominent in a patient with MCTD, significant proximal muscle weakness and diaphragmatic weakness may cause hypoventilatory respiratory failure.

Treatment and Prognosis

Corticosteroids are the mainstay of therapy. In a prospective study of 34 patients with MCTD, a favorable response to corticosteroids was noted in two-thirds of the patients, though patients with predominantly SSc-like disease respond poorly. Pleurisy responds well to corticosteroid therapy, whereas pulmonary hypertension does not. In a retrospective study of 81 patients, a 5-year follow-up observed six deaths from carcinoma of the esophagus, aspiration pneumonia, pulmonary hypertension, cardiorespiratory arrest, and myocardial infarction.

SJÖGREN'S SYNDROME

Sjögren's syndrome is a chronic, slowly progressive inflammatory autoimmune exocrinopathy of unknown etiology and characterized by keratoconjunctivitis sicca and xerostomia as a result of diminished lacrimal and salivary gland secretion. Recent studies suggest that the systemic manifestations of Sjögren's syndrome are probably caused by the attraction of lymphocytes by different epithelial tissues. Because of the primary role played by epithelium, the term “autoimmune epitheliitis” has been proposed in lieu of Sjögren's syndrome.

When it is not associated with other connective tissue diseases, the term *primary* Sjögren's syndrome is used. *Secondary* Sjögren's syndrome occurs in association with RA, SLE, SSc, myositis, biliary cirrhosis, cryoglobulinemia, vasculitis, and thyroiditis. Approximately half the patients with secondary Sjögren's syndrome have RA. Sjögren's syndrome is a lymphoproliferative disorder; the incidence of lymphoma in patients with chronic Sjögren's syndrome is increased 44-fold. Lymphocytic infiltration of the exocrine glands, reticuloendothelial system, kidneys, muscles, and other organs is present in one-fourth of the patients. When lymphoid tumors occur that have not met the histologic criteria for malignancy, the term pseudolymphoma has been used, although many pseudolymphomas represent low-grade lymphomas.

Pulmonary complications occur in 1.5% to 75% of patients with both primary and secondary Sjögren's syndrome. Significant abnormalities in pulmonary function occur in about 24% of patients, and the most common cause of dyspnea is interstitial fibrosis, with a prevalence rate of about 8%. In a study of 343 patients with the syndrome, 9% were found to have respiratory involvement. The pulmonary manifestations described in the literature are listed in Table 4.

Nonspecific interstitial pneumonitis
Lymphocytic interstitial pneumonitis
Desiccation of the upper respiratory tract (xerotrachea)
Recurrent tracheobronchitis
Lymphocytic bronchitis
Lymphoma
Bronchiectasis
Obstructive disease of large and small airways
Bronchiolitis obliterans and organizing pneumonia (BOOP)
Localized lung infiltrates, nodules
Discoid atelectasis
Asthma
Pleurisy, pleural effusion
Pulmonary hypertension
Amyloidosis (secondary)
Vasculitis
Diaphragmatic myopathy

TABLE 4. *Pulmonary complications in Sjögren's syndrome*

Airway Disease

Xerotrachea refers to drying of upper airways. It is more common in those with the primary extraglandular form. However, there is no convincing evidence of diminished mucosal secretions or ciliary dysfunction. Nonproductive cough despite normal chest roentgenogram and pulmonary function tests is noted in 17% of patients.

Pulmonary function tests have shown obstructive phenomena in 2.5% to 35% of patients with both primary and secondary forms of Sjögren's syndrome. Patients with both RA and Sjögren's syndrome are more likely to demonstrate obstructive airway disease. Pulmonary functional, roentgenologic, and histopathologic studies have shown that the lesion starts peribronchially. Lymphocytic bronchitis is partly responsible for the obstructive disease, even though mononuclear cell infiltrates can be seen around small airways. Invasion of bronchial mucosa by lymphocytes may represent low-grade lymphoma.

Diffuse Interstitial Process

Diffuse interstitial pulmonary process develops in 15% to 38% of patients with Sjögren's syndrome. Bronchoalveolar lavage may yield increased percentages of lymphocytes and neutrophils, suggesting a subclinical alveolitis. The physiological dysfunction is usually mild. Clinically, lymphocytic interstitial pneumonitis should be differentiated from nonlymphocytic interstitial pneumonitis (see below). A study of 20 patients with Sjögren's syndrome observed pulmonary symptoms in 18, and nine exhibited restrictive lung dysfunction and interstitial involvement. Bronchoalveolar lavage showed higher cell counts with increases of lymphocytes and/or polymorphonuclear cells. Lung biopsy in 12 patients showed follicular bronchiolitis, lymphoid interstitial pneumonia, and lung fibrosis with honeycombing.

Lymphocytic Interstitial Pneumonitis

Lymphocytic interstitial pneumonitis is characterized by parenchymal lung infiltrates consisting of small lymphocytes, plasma cells, and transformed lymphocytes (Fig. 16). Chest roentgenograms show a diffuse interstitial process that is predominantly basal in distribution. Among 343 patients with Sjögren's syndrome, eight (2.3%) developed lymphoproliferative pathology in the lungs; three had lymphocytic interstitial pneumonitis, two had pseudolymphoma, and three were found to have lymphoma. Lymphocytic interstitial pneumonitis should be considered a precursor to the development of lymphoma. Bronchoalveolar lavage may aid in the in vestigation of the clonality of lymphocytes which may allow early and specific diagnosis of lymphomatous proliferation.

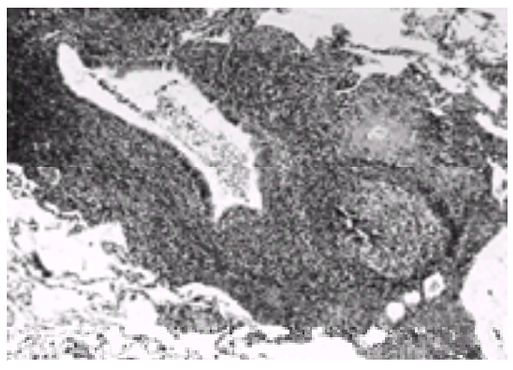

FIG. 16. Chronic bronchiolitis in Sjögren's syndrome with marked chronic inflammation in the wall of the bronchiole associated with lymphoid hyperplasia with germinal centers (*right*).

Pseudolymphoma

Localized lymphoid infiltrates form pseudolymphomas that are clinically and histologically difficult to distinguish from lymphoma. These lesions represent the mid-portion of the spectrum from benign lymphocytic process to malignant lymphoma. Most pseudolymphomas are probably indolent, well-differentiated lymphocytic and lymphoplasmacytic lymphomas, and the majority demonstrate a benign clinical course, whereas only a few are aggressive. Immunohistochemical techniques have shown that most pseudolymphomas of lung are lymphomas. Some pseudolymphomas and even low-grade lymphomas regress spontaneously or with systemic corticosteroids, but others may develop into more malignant lymphomas. Pseudolymphomas are believed to develop in patients with secondary Sjögren's syndrome

alone. Pseudolymphomas exhibit highly heterogeneous infiltrates consisting of large and small lymphocytes, plasma cells, and reticulum cells.

Pseudolymphomas are generally detected on chest roentgenograms in asymptomatic patients and may appear as rounded mass lesions or nodular lesions. The lesions may be well defined and usually solitary and measure from 1.5 to 6 cm.

Pulmonary Lymphoma

A National Institutes of Health study of 136 women with Sjögren's syndrome, followed for an average period of 8 years, observed development of non-Hodgkin's lymphoma in seven and Waldenström's macroglobulinemia in three patients. The occurrence of lymphoma was 44 times the incidence expected in the general population. Patients with a history of parotid enlargement, splenomegaly, and lymphadenopathy were particularly at risk. Another study of 36 men with Sjögren's syndrome observed lymphoproliferation in 17% and concluded that men are at the same risk as women for the development of lymphoma. The majority of malignant lymphomas reported in patients with this syndrome have been monoclonal B-cell neoplasms.

Pulmonary involvement by lymphoma is more likely to occur in those with systemic lymphoma complicating Sjögren's syndrome. A study of 50 patients with Sjögren's syndrome and associated lymphoma revealed pulmonary involvement in ten patients; the mean age of the ten patients was 59.7 years, and eight were women; the mean duration of the syndrome was 7.2 years, and the mean interval between the onset of the syndrome and lymphoma was 5.4 years. Of the ten patients, four died from 8 to 48 months after lymphoma was diagnosed. Lung biopsies revealed a spectrum of low-grade to high-grade lymphomas.

An initial diagnosis of benign lymphocytic interstitial pneumonitis may, on further pathologic analysis, reveal low-grade lymphomas. Thus, many of the published cases of lymphocytic interstitial pneumonitis may represent malignant lymphoma. It has been proposed that all cases of lymphocytic interstitial pneumonitis are actually low-grade lymphomas. Although it is difficult to differentiate lymphocytic interstitial pneumonitis from malignant lymphoma when the chest roentgenogram reveals an interstitial process, the presence of multiple nodular lesions suggests lymphoma. Hilar lymphadenopathy or masses should also suggest a high likelihood of lymphoma. Patients with low-grade lymphomas fare significantly better than those with high-grade lymphomas. Patients with pulmonary lymphomas are believed to have a better prognosis.

Treatment and Prognosis

Azathioprine-based treatment has been shown to reverse pulmonary abnormalities of Sjögren's syndrome and favorably change the outcome. The treatment of the lymphomas in Sjögren's syndrome depends on the histologic grade of the tumor; low-grade lymphoma may not require chemotherapy. Because of the potential of these tumors to assume the status of high-grade malignancy, close surveillance is indicated. Because most patients with Sjögren's syndrome do not have disabling pulmonary symptoms, only symptomatic therapy is indicated.

RELAPSING POLYCHONDRITIS

Relapsing polychondritis (RPC) is a rare and often episodic form of inflammatory disease of unknown etiology characterized by destructive lesions involving cartilaginous structures of nose, ears, larynx, tracheobronchial tree, cardiac valves, and joints. Clinical manifestations include iritis, episcleritis, hearing deficit, cataract, aortic valvular insufficiency, anemia, elevated erythrocyte sedimentation rate, and abnormal liver functions. The majority of patients are between ages of 40 and 60 years, with equal distribution between the sexes. The disease primarily affects Caucasians.

Relapsing polychondritis, as an idiopathic disorder, is a diagnosis of exclusion. In approximately one-third of published cases, RPC has been associated with Wegener's granulomatosis, RA, SLE, Sjögren's syndrome, ankylosing spondylitis, Reiter's syndrome, Behçet's disease, hypothyroidism, Graves' disease, chronic ulcerative colitis, cryptogenic cirrhosis, cryoglobulinemia, and hydralazine therapy. In many patients, these diseases precede the onset of polychondritis by months to years. Biopsy of affected cartilage is nondiagnostic; only nonspecific cartilaginous destruction is noted. There are no specific serologic or other tests to aid in the diagnosis. If three of the following six criteria are present in the proper clinical setting, then RPC can be suspected: auricular chondritis; nonerosive inflammatory polyarthritis; nasal chondritis; ocular inflammation (conjunctivitis, keratitis, scleritis, episcleritis, uveitis); laryngeal, tracheal, or bronchial chondritis; and cochlear or vestibular damage.

Pulmonary Disease

Recurrent inflammation of the nasal cartilage leads to structural damage and saddle-nose deformity. More than 50% of patients develop respiratory complications. Involvement of the laryngotracheal region portends poor prognosis. Airway pathology includes thickening of mucosa, loss of elasticity, and development of stenotic segments. When multiple cartilaginous segments become affected, expiratory collapse of the airway occurs (Fig. 17). The resultant weak cough, combined with recurrent infections because of the inability to clear mucus, may cause bronchiectasis. Flow–volume curves in patients with significant respiratory symptoms demonstrate the plateau patterns of maximal inspiratory or expiratory flows. Tracheal tomography and cine-computed tomography may provide further insight into the abnormal anatomy of the major airways. Bronchoscopy in more useful in assessing the dynamic function of the airways.

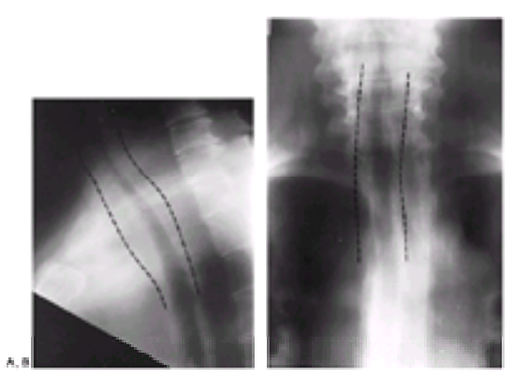

FIG. 17. Tomogram showing severely narrowed trachea as determined by the size of the air tracheogram in relapsing polychondritis. Anteroposterior view **(A)** and lateral view **(B)** delineate the normal dimensions of the trachea.

Treatment and Prognosis

Nonsteroidal antiinflammatory agents or corticosteroid (prednisolone, 30 to 60 mg/dl) often effectively suppresses acute manifestations. Refractory and recurrent disease has been treated with cyclophosphamide, 6-mercaptopurine, azathioprine, cyclosporine A, and dapsone. Major airway stenosis may require insertion of tracheobronchial prosthesis or resection if the strictures are localized. Tracheostomy may aggravate the expiratory collapse. Nasal continuous positive airway pressure or similar physiological stenting may help some patients.

Respiratory failure is the cause of death in up to 50% of patients. Among 112 patients in one report, the median survival period was 11 years from the time of diagnosis. Seven of 41 deaths were attributed primarily to pneumonia or laryngotracheal chondritis, and the 5- and 10-year probabilities of survival were 74% and 55%, respectively.

BIBLIOGRAPHY

Abu-Shakra M, Guillemin F, Lee P. Cancer in systemic sclerosis. *Arthritis Rheum* 1993;36:460–464. *A retrospective chart review of 248 patients with scleroderma who were followed up prospectively revealed that cancers developed in 18 patients (7.3%) during 2001 patient-years at risk; the most frequent types were cancers of the lung (seven patients) and breast (five patients). Older age at diagnosis of scleroderma was a significant risk factor for cancer. Lung cancer was associated with the presence of pulmonary fibrosis.*

Clinical-pathological evaluation and response to treatment. *Am J Respir Crit Care Med* 1996;154:794–799. *A study of 20 patients with Sjögren's syndrome observed pulmonary symptoms in 18 patients and nine patients exhibited restrictive lung dysfunction and interstitial involvement with follicular bronchiolitis, lymphoid interstitial pneumonia, and lung fibrosis with honeycombing. Azathioprine-based treatment favorably changed the outcome in this population.*

Devenyi K, Czirjak L. High resolution computed tomography for the evaluation of lung involvement in 101 patients with scleroderma. *Clin Rheumatol* 1995;14:633–640. *High-resolution computed tomography (HRCT) in 21 patients with various forms of scleroderma revealed ground glass attenuation, ground glass attenuation with fibrosis, fibrosis, subpleural and diffuse honeycombing, and normal findings. The majority of cases with extensive honeycombing of the lungs had anti-Scl-70 autoantibody.*

Fenlon HM, Doran M, Sant SM, Breatnach E. High-resolution chest CT in systemic lupus erythematosus. *Am J Roentgenol* 1996;166:301–307. *The results of this prospective study, the first to describe the high-resolution CT findings in systemic lupus erythematosus, suggest that airways disease, lymphadenopathy, and interstitial lung disease are common thoracic manifestations of systemic lupus erythematosus, whereas pleural abnormalities are less common than previously suggested.*

Frazier AR, Miller RD. Interstitial pneumonitis in association with polymyositis and dermatomyositis. *Chest* 1974;65:403–407. *A study of more than 300 patients with polymyositis-dermatomyositis observed pulmonary manifestations in 9% of patients. The main pulmonary abnormality was the interstitial pneumonitis.*

Gardiner P. Primary Sjögren's syndrome. *Baillieres Clin Rheumatol* 1993;7:59–77. *An exhaustive review of pulmonary complications in Sjögren's syndrome. The discussion estimates that significant abnormalities in pulmonary function are encountered in about 24% of patients with primary Sjögren's syndrome, and the most common cause of dyspnea is interstitial fibrosis, with a prevalence of around 8%.*

Gilligan DM, O'Connor CM, Ward K, Moloney D, Bresnihan B, FitzGerald MX. Bronchoalveolar lavage in patients with mild and severe rheumatoid lung disease. *Thorax* 1990;45:591–596. *A prospective evaluation of 93 patients with rheumatoid arthritis identified 14 patients with subclinical lung disease. An association between subclinical disease and smoking history was noted. Authors conclude that in patients with rheumatoid arthritis with evidence of subclinical pulmonary interstitial disease, bronchoalveolar lavage might be useful in identifying those who may require careful monitoring in the hope that early treatment will prevent severe fibrosis.*

Hansen LA, Prakash UBS, Colby TV. Pulmonary lymphoma in Sjögren's syndrome. *Mayo Clin Proc* 1989;64:920–931. *In this study of 50 patients with Sjögren's syndrome and associated lymphoma, ten had pulmonary involvement by lymphoma. Cough and slowly progressive dyspnea were the most common pulmonary symptoms. Lung biopsies revealed a spectrum of low- to high-grade lymphomas. Authors conclude that pulmonary involvement is common in patients with lymphoma associated with Sjögren's syndrome.*

Harrison NK, Myers AR, Corrin B, Soosay G, Dewar A, Black CM, DuBois RM, Turner-Warwick M. Structural features of interstitial lung disease in systemic sclerosis. *Am Rev Respir Dis* 1991;144:706–713. *This study describes the morphologic features of 49 open-lung biopsies from 34 patients with scleroderma and the clinical diagnosis of interstitial lung disease. Examination of lung tissue showed the earliest changes to include patchy lymphocyte and plasma cell infiltration of the alveolar walls, interstitial fibrosis, and increased macrophages but only occasional polymorphonuclear cells and lymphocytes in the alveolar spaces.*

Bronchiolitis in association with connective tissue disorders. *Clin Chest Med* 1993;14:653–666. *A comprehensive review of obliterative bronchiolitis that occurs in association with various connective tissue disorders. Discussion encompasses noninvasive and invasive diagnostic steps, role of surveillance, and response of bronchiolitis to therapy.*

Wiedemann HP, Matthay RA. Pulmonary manifestations of the collagen vascular disease. *Clin Chest Med* 1989;10:677–722. *An exhaustive review of pleuropulmonary complications in systemic lupus erythematosus, rheumatoid arthritis, scleroderma, dermatopolymyositis, Sjögren's syndrome, and other rheumatologic diseases.*

Worth H, Grahn S, Lakomek HJ, Bremer G, Goeckenjan G. Lung function disturbances versus respiratory muscle fatigue in patients with systemic lupus erythematosus. *Respiration* 1988;53:81–90. *This study of 23 consecutive patients with systemic lupus erythematosus and 17 healthy subjects assessed by electromyography for fatigue of respiratory and leg muscles. Routine lung functions were also measured. The authors conclude that the pattern of lung function data in patients was characteristic neither of lung restriction nor of airway obstruction and that respiratory muscle weakness can explain the decreases in TLC, VC, TGV, FEV_1, P_{Imax}, and P_{emax}.*

Yousem SA. The pulmonary pathologic manifestations of the CREST syndrome. *Hum Pathol* 1990;21:467–474. *Analysis of pulmonary histopathologic abnormalities in 17 patients with the CREST syndrome and related these alterations to clinical and functional abnormalities. Histologic abnormalities included pulmonary vascular changes, primarily intimal fibroelastosis, associated with and without pulmonary hypertension; a pattern of fibrosis indistinguishable from usual interstitial pneumonia; small airways disease; and mixtures of these three patterns. Five patients (29%) had clinical and morphologic pulmonary hypertension.*

Yousem SA, Colby TV, Carrington CB. Lung biopsy in rheumatoid arthritis. *Am Rev Respir Dis* 1985;131:770–777. *A report on 40 patients with rheumatoid arthritis who underwent lung biopsy revealed abnormalities including rheumatoid nodules, interstitial pneumonitis, bronchiolitis obliterans with organizing pneumonia, lymphoid hyperplasia, and cellular interstitial infiltrates.*

CHAPTER

54 Vasculitis Syndromes

Udaya B.S. Prakash

U.B.S. Prakash: Pulmonary and Critical Care Medicine, Mayo Medical School, Mayo Clinic, Rochester, Minnesota 55905.

INTRODUCTION

The primary vasculitis syndromes are a heterogeneous group of disorders of unknown or imprecisely determined etiology characterized by inflammation and necrosis of blood vessels. Depending on the type of vasculitis, the pathologic process may predominantly affect either the arteries or veins or both. Capillaritis is the term used to describe the pathologic process that primarily affects the capillaries. In some cases, capillaritis may be the sole pulmonary vascular manifestation of a systemic disorder. Occurrence of systemic necrotizing vasculitis in association with human parvovirus B19 and hepatitis B and C virus infections has prompted the speculation that certain vasculitic syndromes are infectious in etiology. Secondary vasculitides occur in association with collagenoses, malignancies, immunologic disorders, absence or deficiency of certain chemical mediators in the body, and mycoses, especially from *Aspergillus* and *Mucor* species. Occupational exposure has been suggested as an etiologic factor in Wegener's granulomatosis.

There is no clinically satisfactory classification of vasculitides. In the mid-1980s, the American College of Rheumatology (ACR) used preestablished criteria to determine the incidence of different vasculitis syndromes in 48 centers in the United States and Canada over a 5-year period. Among a total of 1020 patients encountered, only 807 patients met the established criteria for the diagnosis of several types of primary vasculitides. The majority of the remainder had vasculitis secondary to rheumatologic diseases. Indeed, many of the vasculitides are considered as part of the spectrum of collagenoses or rheumatologic diseases. As in the case of rheumatologic diseases, pulmonary complications are common in most of the primary vasculitides.

WEGENER'S GRANULOMATOSIS

Wegener's granulomatosis is a systemic vasculitis of arteries and veins and characterized by necrotizing granulomatous vasculitis of the upper and lower respiratory tract, glomerulonephritis, and variable degrees of small-vessel vasculitis. Wegener's granulomatosis is more likely a necrotizing granulomatous disorder than a true vasculitis. The Wegener's triad consists of necrotizing granulomas of the upper or lower respiratory tract or both, generalized focal necrotizing vasculitis of arteries and veins in lungs (Fig. 1) and other organs, and focal necrotizing glomerulitis. Although renal involvement with focal segmental glomerulonephritis remains a hallmark, the term *limited* Wegener's granulomatosis is used to describe Wegener's granulomatosis involving the respiratory system without glomerulonephritis. It should be noted, however, that many patients with the limited form of Wegener's granulomatosis develop renal involvement in the course of their disease, and renal biopsy shows typical morphology. Histologic features include discrete or confluent granulomatosis and necrotizing granuloma with vasculitis (Fig. 2). Fibrinoid necrosis, microabscesses, focal vasculitis, thrombosis, and fibrous obliteration of vascular lumen may be seen (Fig. 3 and Fig. 4). A report has described 16 cases of Wegener's granulomatosis in which bronchiolitis obliterans-organizing pneumonia (BOOP)-like fibrosis was the main histologic finding. Other atypical histologic variants have been recognized, including bronchocentric inflammation, a marked eosinophil infiltrate, alveolar hemorrhage, and capillaritis or interstitial fibrosis.

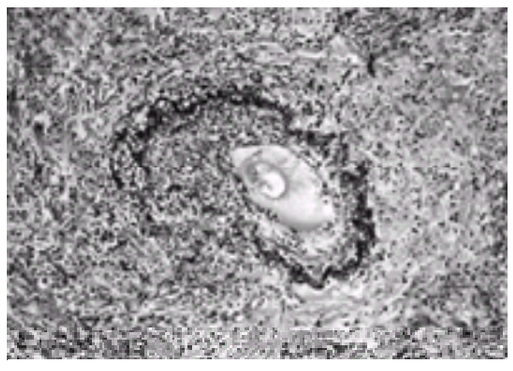

FIG. 1. Wegener's granulomatosis with vasculitis involving a medium-size vein. Inflammatory infiltrate is eccentric and segmental and is associated with destruction of the vascular elastica.

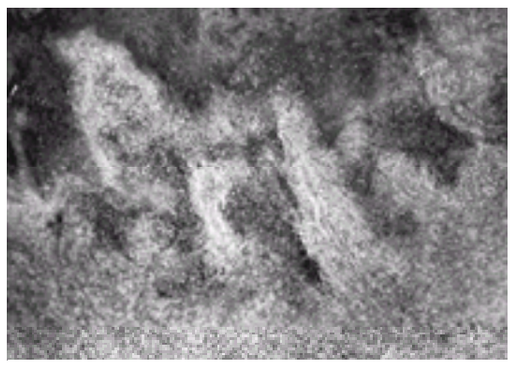

FIG. 2. Geographically dark irregular zones of necrosis in Wegener's granulomatosis are seen in a lung specimen.

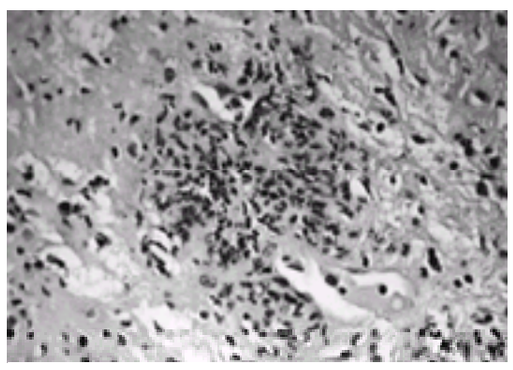

FIG. 3. An early microscopic granuloma in Wegener's granulomatosis manifests as a cluster of cells, often centered on a capillary, with central neutrophilia and surrounding histiocytes. Such a lesion ultimately would enlarge to form the characteristic geographic necrotic Wegener granulomas.

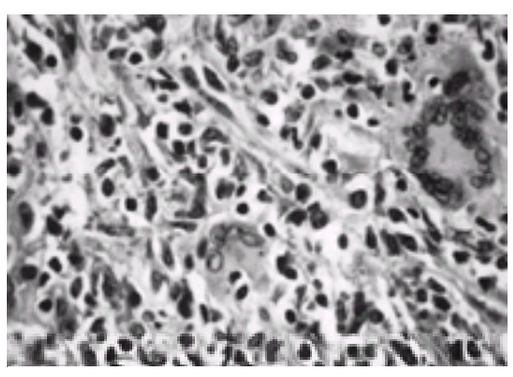

FIG. 4. Background inflammatory infiltrate in Wegener's granulomatosis includes mixed chronic inflammatory cells, usually with numerous plasma cells and occasional eosinophils as well as scattered giant cells. Sarcoid-like granulomas and nonnecrotizing granulomas are lacking.

The etiology of Wegener's granulomatosis is unknown. Occupational exposure has been suggested as an etiologic factor. When 16 cases with Wegener's granulomatosis with renal involvement were compared to 32 age- and sex-matched controls, a sevenfold risk for development of Wegener's granulomatosis was observed in those with history of inhalation of silica-containing compounds and grain dust. A Scandinavian study reported that heterozygotes for the PiZ variant of the a_1-antitrypsin gene have a sixfold risk of developing Wegener's granulomatosis relative to the general population.

The prevalence of Wegener's granulomatosis in the United States is approximately 3.0 per 100,000 persons. The annual incidence of Wegener's granulomatosis in the adult population in the United Kingdom is 8.5 per million. Between 1979 and 1988, 1784 death certificates in the United States listed Wegener's granulomatosis as a cause of death, and an estimated 10,771 hospitalizations included Wegener's granulomatosis among the discharge diagnoses. Some reports have noted a tendency for disease exacerbations during winter, but others have questioned the seasonality.

Among the 807 patients with various vasculitides studied by the ARC, 10.5% had Wegener's granulomatosis. The mean age at onset of symptoms of the disease was 45.2 years, the male-to-female ratio was 2:1, and 91% were Caucasians. Initial symptoms in Wegener's granulomatosis are nonspecific and may include fever, malaise, weight loss, arthralgias, and myalgias. The incidence of involvement of other organs is as follows: skin, 40% to 50%; eyes, 43%; arthralgias, 58%; arthritis, 28%; and neurologic involvement, 25%. The cardiovascular system also may be involved. Patients above the age of 60 years show a relatively low incidence of upper respiratory tract complaints but a high incidence (4.5-fold) of neurologic involvement.

Laboratory tests in patients with Wegener's granulomatosis may reveal mild to moderate normochromic normocytic anemia, mild leukocytosis, mild thrombocytosis, positive rheumatoid factor, and elevations of immunoglobulins IgG and IgA and circulating immune complexes. Highly elevated erythrocyte sedimentation rate (often exceeding 100 mm/hr) is one of the consistent findings. Peripheral blood eosinophilia is not a feature of Wegener's granulomatosis. All of these abnormalities are nonspecific except that they indicate a systemic inflammatory disease. Urinalysis is an important test because hematuria, proteinuria, and red cell casts are observed in 80% of patients.

The antineutrophil cytoplasmic antibodies (ANCA) are used to corroborate the diagnosis of Wegener's granulomatosis and other vasculitis syndromes. The ANCAs are perhaps involved in the pathogenesis of ANCA-associated diseases, and their presence in the blood is considered diagnostic of certain vasculitides. Two main patterns of ANCA are cytoplasmic ANCA (c-ANCA) and perinuclear ANCA (p-ANCA). Almost all c-ANCA are directed to proteinase 3 (Pr3), whereas myeloperoxidase (mpo) is the major target antigen of p-ANCA. The presence of c-ANCA and p-ANCA-mpo is strongly associated with systemic vasculitis, often involving the lungs. Indeed, a study of 220 patients who tested positive for ANCA estimated that the relative frequency of pulmonary involvement was 56% in patients who tested positive for c-ANCA and 33% in patients who tested positive for p-ANCA-mpo. Patients with ANCAs other than c-ANCA (Pr3) and p-ANCA-mpo usually have nonvasculitic diseases or secondary vasculitides such as rheumatoid arthritis, ulcerative colitis, Crohn's disease, autoimmune chronic active hepatitis, primary biliary cirrhosis, sclerosing cholangitis, celiac disease, dermatitis herpetiformis, and aspergillosis with oxalosis.

Cytoplasmic ANCA is highly specific and sensitive for Wegener's granulomatosis. It should be noted, however, that a positive c-ANCA without evidence of disease does not establish the diagnosis. Cytoplasmic ANCA is present in more than 90% of patients with systemic Wegener's granulomatosis, whereas in those with limited Wegener's granulomatosis, the positive rate is in the range of 67% to 86%. The overall sensitivity and specificity are 81% and 98%, respectively, for the diagnosis of Wegener's granulomatosis. However, one prospective study reported that the overall sensitivity of c-ANCA is only 28%, with an overall false-negative rate of 72%. The titers and sensitivity of c-ANCA correlate with activity of the disease, whereas the specificity of the test depends on the type of controls chosen for analysis. In active disease, the sensitivity and specificity are 91% and 98%, respectively, whereas in the inactive disease, the sensitivity and specificity are 63% and 99.5%, respectively. Thus, serial titers of c-ANCA can be used to monitor the disease and to plan long-term therapy. The following points regarding the relationship between Wegener's granulomatosis and c-ANCA are worth reiterating: (1) some patients with active disease show negative c-ANCA; (2) some patients show persistently positive c-ANCA results despite inactive disease or disease in remission; (3) c-ANCA titers may increase without evidence of increase in disease activity; indeed, fewer than 65% of patients show a concurrent change in c-ANCA titers with improvement or worsening of disease; and (4) c-ANCA is present in other diseases such as hepatitis C virus infection, some cases of microscopic polyangiitis, ulcerative colitis, and as a manifestation of sulfasalazine toxicity. A publication indicated that 44% of patients with hepatitis C virus infection tested positive for c-ANCA. The soluble serum thrombomodulin (sTM), a marker of endothelial cell injury, is reported to be a promising marker of disease activity and progression in active forms of limited and generalized Wegener's granulomatosis. The antiendothelial cell antibodies (AECA) also are reported to

correlate with disease activity. Further studies are needed to evaluate the clinical usefulness of these tests.

Acute Airways Disease

Symptoms referable to the head and neck are noted initially by more than 85% of patients with Wegener's granulomatosis. Rhinorrhea, purulent or bloody nasal discharge, nasal mucosal drying and crust formation, epistaxis, and otitis media are common. Deep facial pain from paranasal sinus involvement, nasal septal perforation, and ulceration of the vomer are important signs of Wegener's granulomatosis. The incidence of bacterial infection is increased in Wegener's granulomatosis as the result of a disruption in the mucosal barrier and failure to clear secretions. Superinfection, particularly from *Staphylococcus aureus,* is common. Other clinical signs include aphthous lesions of the nasal and oral mucosa and inflammation and destruction of the nasal cartilages leading to the saddle-nose deformity, which is usually a subacute or, more often, a chronic complication. Ulcerated lesions of the larynx and trachea are present in 30% of untreated cases. Hemoptysis in such cases may arise from mucosal ulcerations in the tracheobronchial tree, and bronchoscopic examination usually reveals extremely friable mucosa that bleeds profusely on instrumentation.

Pulmonary Parenchymal Disease

Although only one-third of patients with Wegener's granulomatosis manifest symptoms of lower respiratory tract involvement, the lower respiratory tract is involved in nearly all patients. The term *limited* Wegener's granulomatosis has been applied to isolated involvement of the lower respiratory tract in the absence of renal disease. When lungs are affected, symptoms include hemoptysis, dyspnea, cough, and chest pain. Hemoptysis, the most common symptom, was noted in 98% of patients studied by the ARC. Overall, pulmonary involvement was seen in 94%, paranasal disease in 91%, and nasal and pharyngeal involvement in 64% of patients.

Chest pain, which also is common, may be caused by pleural effusion, which is described in 5% to 55% of cases of Wegener's granulomatosis. The clinical presentation can vary from subacute nonspecific respiratory illness to rapidly progressive respiratory failure. Pulmonary symptoms are almost always associated with chest roentgenographic abnormalities. The ACR study noted abnormal chest roentgenograms in 65% of patients. An analysis of 80 patients reported from three separate studies observed the following chest roentgenographic abnormalities: unilateral, 55%; bilateral, 45%; infiltrates, 63%; nodules, 31%; infiltrates with cavitation, 8%; and nodules with cavitation, 10%. The nodules usually are rounded, range from a few millimeters to several centimeters in diameter, and commonly are bilateral (Fig. 5). One-third contain cavities, which are irregular in outline, thick-walled, and possess a shaggy inner lining (Fig. 6). Solitary nodules occur in 30% to 40% of patients with Wegener's granulomatosis. Unusual manifestations of the disease include diffuse pulmonary infiltrates (Fig. 7), lymphadenopathy, pneumonic infiltrates, lobar consolidation, and pleural effusions. Pure interstitial infiltrates are uncommon. Diffuse alveolar infiltrates may indicate alveolar hemorrhage.

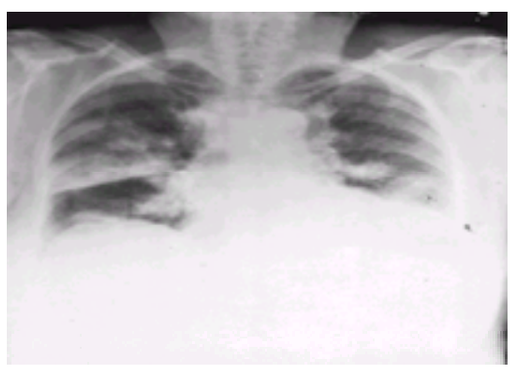

FIG. 5. Bilateral multiple nodular as well as mass-like lesions in Wegener's granulomatosis.

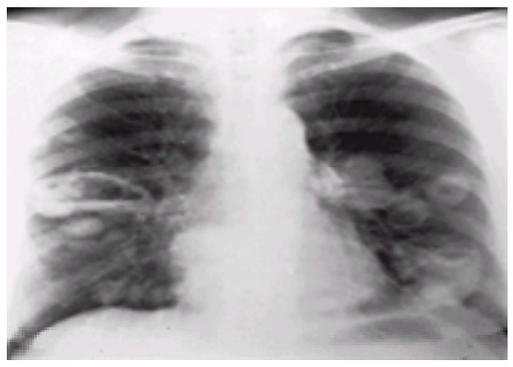

FIG. 6. Bilateral multiple cavitated nodules of various sizes in Wegener's granulomatosis.

FIG. 7. Diffuse micronodular infiltrates in Wegener's granulomatosis.

Before the diagnosis of Wegener's granulomatosis can be firmly established, vasculitis secondary to infectious processes and collagenoses must be excluded. Mycobacteria, fungi, and helminths can cause systemic illness, pulmonary infiltrates, and histologic evidence of granulomatous vasculitis. The ACR classification criteria for Wegener's granulomatosis included four features: nasal inflammation, abnormal chest roentgenogram, abnormal urinary sediment, and granulomatous inflammation on biopsy. However, in the absence of biopsy, hemoptysis was used as a surrogate criterion based on the high incidence (98%) of hemoptysis. Currently, the diagnosis should be based on clinical features, the presence of c-ANCA (Pr3), exclusion of other causes of vasculitis, and biopsy if the diagnosis remains doubtful.

A study of the histologic features in 87 open-lung biopsies from 67 patients (72% of whom had classic Wegener's granulomatosis with renal involvement and 28% of whom had limited disease) yielded the following findings: interstitial fibrosis in 26%; alveolar hemorrhage in 49%; tissue eosinophilia in 100%; organizing intraluminal fibrosis in 70%; endogenous lipoid pneumonia in 59%; lymphoid aggregates in 37%; and a variety of bronchial or bronchiolar lesions including acute and chronic bronchiolitis in 51% and 64%, respectively, follicular bronchiolitis in 28%, and bronchiolitis obliterans in 31%. As noted above, bronchiolitis obliterans-organizing pneumonitis (BOOP) can be the predominant feature.

Alveolar Hemorrhage

Wegener's granulomatosis is an important cause of alveolar hemorrhage syndromes (see Chapter 57). Massive pulmonary alveolar hemorrhage is uncommon. However, it can be the presenting and life-threatening feature of Wegener's granulomatosis. Diffuse pulmonary hemorrhage from necrotizing capillaritis is seen in 5% to

45% of biopsy or necropsy cases. However, diffuse pulmonary hemorrhage is the dominant pathologic finding in fewer than 10% of all specimens. Diffuse alveolar hemorrhage has been noted in 49% of 87 open-lung biopsies from 67 patients. The alveolar hemorrhage occurs more frequently in patients with rapidly progressive glomerulonephritis and renal failure. Upper airway disease is uncommon in these patients. Patients who develop diffuse alveolar hemorrhage exhibit a more fulminant course with an acute mortality of 65%. In patients with active Wegener's granulomatosis who test positive for c-ANCA, renal disease may follow an aggressive course. In the presence of renal dysfunction and urinary sediment abnormalities, differentiating Wegener's granulomatosis from Goodpasture's syndrome (antiglomerular antibody disease) becomes difficult. Biopsy and special immunofluorescent studies may be necessary to establish the diagnosis.

Tracheobronchial Stenosis

Stenosis of major airways is a common complication of Wegener's granulomatosis. Subglottic stenosis is seen in 5% to 8% of treated patients, whereas benign-appearing stenoses of the tracheobronchial tree are more likely in chronic cases and in patients whose disease is stable. In a report on 189 patients studied by the NIH, 43 developed subglottic stenosis; this complication was diagnosed in the absence of other features of active disease in the airways, although the airway problems began while the patients were receiving systemic immunosuppressive therapy for disease activity involving other sites. Tracheostomy was required in ten of 18 patients who were treated with systemic immunosuppressive therapy. In another study of 51 patients with Wegener's granulomatosis, 30 (59%) had endobronchial abnormalities. They were caused by subglottic stenosis in five (17%), ulcerating tracheobronchitis with or without inflammatory pseudotumors in 18 (60%), tracheal or bronchial stenosis without inflammation in four (13%), and hemorrhage without identifiable source in two (4%) patients.

The symptoms tend to be insidious in onset. Pulmonary function tests, particularly inspiratory and expiratory flow–volume loops, may aid in assessing the impairment of the upper airway as well as in the follow-up of these patients. Bronchoscopy is invaluable in the assessment and treatment of airway lesions.

Treatment and Prognosis

Corticosteroids administered in combination with cyclophosphamide result in complete remission in more than 90% of patients. The usual dosage of these is up to 2 mg/kg/day of each orally. In milder cases, corticosteroids alone may be sufficient, although some believe this is inadequate. A report on high-dose prednisone and monthly intravenous cyclophosphamide therapy in 14 consecutive patients with active Wegener's granulomatosis noted long-term remission in 42% of patients. Some patients require prolonged treatment with smaller doses of corticosteroids or cyclophosphamide or both. A prospective study of 43 patients showed that only 42% of the patients showed complete or partial remission that lasted at least 6 months after cessation of pulse cyclophosphamide therapy and that pulse cyclophosphamide therapy is effective in patients with moderate disease activity and low titers of c-ANCA but of little benefit in patients with severe disease. Therefore, pulse cyclophosphamide should not be used as first-line therapy in patients with severe and rapidly progressing disease with high titers of c-ANCA. Refractory disease has been successfully treated in several cases using high-dose intravenous immunoglobulin. As observed earlier, limited Wegener's granulomatosis may not be a distinct entity because most patients with obvious respiratory involvement also have clinically undetectable renal lesions. Although the original description of the limited disease reported that these patients have an excellent prognosis, it is important to treat them aggressively.

Immunosuppression resulting from corticosteroid and cyclophosphamide therapy predisposes these patients to opportunistic infections. The overall incidence of *Pneumocystis carinii* pneumonia in these patients is approximately 6%. Cyclophosphamide predisposes to urologic complications, the most serious being transitional-cell carcinoma of bladder, which develops in 5% of patients. Those at risk are patients whose total cumulative cyclophosphamide exceeds 100 g and whose cumulative duration of therapy exceeds 2.7 years. Microscopic nonglomerular hematuria also is a significant risk factor for the development of bladder cancer. The estimated incidence of bladder cancer after the first exposure to cyclophosphamide is 5% at 10 years and 16% at 15 years.

Relapse of pulmonary Wegener's granulomatosis usually is associated with viral or bacterial infections. Respiratory infection, particularly from *Staphylococcus aureus,* is more common. Nasal carriage rate for this bacteria is higher in patients with Wegener's granulomatosis. If infections are not promptly treated or remain untreated, Wegener's granulomatosis may recur within 1 year. A prospective study has shown that a combination of trimethoprim, 160 mg/day, and sulfamethoxazole, 800 mg/day, is effective as a prophylactic drug to prevent relapse of Wegener's granulomatosis; 82% of treated patients remained in remission at 24 months compared with 60% in the placebo group. Furthermore, the treated patients had fewer respiratory infections. There were no differences in the titers of c-ANCA at any time. The prophylactic drug therapy had to be stopped in 20% of patients because of side effects. A prospective study in 72 patients reported that trimethoprim/sulfamethoxazole induced long-term remission in more than 50% of patients in the initial phase of disease; however, neither trimethoprim/sulfamethoxazole alone nor trimethoprim/sulfamethoxazole plus low-dose prednisone sustained remission in generalized disease. It appears that pregnancy may be a significant contributing factor to the relapse of Wegener's granulomatosis.

Stenosis of large airways may require various types of therapy. In the NIH study on 189 patients with Wegener's granulomatosis, 43 developed subglottic stenosis. Of the 20 patients who were treated with intratracheal dilation and glucocorticoid injection therapy, none required tracheostomy, and six with previous tracheostomies were decannulated. In a study of 51 patients with airway problems, bronchoscopic interventions included dilation by rigid bronchoscope, YAG-laser treatment, and placement of silastic airway stents; only the stents provided persistent airway patency.

Nd:YAG-laser therapy followed by stent dilation or bronchoscopic balloon dilation has been used to treat tracheal stenosis. The CO_2 laser can be used treat subglottic stenosis. Surgical resection and anastomosis of tracheal stenoses has been performed.

The American College of Rheumatology follow-up of 77 patients (over a 4.5-year period) with Wegener's granulomatosis noted 28 deaths; the standardized mortality ratios for women was 4.7, and that for men was 6.8. In a study that compared patients above the age of 60 years to those under this age, the older patients had a markedly higher mortality rate (54% versus 19%; $p < 0.01$); almost all deaths were caused by overwhelming infections.

MICROSCOPIC POLYANGIITIS

Microscopic polyangiitis or arteritis is a pauci-immune small-vessel systemic vasculitis associated with focal and segmental necrotizing glomerulonephritis without clinical or histologic evidence of granulomatosis, malignancy, or other small-vessel vasculitides. Microscopic polyangiitis is distinct from the classic polyarteritis nodosa, which typically affects medium-sized arteries. Pulmonary capillaritis is the most common lesion in microscopic polyangiitis but is absent in classic polyarteritis nodosa. Clinically, renal involvement is the major feature of microscopic polyangiitis and is characterized by rapidly progressive glomerulonephritis. Most of the patients have renal impairment at admission, and renal function deteriorates rapidly without therapy. Microscopic polyangiitis has been noted in approximately 50% of patients with necrotizing (pauci-immune) glomerulonephritis in combination with systemic small-vessel vasculitis but without granulomatous inflammation. Almost all patients are negative for hepatitis B virus surface antigen. Men are more frequently affected than women, and the median age of onset is 50 years. Most patients experience systemic symptoms. Lung involvement is common; pulmonary hemorrhage is observed in 12% to 29% and is an important contributory factor to morbidity and mortality. Microaneurysms, commonly present in polyarteritis nodosa, are rarely seen on visceral angiograms. Microscopic polyangiitis is part of a spectrum of systemic vasculitides. Differentiation between polyarteritis nodosa and microscopic polyangiitis should be based on clinical manifestations (especially lung and kidney involvement), biological signs (ANCA, infection by hepatitis B or C viruses), and angiographic data. Even though the absence of granulomatous reaction is one of the criteria for the diagnosis, an occasional patient develops changes typical of Wegener's granulomatosis. Like Wegener's granulomatosis, microscopic polyangiitis is considered a pauci-immune necrotizing vasculitis because the affected tissue specimens demonstrate normal immunofluorescence and show no evidence of circulating immune complexes.

The ANCAs are detected in 75% of patients with microscopic polyangiitis, and the majority of the ANCAs are of p-ANCA-mpo type. The p-ANCA-mpo is considered to play a role in the pathogenesis of microscopic polyangiitis. In a prospective study of 43 patients presenting with pulmonary hemorrhage, 33 underwent lung biopsies, and all 33 had pauci-immune capillaritis as the main morphologic substrate. Renal involvement (pauciimmune crescentic glomerulonephritis) was common. Of the 43 patients, 13 exhibited c-ANCA (Pr3) and 30 had p-ANCA-mpo. The p-ANCA-mpo was principally found in those patients with pulmonary capillaritis and microscopic polyangiitis. The c-ANCA (Pr3) was mainly detected in patients with alveolar capillaritis and a well-established diagnosis of Wegener's granulomatosis. The myeloperoxidase (mpo) specificity is usually not detected in diseases in which c-ANCA (Pr3) is positive unless the patient subsequently develops Wegener's granulomatosis. One-third of the patients with antiglomerular basement membrane disease (Goodpasture's syndrome) also test positive for p-ANCA-mpo. Patients with Goodpasture's syndrome who test positive for p-ANCA-mpo are more prone to develop fulminant pulmonary hemorrhage. Many patients with pulmonary capillaritis, described below, also may test positive for p-ANCA-mpo.

PULMONARY CAPILLARITIS

Pulmonary capillaritis is strictly a histologic diagnosis and denotes capillary inflammation as the sole or predominant pathologic feature. Classic histologic features include interstitial erythrocytes and/or hemosiderin, fibrinoid necrosis of capillary walls, intraalveolar septal capillary occlusion by fibrin thrombi, neutrophils, and nuclear dust in the interstitium and the adjacent alveoli, and fibrin clots attached to intraalveolar septa. Light microscopy shows extensive intraalveolar hemorrhage. Pulmonary capillaritis is not a single distinct entity, even though it may be the only pulmonary vascular feature of a systemic vasculitis. The major presenting manifestation of pulmonary capillaritis is diffuse alveolar hemorrhage. Not all patients with diffuse alveolar hemorrhage have pulmonary capillaritis. Pulmonary capillaritis has been identified in antiphospholipid antibody syndrome, Behçet's disease, Goodpasture's syndrome, microscopic polyangiitis, systemic lupus erythematosus, Wegener's

granulomatosis, IgA nephropathy, Henoch–Schönlein purpura, unclassified pulmonary–renal syndromes, and phenytoin toxicity. In a study on the histologic features of 25 open-lung biopsies and two autopsy cases from 13 patients with c-ANCA (Pr3) and 14 patients with p-ANCA-mpo, capillaritis was the most common vascular lesion, noted in 63%, and was found with similar frequency in patients with c-ANCA and p-ANCA-mpo. Pulmonary capillaritis is present in up to 40% of patients with Wegener's granulomatosis. It is seldom the only abnormality in Wegener's granulomatosis.

CHURG–STRAUSS SYNDROME

Churg–Strauss syndrome, also known as allergic granulomatosis and angiitis, is separate from hypersensitivity vasculitis and polyarteritis nodosa. Significant confusion exists in the definition of this syndrome. The original report described 13 cases of severe asthma with a strikingly uniform clinical picture including fever, hypereosinophilia, and vascular abnormality in various organ systems. The records of 11 patients who died were located through autopsy files, and in all 11 the original histologic diagnosis was polyarteritis nodosa. In 1981, the syndrome was redefined to include eosinophilic pneumonitis, eosinophilic nonnecrotizing angiitis, bronchocentric granulomatosis, allergic granuloma, and necrotizing angiitis. Nevertheless, Churg-Strauss syndrome is characterized by some as an overlap syndrome that includes hypereosinophilic disease (Löffler's syndrome), systemic vasculitides (polyarteritis nodosa and hypersensitivity vasculitis), and Wegener's granulomatosis. In many patients, the clinical and pathologic features overlap those of other systemic vasculitides. The confusion is further exacerbated by the associations, made in the published literature, among Churg-Strauss syndrome and bacterial endocarditis, chronic active hepatitis, leukemia, lymphoma, myeloma, rheumatoid arthritis, systemic lupus erythematosus, and ulcerative colitis.

Churg-Strauss syndrome is an uncommon disease. In the ACR study of 807 patients with various vasculitides, Churg-Strauss syndrome constituted only 2.5% of cases. At a large tertiary medical center, only 30 cases were identified between 1950 and 1974.

The two diagnostically essential lesions of Churg-Strauss syndrome are granulomatous or nongranulomatous angiitis and extravascular necrotizing granulomas, usually with eosinophilic infiltrates. The angiitis is disseminated and involves pulmonary and systemic arteries and veins (Fig. 8). Unlike Wegener's granulomatosis, extrapulmonary lesions are found more commonly in the gastrointestinal tract, spleen, and heart than in the kidney. Thus, renal failure is rarely seen in Churg-Strauss syndrome. Other characteristic features include pulmonary and systemic vasculitis, extravascular granulomas, and eosinophilia occurring almost exclusively in patients with asthma or a history of allergy. The limited Churg-Strauss syndrome occurs in isolated organs or tissues and in some patients with collagenoses or autoimmune disorders. The Churg-Strauss granulomas of cutaneous and subcutaneous tissues lack diagnostic specificity because approximately 50% of these lesions occur in systemic diseases other than Churg-Strauss syndrome. Hypereosinophilia in peripheral blood and elevation of serum IgE are common.

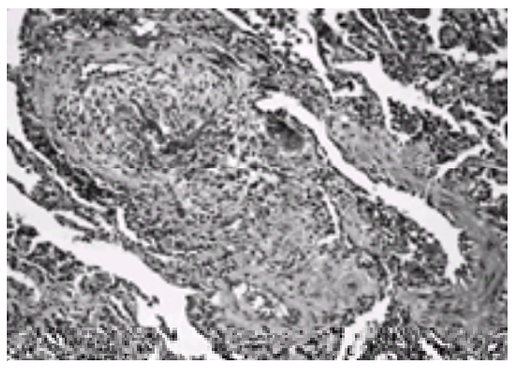

FIG. 8. Churg–Strauss syndrome involving the lung shows mixed inflammatory infiltrates including occasional giant cells *(upper center)* as well as a necrotic granuloma with central eosinophilic debris involving a vessel wall *(upper left).*

Upper Airways Disease

The 20 patients studied by the ACR had a mean age of 50 years at the onset of Churg-Strauss syndrome. Nasal symptoms such as allergic rhinitis, nasal polyps, nasal mucosal crusting, and septal perforation are present in more than 70% of patients. Nasal polyps are the major clinical finding. All 20 patients in the ACR study had chronic paranasal sinus pain or tenderness, 18 had seasonal allergy, and 14 had opacification of paranasal sinuses. In contrast to Wegener's granulomatosis, major airway involvement is seldom seen in Churg-Strauss syndrome.

Pulmonary Disease

The major pulmonary symptom in Churg-Strauss syndrome is related to underlying asthma, which is believed to be present in all patients, although the syndrome has been described in the absence of asthma in a 38-year-old man. In the ACR report on 20 patients, 19 had asthma, and all had transitory pulmonary infiltrates on the chest roentgenogram, peripheral blood eosinophilia, and mononeuritis or polyneuritis multiplex. The 15 patients, among 30 patients reported in one series, who died from Churg-Strauss syndrome had asthma for a mean interval of only 3 years before the onset of vasculitis; the mean duration of asthma among the remaining 15 survivors was 13 years. A phasic pattern of Churg-Strauss syndrome has been described, beginning with allergic rhinitis, evolving into asthma, followed by peripheral blood eosinophilia and eosinophilic tissue infiltrates, and ultimately developing to vasculitis.

In one study of 154 patients, 84 of whom were male, the mean age was 28 years at the onset of allergic rhinitis, 35 years at the onset of asthma, and 38 years when vasculitis was diagnosed. The mean peak eosinophil count was 12.9×10^9/L. Anemia was present in 83%, granulomas in 40%, tissue eosinophilia in approximately 50%, and vasculitis in more than 70%. The patients surviving longer than 1 year had a mean of 6.6 years interval between the onset of asthma and vasculitis. Whereas those who died within 1 year of onset of vasculitis had a mean interval of 4.2 years. Respiratory failure was the cause of death in 2%; 8% died from status asthmaticus. The main causes of mortality were heart failure (48%), renal failure (18%), cerebral hemorrhage (16%), and gastrointestinal hemorrhage (8%). Massive pulmonary alveolar hemorrhage, although rare, has been described in Churg-Strauss syndrome. Bronchoalveolar lavage in untreated patients has shown a high percentage of eosinophils, even though no significant correlation could be established between these results and clinical data, of pulmonary function abnormalities.

Chest roentgenographic abnormalities are present in more than 60% of patients. The findings may include patchy and occasionally diffuse alveolar–interstitial infiltrates in the perihilar area with a propensity to occur in the upper two-thirds of the lung fields (Fig. 9). Areas of cavitation rarely occur. Nodular changes seen in Wegener's granulomatosis are uncommon in Churg-Strauss syndrome, though pleural effusion can occur.

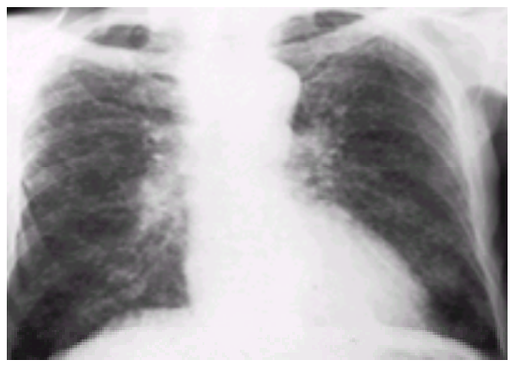

FIG. 9. Diffuse fine nodular infiltrates in Churg–Strauss syndrome. Note the relative sparing of lower lung zones and the hyperinflation from asthma.

Treatment and Prognosis

None of the 20 patients described in the ACR report died from Churg-Strauss syndrome. Dramatic response is usual following high-dose systemic corticosteroid

therapy, which should be instituted as soon as the diagnosis is made. In refractory cases, therapy using high doses of intravenous immunoglobulin has been shown to be successful.

GIANT-CELL ARTERITIS

Giant-cell arteritis, also known as *temporal arteritis, cranial arteritis,* and *granulomatous arteritis,* was the most common form of vasculitis, observed in 26.5% of 807 patients with various types of vasculitides studied by the ACR. Giant-cell arteritis is a vasculitis of unknown etiology, and, although morphologic findings are variable, the characteristic findings consist of lymphocytic infiltration with fragmentation of the internal elastic lamina, granulomatous inflammation, histiocytes, and multinucleate giant cells. The classic pathologic features of giant-cell arteritis are seen in approximately 60% of temporal artery biopsies. Although giant-cell arteritis has been described in association with polymyalgia rheumatica, the relationship between these two entities remains uncertain. Giant-cell arteritis usually affects middle-aged or older persons. There has been an increase in the annual incidence of giant-cell arteritis, with rates of 24.1 cases per 100,000 persons per year reported in the mid-1980s.

The onset of arteritis and blindness may be sudden, but usually the clinical illness has a gradual onset, with the development of nonspecific systemic symptoms such as low-grade fever, malaise, and weight loss. Headache, variable but often severe, is the most common symptom in giant-cell arteritis. The generalized symptoms may be followed by more specific symptoms such as jaw claudication and sudden loss of vision. Amaurosis fugax is observed in 20% and visual loss in 10% of cases. There are no specific laboratory tests available to diagnose giant-cell arteritis, though a moderate elevation of erythrocyte sedimentation rate is common. Overlapping features of giant-cell arteritis and Wegener's granulomatosis occur in some patients.

Pulmonary Involvement

Pulmonary complications of giant-cell arteritis were first recognized in 1984, when a report described 16 patients with giant-cell arteritis and observed that 9% of them had prominent respiratory tract symptoms. The presenting symptoms originated from the respiratory tract in 4%, and the respiratory symptoms, which included cough, sore throat, and hoarseness, were the initial findings in ten patients and resolved quickly when corticosteroids were given. A population-based study of 94 patients with giant-cell arteritis noted respiratory symptoms in 30%. With the progressive increase in the population of the elderly, giant-cell arteritis is an important diagnosis in any older patient with a new cough or throat pain without obvious cause.

Isolated small airways disease has been detected in 46% of patients with giant-cell arteritis, but the abnormalities have not been significantly different from those of the controls; chest roentgenograms in those with abnormal pulmonary function tests have been normal. However, pulmonary nodules, interstitial infiltrates, and occlusion and aneurysms of the pulmonary artery have been described. Multinodular pulmonary lesions and a diffuse interstitial pattern have resolved following corticosteroid therapy. Publications have included individual case reports of giant-cell arteritis in association with asthma, eosinophilic interstitial infiltrates, small lung nodules, pulmonary vascular disease, and focal necrosis as well as granulomatous inflammation of large and medium pulmonary arteries, as well as giant-cell arteritis limited to large pulmonary arteries. Pleural effusion has been described in a patient as the presenting manifestation of giant-cell arteritis.

Treatment and Prognosis

Virtually all patients respond favorably to systemic corticosteroids. Uniform resolution of pulmonary complications are reported following corticosteroid therapy among the patients in the literature just cited.

BEHÇET'S DISEASE

Behçet's disease is a chronic, relapsing multisystemic inflammatory disorder characterized by aphthous stomatitis along with two or more of the following: aphthous genital ulcerations, uveitis, cutaneous nodules or pustules, synovitis, or meningoencephalitis. Major and minor diagnostic criteria have been established. The prevalence rates in Japan (1:16,000) are approximately equivalent to those in the United States (1:20,000). However, the disease runs a more severe course in the Japanese and in patients from the eastern Mediterranean. HLA-B5 and its subtype B51 are three to six times more common, and the presence of B51 antigen indicates a severe course.

Histologic examination of mucocutaneous lesions is nonspecific. When present, the vasculitic lesions may exhibit varying degrees of severity with lymphocytic and plasma cell infiltration and deposition of IgM and C3 in the dermal vessels. Any large or small artery, vein, or organ may be involved in an unpredictable combination. Occlusion of major vessels and aneurysms occurs in 10% to 37% of patients. Thrombosis of superficial and deep veins of both upper and lower extremities and superior and inferior vena cavae develops in 7% to 37% of patients. Renal involvement is uncommon.

Pulmonary Involvement

The most serious respiratory complication is the occurrence of massive hemoptysis. An earlier review of the literature noted pulmonary involvement in only 13 patients, four of whom developed massive hemoptysis. Another report noted a definite clinical pattern of hemoptysis, fever, chest pain, and dyspnea in all 28 patients. Lung involvement was characteristically associated with active disease at other sites, and patients often had hemoptysis. Thrombophlebitis and hemoptysis were more common in men. Serious hemoptysis was common, initially responsive to corticosteroid therapy, showed a propensity to recur, and was the cause of death in 39%; and all deaths from hemoptysis occurred within 6 years of the onset of disease.

Another report on 49 patients with respiratory involvement noted that recurrent dyspnea, cough, chest pain, and hemoptysis were the primary clinical signs, particularly in young men, and appeared 3.6 years after the initial presentation of Behçet's disease. Fever, elevated erythrocyte sedimentation rate, and anemia were common, and chest roentgenograms demonstrated pulmonary infiltrates, pleural effusions, and prominent pulmonary arteries (Fig. 10). Aneurysms of the pulmonary artery were detected in 7 of 13 patients who underwent angiography.

FIG. 10. Behçet's disease showing loss of lung volume on the right as a result of right lower lobectomy to treat a bronchoarterial fistula that caused massive hemoptysis. Small infiltrates seen in both lungs were caused by minor intraalveolar bleeding.

A report on Behçet's disease in 111 patients from Saudi Arabia revealed a male-to-female ratio of 3.4:1, a mean age of 29 years, oral ulcer in all patients, genital ulcer in 87%, ocular involvement in 65%, pleuropulmonary manifestations in 16%, deep venous thrombosis in 25%, and arterial thrombosis and aneurysm in 18%. Another publication on 12 patients with Behçet's disease reported that the chief complaint was hemoptysis of varying degree in 11 of the 12 patients. Chest roentgenographic abnormalities included unilateral hilar enlargements, elevated diaphragm, horizontally or obliquely oriented linear opacities, diffuse ill-defined infiltrates in the upper and lower zones, wedge-shaped peripheral opacities, and bilateral pleural effusions. Computed tomography of the thorax in nine patients with Behçet's disease and pulmonary involvement showed aneurysms, narrowing, and cutoffs of the main, lobar, segmental, or peripheral branches of the pulmonary artery and irregular configuration of other pulmonary vessels. Pulmonary angiography revealed amputation of branches of the pulmonary artery and aneurysmal dilations.

Pathologic analysis of lung tissue has shown vasculitis of pulmonary vessels of various sizes, thrombosis, pulmonary embolism, destruction of the elastic laminae, aneurysms, aphthous lesions of the tracheobronchial tree, and arterial–bronchial fistulae. Other abnormalities described include mucoid degeneration and intimal thickening of larger elastic pulmonary arteries, with medial hyperplasia, intimal fibroplasia, and angiomatoid lesions in muscular pulmonary arteries. Recurrent pneumonia and bronchial obstruction from mucosal involvement have also been reported. Immunopathologic studies indicate that pulmonary vasculitis is a result of

circulating immune complexes.

Aneurysms of the pulmonary artery communicating with the bronchial tree (bronchovascular anastomosis) should be considered in patients with Behçet's disease and hemoptysis. Because of the high incidence of deep vein thrombosis of the extremities and the vena cavae, pulmonary embolism commonly occurs in these patients. Ventilation-perfusion scans are misleading, and anticoagulant therapy for presumed pulmonary embolism can be catastrophic. Thrombolytic therapy, however, has been used with success. Even though pulmonary angiography is diagnostic, it has been stated that the chest roentgenograph is the best diagnostic method for evaluating thoracic involvement in Behçet's disease. Because aneurysms develop at the arterial puncture sites and veins become quickly thrombosed after injection of contrast material, angiography and venography should be avoided whenever possible. Computed tomography and magnetic resonance imaging are less invasive and safer in the detection of pulmonary artery aneurysms.

Chest roentgenograms may show patchy interstitial infiltrates, rounded opacities, and lobar consolidations. Cavitation and pleural involvement are uncommon. Proximal perihilar densities or opacities usually represent the lobular or segmental pulmonary artery aneurysms. Tuberculosis has been reported in patients with Behçet's disease.

Treatment and Prognosis

Corticosteroids are palliative. However, sudden deaths in corticosteroid-treated patients have indicated that corticosteroid alone may be inadequate. Drugs such as colchicine, chlorambucil, methotrexate, and azathioprine may be needed for chronic therapy. Anticoagulant therapy should be avoided in the presence of pulmonary arteritis and fistula, even though successful use of a thrombolytic drug has been reported in patients with thrombotic complications. The prognosis is poor in those who develop significant hemoptysis or diffuse pulmonary infiltrates. A review of 49 patients with respiratory involvement from Behçet's disease recorded 16 deaths, 15 from fatal pulmonary hemorrhage; 80% died within 2 years after the onset of lung disease.

TAKAYASU'S ARTERITIS

Takayasu's arteritis, also described as *pulseless disease, aortic arch syndrome,* or *reversed coarctation,* is a chronic inflammatory disease of unknown etiology that primarily affects the aorta and its major branches (including the proximal coronary arteries and renal arteries) and the elastic pulmonary arteries. Among the 807 patients with various vasculitides studied by the ACR, 7.8% met the criteria for Takayasu's arteritis.

The disease primarily occurs in young adults of Asian descent, although it has been described in the population in the West. The female-to-male ratio is 8.5:1, and 80% of patients are between 11 and 30 years of age. Pulseless disease and aortic arch syndrome are classic manifestations, but claudication and renovascular hypertension may be the more disabling complications of the disease. Initial or acute clinical features of Takayasu's arteritis include fever, malaise, weight loss, arthralgias, and night sweats lasting for 4 to 6 weeks. Chronic disease is the result of ischemia of affected organs.

Pulmonary Involvement

Although clinically not apparent, involvement of the pulmonary artery is common. Up to 50% of all patients with Takayasu's arteritis develop lesions generally localized to medium and large pulmonary arteries. One report described three patients with disease involving the aorta and its major branches, and all exhibited a unique small pulmonary arteriopathy characterized by the deficiency of the outer media, with capillary ingrowth and thickened, fibrosed intima; other histologic features included granulomatous arteritis, transmural inflammation, patchy destruction of the medial musculoelastic lamellae, and lymphoplasmacytic infiltrates confined to the media with a variable number of giant cells. Such abnormalities lead to pulmonary arterial occlusion and stenoses, which are found in the majority of cases.

A retrospective study of 180 perfusion lung scans of 120 patients with Takayasu's arteritis showed abnormalities in 76% of the patients. Initial anomalies developed in the upper lobes, whereas the middle and lower lobes were affected at later stages of the disease. There was a poor correlation between these abnormalities and results of spirometric and arterial blood gas analysis. In another study, intravenous digital subtraction angiography in 42 patients with Takayasu's arteritis showed involvement of the pulmonary artery in 14% of patients, even though the respiratory problem was not suspected clinically in any patient and the chest roentgenograms were abnormal in only two. A comparison study of 59 patients with Takayasu's arteritis showed that although chest roentgenograms were abnormal in 68%, pulmonary angiography revealed arterial occlusions in 86%. Because the disorder affects women in childbearing age, it may be recognized the first time during pregnancy. Massive hemoptysis that occurred in a pregnant woman and led to the diagnosis of Takayasu's arteritis has been described.

There are case reports of diffuse unilateral involvement of the right pulmonary artery associated with fistulas between the right coronary artery and the right pulmonary artery or between the right bronchial artery and the right pulmonary artery, with pulmonary hypertension as the presenting manifestation, and interstitial pulmonary fibrosis.

Treatment and Prognosis

Corticosteroid therapy has resulted in symptomatic remission within days to weeks. Patients with significant vascular disease may require surgical treatment. Death is usually the result of vascular complications such as rupture of an aneurysm, myocardial infarction, congestive cardiac failure, or cerebrovascular accident. Pulmonary involvement signifies a poor prognosis.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura, also known as *anaphylactoid purpura* or *allergic purpura,* is a syndrome characterized by acute purpura, arthritis, colicky abdominal pain, and nephritis. Although Henoch-Schönlein purpura is much more common in children, an adult form of the disease exists. Among the 807 cases of various vasculitides studied by the ARC, Henoch-Schönlein purpura accounted for 10.5% of cases. The mean age of the patients was 17.4 years, and nearly two-thirds were younger than 16 years old. The male-to-female ratio was approximately 1.

Pathologic features include acute arteriolitis and venulitis in the superficial dermis and the bowel. Proliferative and necrotizing glomerulonephritis usually is mild. A similar type of renal lesion is seen in patients with infective endocarditis, Wegener's granulomatosis, systemic lupus erythematosus, Goodpasture's syndrome, and polyarteritis nodosa. Immunofluorescence microscopy exhibits large deposits of IgA in the skin and kidney, but the presence of this immunoglobulin as a diagnostic indicator is questionable. Adults with Henoch-Schönlein purpura exhibit elevations in serum IgA- and IgG-containing complexes.

Palpable purpura, usually distributed over the buttocks and lower extremities, and fever are generally the first signs of Henoch-Schönlein purpura. The purpura may precede, accompany, or follow arthralgias and abdominal colic. The triad of purpura, arthritis, and abdominal pain is present in approximately 80% of patients. Joint involvement is typically monoarticular and transient, involves large joints, and causes pain out of proportion to objective evidence of synovitis. Peritonitis and melena are common.

Pulmonary Involvement

Lung involvement is rare in Henoch-Schönlein purpura. Indeed, among the 85 cases of Henoch-Schönlein purpura studied by the ARC, not a single respiratory complication was described. However, several pulmonary complications occur including perihilar patchy opacities, reticulonodular changes, and pulmonary alveolar hemorrhage. Pulmonary hemorrhage in Henoch-Schönlein purpura carries a high mortality if it is not aggressively treated. A publication on four patients with Henoch-Schönlein purpura and pulmonary hemorrhage reported that three patients survived the episode, whereas three of the four cases reported earlier in the literature did not. Several adult cases of pulmonary hemorrhage with pulmonary capillaritis have been described.

Lung function tests in 29 children with HenochSchönlein purpura at the initial phase of the disease revealed a decrease in lung diffusing capacity for carbon monoxide in 28 patients. Lung volumes and blood gas values were normal. Slight roentgenologic signs of interstitial lung involvement were observed in 18 of 26 patients. The diminished lung diffusing capacity for carbon monoxide is probably related to alteration of the alveolar capillary membrane by circulating immune complexes.

Treatment and Prognosis

High-dose corticosteroid therapy (0.5 to 1.0 mg/kg per day) results in full recovery. However, relapse of purpura, abdominal pain, and arthritis may occur for 3 to 6 weeks before the disease resolves completely.

URTICARIAL VASCULITIS

Urticarial vasculitis is a systemic disorder characterized by urticarial wheals or papules similar to those in the usual urticaria, with itching and arthralgias, in 60% of cases, arthritis in 28%, abdominal pain in 25%, and glomerulonephritis in 5%. Angioedema, fever, uveitis, episcleritis, and seizures also may occur. Urticarial vasculitis with or without hypocomplementemia occurs in systemic lupus erythematosus. The erythrocyte sedimentation rate is elevated in 66% of patients, and hypocomplementemia is seen in 38%. The hypocomplementemic form of urticarial vasculitis has been associated with pulmonary complications.

Vasculitis of the pulmonary vasculature is not characteristic of this disease. However, obstructive pulmonary disease occurs in many of these patients. Airways disease results from a combination of smoking and an immunologic process that has yet not been identified. Up to 62% of patients with hypocomplementemic urticarial vasculitis develop chronic obstructive pulmonary disease, with tobacco smoking contributing to rapid progression of the disease. A publication reported that among 17 patients with hypocomplementemic vasculitis, 11 had dyspnea, and all dyspneic patients had moderate to severe airflow obstruction, which progressed in all 11 and subsequently improved in only one. Six of the 11 patients died of respiratory failure, one underwent lung transplantation, and three of the remaining four had moderately severe to life-threatening respiratory insufficiency. Treatment did not appear to alter the progression of obstructive lung disease. In contrast, renal insufficiency in two patients improved with treatment. Another report on 16 patients with hypocomplementemic urticarial vasculitis reported severe obstructive airways disease in eight of ten smokers studied, one of whom died of lung disease. Severe obstructive pulmonary disease developed in three patients at a young age after smoking cigarettes for a relatively low number of pack-years. A review of 72 cases of biopsy-proved urticarial vasculitis revealed that 32% had hypocomplementemia and 21% had obstructive lung disease. Case reports of bilateral pleural effusion and pulmonary capillaritis characterized by repeated episodes of diffuse alveolar hemorrhage as well as progressive irreversible airway dysfunction have been published.

LEUKOCYTOCLASTIC VASCULITIS

Leukocytoclastic vasculitis is characterized by necrotizing vasculitis and fibrinoid necrosis of the vessel walls, with leukocytoclasis of the inflammatory cells in the wall of the vessel. Leukocytoclastic vasculitis may occur in association with inflammatory, autoimmune, and malignant disease. It commonly presents as palpable purpura.

Several respiratory complications have been described. Patchy pneumonitis secondary to biopsy-proved leukocytoclastic vasculitis of the pulmonary veins, manifested by hemoptysis and pleuritic chest pains, has been described in a patient who also exhibited obstructive airways disease.

MIXED CRYOGLOBULINEMIA

Mixed cryoglobulinemia is manifested by recurrent purpura, arthralgias, systemic involvement, and, frequently, elevated cryoglobulin and rheumatoid factor. Biopsy of vascular structures reveals findings similar to those in leukocytoclastic vasculitis. The most serious complication is glomerulonephritis caused by deposition of immune complexes. Lung function tests in 19 patients (17 of whom were female, with a mean age of 49.6 years) showed diminished diffusing capacity of lung for carbon monoxide and maximal expiratory flow at 50% of forced vital capacity, total lung capacity, and functional residual capacity. Respiratory complications described include bronchiectasis, pulmonary fibrosis, pulmonary insufficiency, and Sjögren's syndrome-like illness with lung involvement. Severe pulmonary hemorrhage also has been described in cryoglobulinemia.

Bronchoalveolar lavage and pulmonary function tests in 16 nonsmoking women with mixed cryoglobulinemia associated with hepatitis C virus, free of clinical pulmonary symptoms, and with normal chest roentgenograms showed a subclinical T-lymphocytic alveolitis without evidence of deterioration in lung function. No correlations between bronchoalveolar lavage results and pulmonary function tests were found; a 5-year follow-up of five patients did not demonstrate deterioration in lung function. Several reports have been published on the occurrence of diffuse pulmonary vasculitis with alveolar hemorrhage and bronchiolitis obliterans-organizing pneumonia in association with essential mixed cryoglobulinemia.

POLYARTERITIS NODOSA

Polyarteritis nodosa is characterized by a necrotizing arteritis of small and medium muscular arteries, affecting multiple organ systems. The ACR study of 807 patients with various vasculitic syndromes recorded polyarteritis in 14.6%. Differentiating polyarteritis nodosa from Churg-Strauss syndrome can be difficult. This confusion is accentuated by the fact that many reports include Churg-Strauss syndrome, classic polyarteritis nodosa, and other vasculitic syndromes under the umbrella of polyarteritis nodosa group of systemic vasculitides.

It is important to recognize that polyarteritis nodosa rarely involves the lungs. In the ACR study of 118 patients with polyarteritis nodosa, pulmonary complications were not observed in a single patient. The literature cites vasculitis in the bronchial and pulmonary vessels, but many of the patients exhibited granulomatous lesions with eosinophilic infiltrates, features more in accordance with the diagnosis of Churg–Strauss syndrome. A study published in 1993 on pathologic analysis of pulmonary diseases in ten autopsy cases of polyarteritis nodosa noted arteritis affecting bronchial arteries in seven patients and diffuse alveolar damage involving all lobes bilaterally in five patients. The diffuse alveolar damage was acute in two patients and organizing in three. Five patients died of respiratory failure resulting from diffuse alveolar damage. Anecdotal cases of pulmonary arterial involvement have been described.

EOSINOPHILIA-MYALGIA SYNDROME

The eosinophilia-myalgia syndrome is a multisystem inflammatory disease with characteristic features of myalgia and eosinophilia. This syndrome occurred in epidemic proportions in the United States during 1989, affecting more than 1500 persons and causing approximately 30 deaths. Cases of the eosinophilia-myalgia syndrome have been reported from Canada, Europe, and other countries.

Epidemiologic studies have demonstrated that the eosinophilia-myalgia syndrome is the result of ingestion of L-tryptophan, used by lay people as a remedy for insomnia, depression, premenstrual syndrome, and other health disorders. Several contaminants—3(phenylamino)alanine, 1,1'-ethylidenebis(tryptophan), and 3-anilino-L-alanine—involved in the manufacturing of L-tryptophan have been implicated as the causative agents of both the eosinophilia-myalgia syndrome and the Spanish toxic oil syndrome.

The clinical manifestations resemble those of the Spanish toxic oil syndrome, caused by ingestion of adulterated rapeseed oil. Symptoms and signs include myalgias, fatigue, muscle weakness, arthralgias, edema of the extremities, skin rash, oral and vaginal ulcers, scleroderma-like changes, fasciitis, ascending neuropathy, and profound eosinophilia.

Respiratory complications were observed in approximately 60% of patients with the eosinophilia-myalgia syndrome. Pulmonary manifestations included parenchymal lung infiltrates associated with severe respiratory distress and progressive hypoxemia, pleural effusion, diffuse bilateral reticulonodular infiltrates, and pulmonary hypertension. In a study of five cases of pathologically proved eosinophilia-myalgia syndrome, all patients were women ranging in age from 34 to 65 years, and all presented with pulmonary symptoms that began after 1 to 9 months of L-tryptophan therapy. Four patients exhibited peripheral eosinophilia and bilateral interstitial infiltrates (one had a normal chest roentgenogram). Lung specimens revealed vasculitis and perivasculitis associated with eosinophilia and mild interstitial pneumonitis. Clinical or morphologic evidence of pulmonary hypertension was noted in three, and one patient had follicular bronchiolitis. Whereas four patients responded promptly to discontinuation of Ltryptophan ingestion and systemic corticosteroids, one patient showed only minimal symptomatic improvement.

Other histologic changes described in the lungs of patients with the eosinophilia-myalgia syndrome have included alveolar exudate made up of eosinophils and histiocytes, changes characteristic of hypersensitivity pneumonitis, interstitial and perivascular infiltrates, and fibrointimal hyperplasia of small pulmonary vessels (Fig. 11).

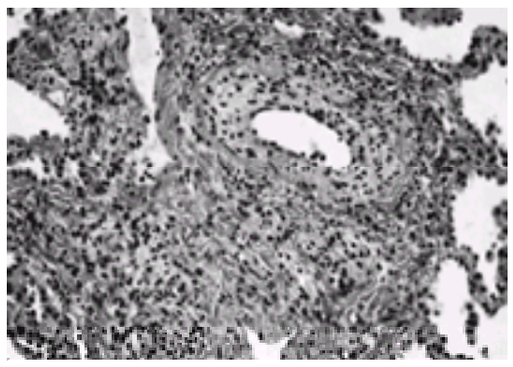

FIG. 11. Pulmonary involvement in L-tryptophan-induced eosinophilia-myalgia syndrome. A mixed inflammatory infiltrate involves a septal vein. There is marked intimal proliferation and infiltration by cells that include relatively numerous eosinophils.

SECONDARY VASCULITIS

Many of the rheumatologic diseases, discussed in Chapter 53, may exhibit secondary vasculitic processes in the organs involved. Infectious processes, particularly secondary to *Aspergillus* and *Mucor* species, invade vascular structures and produce secondary vasculitis. The role of hepatitis C virus in the causation of vasculitis is now well recognized. Certain drugs and chemicals also can induce vasculitis. Other uncommon secondary vasculitic entities include benign lymphocytic angiitis and granulomatosis, bronchocentric granulomatosis, and necrotizing sarcoid angiitis. Whether these are distinct entities or represent uncommon phases of the vasculitides discussed in this chapter is unclear.

Clinical and serologic findings in 18 patients. *Medicine* 1995;74:24–41. *A report on 18 patients with hypocomplementemic urticarial vasculitis and high incidences of angioedema, ocular inflammation, glomerulonephritis, and obstructive pulmonary disease. Lung biopsies showed severe pulmonary emphysema without vasculitis. Treatment did not appear to alter the progression of obstructive lung disease.*

CHAPTER

55 Immunodeficiency Diseases

Udaya B.S. Prakash

U.B.S. Prakash: Pulmonary and Critical Care Medicine, Mayo Medical School and Mayo Medical Center, Rochester, Minnesota 55905.

INTRODUCTION

Immunodeficiency diseases are encountered in different forms, often in association with other diseases. Disorders of immunodeficiency, whether total or partial, can be congenital or acquired. These disease states are the consequences of impaired function in one or more components of the immune system, including both B and T lymphocytes, phagocytes, and the complement system. Immunodeficiency can develop as a sequel of malignancy, long-term corticosteroid therapy, cytotoxic chemotherapy, malnutrition, or alteration of the helper-suppressor T-lymphocyte ratio as seen in the acquired immunodeficiency syndrome (AIDS). Because the clinical features of immunodeficiency states are not highly specific and vary from one entity to another, definitive diagnosis is often delayed. Normally, these immunodeficiency syndromes are recognized when a subject develops a predisposition to unusual or recurrent infections. The majority of these infections occur in the respiratory system and are the most common cause of morbidity and mortality.

In this chapter, immunodeficiency syndromes and etiologic and diagnostic evaluation of the immunocompromised patients including recipients of bone marrow and heart organ transplantations are discussed. Pulmonary complications of human immunodeficiency virus infection (HIV) are discussed in Chapter 26.

IMMUNODEFICIENCY SYNDROMES

X-Linked Agammaglobulinemia

Also known as Bruton's infantile agammaglobulinemia, X-linked agammaglobulinemia is a disease characterized by a disorder of B-lymphocyte maturation. As a result, the synthesis and secretion of immunoglobulins and antibodies are deficient or absent, leading to recurrent infections. T-lymphocyte function remains intact, and indeed, the number of T cells is usually increased. A diagnosis of X-linked agammaglobulinemia is considered if serum levels of IgG, IgA, and IgM are significantly below the 95% confidence limits for appropriate age- and sex-matched controls. The total immunoglobulin level in patients with X-linked agammaglobulinemia usually is less than 100 mg/dl.

Clinically, recurrent sinopulmonary infections, otitis, meningitis, and skin lesions (eczema) are encountered in infants between 4 and 6 months of age. Allergic rhinitis and asthma occur at a higher rate than in the normal population. Undue susceptibility to bacterial infections is seen, usually after the first year of life. An important clue to the diagnosis is a unique susceptibility to infection with encapsulated pyogenic organisms, including *Streptococcus pneumoniae, Streptococcus pyogenes, Hemophilus influenzae, Pseudomonas aeruginosa,* and staphylococci. This phenomenon probably reflects a requirement for specific opsonization of these bacteria before efficient phagocytic cell ingestion is possible. Recurrent purulent sinusitis, bronchitis, and pneumonia, if untreated, may develop into progressive bronchiectasis and secondary respiratory failure. Adults with the disease are specially prone to *Mycoplasma* infection of the respiratory tract. *Pneumocystis carinii* pneumonia, although rare in agammaglobulinemia, has been described in congenital agammaglobulinemia. There is no evidence of increased susceptibility to viral infections of the respiratory system, but these patients are prone to viral infections of the central nervous system. Restrictive lung disease and lymphocytic interstitial pneumonitis are the other long-term pulmonary complications.

In a multicenter study involving 96 patients (53 familial and 43 nonfamilial) with X-linked agammaglobulinemia, pulmonary infections were observed in 65%: pneumonitis in 56%, bronchitis in 9%, and bronchiolitis in 5%. Bacterial cultures of sputum were available for 33 patients with chronic or recurrent pneumonia; bacterial species isolated included *H. influenzae* in 82%, *S. aureus* in 27%, and *S. pneumoniae* in 21%. Chronic pulmonary disease was the most frequent long-term complication, occurring in 46% of all patients. The prevalence of lung disease was age-related, present in 13% of those younger than 10 years and 76% of those older than 20.

High-dose intravenous immunoglobulin therapy has been shown to prevent recurrent infections. A clinical evaluation of 10 patients with X-linked agammaglobulinemia followed for a mean of 12.5 years reported that most patients treated with intramuscular gamma globulin and long-term oral antibiotics had very few pneumonias.

Common Variable Immunodeficiency

Common variable immunodeficiency, also known as acquired agammaglobulinemia, is among the most frequently encountered primary immunodeficiency disorders. Genetic basis exists for this disorder because it more commonly occurs in first-degree relatives of patients with selective IgA deficiency. A primary defect in B-cell maturation is the problem. Most patients with this disorder have normal number of immunoglobulin-bearing B cells in their blood and lymphoid tissue but lack mature plasma cells. Depressed T-cell function has been noted. Serum levels of IgG are absent or low, and IgA and IgM are variably diminished; thus, antibody production is diminished. There is, however, a tendency to autoantibody formation. The role of immunologic defense mechanisms in the development of acute or recurrent or chronic sinusitis is obviously important, but the incidence of such immune problems is unknown. Common variable immunodeficiency has been known to be associated with thymoma, hemolytic anemia, gastric atrophy, achlorhydria, follicular lymphoid hyperplasia, celiac disease-like syndrome, and several other disorders.

Common variable immunodeficiency occurs in both sexes and usually presents in the second or third decade, although its onset may occur at any age. Pulmonary disease occurs more commonly and is more severe than in patients with X-linked agammaglobulinemia. Sinopulmonary infections begin in the second or third decade. Chronic complications include bronchitis, cystic bronchiectasis, patchy pulmonary fibrosis, and interstitial pneumonitis. Infections caused by encapsulated bacteria are more common. Bronchiectasis and obstructive airway disease occur in up to 40% of patients. Roentgenographic features may include atelectasis, bronchiectasis (Fig. 1), and homogeneous and heterogeneous segmental opacities. Patients with late-onset agammaglobulinemia and recurrent pulmonary infections have occasionally presented with pulmonary hypertrophic osteoarthropathy. In a review of patients who developed pneumonia or empyema as a result of infection with *Moraxella catarrhalis,* nearly one-third were found to have immunoglobulin abnormalities. Bronchiolitis obliterans with organizing pneumonitis (BOOP) and allergic

bronchopulmonary aspergillosis also are described in common-variable immunodeficiency.

FIG. 1. Bronchography demonstrating bronchiectasis of both lower lobes in a patient with acquired agamma-globulinemia.

A clinical evaluation of 12 patients with common-variable immunodeficiency followed for a mean of 10.5 years revealed that most patients treated with intramuscular g-globulin and long-term oral antibiotics had very few pneumonias.

Selective Immunoglobulin Deficiencies

Selective deficiencies of one or more, but not all, immunoglobulin subclasses are characterized as dysgamma-globulinemias. Patients with these disorders usually demonstrate normal total serum IgG concentrations. Thus, it is important to measure levels of IgG subclasses in patients suspected of having selective immunoglobulin deficiencies. It is also important to recognize that the majority of patients with selective deficiencies of IgG subclasses are asymptomatic, and routine administration of intravenous immunoglobulin therapy is not justified unless they are known to have clinical features of the disorder.

Immunoglobulin A deficiency (less than 10 mg/dl), whether isolated or in combination with deficiency of another Ig subclass, is the most commonly occurring immunoglobulin deficiency. The estimated incidence of selective IgA deficiency ranges from one in 333 to one in 1000, with most occurring sporadically, although some persons inherit it as an autosomal dominant or a recessive trait. Deficiency of IgA, combined with deficiencies of IgG_2 and IgG_4, increases the risk of recurrent respiratory infections. Bronchitis and bronchiectasis are associated with greater numbers of cells that produce IgA in the bronchi because cells that contain IgA_1 predominate in the major bronchi and the number of cells containing IgA_2 is higher in the bronchi than in nonmucosal lymphoid tissues. A study that evaluated 29 patients with IgA deficiency and recurrent upper and lower respiratory infections observed decreased levels of IgG_2 and IgG_3 in 21% of patients; low levels of IgG_2 and IgG_3 were also significantly related to abnormal lung functions. These studies suggest that there may be a causal relationship between low levels of IgG subclasses and deterioration in lung function, implying that patients with combined IgA and IgG subclass deficiencies may benefit from immunoglobulin prophylaxis. As is the case in common-variable immunodeficiency, selective IgA deficiency frequently exists with rheumatologic and collagen disorders including rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis, ankylosing spondylitis, thyroiditis, diabetes mellitus, hepatitis, drug toxicity, and a significant number of other disorders.

Respiratory complications usually are mild and include atopic asthma, repeated respiratory infections, bronchiectasis, sinusitis, and otitis media. Pulmonary hemosiderosis has been described in some patients. A prospective study of 43 children reported that the probability of developing asthma was much higher in those without any measurable IgA and elevated IgE. Variable deficiencies of IgG and IgA in children have been associated with lymphoid interstitial pneumonitis. The factors responsible for the B-lymphocyte dysfunction and lymphoid infiltrations in the pulmonary parenchyma are unknown.

Recurrent bacterial infections of the lungs and upper respiratory tract are common in these patients. Selective IgG subclass (IgG_1, IgG_2, IgG_3, and IgG_4) deficiencies predispose patients to recurrent infections of the ears, upper respiratory tract, and lungs. Encapsulated bacteria such as *S. pneumoniae* and *H. influenzae* are responsible. Deficiencies of IgG, especially subclasses IgG_2 and IgG_4 (often in combination with IgA) or IgG_4 alone, correlate well with upper respiratory tract infections and chronic bronchial inflammation that contribute to bronchiectasis. Asthma has been noted in some patients with this disorder. Deficiency of IgG_3 and poor response to pneumococcal antigen 7 were demonstrated in more than 50% of 61 pediatric patients with refractory sinusitis. Isolated IgG_4 deficiency appears to be associated with impaired respiratory tract defenses and may occur in the absence of an easily definable antibody deficiency state. Acquired hypogammaglobulinemia rarely is associated with obstructive lung disease, and the pathogenesis of lung disease may be related to an associated increase in elastase load and a reduction in protease inhibitor function.

Functional deficiency of IgG may come to light in patients who present with recurrent pulmonary infections, but such patients may have normal serum levels of IgG. Furthermore, combined deficiencies of IgG_2 subclass and IgG- and IgM-specific antibodies may be associated with normal serum immunoglobulin concentrations. For instance, IgG_2 contains an important group of antibodies against common bacteria such as *S. pneumoniae* and *H. influenzae,* and patients with this isolated deficiency may develop recurrent sinopulmonary infections despite normal serum levels of total IgG. Patients with community-acquired pneumonia of bacterial or unknown cause generally demonstrate decreased concentrations of serum IgG_2 subclass at the time of admission, after recovery, and 9 months later. In patients with recurrent lung infections and bronchiectasis who show normal serum concentrations of immunoglobulins, it is important to determine both IgG subclasses and antibody production because immunoglobulin replacement has been shown to be beneficial in these patients. Other functional deficiencies of IgG result from an absence of IgG antibody response to polysaccharide antigens and antibody deficiency because of IgG degradation, such as that found in cystic fibrosis. Immunoglobulin G subclass deficiencies, particularly IgG_1, appear to be related to long-term, low-dose corticosteroid therapy in patients with obstructive lung disease. After immunization with pneumococcal vaccine, the increases in serum concentrations of IgG subclass and antipneumococcal antibodies in patients do not differ from those in control subjects.

Familial deficiency of serum IgE, presumably an autosomal dominant trait with variable penetrance, associated with sinopulmonary infections has been described. Examination of sera from 23 family members, of whom 14 were symptomatic, revealed very low levels (less than 5 IU/ml) of serum IgE in 12 of the symptomatic group.

Selective IgM deficiency (less than 10 mg/dl) is a rare disorder. Respiratory complications described have included otitis, bronchiectasis, and lung infections caused by streptococci, mycobacteria, and other organisms. There is no specific therapy other than appropriate antimicrobial treatment of bacterial infections.

Hyperimmunoglobulinemia E

Hyperimmunoglobulinemia E, also known as Job's syndrome or Buckley's syndrome, is a rare disorder characterized by phagocyte dysfunction, high serum IgE (often above 4000 IU/ml) and IgD levels, poor antibody- and cell-mediated responses to new antigens, blood and sputum eosinophilia, and normal concentrations of IgG, IgA, and IgM. Both sexes are affected; an autosomal dominant form of inheritance has been suggested. More than 100 cases of this disorder have been described, mostly in young children. Severe and recurrent staphylococcal abscesses involving skin, lungs, and joints begin in infancy.

Clinically, the syndrome may include eczematoid dermatitis, dysmorphic syndrome with retarded growth, coarse facies, prognathism, osteogenesis imperfecta, and axial osteoporosis. Respiratory complications include sinusitis, pneumonia, and bronchiectasis caused by *S. aureus, S. pneumoniae,* gram-negative bacilli, *Candida albicans,* and *Aspergillus* species, pneumatoceles, and chronic dermatitis. Asthma has been reported in approximately 10% of patients. The frequency of pneumatoceles is remarkably high, and surgical therapy often is necessary (Fig. 2). The primary chest roentgenologic abnormalities include recurrent lung infiltrative process and pneumatoceles. Pneumothorax may occur occasionally.

FIG. 2. Hyperimmunoglobulinemia E syndrome (Job's syndrome) with left lung abscess caused by *Staphylococcus aureus.* Beginning stages of pneumatoceles, a common complication in this syndrome, can be seen.

Hyperimmunoglobulinemia M

Hyperimmunoglobulinemia M with hypogammaglobulinemia is an uncommon syndrome that has been described as both an X-linked and an autosomal recessive disease. Patients with this disorder become symptomatic during the first or second year of life. Occasional sporadic cases occur in later life. The tests of cellular immunity are normal, but abnormalities in immunoglobulin production are believed to be the result of dysfunctional regulation of B cells by defective T cells. Patients with this syndrome usually exhibit elevated levels of IgM and IgD but very low levels of IgA and IgG. Patients demonstrate a propensity to pyogenic infections, including otitis media, sinusitis, and pneumonia. Because these patients do not have the ability to make IgG antibodies, the therapy includes monthly immunoglobulin administration.

Thymic Aplasia

Congenital thymic aplasia or DiGeorge's syndrome, is characterized by thymic aplasia or hypoplasia due to dysmorphogenesis in the third and fourth pharyngeal pouches during embryogenesis. Other abnormalities that result from this include failure of the development of parathyroid glands, neonatal hypocalcemia and tetany, and cardiac defects, including tetralogy of Fallot, right-sided aortic arch, and truncus arteriosus. Immunologic defect is the result of T-lymphopenia. Lymphocyte counts are normal, but all lymphocytes are B cells. Serum immunoglobulin concentrations usually are normal, but IgG and IgA antibody responses frequently are impaired.

Pulmonary complications described include both viral and bacterial infections and interstitial pneumonitis. Other pulmonary abnormalities reported include hypoplastic lungs with abnormal anatomic location and hypoplastic pulmonary artery.

Wiskott–Aldrich Syndrome

The Wiskott–Aldrich syndrome is a rare X-linked immunologic disorder characterized by the clinical triad of eczema, profound thrombocytopenia with purpura, and recurrent infections. Deficiency of IgM, elevated levels of IgA and IgG, and very high levels of IgE are seen frequently.

Respiratory complication in the form of otitis media followed by pneumonia is common. In younger patients, bacterial infections are more commonly caused by encapsulated organisms. Patients are also susceptible to herpes simplex, cytomegalovirus, *P. carinii,* and varicella infections. Gram-positive and gram-negative bacterial infections are common. Pulmonary vasculitis with features typical of lymphomatoid granulomatosis has been described. Survival beyond the teenage years is uncommon. Nearly 12% of patients develop fatal malignant neoplasms, and more than 80% of these lesions are leukemias and lymphoreticular tumors. However, infections and bleeding are the major causes of mortality.

Idiopathic $CD4^+$ T-Lymphocytopenia

A report on four patients with opportunistic infections and without major risk factors for HIV infection described the phenomenon of idiopathic $CD4^+$ T-lymphocytopenia. All four patients had severe, persistent $CD4^+$ T-lymphocytopenia (range, 12 to 293 cells/mm^3); the $CD4^+$ cell count progressively declined in only one. All four patients had significantly reduced numbers of circulating $CD8^+$ T cells, natural killer cells, or B cells (or all three). All presented with severe opportunistic infections including *Pneumocystis carinii* pneumonia, cryptococcal meningitis (two patients, one with concurrent pulmonary tuberculosis), and histoplasmosis-induced brain abscess. During up to 68 months of observation, none of the four patients had evidence of infection with HIV.

Ataxia-Telangiectasia

Transmitted as an autosomal recessive disease, hereditary ataxia-telangiectasia is characterized by progressive cerebellar ataxia followed by choreoathetoid movements and, several years later, development of ocular and cutaneous telangiectasia. Dysfunctional helper T cells may account for the underlying diminished activity of B cells. Lack of both serum and secretory fractions of IgA is noted in more than 80% of patients, and serum IgA is absent in approximately 50%. Deficiency of IgG_2 is common. Isolated deficiency of IgG_4 with normal levels of total IgG and other subclasses occurs.

Chronic sinopulmonary infections caused by bacteria occur in 80% of patients. These may lead to severe bronchiectasis. This complication has been observed in children as well as in adults. Repeated infections of the sinuses and lungs from viral agents and bacteria are common (Fig. 3). Chest roentgenograms have demonstrated a prominent, symmetric thicket-like pattern in the lungs. One study of 160 patients with ataxia-telangiectasia reported recurrent sinopulmonary infections in 66% of patients and low or absent serum IgA in 51%.

FIG. 3. Bilateral lower-lobe infiltrates in a child with ataxia-telangiectasis. This patient has recurrent pulmonary infections caused by *Hemophilus influenzae.*

Patients with ataxia-telangiectasia have a marked propensity to develop lymphoma and acute lymphocytic leukemia, and more than 10% succumb to malignancy.

Nezelof's Syndrome

Nezelof's syndrome denotes thymic dysplasia with normal immunoglobulins. It is an inherited disorder characterized by lymphopenia, diminished lymphoid tissue, abnormal architecture of thymus, and normal or elevated immunoglobulin levels. Flawed function of interleukin-2 has been observed in several patients. Deficiency of T-cell function is the main abnormality in these patients, although Nezelof's syndrome sometimes is discussed in conjunction with the severe combined immunodeficiency syndrome. Although this is normally a disease of children, several adult cases have been described. Recurrent respiratory infections secondary to

bronchiectasis and sinusitis are common. Fatal bronchiolitis caused by cytomegalovirus has been described in a child.

Hyposplenism

Decreased or absent splenic function occurs in congenital aplasia, splenectomy, hyposplenism secondary to hemolytic states, malignancy involving the spleen, and chronic sickle-cell disease. Phagocytosis of encapsulated bacteria is dependent on normal splenic function. Hyposplenism results in loss of protection against encapsulated organisms such as *S. pneumoniae* and *H. influenzae.* Pneumococcal vaccine and prompt treatment of infections are important.

PULMONARY DISEASE IN THE IMMUNOCOMPROMISED PATIENT

The term immunocompromised patient or compromised host generally describes a patient whose defense mechanisms are impaired, thereby rendering the patient more susceptible to infections. However, the pulmonary abnormalities in these patients do not always represent an infectious process. The etiologic possibilities for the abnormal chest roentgenogram in the immunocompromised patient are varied because the lungs are involved in most of the complications in such a patient. If the pulmonary involvement is diffuse, the mortality approaches 50%.

Most immunocompromised patients with diffuse pulmonary infiltrates exhibit typical clinical features: fever, nonproductive cough, dyspnea, abnormal chest roentgenograms, anemia, normal or low leukocyte count, decreased platelet count, and hypoxemia of varying degree. Many of these features also are dependent on the underlying primary disease. The chest roentgenogram is rarely helpful in making a definitive diagnosis. Faced with a rapidly deteriorating immunocompromised patient with progressive chest roentgenographic abnormalities, the clinician is forced quickly to consider a myriad of diagnoses. Simplifying the possibilities by grouping the differential diagnoses in such a patient is extremely helpful in planning the appropriate diagnostic procedures and administration of optimal therapy (Table 1). In almost all immunocompromised patients, the first indicator of respiratory complication is an abnormal chest roentgenograph. The abnormal chest roentgenogram in the immunocompromised patient may indicate one or more of the following diagnoses: (1) extension of the basic disease process, (2) opportunistic infection, (3) drug-induced lung disease, (4) alveolar hemorrhage, (5) nonspecific interstitial pneumonitis, (6) lymphocytic interstitial pneumonitis, (7) B-cell neoplasia and other cancers associated with chronic immunosuppression, (8) a new pulmonary problem unrelated to the preceding diagnoses, or (9) a combination of two or more of the preceding diagnoses. Among these, the first four complications can produce acute or life-threatening respiratory distress, whereas the others can be subclinical and cause subacute or slowly progressive chronic illness.

Extension of basic disease process into the lungs
Opportunistic lung infections
Drug-induced lung disease
Alveolar hemorrhage
Obstructive airways disease
Nonspecific interstitial pneumonitis
Lymphocytic interstitial pneumonitis
Pulmonary "immune" neoplasia
Pulmonary problem unrelated to immunodeficiency
Combination of two or more of the above

TABLE 1. *Differential diagnosis of pulmonary disease in the immunocompromised patient*

Up to one-third of immunocompromised patients have two or more of the complications listed above. The most common types of impaired defense mechanisms are reductions in the number of granulocytes, B lymphocytes, and T lymphocytes. Nearly one-fourth of the pulmonary complications in these patients are noninfectious. The increasing use of chemotherapeutic agents, with consequently more frequent remissions and relapses of the basic disease process and more frequent cytotoxic pulmonary reactions to the chemotherapy, has made it increasingly difficult to pinpoint the cause of a pulmonary abnormality in a compromised host. Because some of the respiratory problems are associated with a rapid downhill clinical course, it is imperative that diagnostic consideration of an abnormal pulmonary process include the following steps: (1) recognition of the patient as an immunocompromised host, (2) definition of the derangement of the host defense mechanism, (3) categorization of chest roentgenographic and computed tomographic abnormalities, (4) assessment of the degree of urgency with regard to various diagnostic procedures, and (5) determination and performance of the most productive diagnostic procedure. This step-by-step approach is most likely to help in designing the optimal therapy in this group of patients.

Recognition that the patient is at added risk of infection is the first important step toward diagnosis of the pulmonary process. The various immunodeficiency syndromes that may be seen in immunocompromised patients were discussed earlier. The patients who are organ transplant recipients, discussed below, should be included in this category of immunocompromised patients. Additionally, local mechanical factors that predispose these patients to special problems include diseases of the airways, defects in mucociliary clearance, deficiency of secretory IgA, absence of surfactant from acute lung injury, and preexisting pulmonary structural damage such as bullous lesions, bronchiectasis, ancient cavities, and a fibrotic process. The etiologic factors of pulmonary abnormalities in compromised hosts are outlined in Table 2 and Table 3. Each of the broad categories of diagnostic possibilities listed in Table 1 is briefly described below.

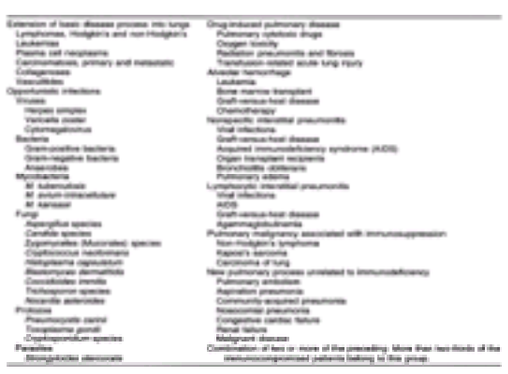

TABLE 2. *Etiologic classification of pulmonary complications in the immunocompromised patient*

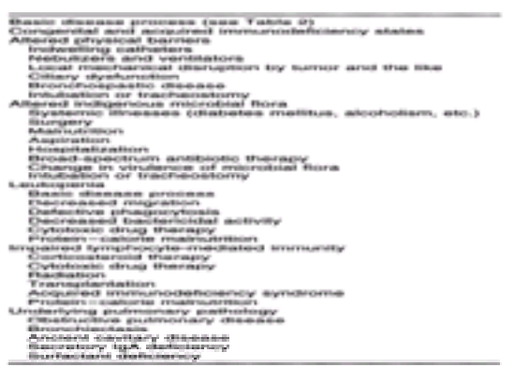

TABLE 3. *Factors predisposing the host to opportunistic pulmonary infection*

Differential Diagnosis

Pulmonary Extension of Basic Disease Process

The basic disease processes listed in Table 2 are often associated with various degrees of suppression of immune defense mechanisms. In the present context, patients with such disorders may be considered as compromised hosts. When presented with pulmonary problems in such a patient, the clinician must ascertain whether the pulmonary manifestations represent extension of the basic disease into the lungs or other complications. Intrathoracic spread of primary pulmonary and extrapulmonary malignancies together constitutes the most common cause of pulmonary extension of the basic disease process. Lymphangitic metastases from pulmonary and nonpulmonary malignancies should be included in the differential diagnosis of lung infiltrates in this group.

Hematologic malignancies, especially leukemias and lymphomas, also can produce chest roentgenographic abnormalities (Fig. 4). Leukemias as a group exhibit mediastinal and hilar lymphadenopathy in 50% of cases at autopsy and pulmonary involvement in 25%. Occasionally, patients may present with acute respiratory distress from extensive leukemic infiltrates in the lungs. Hodgkin's lymphoma produces roentgenographically detectable mediastinal lymphadenopathy in 50% of patients and pulmonary parenchymal lesions in 30%. Non-Hodgkin's lymphoma exhibits mediastinal lymphadenopathy in 35% of cases. Primary pulmonary lymphoma may present as an alveolar infiltrate or as a homogeneous mass. In such cases, elaborate diagnostic investigations may be necessary to rule out an extrapulmonary focus of the lymphoma. Lung involvement is more common in untreated lymphoproliferative diseases than in myeloproliferative diseases. Opportunistic infections are the most common cause of morbidity and mortality in these patients. However, opportunistic infections of lungs are very uncommon in patients with hematologic malignancies who have no history of chemotherapy, radiation therapy, bone marrow transplantation, or malnutrition.

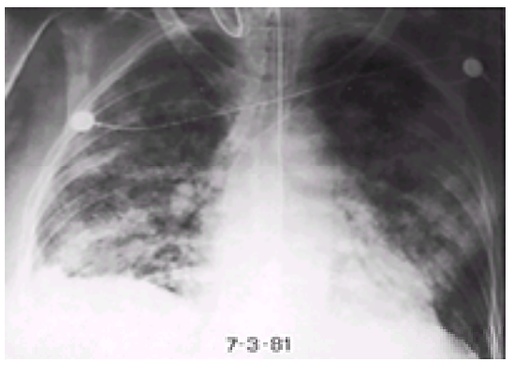

FIG. 4. Pulmonary extension of non-Hodgkin's lymphoma refractory to chemotherapy. Diffuse alveolar infiltrates are seen in both lungs.

Collagenoses and vasculitides are often associated with pulmonary manifestations. Untreated rheumatologic entities such as rheumatoid arthritis, systemic lupus erythematosus, progressive systemic sclerosis or scleroderma, polymyositis-dermatomyositis, Sjögren's syndrome, mixed connective tissue disease, Wegener's granulomatosis, temporal arteritis, and Churg–Strauss vasculitis are well-known causes of pulmonary complications. Pulmonary manifestations of these disorders are discussed at length in Chapter 53 and Chapter 54. As in the case of malignancies, pulmonary opportunistic infections are uncommon in these patients unless they have received prolonged immunosuppressive therapy for their disease. Because the majority of patients with symptomatic rheumatologic and vasculitic disorders are treated with immunosuppressive therapy, they become prime targets for opportunistic infections, drug-induced lung disease, and other pulmonary complications.

Opportunistic Pulmonary Infections

Overwhelming pneumonias remain an important cause of morbidity and mortality. Many of these infections progress rapidly and are fatal. An immunocompromised patient is prone to develop pulmonary infections caused by viruses, bacteria, mycobacteria, fungi, protozoa, and parasites. In the setting of immunocompromised status, the clinical manifestations of viral pneumonitis are variable. Fever may be impressive or absent. Cough and dyspnea are present in most patients, as are varying degrees of hypoxemia and chest roentgenographic abnormalities. Cytomegalovirus and herpes zoster virus infections are seen in patients with a wide variety of underlying problems. Hematologic malignancies, corticosteroid therapy, and broad-spectrum antibiotics may predispose patients to primary varicella pneumonia. Pulmonary cytomegalovirus infection not detected by conventional histologic examination may be present in patients with diffuse alveolar damage associated with bone marrow transplantation.

Because most immunocompromised patients are hospitalized, hospital-acquired pneumonitis is a major threat to their lives; infections caused by gram-positive, gram-negative, and anaerobic bacteria are common. Oropharyngeal colonization by gram-negative organisms is increased in patients with chronic alcoholism, chronic obstructive pulmonary disease, diabetes mellitus, congestive cardiac failure, immunologic diseases, bronchiectasis, azotemia, intubation, tracheostomy, and malnutrition, and in those on chronic antimicrobial therapy and corticosteroid therapy. Carrier rates for aerobic gram-negative rods in pharyngeal secretions have been found to be higher for alcoholics and diabetics. Patients with malignant disease are frequently at risk of developing a wide variety of infections as a result of their immune-suppressed state. *Moraxella catarrhalis,* a gram-negative bacterium, has emerged as an opportunistic organism. Nearly one-third of the cases of pneumonia and empyema caused by *M. catarrhalis* have occurred in patients with various immunologic abnormalities.

Fungal infections, particularly aspergillosis and candidiasis, are common in leukemic patients, in debilitated individuals, and in those receiving long-term antimicrobial therapy. Immunocompromised patients, especially those with severe and sustained granulocytopenia, have a high propensity to develop potentially fatal *Aspergillus* and *Candida* infections. *Candida* epiglottitis has been described in these patients either as a localized lesion or as a source of *Candida* bronchopneumonia. Infection with *C. neoformans* may be seen in patients receiving corticosteroid therapy for sarcoidosis and in patients with chronic pulmonary disease. *Aspergillus* exists commonly as a saprophyte. Invasive and disseminated aspergillosis, however, is almost always seen in patients with malignancy or severe immunosuppression. Granulocytopenic patients with leukemic are particularly susceptible. *Nocardia asteroides* becomes an opportunistic invader in patients with chronic diseases, especially those receiving corticosteroid therapy and patients with preexisting lung diseases such as bronchiectasis.

Pneumocystis carinii is a relatively common pulmonary pathogen in immunocompromised patients, especially those receiving corticosteroids and other immunosuppressive agents, and in those with underlying diseases, including hematologic malignancies, solid tumors, organ transplants, and collagen-vascular diseases. The most common disease associated with *P. carinii* infection is AIDS. Coexisting pulmonary infection is a major negative prognostic factor in patients with *P. carinii* pneumonia.

Drug-Induced Lung Disease

Many drugs, including thoracic radiation, employed for the purposes of immunosuppression and therapy of immunologic and neoplastic diseases, render the lungs vulnerable to various types of damage mediated by different pathogenic mechanisms. Although some chemotherapeutic agents have cumulative dosage thresholds, others produce idiosyncratic reactions in the lungs. As discussed above, immunosuppression caused by the chemotherapeutic drugs renders patients susceptible to opportunistic lung infections. Diagnosis of a pulmonary process becomes a formidable challenge when the patient is receiving such treatment. In addition to excluding the possibilities of extension into the lungs of the basic disease and the presence of an opportunistic infection, one has to rule out a drug-induced pulmonary response. The drug-induced lung diseases are discussed at length in Chapter 22. Only brief discussions on lung disease caused by commonly used chemotherapeutic agents and corticosteroids are included below.

Bleomycin is a commonly used chemotherapeutic agent and a well-known cause of chronic interstitial pneumonitis-fibrosis. The drug has a propensity to concentrate in lung tissue and initiate oxidant-mediated injury to both alveolar and capillary cells. Pulmonary toxicity occurs in up to 40% of patients. The risk factors for the development of interstitial pneumonitis-fibrosis include age over 70, total dose in excess of 400 units, concurrent or simultaneous administration of oxygen, radiation, and granulocyte colony-stimulating factor, and renal insufficiency. Delayed occurrence of bleomycin lung can be seen months or years later, when bleomycin therapy is followed later by the administration of oxygen, radiation, or other chemotherapy drugs. Chest roentgenographs resemble those in idiopathic pulmonary fibrosis. Hypersensitivity lung disease and acute chest pain syndrome can be independent of cumulative dose. Hypersensitivity lung disease is associated with skin rash, eosinophilia, and reticulonodular infiltrates. The acute chest pain syndrome is associated with intravenous infusion and may be accompanied by pleuropericarditis.

Busulfan (Myleran), a chemotherapeutic agent used in the treatment of leukemia, causes clinical pulmonary toxicity in up to 5% of patients and subclinical lung damage in nearly half. Although pulmonary toxicity is more likely to occur if the total dose exceeds 500 mg, it is not always dose-dependent. Use of other chemotherapeutic agents and radiation increases the risk of lung toxicity. Slowly progressive interstitial pneumonitis-fibrosis associated with cough, dyspnea, and fever may appear

weeks, months, or years later (Fig. 5).

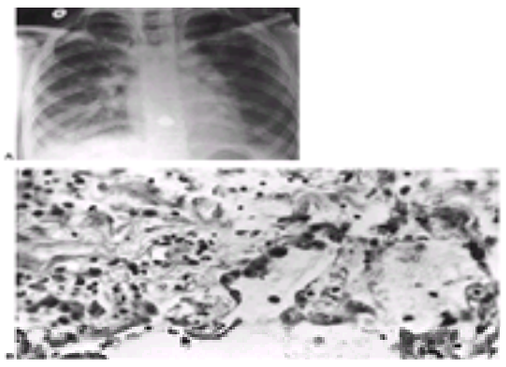

FIG. 5. Cytotoxic pulmonary damage secondary to busulfan in the immunocomprised patient. **(A)** Chest roentgenogram shows diffuse alveolar-interstitial infiltrates. **(B)** Lung biopsy demonstrates inflammatory changes, fibrosis, and hypertrophy of alveolar lining cells following busulfan therapy.

Cyclophosphamide causes dyspnea, nonproductive cough, and fever associated with interstitial pneumonitis-fibrosis or reticulonodular process within 2 weeks of therapy. The incidence of lung toxicity from cyclophosphamide alone is about 1% but increases when other drugs are used.

Mitomycin is associated with lung toxicity in up to 12% of patients. The threshold for lung toxicity is about 30 mg/m^2 of body surface area. Pulmonary toxicity is greatly enhanced when mitomycin is administered with bleomycin, cisplatin, and vincristine. Acute dyspneic episodes and acute noncardiogenic pulmonary edema associated with bronchospasm occur in up to 4% of patients who receive mitomycin therapy along with vinca alkaloids, sometimes within hours of vinca administration. Alveolar hemorrhage and noncardiogenic pulmonary edema may complicate mitomycin-induced hemolytic-uremic syndrome. Interstitial pneumonitis-fibrosis usually occurs 2 to 4 months after therapy and responds to corticosteroid therapy.

Methotrexate produces pulmonary toxicity in up to 8% of patients who receive high doses of the drug. The risk of pulmonary disease is directly related to the frequency with which the drug is administered. Chronic low-dose therapy used in rheumatologic diseases also is capable of causing lung damage. Respiratory manifestations include acute pleuritic chest pain with pleural effusion, noncardiac pulmonary edema following intrathecal administration of the drug, hypersensitivity lung disease that occurs several days after therapy, and subacute to chronic pneumonitis-fibrosis with subacute onset of dyspnea, cough, fever, and myalgias. Eosinophilia is common. Lung biopsy may show small interstitial granulomas; the bizarre type II pneumocytes seen in lung diseases induced by other chemotherapeutic agents are conspicuously absent.

Chemotherapeutic agents, other than those above, with known pulmonary toxicity include azathioprine (chronic interstitial process), carmustine (chronic interstitial process), chlorambucil (interstitial process), cytosine arabinoside (noncardiac pulmonary edema), ifosamide (chronic interstitial process), interleukin-2 (chronic interstitial process), melphalan (subclinical interstitial process), and 6-mercaptopurine (chronic interstitial process). Radiation-induced pneumonitis can confuse the issue, particularly in a patient with an intrathoracic neoplasm or a breast cancer for which radiation is administered, with exposure of adjacent lung to radiation.

Corticosteroid therapy is a well-known risk factor for the development of opportunistic infections. Corticosteroid-induced panlymphopenia predisposes patients to opportunistic infections. As little as 2.5 mg prednisone given every 6 hr has the ability to depress the helper–suppressor T-cell ratio. Corticosteroid-induced lymphopenia is maximal 4 to 6 hr after a single administration of the drug but disappears within 24 hr. The decrease in the helper–suppressor T-cell ratio results from a disproportionate decrease in the number of helper-inducer T cells. B lymphocytes are less affected than the T cells. Long-term administration (prednisone equivalent of more than 15 mg/day for 6 months or longer) is likely to produce prolonged lymphopenia and thus to expose the patient to the risk of opportunistic infections. Most opportunistic infections usually occur in patients on very high doses (more than 40 mg/day).

Protein-calorie malnutrition adversely affects more or less all immunocompetent cells. It results in the impaired function of phagocytes and decreases both the quantity and quality of lymphocytes. Protein-calorie malnutrition is generally considered the most frequent cause of immunodepression.

Alveolar Hemorrhage

Pulmonary alveolar hemorrhage is an important cause of respiratory symptoms and respiratory distress syndrome in immunocompromised patients. This complication accounts for 11% to 64% of pneumonic infiltrates in this group of patients. However, alveolar hemorrhage is rarely the sole cause of pulmonary infiltrates, with fewer than 5% exhibiting pulmonary hemorrhage as the only respiratory manifestation. Even when it is clinically considered an isolated phenomenon in immunocompromised patients, it is important to consider and exclude occult invasive aspergillosis infection. Indeed, close to 50% of patients with severe pulmonary hemorrhage may have documented aspergillosis. A significant association exists between thrombocytopenia and *Aspergillus* infection and pulmonary hemorrhage. Alveolar hemorrhage is also associated with other complications such as mucormycosis, pulmonary venoocclusive disease, graft-versus-host disease, mitomycin therapy, or other processes. Alveolar hemorrhage is seen more frequently in recipients of heart transplant. In one study, 75% of bronchoalveolar lavage samples deemed positive for alveolar hemorrhage were in heart transplant recipients. In another study, alveolar hemorrhage was detected in 21% of 141 consecutive recipients of autologous bone marrow transplant. Alveolar hemorrhage is significantly associated with thrombocytopenia (platelet count less than 50,000/mm^3), other coagulopathies, renal failure (serum creatinine ^{3}2.5 mg/dl), history of heavy smoking (>10 pack-years), leukopenia, thoracic radiation, and chemotherapy.

The difficulty in establishing the diagnosis of alveolar hemorrhage can be ascribed to the following factors: highly nonspecific clinical and roentgenographic features, absence of hemoptysis in most patients, and lack of specificity of imaging procedures including chest roentgenography, high-resolution computed tomography, and radionuclide scans. Carbon monoxide diffusing capacity, when tested serially, has been reported to increase with alveolar bleeding as a result of increased uptake of carbon monoxide by the red blood cells in the alveoli. The necessity to obtain this test serially in a sick patient renders it impractical. Furthermore, its reliability in the diagnosis of alveolar hemorrhage has not been established. Although thoracoscopy and open-lung biopsy can document the diagnosis, they are high-risk procedures in these patients. Bronchoalveolar lavage has been used to diagnose alveolar hemorrhage in immunocompromised patients. The mere presence of hemosiderin-laden macrophages in the bronchoalveolar lavage effluent without quantification is not diagnostic. Therefore, estimation of the number of hemosiderin-laden macrophages is used to diagnose this complication. In a study of 240 bronchoalveolar lavage samples in 194 immunocompromised hosts, the presence of at least 20% siderophages was considered to be diagnostic of alveolar hemorrhage. By this definition, alveolar hemorrhage was present in 87 (36%) of the samples; 20% to 65% siderophages was related to moderate hemorrhage (Golde score between 20 and 100), and a percentage greater than 67% was related to severe hemorrhage (Golde score >100). Even when a diagnosis of alveolar hemorrhage is established, it is essential to exclude coexistence of basic disease process and infections in the lungs.

Obstructive Airways Disease

Progressive airways disease leading to life-threatening respiratory distress is one of the most serious pulmonary complications encountered in immunocompromised patients. Obstructive airways disease occurring as a result of the immunocompromised status is almost exclusively limited to organ transplant recipients. Patients with graft-versus-host disease are at risk of developing this complication. Bronchiolitis obliterans that occurs in patients with rheumatoid arthritis and other collagen diseases is not considered here. It is, however, important to recognize that in a patient with rheumatoid arthritis or other collagenoses who is being treated with specific nonsteroidal antiinflammatory agents such as penicillamine or gold preparations who develops features of obstructive airway disease, the drugs themselves may be responsible for the airways disease.

Obstructive airways disease can occur in the form of bronchospastic disease, lymphocytic bronchitis, or bronchiolitis obliterans. Lymphocyte-mediated pathologic process is most likely responsible for these complications. The clinical features of the various types of obstructive airways diseases are reviewed below under the discussion on pulmonary complications in organ transplant recipients.

Nonspecific Interstitial Pneumonitis

Nonspecific pathologic changes are common in the lung tissue of immunocompromised patients with a diffuse pulmonary process (Fig. 6). The nonspecificity of biopsy-based diagnosis is helpful in excluding other causes of interstitial process. For example, in a study of 70 immune-suppressed patients with diffuse lung disease who underwent open-lung biopsy, even though the procedure provided diagnostic accuracy in 97%, 45% of the diagnoses were nonspecific (fibrosis); there was no significant difference in mortality between those with a specific diagnosis and those without, nor between those whose biopsy diagnosis caused an alteration of their

therapy and those for whom it did not. In contrast, another study noted a recovery rate of only 25% in those without a specific diagnosis following lung biopsy, whereas in patients in whom a treatable problem had been diagnosed, the overall recovery rate was 70%.

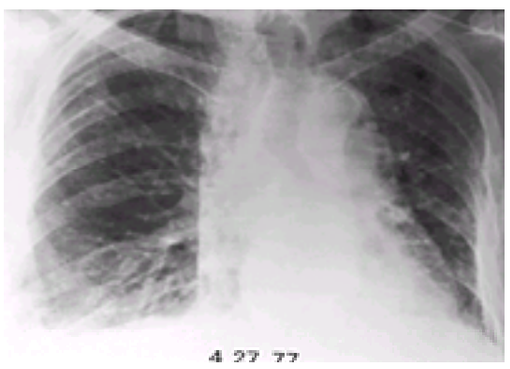

FIG. 6. Nonspecific interstitial pneumonitis in an immunocomprised patient who developed dyspnea and cough after thoracic radiation and multiple courses of chemotherapy for Hodgkin's lymphoma. Open-lung biopsy revealed nonspecific inflammation and fibrosis.

High-dose whole-body irradiation is commonly included in conditioning regimens for bone marrow transplantation for treatment of patients with hematologic malignancies. Interstitial pneumonitis is a major complication after bone marrow transplantation, and nearly one-fourth of all bone marrow transplant patients die from this complication. In approximately half these patients, an infectious agent, particularly cytomegalovirus, is involved. Additional factors such as remission-induction chemotherapy, cyclophosphamide, methotrexate, cyclosporine, and graft-versus-host disease combine to cause interstitial lung disease in these patients. Lymphocytic interstitial pneumonitis associated with bone marrow transplantation is considered in Chapter 56.

Lymphocytic Interstitial Pneumonitis

The differential diagnosis of lymphocytic interstitial pneumonitis is discussed in Chapter 56. In the immunocompromised patient, the etiology for lymphocytic interstitial pneumonitis includes viral infections, AIDS discussed earlier (also see Chapter 56), graft-versus-host disease, and agammaglobulinemia. Because many of the diseases associated with lymphocytic interstitial pneumonitis involve lymphoma, immunocompromised patients with lymphocytic interstitial pneumonitis should be closely observed for the possibility of lymphoproliferative disease.

Pulmonary "Immune" Neoplasia

Non-Hodgkin's lymphomas occur with increasing frequency in immunocompromised patients as a result of iatrogenic immunosuppressive therapy. Such lymphomas are more common in organ transplant recipients than in other immunocompromised patients. Lymphomas may be oligoclonal or polyclonal in origin (Fig. 7) and may be related to the use of cyclosporine. In contrast, non-Hodgkin's lymphomas seen in AIDS are Burkitt-like lymphomas, B-cell lymphomas, or B-cell immunoblastic sarcomas, with or without plasmacytoid features. They tend frequently to be extranodal.

FIG. 7. B-cell lymphoma developing in right upper lobe in a patient on chronic immunosuppressive therapy following renal transplantation.

As a result of successful treatment with radiation, chemotherapy, or both, patients with lymphoma are living longer. Long-term follow-up of these patients has shown an increased incidence of lung carcinoma. Patients treated for Hodgkin's and non-Hodgkin's lymphoma accrue a relative risk two to three times that of the normal population for developing newer malignancies. Previous radiation therapy also may increase the risk of developing pulmonary nonlymphomatous malignancies.

Small-cell carcinoma is the predominant histologic type of lung cancer in both smoking and nonsmoking irradiated patients. However, patients with Hodgkin's lymphoma who receive supradiaphragmatic irradiation or combined-modality therapy may be at higher risk for developing non-small-cell carcinoma of the lung. In a study of such patients, the risk ratio for the development of lung cancer among Hodgkin's lymphoma patients was 5.6 times that expected in the general population. The median age at diagnosis of Hodgkin's lymphoma and lung carcinoma was 39 and 45 years, respectively. The interval between the diagnosis of Hodgkin's lymphoma and metachronous lung cancer averaged 7 years but appeared to vary inversely with age, thus emphasizing the need for close long-term observation.

Pulmonary Problems Unrelated to Immunodeficiency

The immunocompromised patient is more susceptible to the medical processes that affect nonimmunocompromised subjects. An abnormal chest roentgenogram in an immunocompromised patient may represent cardiac or noncardiac pulmonary edema, pulmonary embolism, community-acquired pulmonary infections, aspiration pneumonitis, or the delayed effects of thoracic irradiation. More than one-third of immunocompromised patients will demonstrate a combination of two or more of these complications.

Pulmonary Complication in Organ Transplant Recipients

The lungs more frequently manifest complications following organ transplantation than other organs. Respiratory complications are often the initial or presenting feature in these patients. Pulmonary complications in organ transplant recipients can be related to infection, transfusion of blood products, immunosuppressive drugs, graft-versus-host disease, alveolar hemorrhage, or obliterative bronchiolitis. Pulmonary infections are the most common cause of death in patients with organ transplants. Some complications are more commonly encountered with certain types of organ transplants, whereas others are nonspecific and occur in most organ recipients, irrespective of the organ transplanted. Pulmonary infection by *P. aeruginosa* should be considered in all patients hospitalized for more than 48 hrs. The crude mortality secondary to bacterial pneumonia in solid-organ transplantation exceeds 40%. Gram-negative bacilli, *S. aureus,* and *Legionella* predominate in the first 3 months after transplantation and are associated with mortality rates in excess of 60%. Bacterial pneumonias after 3 months are caused by *S. pneumoniae* and *H. influenzae* and are associated with lower mortality.

The following is a brief discussion of the common pulmonary complications among recipients of bone marrow and heart transplantations. Lung transplantation and related complications are discussed in Chapter 52. Respiratory complications in kidney and liver transplant recipients are discussed in Chapter 57 and Chapter 58, respectively.

BONE MARROW TRANSPLANTATION

Pulmonary complications occur in 40% to 60% of patients with bone marrow transplants and are often serious and life-threatening. One of the contributing factors is the presence of suboptimal pulmonary functions before bone marrow transplantation as a result of multiple episodes of infections, cytotoxic chemotherapy, and total-body

irradiation. The pulmonary complications seen in bone marrow transplantation can be broadly classified as early and late (Table 4). Pneumonia complicates approximately half of all bone marrow transplantations. In approximately one-third of the cases, no specific cause is identified, and the term *idiopathic pneumonia syndrome* has been used to describe this.

Clinical and roentgenographic features	Differential diagnosis
Early*	
Pulmonary edema	Fluid overload Myocardial injury Acute hemorrhagic edema (cyclosporine toxicity) Transfusion reactions Septicemia
Adult respiratory distress syndrome	Pulmonary edema
Bronchopneumonia	Idiopathic Bacterial Fungal (aspergillosis, candidiasis) Viral (cytomegalovirus)
Interstitial pneumonitis	Idiopathic Infectious (*Pneumocystis carinii*, cytomegalovirus) Pulmonary embolism Venoocclusive disease
Late†	
Bronchopneumonia	Bacterial Viral Fungal Protozoal (*Pneumocystis carinii*) Pulmonary embolism (fat embolism) Venoocclusive disease
Interstitial pneumonitis	Nonspecific interstitial pneumonitis Bronchiolitis obliterans Lymphocytic interstitial pneumonitis

*Occurring within 100 days of transplantation.
†Occurring 100 days or more after transplantation.

TABLE 4. *Pulmonary complications following bone marrow transplantation*

Viral infection occurs commonly in bone marrow transplant recipients. Overall, 80% of all bone marrow transplant recipients develop cytomegalovirus pneumonia, generally 30 to 150 days after transplantation. However, cytomegalovirus pneumonia is uncommon in recipients of autologous or syngeneic bone marrow transplants. Pneumonia from cytomegalovirus carries a mortality rate of approximately 90%. Risk factors for developing cytomegalovirus pneumonia include advanced age of patients, seropositivity, multiple blood transfusions, total body radiation, and presence of graft-versus-host disease. Pretransplantation pulmonary dysfunction is a strong predictor and risk factor for the posttransplantation development of cytomegalovirus pneumonia and interstitial process. Other viral infections, including herpes simplex, parainfluenza, and the respiratory syncytial viruses, are uncommon.

Bacterial infection is uncommon during the early stages after bone marrow transplantation. However, the overall incidence is 20% to 50%. During the early granulocytopenic period, gram-negative organisms predominate. Most late cases of bacterial pneumonia (occurring more than 6 months after bone marrow transplantation) are encountered in patients with graft-versus-host disease.

Fungal infections of the lung are more likely in neutropenic patients receiving broad-spectrum antibiotics. Infections caused by *Aspergillus* species are the most common and most lethal. Among 271 consecutive patients treated with bone marrow transplantation during a 9-year interval, *Aspergillus* pneumonia was noted in 36%; the crude mortality for these patients was 95%. Invasive aspergillosis may present with fever, dyspnea, cough, pleuritic chest pain, and hemoptysis. Chest roentgenologic abnormalities include diffuse or focal interstitial infiltrates, triangular peripheral infiltrates caused by infarction, and cavitated lesions. The diagnosis is established by documentation of fungal invasion of the pulmonary parenchyma, although the presence of *Aspergillus* species in respiratory secretions in the appropriate clinical setting may be highly suggestive.

Tracheobronchial aspergillosis is another serious complication in neutropenic and other immunocompromised patients, including those with AIDS and recipients of a lung or heart-lung transplant. In the latter group, the tracheobronchial anastomotic sites seem particularly affected by the process. Clinically, cough, upper airway wheezes, and progressive dyspnea are present in most patients. Respiratory failure can result from tracheobronchial obstruction. Bronchoscopy is both diagnostic and initially therapeutic in the relief of dyspnea by removal of the obstructing pseudomembrane secondary to tracheobronchial aspergillosis. Results of clinical trials in which prophylactic aerosolized amphotericin B, in doses varying from 5 mg to 100 mg, or oral itraconazole suggest that in high-risk patients these treatments are well tolerated and efficacious in preventing disseminated tracheobronchial aspergillosis. Infections by *Candida albicans* and the zygomycetes as well as other fungi are also seen.

Mycobacterial infections are uncommon after allogeneic bone marrow transplantation, although several cases of infections caused by *M. avium* complex have been described. The incidence of *P. carinii* pneumonitis is greater in patients who receive total body radiation before bone marrow transplant. The incidence, however, of *P. carinii* pneumonia in bone marrow transplant recipients is low, with only 4% of cases of interstitial pneumonitis being caused by *P. carinii.* Prophylactic administration of trimethoprim–sulfamethoxazole before bone marrow transplantation and after marrow engraftment is responsible for the low incidence.

Pulmonary edema is perhaps the earliest and most common complication of bone marrow transplantation. This phenomenon usually is seen 2 to 3 weeks postoperatively. The etiology for the pulmonary edema includes fluid overload, cardiac dysfunction caused by chemotherapy with doxorubicin hydrochloride (Adriamycin), transfusion-related acute lung injury, graft-versus-host disease, fat embolism syndrome, renal dysfunction, and, occasionally, irradiation. Congestive cardiomyopathy associated with the use of Adriamycin and daunorubicin is dose dependent (>550 mg/m^2). Pulmonary edema, both cardiogenic and noncardiogenic, is rapid in onset and occurs between the second and third week posttransplantation. Hemorrhagic pulmonary edema is more likely in those receiving mismatched transplants and high doses of cyclosporine. It also may result from fluid retention, hypoalbuminemia, hypotension, and incipient renal failure.

Graft-versus-host reaction that occurs after bone marrow transplant is responsible for the majority of the noninfectious pulmonary complications, which include acute noninfectious pneumonia, lymphocytic bronchitis, patchy interstitial pneumonitis, lymphocytic interstitial pneumonitis, and obstructive airway disease including bronchiolitis obliterans. Contributing factors include higher radiation dose to the lung, posttransplant pulmonary infection, particularly cytomegalovirus infection, and chemotherapy.

Lymphocytic bronchitis as a result of graft-versus-host reaction occurs in 25% of allogeneic bone marrow transplant recipients. It is manifested by lymphocytic infiltration of the bronchial mucosa, loss of cilia and goblet cells, and occasional necrosis of mucosa and submucosa. The lymphocytic bronchitis may be complicated by bronchopneumonia, frequently caused by *Pseudomonas aeruginosa.* Lymphocytic interstitial pneumonitis is a late complication of bone marrow transplantation, but the relationship between lymphocytic interstitial pneumonitis and graft-versus-host disease is uncertain. Several large studies have shown that clinical chronic graft-versus-host disease is present in all bone marrow transplant recipients before or concurrent with the onset of posttransplant obstructive lung disease.

Unexplained pleural effusions occur in recipients of allogeneic bone marrow transplants but not autologous transplants. The effusions are more common in patients with acute and/or chronic graft-versus-host disease. Acute graft-versus-host disease has been implicated in endothelial cell injury. This mechanism may be responsible for the high occurrence rate of alveolar hemorrhage in bone marrow transplant recipients with graft-versus-host disease. In one series, 59% of the patients with significant acute graft-versus-host disease died of acute respiratory failure as a result of recent pulmonary hemorrhage as opposed to 25% of those without acute graft-versus-host disease.

Nonspecific interstitial pneumonitis is a serious threat after bone marrow transplantation (Fig. 8). It occurs in 35% to 50% of recipients of allogeneic transplants and in approximately 20% of syngeneic or autologous bone marrow transplants. In approximately 50% of these patients, an infectious agent, particularly cytomegalovirus, is involved. Progressive dyspnea, cough, end-inspiratory crackles, interstitial infiltrates on chest roentgenogram, and hypoxemia occurring 40 to 75 days after grafting should strongly suggest interstitial pneumonitis. Factors contributing to the development of this complication include the following: older patients for whom there is a long interval between primary diagnosis of leukemia and bone marrow transplantation and who are then treated with cyclosporin and develop graft-versus-host disease; HLA disparity; graft-versus-host disease; and combined chemotherapy and radiation therapy prior to transplantation. The probability of developing interstitial pneumonitis from radiation during the first year is approximately 31%. High-dose radiation therapy results in significantly reduced diffusing capacity for carbon monoxide for the first 3 months, followed by some improvement over a 2- to 3-year period.

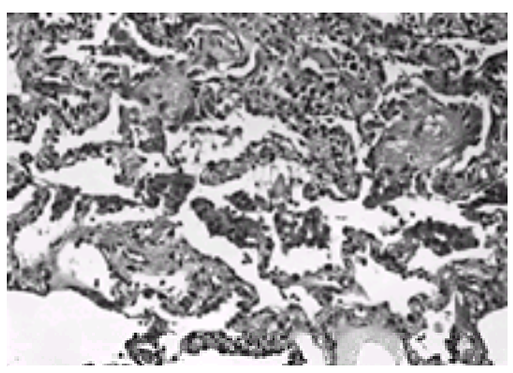

FIG. 8. Idiopathic interstitial pneumonitis in a bone marrow transplant recipient has the pattern of diffuse alveolar damage. Mild thickening and inflammatory infiltrate of alveolar septa lined by type II pneumocytes as well as edema fluid, exudate, and macrophages are present in the alveoli.

Lymphocytic alveolitis is a late occurrence and usually is seen in those with chronic graft-versus-host disease. The interstitial process is indistinguishable from nonlymphocytic interstitial pneumonitis and occurs after a median period of over 200 days after allogeneic bone marrow transplantation. Bronchoalveolar lavage shows lymphocytosis, with an overall expansion of $CD8^+$ subsets.

Obstructive lung disease as a result of bronchiolitis obliterans occurs in up to 15% of all bone marrow transplant recipients (Fig. 9). Bronchiolitis obliterans usually occurs within 5 months of bone marrow transplantation, although it can occur 9 months to 2 years after transplantation. Even though bronchiolitis obliterans more commonly occurs after allogeneic bone marrow transplantation, it has been reported following autologous bone marrow transplantation. Different pathologic mechanisms contribute to the pathogenesis of obstructive lung disease in these patients. Bronchiolitis obliterans occurs more commonly in patients with graft-versus-host disease, cytomegalovirus, and other viral and nonviral infections, radiation, and recurrent gastroesophageal reflux. Respiratory failure requiring assisted mechanical ventilation in 23% of patients has been reported. Clinically, the patient develops dyspnea, cough, hyperinflation of the thoracic cage on chest roentgenogram, and reduced elastic recoil pressure. The clinical course is variable and the mortality high, although some patients respond to corticosteroids and azathioprine.

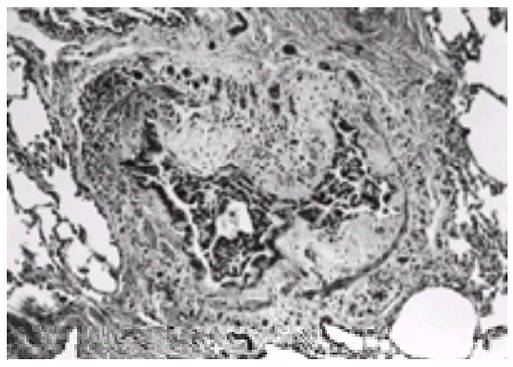

FIG. 9. Bronchiolitis obliterans-associated progressive airflow obstruction following bone marrow transplantation. Note fibrous thickening of the submucosa and distortion of the muscularis with resultant compromise in the bronchiolar lumen.

Pulmonary venoocclusive disease has been observed in patients receiving chemotherapy and after bone marrow transplantation. Other etiologic factors for pulmonary venoocclusive disease include radiation, multiple high-dose chemotherapies, and acute graft-versus-host disease. Endothelial damage from radiation therapy and cytotoxic chemotherapy also may predispose to thrombosis of pulmonary veins. Significant association has been found between bacterial pneumonia and venoocclusive disease and chronic graft-versus-host disease. Clinical features consist of progressive dyspnea and signs of right-sided congestive cardiac failure. High-dose corticosteroids have been used with mixed results. Pulmonary embolism is uncommon in bone marrow transplant recipients.

HEART TRANSPLANTATION

Many of the complications observed in bone marrow transplant recipients also occur in recipients of heart transplant. Among the solid organs transplant recipients, the incidence of bacterial pneumonia is highest in recipients of heart-lung (22%) and intermediate in recipients of heart transplants (5%). A publication on 200 episodes of infections occurring in 73 heart-lung transplant recipients reported that cytomegalovirus was the most common viral agent, accounting for 15% of infections and usually occurring in the second month after transplantation; *P. carinii* occurred 4 to 6 months after transplantation, and *Nocardia* later than 12 months after transplantation.

A multiinstitutional study of 814 consecutive patients from 24 institutions undergoing primary heart transplantation between 1990 and 1991 with mean follow-up of 8.2 months noted that the lung was the most common organ infected; the mortality rate was 23%. Bacterial and viral infections were most common, 47% and 41%, respectively, with fungi and protozoa accounting for 12%. Overall mortality per infection was 13%, but mortality with fungal infections was 36%. The single most frequently isolated infectious organism was cytomegalovirus, accounting for 26% of all infections.

Bronchiolitis obliterans is one of the most important complications of heart-lung transplantation, occurring in 10 to 50% of patients who leave the hospital with normal cardiopulmonary function. The obliterative bronchiolitis is a manifestation of lymphocyte-mediated chronic rejection. In a study of 32 recipients of single, double, or heart-lung transplantation who were followed-up for at least 3 months posttransplant, 50% of patients developed bronchiolitis obliterans, which was associated with a 56% mortality. Cytomegalovirus infection occurred with greater frequency in patients with bronchiolitis obliterans and, in most cases, preceded or occurred concomitantly with the diagnosis of acute rejection or bronchiolitis obliterans. Although bronchiolitis obliterans may appear as early as 2 months and as late as 4 years posttransplantation, it usually occurs between 8 to 12 months. One study assessed the risk factors for the development of obliterative bronchiolitis in a large group of heart-lung transplant recipients and concluded that acute rejection is the most significant risk factor.

Even though the ventilatory response to exercise is significantly improved after heart transplantation, the gradual deterioration in pulmonary function tests indicates the possibility of bronchiolitis obliterans. Spirometry is a sensitive indicator of early pathologic changes caused by bronchiolitis. The earliest physiological abnormality is the reduction in forced expiratory flow during the middle half of exhalation ($FEF_{25–75}$). Periodic pulmonary function testing is indicated to detect the occurrence and to monitor the obstructive airway disease. High-resolution computed tomography may show the typical mosaic pattern with signs of air trapping in the peripheral lung zones. Aggressive immunosuppressive therapy in the initial stages may retard the rate of progression.

When bronchiolitis obliterans is suspected, the diagnosis should be confirmed by lung biopsy if possible. Bronchoalveolar lavage can diagnose opportunistic infections in these patients, but it is not diagnostic for bronchiolitis obliterans. Obliterative bronchiolitis responds, if detected early, responds to augmented immunosuppressive therapy. Therefore, many centers routinely perform surveillance bronchoscopic lung biopsy. Azathioprine and cyclosporin are currently the main drugs used to treat acute rejection and bronchiolitis obliterans.

Pulmonary edema is common in the immediate postoperative period after heart transplantation. Atelectasis can be expected in 65% to 90% of patients undergoing heart transplantation, and although nearly 50% of patients develop bilateral atelectasis, the vast majority exhibit atelectasis of the left lower lobe. Left hemidiaphragmatic dysfunction from paresis or paralysis is the result of hypothermic cardioplegia and can last from weeks to months.

Pleural effusions also occur in up to 78% of patients who undergo heart transplantation. The etiologies are multifactorial. Most effusions are small, bilateral, and often associated with atelectasis. Collection of fluid or blood in the mediastinum may be seen in heart transplant recipients.

Mediastinitis, usually caused by bacteria, is a serious complication of cardiac surgery and should be considered in any patient who presents with fever, leukocytosis, inflammation, or instability of the sternal wound after cardiac transplantation. Other complications reported following heart transplantation include trapping and incarceration of the right lower lobe in the left hemithorax.

The incidence of developing malignancy after heart transplantation is approximately 7%, the majority being lymphomas.

DIAGNOSTIC APPROACH TO PULMONARY PROBLEMS IN THE COMPROMISED HOST

As discussed earlier, when one is confronted with a compromised host with an abnormal chest roentgenogram, one must consider various etiologic factors (see Table 2 and Table 3). A detailed history and complete physical examination will provide important clues to diagnosis. Routine laboratory procedures such as blood counts, cultures of blood and urine, and other analyses, when used appropriately, will provide additional help. The choice of diagnostic approach depends on the expertise available in one's own institution, the sensitivity of the procedure for the diagnosis of likely processes in the differential diagnoses, the severity of the patient's illness,

and the rapidity with which the illness is progressing.

IMAGING PROCEDURES

Chest roentgenograms are essential for characterizing the abnormalities and for narrowing the spectrum of possible diagnoses. However, it should be stressed that the typical roentgenographic features produced by isolated disease entities may not manifest their classic form in the case of a compromised host because of the effect of various factors on the lung, including opportunistic infections, cytotoxic changes, and radiation pneumonitis. Furthermore, because most of these patients are very sick and debilitated, obtaining roentgenographs of optimal quality may be difficult. Lateral decubitus films may help in confirming the presence of free pleural effusions. A study of chest radiographs in 149 consecutive acute pulmonary complications (25 in HIV-infected and 125 in non-HIV-infected patients) in immunocompromised patients observed that the most common complication in patients with AIDS was *P. carinii* pneumonia, and in the non-AIDS patients, the most common complications included invasive aspergillosis, drug reaction, and *P. carinii* pneumonia. The radiologists made the correct first-choice diagnosis in 90% of patients with AIDS and 34% of patients with non-AIDS patients. In non-AIDS patients with invasive pulmonary aspergillosis, drug reaction, and *P. carinii* pneumonia, the correct first-choice diagnosis was made in 38%, 26%, and 43% of readings, respectively.

Computed tomography of the chest with high-resolution imaging (HRCT) is invaluable in the diagnosis of pulmonary processes in immunocompromised patients. Several studies have documented the usefulness of HRCT in the detection of bronchiectasis in patients with immunodeficiency syndromes. The diagnosis of bronchiolitis obliterans with organizing pneumonia (BOOP) may be suggested by the HRCT images. The CT imaging is helpful in providing the bronchoscopist and the surgeon with a road map to the most abnormal anatomic area to plan procedures such as bronchoscopy or open-lung biopsy.

Assessing the degree of clinical urgency is of great importance in these patients, for in the absence of a specific diagnosis and proper therapy, many follow a rapid downhill course. The selection and prompt application of an appropriate investigative procedure help to reach proper decisions and provide optimal therapy. When routine blood tests, cultures from extrapulmonary sources, and biopsies fail to yield a specific answer, the course of diagnostic procedures is shown in Fig. 10.

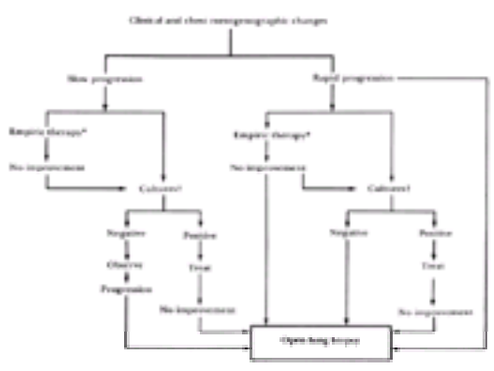

FIG. 10. Diagnostic approach to the immunocompromised patient with an abnormal chest roentgenogram. *Empiric therapy should be individualized and may include antiviral, antibacterial, and antifungal drugs and trimethoprim-sulfamethoxazole against *Pneumocystis carinii.* It may also include systemic corticosteroids, discontinuation of cytotoxic drugs, and therapy for pulmonary edema. +Cultures should be individualized depending on the clinical situation and chest roentgenographic abnormalities, but may include blood and other easily obtainable body fluids and secretions and bone marrow, as well as bronchoalveolar lavage and transbronchial lung biopsy.

When the battery of routine tests fail to provide clues to the etiology of the pulmonary process, direct examination of specimens from the respiratory tract is indicated. This can be accomplished by one or more the following: (1) study of easily obtainable secretions and fluid (sputum, gastric washings, and pleural fluid), (2) percutaneous (transthoracic) needle aspiration and needle biopsy of pleura and lung, (3) diagnostic bronchoalveolar lavage, (4) bronchoscopic brushing and aspirations or bronchoscopic lung biopsy, and (5) thoracoscopic or thoracotomy biopsy of pleura and lung. To reiterate, the degree of diagnostic urgency and the appropriateness of a given procedure should be weighed against the potential effect of delay on the subsequent outcome. The procedures just listed have varying yields and complication rates. The following is a brief summary of these aspects.

RESPIRATORY SECRETIONS AND FLUIDS

Sputum cultures usually are of limited value in diagnosing bacterial infections in the immune-suppressed host. However, induced sputum is valuable in the detection of *P. carinii.* Overwhelming growth of saprophytic fungi in the oropharyngeal regions of these patients is a hindrance in isolating true pathogenic bacteria and fungi. Sputum examination is also valuable in diagnosing mycobacterial infections and bronchogenic carcinoma. Gastric washings are helpful in the diagnosis of tuberculosis and certain fungal infections. Pleural fluid culture is very useful in diagnosing bacterial infections and malignancies. Minor pneumothoraces occur in fewer than 5% of thoracenteses and in fewer than 10% of pleural biopsies. Transtracheal and transthoracic needle aspirations are rarely indicated in patients with diffuse lung disease. Peripherally localized nodular lesions and lung masses are better approached by CT-guided transthoracic needle aspirations.

BRONCHOSCOPY

Flexible bronchoscopy has become the procedure of choice for diagnosing opportunistic pulmonary infections in patients with AIDS and in other immunocompromised patients. It is probably the safest of the invasive pulmonary diagnostic procedures. With supplemental oxygenation and appropriate preparation, the procedure can be performed in patients with severe hypoxemia. Furthermore, bronchoscopy and bronchoalveolar lavage can be performed in patients with severe thrombocytopenia, other coagulation disorders, and renal failure; the risk of hemorrhage is minimal. Major complications occur in less than 1% of patients. Both diagnostic bronchoalveolar lavage and bronchoscopic lung biopsy should be considered if diffuse lung infiltrates are present. Bronchoalveolar lavage alone, however, is adequate in the diagnosis of infections caused by *P. carinii,* bacteria, viruses, and mycobacteria. Lung biopsy is necessary to document tissue invasion by the fungi. Bronchoscopic lung biopsy, when used with bronchoalveolar lavage, increases the diagnostic yield in patients with *P. carinii* pneumonia, mycobacteriosis, and lymphangitic carcinomatosis. An overall diagnostic yield from bronchoalveolar lavage and bronchoscopic lung biopsy in the diagnosis of *P. carinii* in immunocompromised hosts is 82% and 92%, respectively. One study in patients with AIDS reported that an additional 8% of *P. carinii* pneumonia diagnoses, which were missed by bronchoalveolar lavage, were made by bronchoscopic lung biopsy. The study also documented that bronchoscopic lung biopsy is much more important to diagnose infections other than those caused by *P. carinii.* A staged approach is an option: for patients in whom *P. carinii* pneumonia is a major diagnostic consideration but whose sputa are negative for *P. carinii,* only a diagnostic bronchoalveolar lavage is performed initially; bronchoscopic lung biopsy is added to the initial bronchoalveolar lavage if other diagnostic possibilities are considered likely; and if the initial bronchoalveolar lavage is nondiagnostic despite strong clinical suspicion of *P. carinii,* a bronchoscopic lung biopsy is performed. Bilateral bronchoalveolar lavage has been shown to increase the diagnostic yield significantly in patients with opportunistic pulmonary infections. Cytomegalovirus can frequently be diagnosed from examination and culture of the diagnostic bronchoalveolar lavage fluid. Recovery of *M. avium* complex is highest with culture of both washings and lavage. Bronchoalveolar lavage in patients with leukemia and pulmonary infiltrates is not helpful in diagnosing invasive aspergillosis, unless a lung biopsy also is performed.

Extension of basic disease process into the lungs may require lung biopsy, although bronchoalveolar lavage provides a high diagnostic yield (over 75%) in patients with lymphangitic pulmonary metastasis. Bronchoscopic lung biopsy is routinely employed by many in the follow-up of patients who undergo lung or heart-lung transplantation because obliterative bronchiolitis, a common complication in this group of patients, responds to treatment with augmented immunosuppression when it is detected early by surveillance bronchoscopic lung biopsy.

LUNG BIOPSY

Thoracoscopy, which allows biopsy of pleura or lung under direct vision, is an excellent way to obtain material for culture as well as for histologic analysis. Open-lung biopsy is a more invasive pulmonary diagnostic procedure. This procedure yields the diagnosis in up to 95% of patients. With increasing use of bronchoalveolar lavage and thoracoscopy, the number of open-lung biopsies has decreased.

Cardiac Transplant Research Database Group. *J Heart Lung Transplant* 1994;13:381–392. *Report on 814 consecutive patients from 24 institutions undergoing primary heart transplantation between 1990 and 1991 with mean follow-up of 8.2 months (range 0 to 18 months) noted the following: the most common organ infected was the lung, with a mortality of 23%, and the single most frequent infecting organism was cytomegalovirus, accounting for 26% of all infections.*

Nysom K, Holm K, Hesse B, Ulrik CS, Jacobsen N, Bisgaard H, Hertz H. Lung function after allogeneic bone marrow transplantation for leukaemia or lymphoma. *Arch Dis Child* 1996;74:432–436. *Analysis of longitudinal data on the lung function of 25 of 29 survivors of childhood leukemia or lymphoma, who had been conditioned with cyclophosphamide and total-body irradiation before allogeneic bone marrow transplantation showed that none developed chronic graft-versus-host disease. Transfer factor and lung volumes were reduced immediately after bone marrow transplantation but increased over the following years, only to be followed by significantly reduced transfer factor, total lung capacity, and forced vital capacity. None of the patients had pulmonary symptoms, and changes were unrelated to their age at bone marrow transplantation.*

Obregon RG, Lynch DA, Kaske T, Newell JD Jr, Kirkpatrick CH. Radiologic findings of adult primary immunodeficiency disorders. Contribution of CT. *Chest* 1994;106:490–495. *Study to assess the role of CT scan in 22 patients with primary immunodeficiency disorders (19 with B-cell deficiency and three with T-cell deficiency) reported that CT is valuable for detection of bronchiectasis in subjects with B-cell immunodeficiency.*

Popa V. Airway obstruction in adults with recurrent respiratory infections and IgG deficiency. *Chest* 1994;105:1066–1072. *A study of 42 adults with recurrent respiratory infections and common-variable immunodeficiency or IgG subclass deficiency concluded that chronic obstructive bronchitis produced by smoking is a major determinant of airway obstruction and that historic, clinical, or radiologic features of recurrent respiratory infections, the type of IgG deficiency, or therapy with intravenous Ig do not affect pulmonary function tests.*

Primack SL, Muller NL. High-resolution computed tomography in acute diffuse lung disease in the immunocompromised patient. *Radiol Clin North Am* 1995;32:731–744. *A review of the role of high-resolution CT (HRCT) scanning in the assessment of acute diffuse lung disease in immunocompromised patients. The HRCT may demonstrate abnormalities when the radiograph is normal. Because HRCT is superior in demonstrating the distribution and extent of parenchymal abnormalities, it is also helpful as a guide to the optimal type and site of lung biopsy.*

Rosenow EC 3rd, Limper AH. Drug-induced pulmonary disease. *Semin Respir Infect* 1995;10:86–95. *A detailed review of pulmonary complications induced by drugs. The discussion also involves the drug-induced respiratory complications in an immunocompromised host receiving chemotherapeutic agents.*

Sargent MA, Cairns RA, Murdoch MJ, Nadel HR, Wensley D, Schultz KR. Obstructive lung disease in children after allogeneic bone marrow transplantation: evaluation with high-resolution CT. *Am J Roentgenol* 1995;164:693–696. *High-resolution CT scans of the lungs in seven children (with chronic graft-versus-host disease) who developed chronic obstructive lung disease after bone marrow transplantation showed areas of parenchymal hypoattenuation in all lobes. Expiratory air trapping and subsegmental or segmental bronchial dilation also were seen. The abnormalities were similar to those observed in patients with bronchiolitis obliterans.*

Schoettler JJ, Schleissner LA, Heiner DC. Familial IgE deficiency associated with sinopulmonary disease. *Chest* 1989;96:516–521. *Three generations of relatives (sera of 23 family members, 14 with a history of excessive sinopulmonary infections) of 58-year-old nonidentical twins with chronic bronchitis and fibrotic lung disease were evaluated for deficiencies of IgGs. Of 14 symptomatic family members, 12 had serum IgE concentrations less than 5 IU/ml. Inheritance of low IgE appeared to be autosomal dominant, with variable penetrance.*

Skull S, Kemp A. Treatment of hypogammaglobulinaemia with intravenous immunoglobulin, 1973–93. *Arch Dis Child* 1996;74:527–530. *A study over a 20-year period showed that children with hypogammaglobulinemia who receive replacement treatment grow normally and have the infection incidence of nonimmunodeficient children.*

Sutedja TG, Apperley JF, Hughes JM, Aber VR, Kennedy HG, Nunn P, Jones L, Hopper L, Goldman JM. Pulmonary function after bone marrow transplantation for chronic myeloid leukaemia. *Thorax* 1988;43:163–169. *Pulmonary function was measured before and at intervals after treatment in 44 patients who received a bone marrow transplant. The major factors associated with deterioration in pulmonary function at 6 and 12 months after transplantation in the 34 survivors were transplantation with T-cell-depleted donor marrow and higher total-body irradiation dose, chronic graft-versus-host disease, and acute graft-versus-host disease.*

Sweinberg SK, Wodell RA, Grodofsky MP, Greene JM, Conley ME. Retrospective analysis of the incidence of pulmonary disease in hypogammaglobulinemia. *J Allergy Clin Immunol* 1991;88:96–104. *A retrospective evaluation of clinical records, chest x-rays, and pulmonary function tests of ten patients with X-linked agammaglobulinemia followed for a mean of 12.5 years and 12 patients with common variable immunodeficiency followed for a mean of 10.5 years revealed that most patients treated with intramuscular g-globulin and long-term oral antibiotics had very few pneumonias. Pulmonary disease was more common and more severe in the group with common-variable immunodeficiency*.

Tait RC, Burnett AK, Robertson AG, McNee S, Riyami BM, Carter R, Stevenson RD. Subclinical pulmonary function defects following autologous and allogeneic bone marrow transplantation: relationship to total body irradiation and graft-versus-host disease. *Int J Radiat Oncol Biol Phys* 1991;20:1219–1227. *Pulmonary function results pre- and posttransplant, to a maximum of 4 years, were analyzed in 98 patients with hematologic disorders undergoing allogeneic (*n = *53) or autologous bone marrow transplantation (*n = *45). Significant obstructive ventilatory defects occurred in patients with graft-versus-host disease. After exclusion of patients with GVHD (30% of allografts), there was no significant difference in pulmonary function abnormalities between autograft and allograft recipients.*

Weiss SM, Hert RC, Gianola FJ, Clark JG, Crawford SW. Complications of fiberoptic bronchoscopy in thrombocytopenic patients. *Chest* 1993;104:1025–1028. *In this study of 47 bone marrow transplant recipients with thrombocytopenia, bronchoscopy was performed nasally in 37, orally in five, and via endotracheal tube in 16. Complications occurred in seven of 58 (12%) thrombocytopenic patients (epistaxis and/or hemoptysis, four; bradycardia, two; bronchospasm, one), of which all but one were minor and self-limiting. One life-threatening complication of severe epistaxis occurred during a transoral FOB in a patient with prior epistaxis.*

Witte RJ, Gurney JW, Robbins RA, Linder J, Rennard SI, Arneson M, Vaughan WP, Reed EC, Dicke KA. Diffuse pulmonary alveolar hemorrhage after bone marrow transplantation: radiographic findings in 39 patients. *Am J Roentgenol* 1991;157:461–464. *Among 39 bone marrow transplant recipients with a diagnosis of diffuse alveolar hemorrhage, the initial radiographic abnormalities developed an average of 11 days after bone marrow transplantation, and the radiographic abnormalities preceded the clinical diagnosis by an average of 3 days. The initial radiographic pattern was interstitial in 27 and alveolar in ten. The mortality rate in patients with diffuse alveolar hemorrhage was 77%.*

Yousem SA. The histological spectrum of pulmonary graft-versus-host disease in bone marrow transplant recipients. *Hum Pathol* 1995;26:668–675. *The histologic changes in 17 lung specimens in bone marrow transplant recipients included diffuse alveolar damage, lymphocytic bronchitis/bronchiolitis with interstitial pneumonitis, bronchiolitis obliterans with organizing pneumonia, and cicatricial bronchiolitis obliterans. Pulmonary disease correlated with the presence of graft-versus-host disease at extrathoracic sites. Patients with active lymphocytic bronchitis/bronchiolitis, cicatricial bronchiolitis obliterans, and diffuse alveolar damage had particularly poor outcomes.*

CHAPTER

56 Hematologic Diseases

INTRODUCTION

The erythropoietic system plays a major role in tissue oxygenation because the erythrocytes are the primary carriers of oxygen in the form of oxyhemoglobin. Therefore, anemia, polycythemia, abnormal hemoglobins, and significant changes in blood volume frequently produce alterations in various respiratory functions. Additionally, myeloproliferative, lymphoproliferative, and plasmacytic disorders and other hematologic malignancies frequently affect the pulmonary system. Pulmonary complications are the most common cause of mortality in patients with hematologic malignancies. Respiratory manifestations in these disorders may be caused by pulmonary extension of the basic disease process, cytotoxic drug-induced pulmonary pathology, opportunistic infections, or a combination of these factors. This chapter discusses the various thoracic manifestations in hematologic diseases. Pulmonary complications in bone marrow transplantation are discussed in Chapter 55.

HEMOGLOBINOPATHIES

A *hemoglobinopathy* is an abnormality of hemoglobin synthesis manifested by the production of globin with a structural abnormality. More than 90% of these abnormalities are the result of single amino acid replacements. The clinically significant hemoglobinopathies, as far as the pulmonary system is concerned, include sickle syndromes, hemoglobinopathies with high oxygen affinity (familial erythrocytosis), hemoglobinopathies with low oxygen affinity (familial cyanosis), M hemoglobinopathies (familial cyanosis), and methemoglobinemia and sulfhemoglobinemia. Although cyanosis as a result of these disorders is rare in clinical practice, the possibility of abnormal hemoglobin should be considered in the differential diagnosis of a cyanotic patient (Table 1).

Inadequate oxygenation of hemoglobin (common)
Pulmonary diseases
Cardiac and noncardiac right-to-left shunt
Vascular collapse (shock)
Low-oxygen-affinity hemoglobin variant
Methemoglobinemia (uncommon)
Hereditary (congenital)
Cytochrome b_5 reductase deficiency
M hemoglobinopathies
Acquired (toxic)
Nitrites and nitrates: amyl nitrite, nitroglycerine, nitroprusside, silver nitrate, sodium nitrite
Other drugs: acetanilid, benzocaine, lidocaine, phenazopyridine, phenacetin, procaine, sulfonamides
Industrial and environmental toxins: aniline dyes, chlorate, etc.
Sulfhemoglobinemia (uncommon)
Congenital (?)
Acquired: acetaminophen, acetanilide, arylamines, phenacetin, sulfur, toxins, etc.
Pseudocyanosis
Argyria
Hemochromatosis
Chloroma

TABLE 1. *Differential diagnosis of cyanosis*

Hemoglobinopathies with High Oxygen Affinity

More than 120 human hemoglobin variants are known to exhibit increased oxygen affinity. By definition, these hemoglobins demonstrate a shift to the left of the whole-blood oxygen dissociation curve. The hemoglobinopathies with high oxygen affinity result from amino acid substitution at sites crucial to hemoglobin function. These disorders are manifested in the heterozygous state and follow an autosomal codominant pattern of inheritance. A partial list of abnormal hemoglobins with increased affinity for oxygen include Chesapeake, J-Capetown, Malmo, Yakima, Kempsey, Ypsilanti, Hiroshe, Brigham, Rainier, Bethesda, Hiroshima, Little Rock, Olympia, Tarrant, Sureness, Helsinki, Creteil, Hotel Dieu, Radcliffe, Alberta, British Columbia, Heathrow, San Diego, Syracuse, York, and Cowtown.

Many of these hemoglobinopathies are manifested by secondary erythrocytosis. Most patients are asymptomatic, and the diagnosis is considered when unexplained erythrocytosis is detected. Patients with hemoglobin variants with a marked increase in oxygen affinity may demonstrate cyanosis. Because of the defective hemoglobin function, the arterial blood is partially unsaturated despite normal oxygen tension, which results in elevated levels of deoxyhemoglobin in the blood—hence

the cyanosis. However, the cyanosis is a cosmetic problem and warrants no specific therapy. Several individuals with high-affinity variants have had persistent leukocytosis, and an occasional subject has exhibited splenomegaly. Pulmonary fibrosis has been described in several members of a family with hemoglobin Malmo, but the occurrence seems coincidental.

Hemoglobinopathies with Low Oxygen Affinity

More than a dozen variants of hemoglobinopathies with low oxygen affinity have been described. A partial list includes Kansas, Beth Israel, St. Mande, Titusville, Connecticut, Bologna, Rothschild, Mobile, Hope, J-Cairo, Raleigh, Vancouver, Presbyterian, and Yoshizuka. Many affected family members exhibit slightly diminished hemoglobin levels. The shift to the right of the oxyhemoglobin dissociation curve reduces the erythropoietin-mediated stimulus to erythropoiesis. In hemoglobin Kansas, cyanosis in heterozygotes results from increased deoxyhemoglobin. The patients with hemoglobin Kansas demonstrate a marked decrease in whole-blood oxygen affinity. Despite the diminished oxygen content of the arterial blood, the shift to the right of the oxyhemoglobin dissociation curve allows adequate oxygen release. The subjects with hemoglobin Kansas may develop limited tolerance to strenuous muscular exercise, which depends on a greatly increased oxygen unloading.

In addition to hemoglobin Kansas, cyanosis can be seen in hemoglobin variants Beth Israel and St. Mande. Both have amino acid substitutions at the same site as hemoglobin Kansas (i.e., a substitution of threonine for asparagine at 102). Familial pulmonary hypertension has been described in association with abnormal hemoglobin with low oxygen affinity.

M Hemoglobinopathies

The main group of hemoglobins that produce cyanosis are known as *M hemoglobinopathies.* Hemoglobins M-Boston, M-Iwate, M-Saskatoon, M-Hyde Park, and M-Milwaukee exhibit abnormal absorbance spectra owing to the oxidation of the heme iron in the affected subunit. These hemoglobinopathies behave as autosomal codominant mutations. In the heterozygous state, they produce methemoglobinemia, which results in chronic cyanosis. The Bohr effect is markedly decreased to absent in the a-chain variants but normal to only slightly decreased in variants of the b chain. Thus, hemoglobins Iwate and Boston, both associated with a-chain alterations, show decreased oxygen affinity and decreased Bohr effect; hemoglobins Hyde Park and Saskatoon, which exemplify b-chain mutations, have essentially normal oxygen affinity and Bohr effect.

The predominant characteristic of hemoglobin M disorders is the presence of cyanosis from early childhood. Subjects with a-chain variants (M-Boston and M-Iwate) are cyanotic at birth, whereas those with b-chain variants (M-Saskatoon, M-Hyde Park, M-Milwaukee) do not exhibit cyanosis until approximately 5 to 6 months of age, when fetal hemoglobin is replaced by adult hemoglobin. Hemoglobin Freiburg, resulting from a b-chain mutation, is associated with mild cyanosis, whereas hemoglobin Seattle is not associated with cyanosis but does show decreased oxygen affinity. Despite the cyanosis in these hemoglobinopathies, there is no evidence of cardiac disease or clubbing. Exertional dyspnea is not a feature.

Methemoglobinemia and Sulfhemoglobinemia

Methemoglobinemia results when more than 1% of hemoglobin is oxidized to ferric form. When hemoglobin is oxidized to methemoglobin, the heme iron becomes Fe^{3+} and is incapable of binding oxygen. Methemoglobin content of normal red cells is less than 1%. When methemoglobin level exceeds 1.5 g/dl (10% of total hemoglobin), cyanosis becomes clinically obvious. Both hereditary (congenital) and acquired forms of methemoglobinemia exist. *Congenital methemoglobinemia* results from either hereditary deficiency of the enzyme cytochrome b_5 reductase (methemoglobin reductase) or the presence of one of the M hemoglobins. The major clinical feature is presence of cyanosis without cardiopulmonary problems.

Acquired methemoglobinemia, also known as *toxic methemoglobinemia,* results when drugs or toxins oxidize hemoglobin directly in the circulation or facilitate its oxidation by molecular oxygen (see Table 1). Toxic methemoglobinemia may be acute or chronic. In the latter, chronic administration of the offending agent leads to an increased steady-state concentration of methemoglobin that results in asymptomatic cyanosis. Blood gas analysis usually reveals normal arterial oxygen tension with disproportionately low arterial oxygen saturation and increased levels of methemoglobin. Acute methemoglobinemia, especially when the level of methemoglobin exceeds half the total hemoglobin, may present a serious medical emergency. When the methemoglobin level exceeds 35%, headaches, weakness, and dyspnea develop. The severity of methemoglobinemia depends on the dose of the causative agent as well as on the susceptibility of the exposed individual. Levels in excess of 80% are incompatible with life. Severe toxic methemoglobinemia should be treated with intravenous methylene blue (2 mg/kg).

Sulfhemoglobinemia refers to the presence, in peripheral blood, of hemoglobin derivatives that are poorly characterized chemically. Occasionally, subjects exposed to oxidant compounds will develop cyanosis that cannot be explained by simple hemoglobin oxidation. Because of its high absorbance in the red region of the visible spectrum, sulfhemoglobinemia causes more cyanosis than an equivalent percentage of methemoglobinemia. Congenital and acquired forms of sulfhemoglobinemia have been described. A number of pharmacologic and other agents (see Table 1) also produce sulfhemoglobinemia and cyanosis.

Sickle Cell Anemia

Sickle cell disease is caused primarily by hemoglobin SS, SC, or Sb thalassemia. Sickle cell anemia is a chronic, hereditary hemolytic disease resulting from clinical expression of homozygosity for hemoglobin S. The affected persons predominantly belong to the black race who have inherited the mutant gene from both parents. Pulmonary complications are common in patients with sickle cell anemia (SS hemoglobin) but less so in patients with SC hemoglobin. Pulmonary complications are important causes of morbidity and mortality.

Pneumococcal pneumonia is a major cause of morbidity and mortality in children with sickle cell disease. Pneumonia, especially in children and probably in all age groups, is the most common lung disease encountered in sickle cell anemia, where its incidence is 20 times greater than in the normal population. The major factors that predispose these patients to infections include abnormal complement activity, poor splenic function, and a lack of type-specific pneumococcal antibody. Local factors such as previous or concomitant pulmonary damage by vasoocclusion probably play a role. In children with sickle cell disease, the incidence of pneumonia increases significantly after the age of 8 months. The pneumonia in children usually is caused by *Streptococcus pneumoniae,* whereas in adults, *Staphylococcus aureus* or *Haemophilus* species predominate. The majority of suspected pneumonias in adults are caused by pulmonary embolism, and the differentiation of infectious pneumonia from acute chest syndrome or pulmonary embolism is difficult. One study of 166 patients with sickle cell anemia reported that 45% were hospitalized because of acute bacterial pneumonia, and half of this group had positive bacterial cultures. However, in another study of 18 patients with acute chest syndrome, respiratory secretion was obtained via bronchoscopy, and the study concluded that bacterial pneumonia was uncommon in this group of patients. Multilobar involvement is not uncommon, with the upper and middle lobes being involved more often than the others. Administration of pneumococcal vaccine is mandatory in patients with sickle cell anemia.

Fungal infections are uncommon in patients with sickle cell anemia, but occasional cases of cryptococcal infection have been described. Although a higher incidence of tuberculosis has been reported by some, others have not been able to substantiate this.

The *acute chest syndrome* (also called sickle chest syndrome, chest crisis, pulmonary sickle crisis, and pulmonary infarction) is seen in up to 35% of patients hospitalized with sickle cell disease; it is associated with significant morbidity and is the leading cause of death in patients with sickle cell disease. It is a common manifestation of sickling-induced vasoocclusive crises. The syndrome is characterized by fever, chest pain, and pulmonary infiltrates. Sudden onset of pleuritic chest pains, cough without hemoptysis, fever, and leukocytosis are common. Hypoxemia ($P_aO_2 < 50$ mmHg) is present in up to 40% of patients. Dense bilateral lower-lung consolidations are common. A retrospective analysis of 100 hospitalized pediatric cases of sickle cell anemia revealed lower-lobe pulmonary infiltrates in 86% and upper- and middle-lobe infiltrates in 25% and 22%, respectively; pleural effusions were observed in 38%. Sickle cell crisis may be precipitated by asthmatic attacks.

Bone marrow fat embolism of pulmonary vasculature is a common complication in patients with sickle cell disease and is responsible for many cases of severe acute chest syndrome. To diagnose fat embolism, one study evaluated the presence of fatty macrophages recovered by bronchoalveolar lavage in 20 consecutive patients with acute chest syndrome; a cutoff of >5% of alveolar macrophages containing fat droplets was determined (from a control group) for the diagnosis of fat embolism. In 12 episodes of acute chest syndrome, bronchoalveolar lavage yielded >5% of fatty macrophages (median 47%; range 10% to 100%), and in 11 cases, fat embolism was associated with proven or probable bone marrow infarction. Overall, the diagnostic yield of bronchoalveolar lavage for fat embolism was 60%.

Secretory phospholipase A_2 as an important mediator of acute lung injury of the fat embolism syndrome has been used for the diagnosis; phospholipase A_2 activity appears to correlate with acute chest syndrome.

Pulmonary complications are common in patients with sickle cell disease who are hospitalized with acute chest syndrome. Incentive spirometry has been shown to prevent the pulmonary complications associated with the acute chest syndrome. A prospective, randomized trial in 29 patients (8 to 21 years of age) with sickle cell diseases who had 38 episodes of acute chest or back pain above the diaphragm and were hospitalized showed that the incidence of thoracic bone infarction was 40% (15 of 38 hospitalizations). Pulmonary complications in the form of atelectasis or infiltrates developed during only one of 19 hospitalizations of patients assigned to the

spirometry group, as compared with eight of 19 hospitalizations of patients in the nonspirometry group.

Pulmonary pathologic features include pulmonary vascular occlusion, capillary stasis, thrombus formation, infarction, alveolar wall necrosis, and emboli of necrotic bone marrow. These complications are more common in women, particularly during late pregnancy or shortly after delivery. Patients with hemoglobin SC disease may be at risk of *in situ* thrombosis of pulmonary vessels. The roentgenographic appearance of these lesions is no different from that produced by thromboemboli. A postmortem study of 36 older patients with sickle cell disease identified thromboemboli in most. However, pulmonary infarction is a much less frequent complication among younger patients. Anticoagulant therapy does not help. Although circulatory stasis may develop *in situ,* vascular occlusion by marrow embolus is probably a more common cause of pulmonary infarction and has been discovered at autopsy in 13% of patients with sickle cell disease. In patients with sickle cell anemia, pulmonary hemosiderosis may result from repeated blood transfusions.

Pulmonary edema is another complication of sickle cell crisis. Vigorous hypotonic fluid replacement and parenteral analgesic therapy, commonly used in patients in sickle cell crisis, may contribute to its development. Autopsy findings in patients who died from pulmonary edema are consistent with a diffuse pulmonary vasoocclusive disease.

Decreased diffusing capacity of lung for carbon monoxide has been demonstrated in sickle cell anemia and has been attributed to a loss of membrane area as a result of obstruction of pulmonary vessels. Other physiological studies have shown a decreased vital capacity, normal maximal breathing capacity, arterial oxygen desaturation, and a widened alveolar–arterial oxygen tension difference in most patients with the disease. Both venoarterial shunting and abnormal ventilation–perfusion relationships play major roles in this. The arterial oxygen desaturation predisposes to *in vivo* sickling and its consequences. The heterozygous state of sickle cell trait (hemoglobin AS) may lead to abnormal pulmonary function, as a result of sickling, at high altitudes. The sickling phenomenon can result in pulmonary thromboembolism and can further aggravate sickling, with deterioration in hypoxia. Short exposures to hypoxia at high altitudes do not acutely or cumulatively alter diffusing capacity or spirometric values in healthy persons with sickle cell trait.

Sickle cell disease and sarcoidosis are two disorders commonly affecting black people. Studies have shown the prevalence rates of hemoglobinopathies in sarcoid patients to be 18% to 20%.

b-Thalassemia Major

Thalassemia major is characterized by an unbalanced synthesis of globin chain, resulting in ineffective hematopoiesis and severe anemia. Severe hemolytic anemia and ineffective erythropoiesis from infancy are the main characteristics of this disorder. The ability of these patients to increase their oxygen-carrying capacity with physical stress is limited. Patients succumb at a young age to congestive cardiac failure. Patients with thalassemia major who are chronically transfused exhibit a high cardiac output during exercise, regardless of hemoglobin concentration, and the mechanism for this phenomenon is unknown. Cardiopulmonary evaluation of 35 patients with homozygous b-thalassemia observed hypoxemia in 85%, reduced lung volumes and flow rates in 51% and 63%, respectively, and diminished diffusing capacity for carbon monoxide in 50%. Pulmonary hypertension was present in 75%, and right ventricular dysfunction was more prevalent than left ventricular dysfunction. The possible causes for these complications include left ventricular failure, iron deposits in the pulmonary vessels, and a hypercoagulable state with thrombotic obstruction of the pulmonary arteries. Transfusion-induced decreases in forced vital capacity and P_aO_2 in the absence of pulmonary edema have been observed, but the mechanism is unclear.

HEMORRHAGIC DISEASES

Pulmonary complications such as pulmonary embolism and alveolar hemorrhage can result from an underlying disorder of coagulation. Both hypercoagulable and hypocoagulable states may be associated with these complications. The presence of a hemorrhagic disorder predisposes to pulmonary bleeding, and the risk of bleeding is increased if the patient has a preexisting pulmonary lesion such as a tumor, bulla (Fig. 1), cyst, cavity, or bronchiectasis.

FIG. 1. Hemorrhage into a bullous lesion in the right lower lobe in a patient with excessive bleeding tendency secondary to coumarin therapy.

Hemophilia

Classic hemophilia is the result of functional deficiency of antihemophilic factor (factor VIII) because of an X-linked recessive gene. The most serious complication is the occurrence of the acquired immunodeficiency syndrome (AIDS) in those who were administered factor VIII contaminated by the human immunodeficiency virus. This risk has significantly diminished as a result of stringent improvements in blood banking. Pulmonary manifestations are unusual in hemophilia but have included spontaneous pneumothorax, hemomediastinum, tracheal obstruction by a hematoma, and pleural hematomas. In a review of chest roentgenograms, abnormalities were recorded in 26 of 33 adult hemophiliacs; scarring, fibrosis, and pleural thickening were seen in 12 cases, and abnormalities of pulmonary vessels were seen in the remaining 14, of which four had evidence of hyperinflation. Several cases of primary pulmonary hypertension have been described in patients receiving factor VIII infusion.

Disseminated Intravascular Coagulation

Pulmonary hemorrhage occurs in patients with disseminated intravascular coagulation and other coagulopathies. The incidence of pulmonary hemorrhage is estimated to be approximately 14% in disseminated intravascular coagulation. Often, it is subclinical with very little or no hemoptysis and patchy nondescript lung infiltrates. Massive bleeding is uncommon. The pulmonary hemorrhage syndrome has features in common with the adult respiratory distress syndrome, such as hyaline membrane formation and pulmonary hypoperfusion. Thrombocytopenia has been shown to lead to the development of pulmonary hematoma, hemothorax, and fatal pulmonary hemorrhage.

Pulmonary infarction has been described in several patients with disseminated intravascular coagulation. Thromboembolism and hemorrhage are the main pathologic findings in the lungs of patients dying with disseminated intravascular coagulation. A postmortem comparative study of 87 patients whose illnesses were complicated by disseminated intravascular coagulation and 64 control patients observed thromboembolism in 51 cases (59%), infarction in six, hemorrhage in 14, microscopic fibrin thrombosis in 43 (49%), and microthromboembolism in 45 (52%) patients with disseminated intravascular coagulation. The frequency of pulmonary infarction increased in proportion to the frequency of thromboembolism. In the control group, macroscopic thromboembolism was identified in 20 cases (31%).

MYELOPROLIFERATIVE DISORDERS

Leukemia

Pulmonary involvement in leukemia occurs more often than is usually suspected. The reported mortality rate associated with pulmonary complications in leukemia is approximately 60% to 65%. The respiratory complications depend on the type of leukemia, the nature and course of treatment, and the presence or absence of significant neutropenia. Many of the complications, particularly infections, are secondary to the immunocompromised status of leukemic patients, which is caused either by the leukemic state itself or by treatment.

Infectious pneumonia is a frequent and often fatal complication and is responsible for up to 75% of deaths in patients with acute leukemia. In a series of 68 leukemic

patients with pulmonary infiltrates, 82% of focal and 35% of diffuse infiltrates were caused by infectious causes. Gram-negative organisms are the most common cause of pneumonia. Fungal pneumonia occurs in up to 30% of patients. In acute leukemia, *Pneumocystis carinii* pneumonia occurs less often in adults than in children. In a review of 53 cases of *P. carinii* pneumonia, including four in children, leukemia was the underlying hematologic disorder in 28%. In another study, 52 episodes of pneumonia were recorded among 68 leukemic patients; most pneumonias were caused by gram-negative bacilli, with a 25% incidence of fungal pneumonia. The overall mortality was 65%. In childhood leukemia, viruses are more important as respiratory pathogens and are major causes of morbidity.

Granulocytopenia, hypogammaglobulinemia, and lymphocytic bronchitis in graft-versus-host disease may follow bone marrow transplantation and predispose these patients to infectious complications (see Chapter 55). Granulocytopenia in leukemic patients poses a significant risk of invasive aspergillosis and acute respiratory distress syndrome because invasive pulmonary aspergillosis is a life-threatening complication. The risk for the development of invasive aspergillosis is directly proportional to the duration of granulocytopenia. The rapidity of bone marrow recovery markedly influences the clinical and roentgenographic course of the disease. For patients with acute leukemia, granulocytopenia persisting longer than 3 weeks is the major risk factor for developing this life-threatening infection. In an observation of such patients, granulocyte recovery, with counts exceeding 500/mm^3, was followed by cavitary pulmonary aspergillosis in 73%. Nearly one-third of the patients with malignancies who receive empiric antibiotic therapy during episodes of granulocytopenia develop pulmonary fungal infections. Massive hemoptysis may occur in some patients. Prognosis has been uniformly poor, with mortality rates exceeding 70% in some series. A study reported that early diagnosis of aspergillosis in leukemic patients on chemotherapy can be established by computed tomography, which will reveal a characteristic progression from multiple fluffy masses to cavitation or air crescent formation.

Zygomycosis (mucormycosis) of lung is another serious fungal infection in severely neutropenic patients. It also can occur, however, in nonneutropenic patients and in patients long after hospital discharge following bone marrow transplantation. In a 17-year consecutive series of patients with bone marrow transplant, 0.9% (13 patients) of 1500 patients developed mucormycosis; ten allogeneic and three autologous transplant recipients. Seven patients were neutropenic. Six infections occurred within 90 days of transplant, and six occurred at or within several days of autopsy. Sites of infection were lung and brain in four, sinonasal region in three, lung in two, disseminated in two, and lung and kidney in one patient. Death from mucormycosis occurred in ten (77%) of 13 patients.

Hypogammaglobulinemia, related to inherent abnormalities of B-lymphocyte function and T-cell imbalances, is present in approximately 50% of patients with chronic lymphocytic leukemia. Infections, particularly with encapsulated microorganisms, are a frequent cause of morbidity and mortality.

Hairy-cell leukemia is an unusual hematologic malignancy and may exhibit splenomegaly, pancytopenia, and circulating mononuclear cells with prominent cytoplasmic projections. Infections are secondary to granulocytopenia and defects in cell-mediated immunity. Bacterial, fungal, and mycobacterial infections occur frequently. Disseminated infections caused by *Mycobacterium kansasii* and *M. avium* complex occur in patients with hairy-cell leukemia.

Autopsy studies have revealed that noninfectious intrathoracic involvement by leukemia is a common late development. Mediastinal and hilar adenopathy is seen in 50% of cases, and pulmonary parenchyma is involved in approximately 25%. Acute myelogenous leukemias produce pulmonary parenchymal leukemic infiltrates more commonly than the chronic varieties, but among the chronic group, lymphocytic leukemia is more likely than the granulocytic type to invade pulmonary parenchyma (Fig. 2 and Fig. 3). The usual roentgenographic abnormality within pulmonary parenchyma is a diffuse bilateral reticulonodular infiltration resembling that of lymphangitic metastasis (Fig. 4). This is not uncommon in the terminal stages of leukemia. However, several cases of acute leukemia presenting with diffuse pulmonary infiltrates and respiratory failure have been described. As noted above, in patients who are granulocytopenic, presence of diffuse lung infiltrates should warn of the possibility of invasive aspergillosis (Fig. 5). Rapidly progressive pulmonary infiltrates have been noted as a major clinical problem in chronic myelogenous leukemia. The leukemic infiltrates may be parenchymal (focal or diffuse), pleural, peribronchial, or endobronchial. In the Richter's transformation, chronic lymphocytic leukemia may convert from a low-grade histologic picture to high-grade non-Hodgkin's lymphoma and produce hilar or mediastinal lymphadenopathy. Pleural effusion, usually unilateral, is seen in up to 25% of cases.

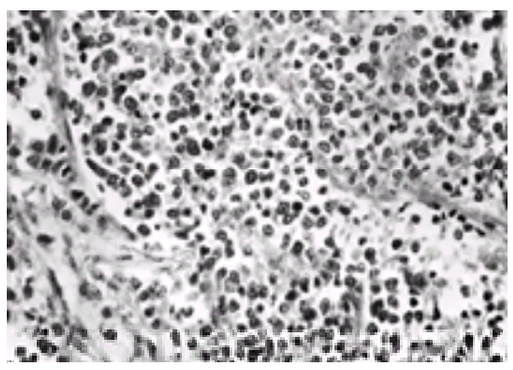

FIG. 2. Pulmonary infiltration by acute granulocytic leukemia.

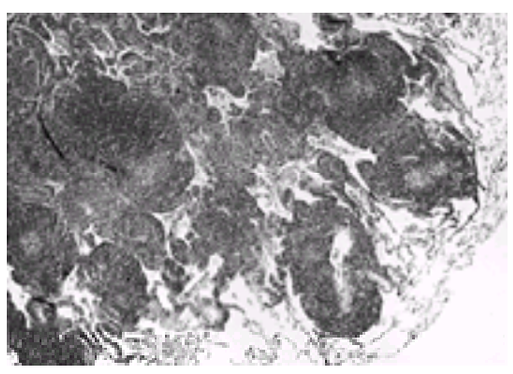

FIG. 3. Pulmonary involvement by chronic lymphocytic leukemia. A dense infiltrate of small lymphocytes can be seen around vessels and in alveolar septa.

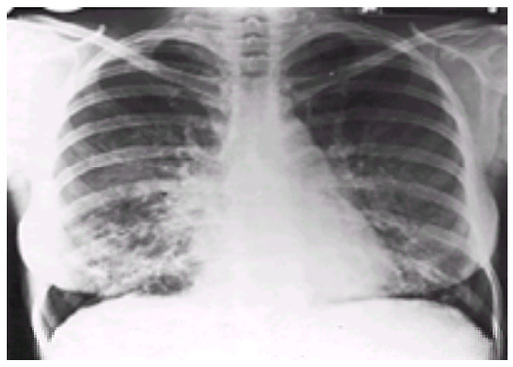

FIG. 4. Leukemic infiltrates in the lower lobes of both lungs in a patient with acute monomyelocytic leukemia.

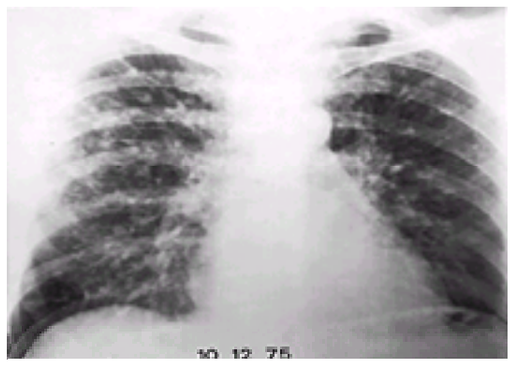

FIG. 5. Diffuse nodular-reticular infiltrates in a severely granulocytopenic patient on chemotherapy for acute monomyeloctic leukemia.

Pulmonary alveolar hemorrhage is found often at autopsy in leukemic patients. In a necropsy study of 50 patients with acute leukemia, pulmonary hemorrhage and leukemic pulmonary infiltrates were recorded in 54% and 64%, respectively. Pulmonary hemorrhage usually is associated with thrombocytopenia and may be extensive. Another predisposing cause is invasive pulmonary aspergillosis. The majority of patients with pulmonary alveolar hemorrhage do not exhibit hemoptysis.

Hyperleukocytosis denotes peripheral white blood cell count in excess of 50,000/mm^3. This condition has the potential to cause pulmonary leukostasis, which is a serious, frequently fatal, complication. Pulmonary leukostasis usually occurs in patients with acute granulocytic leukemias. A clinicopathologic study of 16 leukemic patients with circulating leukocytes counts of less than 50,000/mm^3 and pulmonary leukostasis concluded that hyperleukocytosis *per se* cannot be the cause of pulmonary leukostasis but that other factors, such as the presence of circulating blasts and the affinity of neoplastic cells for the pulmonary endothelium, may be related to the development of acute respiratory distress. Leukemic cell lysis pneumopathy, which occurs as a result of pulmonary vascular occlusion by destroyed leukemic cells within 48 hrs of initiation of chemotherapy, may cause respiratory failure. The development of acute respiratory failure in patients with hematologic disorders is a life-threatening condition. Irrespective of the etiology of acute respiratory failure in this group of patients, the outcome is dismal, with a mortality rate of 80%.

Granulocyte colony-stimulating factor, by augmenting leukocyte production, pulmonary sequestration of white blood cells, and margination and production of toxic oxygen radicals, may exacerbate underlying subclinical bleomycin pulmonary toxicity. In a series of 12 patients with aggressive non-Hodgkin's lymphoma who received chemotherapy that included bleomycin in combination with recombinant human granulocyte colony-stimulating factor, three of four patients who developed a rapidly progressive pneumonic illness died; no infection was detected. The lung abnormalities were characterized by diffuse infiltrates and hypoxemia. Caution should be exercised before using granulocyte-stimulating factors in bleomycin-containing regimens.

All-*trans* retinoic acid induces complete remission in most cases of acute promyelocytic leukemia. Its use, however, is associated with potentially fatal pulmonary toxicity in approximately 25% of patients in the setting of a rapidly rising peripheral leukocyte count. A prospective multicenter study has shown the efficacy of oral corticosteroid for prophylaxis against pulmonary toxicity from retinoic acid.

In patients with leukemia, lung biopsy may suggest areas of pulmonary alveolar phospholipoproteinosis. This is secondary to the monocytopenia in leukemia. Alveolar macrophages are derived from monocytes, and the deficiency of monocytes in leukemia results in the inability of the limited number of alveolar macrophages to ingest intraalveolar phospholipids. In addition, opportunistic infections and cytotoxic drugs may affect the alveolar clearance of phospholipids and produce patchy areas of secondary pulmonary alveolar (phospholipo)proteinosis. However, this finding is clinically insignificant, and chest roentgenograms may or may not show patchy areas of alveolar infiltrates.

Pseudohypoxemia or spurious hypoxemia, also described as leukocyte larceny, denotes low oxygen tension and saturation in arterial blood in the absence of clinical evidence of tissue hypoxia. This phenomenon occurs in patients with extreme degrees of leukocytosis. During the *in vitro* transportation of an arterial blood sample from the patient to the laboratory, the large number of leukocytes in the syringe consume significant amounts of oxygen, and hence, the measurement reveals a low P_aO_2. Pseudohypoxemia is seen also in patients with severe thrombocytosis.

Polycythemia

Defined as a sustained excess of red blood cell volume, polycythemia occurs in either a primary or a secondary form. Secondary polycythemia is a compensatory mechanism seen in various chronic hypoxemic states. The pulmonary manifestations in patients with such diseases are those of the underlying disease.

Primary polycythemia, or *polycythemia rubra vera,* is a chronic disease of unknown etiology characterized by hyperplasia of all the cellular elements of the bone marrow, nucleated red blood cells being more prominently involved. Chest roentgenographic abnormalities consist of accentuated vascular markings and minor infiltrates and, occasionally, nodular lesions in the midlung zones. Thrombosis, stasis, or infarction in pulmonary veins is believed to produce discrete lesions. Other abnormal roentgenographic findings include enlargement of hilar vessels and passive pulmonary congestion. Symptoms are those of pulmonary insufficiency from pulmonary edema. Acute airway obstruction caused by spontaneous retropharyngeal bleeding and hematoma formation has been described in a patient with polycythemia rubra vera.

Normal arterial oxygen saturation (S_aO_2 > 92%) is regarded as one of the features that differentiates polycythemia vera from the secondary (hypoxemic) form, because almost all patients with primary polycythemia have normal arterial oxygen saturation. However, mild degrees of desaturation may occur with otherwise well-documented polycythemia vera in the absence of cardiopulmonary problems. The pathogenesis of this desaturation is not apparent.

Pulmonary function studies have shown that patients with polycythemia vera usually have normal vital capacity, airway resistance, and alveolar ventilation. The diffusing capacity of lung for carbon monoxide may be slightly increased. This, however, is an inconsistent finding. Pulmonary capillary blood volume and the size of the pulmonary vascular bed may be reduced in some patients, resulting in ventilation–perfusion abnormalities.

LYMPHOPROLIFERATIVE DISORDERS

Hodgkin's Disease

Intrathoracic involvement in Hodgkin's disease is common, occurring in up to 40% of patients, especially in those with advanced stage IIIB or IV disease. Pulmonary involvement may be seen in more than 50% of cases of Hodgkin's lymphoma at postmortem. Intrathoracic involvement is twice as common with Hodgkin's as with non-Hodgkin's lymphoma.

Primary pulmonary Hodgkin's disease is a distinct entity and denotes involvement of the lung without hilar adenopathy or disseminated disease. Fewer than 100 cases of pulmonary Hodgkin's disease have been reported. This form of Hodgkin's lymphoma is more common in women, typically involves upper lung fields, and may appear as a solitary mass or a multinodular process with or without cavitation.

Almost any type of chest roentgenographic abnormality can be seen in patients with thoracic manifestation of Hodgkin's disease. However, the most common abnormality is the enlargement of mediastinal lymph nodes, noted in 50% of cases. Bilateral lymph node enlargement is common, particularly if the paratracheal nodes are involved (Fig. 6). Enlargement also affects retrosternal nodes, posterior mediastinal nodes, and the diaphragmatic group of parietal lymph nodes. Intrapulmonary lymph node involvement may not be visible on the chest roentgenogram (Fig. 7).

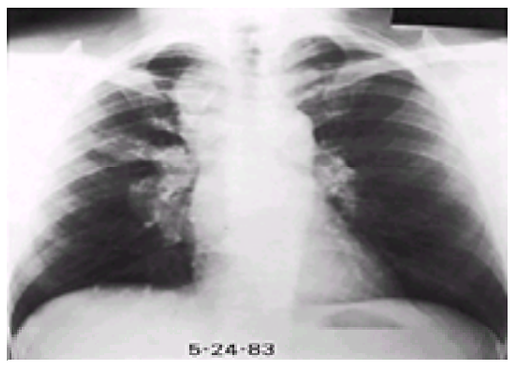

FIG. 6. Bilateral hilar and right paratracheal lymphadenopathy caused by Hodgkin's lymphoma.

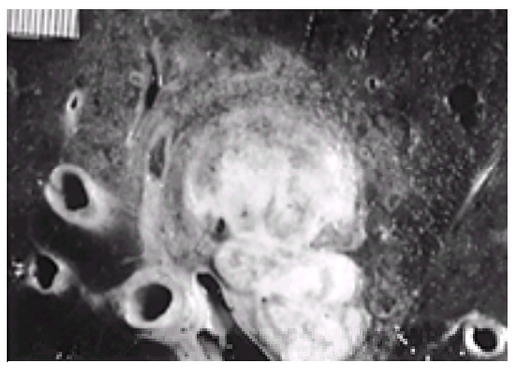

FIG. 7. Involvement of intrapulmonary peribronchial lymph node by Hodgkin's lymphoma, found at autopsy.

Pulmonary parenchymal involvement is seen in up to 30% of patients (Fig. 8, Fig. 9 and Fig. 10), especially in those with the nodular sclerosing type of Hodgkin's disease, and is usually accompanied by mediastinal lymphadenopathy. In a study of 112 patients with advanced Hodgkin's disease, more than 25% were found to have parenchymal disease without lymphadenopathy. The parenchymal features include direct invasion of lung from regional lymph nodes (characterized by linear, feathery densities), massive homogeneous infiltrates with lymphadenopathy, nodular infiltrates, and generalized dissemination resembling miliary tuberculosis. Pulmonary parenchymal involvement ordinarily results from direct extension from mediastinal nodes along the lymphatics of bronchovascular sheaths. The parenchymal masses may develop cavities, and usually these are multiple and located in lower lobes. Cavitation of pulmonary nodules secondary to Hodgkin's disease is rare and has been noted in approximately 55 cases.

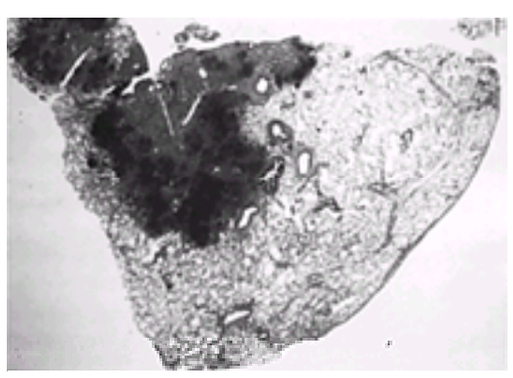

FIG. 8. Hodgkin's lymphoma presenting as a localized nodular lesion. The histologic pattern was nodular sclerosing Hodgkin's lymphoma. Some of the darker nodules of lymphoid tissue seem to be surrounded by a paler fibrous tissue indicative of a nodular sclerosing pattern.

FIG. 9. Hodgkin's lymphoma in the lung as part of disseminated disease at presentation. The lung infiltrates were caused by a cellular proliferation around vessels and airway that have the cytologic features of Hodgkin's lymphoma.

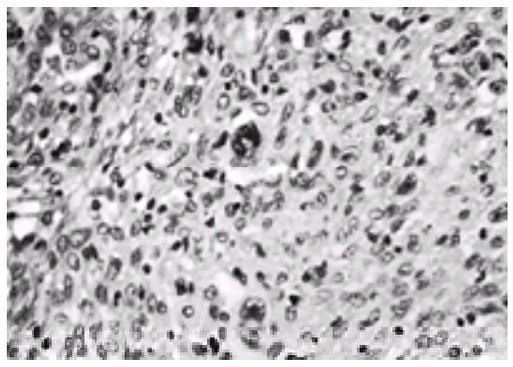

FIG. 10. Hodgkin's lymphoma replacing normal lung parenchyma. Reed-Sternberg cell is the center.

Endobronchial involvement occurs in nearly 5% of patients with Hodgkin's lymphoma. Lobar or segmental atelectasis, cough, and hemoptysis may result. Bronchial mucosal involvement from non-Hodgkin's lymphoma may become severe enough to cause airflow obstruction. Extrinsic compression of the trachea and mainstem

bronchi by large mediastinal Hodgkin's lymphoma can lead to airway obstruction and respiratory failure. Patients may experience varying degrees of dyspnea in supine posture.

Several cases of acute airway obstruction and respiratory failure during general anesthesia have been described. During general anesthesia, the extrinsic airway compression is exacerbated by diminished lung volumes secondary to reduced inspiratory muscle tone, relaxation of bronchial smooth muscle tone and the resultant compressibility of airway, diminished expiratory flow rate, and severely diminished movement of the diaphragm. Pulmonary function tests performed in 43 patients with Hodgkin's disease before mantle irradiation (total dose of 36 to 42 Gy) and at 3, 6, 9, 12, and 15 or more months thereafter have revealed only small variations in the functional indices. More than 5 years after therapy, respiratory symptoms and reduction in lung function occur in nearly one-third of otherwise healthy survivors of Hodgkin's disease. Women are at significant risk for pulmonary complications following therapy for Hodgkin's disease.

Pleural effusion occurs in 30% of patients and usually is associated with other intrathoracic lesions. The main factor responsible for the collection of pleural fluid is the obstruction to lymphatics by the enlarged hilar lymph nodes. The pleural fluid is commonly an exudate, serous, and chylous in one-third. Chylothorax is the accumulation of chyle in the pleural space because of disruption of the thoracic duct or a major lymphatic tributary. Intrathoracic malignancy is the most common cause of chylothorax, and lymphoproliferative disorders are responsible 75% of the time. In a study of 38 patients with chylous effusions, 20 effusions were caused by lymphomas. Diagnostic thoracentesis and needle biopsy of the pleura may aid in determining whether the pleural space or the pleura is involved with Hodgkin's or non-Hodgkin's lymphoma. However, the clinical correlation is extremely important in interpreting cytologic preparations. In one report, pleural biopsy was helpful in diagnosing non-Hodgkin's lymphoma in nine of ten patients. In contrast, a large series demonstrated that the finding of lymphocytic pleuritis on biopsy or lymphocytosis of pleural fluid was nondiagnostic and that clinical correlation was essential to confirm the diagnosis. Massive pleural effusions have occurred as a late complication of radiation therapy for Hodgkin's lymphoma, probably from impaired lymphatic drainage secondary to mediastinal fibrosis induced by radiation.

Spontaneous pneumothorax is an unusual complication in Hodgkin's disease. One study noted 17 episodes of pneumothorax in eight patients, seven with Hodgkin's lymphoma and one with non-Hodgkin's lymphoma. The observed incidence of pneumothorax among 1977 patients with lymphoma was tenfold higher than expected; this included a significantly higher incidence in patients younger than 30 years compared to those older than 30 years and a higher incidence in patients with Hodgkin's lymphoma than in those with non-Hodgkin's lymphoma. This study suggested a strong relationship between radiation and pneumothorax. Pneumothorax associated with lymphoma is more complex and difficult to manage. Other unusual manifestations include thoracic cage involvement and diaphragmatic paralysis.

Non-Hodgkin's Lymphomas

The most common intrathoracic manifestation of non-Hodgkin's lymphoma is mediastinal lymph node enlargement, which is seen in nearly 35% of patients. Primary pulmonary lymphoma ordinarily presents as an alveolar infiltrate or a homogeneous mass. Bronchial obstruction or endobronchial involvement occurs, but less frequently than with Hodgkin's lymphoma.

When the lung is involved by non-Hodgkin's lymphoma, the typical roentgenographic pattern is that of solitary or multiple nodules 3 mm to several centimeters in diameter, more frequently in the lower lobes. Other manifestations are similar to those in Hodgkin's disease. Endobronchial recurrence of non-Hodgkin's lymphoma can be seen in patients who are unresponsive to therapy. Diagnostic bronchoalveolar lavage provides specimens for lymphocyte subtyping and classification of lymphoma.

Pleural effusions are common in non-Hodgkin's lymphoma. Indolent lymphomas may produce chylous pleural effusions. Among 26 pleural effusions associated with non-Hodgkin's lymphomas, 20 were exudative, and five were chylous. Cytologic examinations were positive in 86% of exudative effusions, whereas 61% of pleural biopsies were positive for the disease. In a study of 19 patients with pleural effusion caused by non-Hodgkin's lymphoma, pleural tissue disclosed lymphoma in 17 patients, supporting the contention that pleural effusion in patients with non-Hodgkin's lymphoma is usually secondary to pleural lymphoma rather than to obstruction of mediastinal lymphatics. Systemic chemotherapy results in resolution of pleural effusion in approximately half the patients; the prognosis is poor in those with refractory effusions.

Patients treated for Hodgkin's and non-Hodgkin's lymphoma should be observed for the development of other hematologic and solid neoplasms because these patients accrue a relative risk two to three times that of the normal population of developing newer malignancies. Patients with Hodgkin's disease who receive supradiaphragmatic irradiation or combined-modality therapy may be at higher risk for developing non-small-cell lung cancer. In a study of such patients, the risk ratio for the development of lung cancer among Hodgkin's patients was 5.6 times that expected in the general population. The median ages at diagnosis of Hodgkin's disease and lung cancer were 39 and 45 years, respectively. The interval between the diagnoses of Hodgkin's disease and metachronous lung cancer averaged 7 years but appeared to vary inversely with age.

Primary Lymphoma of the Lung

Primary lymphomas of the lung are rare, representing fewer than 1% of all primary pulmonary malignancies. They usually are well-differentiated B-cell tumors of the IgM type, although a few cases of the IgG and IgA types have been described. Among 62 cases of primary lymphoma of lung, 58 were B-cell and two T-cell type; two other cases could not be classified. The largest group (43 cases) consisted of low-grade B-cell lymphoma of the bronchus-associated lymphoid tissue (BALT). The histologic features were similar to low-grade B-cell lymphoma of the mucosa-associated lymphoid tissue (MALT) of the stomach. The BALT hyperplasia can vary, from multifocal proliferations that arise in and remain in the airway walls (follicular hyperplasia of BALT) to those that form a solitary mass or nodule (nodular lymphoid hyperplasia of BALT or “pseudolymphoma”) to multifocal or diffuse lymphoid hyperplasia of BALT (“lymphoid interstitial pneumonitis”).

The definitive diagnosis of primary pulmonary lymphoma rests on the typical histopathologic and immunochemical staining pattern. Low-grade lymphomas show a peak occurrence in the sixth decade of life, whereas the high-grade lymphomas occur most often in the seventh decade. There is a slight male predominance. Nearly 75% of the patients with low-grade B-cell lymphoma of BALT exhibit solitary or multiple sharply defined lung nodules. The prognosis is favorable in those without systemic symptoms.

The majority of primary extranodal lymphomas (not to be confused with primary lymphoma of lung) originate in MALT, and the term maltoma has been applied to them. The maltomas seem to be associated with good prognosis. In a study of 161 cases of non-Hodgkin's lymphomas and pseudolymphomas of lung, lymphomas were noted in 32%—plasmacytoid lymphocytic and small, cleaved, follicular center-cell lymphomas in 22% and 12% of cases, respectively. The remainder were follicular center-cell lymphomas and B-immunoblastic sarcomas. Most patients were elderly and asymptomatic, and, in most cases, a solitary nodule or infiltrate was seen on the chest roentgenogram. Hilar lymphadenopathy was also observed.

Mycosis Fungoides and Sezary Syndrome

Cutaneous T-cell lymphomas encompass a spectrum of diseases, including mycosis fungoides and Sezary syndrome, characterized by the malignant proliferation of phenotypically mature T lymphocytes with a propensity to infiltrate the skin. Microscopic infiltration of the lung parenchyma occurs in 43% to 56% of these patients. Lung biopsy and sometimes the sputum cytology will show distinctive large and small mononuclear cells with an indented cerebriform and hyperchromatic nuclei. Lymphadenopathy precedes visceral involvement. Pulmonary manifestations may include diffuse basilar infiltrates, nodular densities, perihilar densities, pneumonic processes, consolidative lesions, and pleural effusion. Hemoptysis and hypoxemia are described. Rapid pulmonary dissemination can occur in Sezary syndrome.

LYMPHOMATOID GRANULOMATOSIS

Recently renamed *angiocentric T-cell lymphoma,* lymphomatoid granulomatosis is also known polymorphic reticulosis, midline malignant reticulosis, midline granuloma, and Stewart's granuloma. Even though clinically and roentgenologically lymphomatoid granulomatosis mimics Wegener's granulomatosis and is frequently discussed in the context of vasculitides, lymphomatoid granulomatosis is a lymphoproliferative disorder and not a primary vasculitis. Similarities have been noted in the histologic patterns of lymphomatoid granulomatosis and Epstein–Barr virus (EBV)-associated lymphoproliferative disease involving the lung. Epstein–Barr virus has also been identified by polymerase chain reaction in most cases of pulmonary lymphomatoid granulomatosis. It appears that some cases of lymphomatoid granulomatosis represent B-cell lymphoma associated with EBV infection, whereas others (perhaps those limited to head and neck region) are of T-cell origin and are probably unrelated to EBV infection. However, because of the similarity between lymphomatoid granulomatosis and nasal angiocentric lymphoma, the term angiocentric immunoproliferative lesion has been proposed for both entities.

A familial lymphoproliferative disorder is described in three male siblings with primary pulmonary involvement manifested as either lymphoid interstitial pneumonia or an angiodestructive lesion resembling lymphomatoid granulomatosis. Epstein–Barr virus, frequently associated with proliferative lesions in men in the X-linked lymphoproliferative syndrome, was not demonstrated in any of the pulmonary lesions. The lack of involvement by EBV in the pulmonary lesions suggests that this is perhaps a previously undescribed familial lymphoproliferative disorder.

Morphologically, lymphomatoid granulomatosis is a destructive angiocentric process characterized by prominent vascular infiltrates and necrosis of medium and small blood vessels with formation of granulomas (Fig. 11). Impairment of the immune system of unknown causes may predispose patients with lymphomatoid

granulomatosis to develop anergy and, eventually, lymphoma. Histologic features often include a spectrum of benign-appearing lymphocytic interstitial pneumonitis to overtly malignant lymphoma in the same patient. Progression to non-Hodgkin's T-cell lymphoma occurs in over 50% of patients. Lymphomatoid granulomatosis is an uncommon disease, with approximately 350 cases reported. The disease usually presents during middle age, and there is a slightly higher prevalence in men. The presenting symptoms are nonspecific and include fever, malaise, and weight loss. Lymphomatoid granulomatosis can affect any organ system, but the disease is found with greatest frequency in the central nervous system, skin, kidney, and lymphatic system. Nearly one-fourth of patients demonstrate involvement of the central nervous system. Ataxia, hemiparesis, blindness, and dizziness are the presenting symptoms. Almost half of patients with lymphomatoid granulomatosis develop skin lesions in the form of erythematous, macular, or plaque-like lesions over the extremities.

FIG. 11. Lymphomatoid granulomatosis showing angiocentric infiltration by dense lymphoid infiltrates. Cytologically, this case had features of a diffuse large-cell lymphoma.

Laboratory tests are not helpful in the diagnosis. Leukocytosis (in 30% of patients), leukopenia (in 20% of patients), mild to moderate elevation of the erythrocyte sedimentation rate, and mild elevations of IgG or IgM may be present. Urinalysis usually is normal in patients with lymphomatoid granulomatosis because the glomerulus is characteristically spared.

The diagnosis of lymphomatoid granulomatosis requires biopsy examination of the affected tissue, usually lung, skin, or head and neck lesions. Lung biopsy characteristically shows an angiocentric angiodestructive infiltration of atypical lymphocytoid and plasmacytoid cells (Fig. 11).

Pulmonary Disease

Pulmonary involvement is present in virtually all patients with lymphomatoid granulomatosis. Along with the systemic symptoms, cough and dyspnea are prominent respiratory symptoms. If head and neck areas are involved, patients may present with symptoms similar to those of Wegener's granulomatosis. Hemoptysis is more likely in those with cavitated lung lesions. Chest roentgenograms most frequently disclose nodular infiltrates. Nodular densities may cavitate and are more common in the lower lung zones. In one series, multiple nodules with poorly defined borders were observed in 88% of patients, with cavitation in 25%. Occasionally, alveolar infiltrates are noted. Pleural effusions occur in 25% of patients. One review of 173 patients collected from two separate series noted the following chest roentgenologic abnormalities: multiple bilateral nodules in 80% of patients; cavitation of nodules in 30%; air bronchograms in 35%; pleural effusion in 33%; atelectasis in 30%; pneumonitis or mass-like lesions in 30%; and pneumothorax in 5% (Fig. 12 and Fig. 13).

FIG. 12. Bilateral multiple nodular lesions in lymphomatoid granulomatosis.

FIG. 13. Bilateral multiple nodules of varying sizes in lymphomatoid granulomatosis. Several nodules are cavitated.

Presence of hilar or mediastinal lymphadenopathy usually signifies lymphomatous transformation. Unilateral or bilateral large pulmonary masses measuring more than 10 cm in diameter often signal the presence of lymphoma.

Airway involvement is unusual but can be extensive. Pathologic findings described include bronchiolitis obliterans, bronchial ulceration, and destruction and occlusion of bronchioles by masses of inflammatory cells and fibrous tissue.

Treatment and Prognosis

There is no definitive therapy for lymphomatoid granulomatosis. In most patients, a therapeutic approach similar to that for highly malignant lymphoma must be considered. Adequate clinical staging and multiple biopsies to assess properly the degree of malignancy are necessary before multiple-drug therapy can be started. Multiple chemotherapeutic agents with a corticosteroid may be needed in patients who demonstrate highly malignant features. Preliminary reports indicate that interferon-a_{2b} is effective. Localized lesions in the head and neck area may respond to radiation. Progressive respiratory involvement, usually because of lymphoma and related complications, is the most frequent cause of death. Fever, leukopenia, cutaneous anergy, and hepatomegaly are considered poor prognostic indicators.

Pseudolymphoma

Lymphoid tumors that do not fulfill the criteria for malignant lesions have been called pseudolymphoma, although many pseudolymphomas have been reclassified as

indolent well-differentiated lymphocytic and lymphoplasmacytic lymphomas on the basis of immunologic proof of clonality. In a study of 161 cases of primary non-Hodgkin's lymphomas of the lung, pseudolymphoma was observed in 14%. Pseudolymphoma of the lung is characterized pathologically by the presence of a mixed cellular infiltrate (mostly mature lymphocytes), the presence of germinal centers, and regional lymph nodes free of lymphoma. Nonetheless, it often is difficult to distinguish pulmonary pseudolymphoma, lymphoma, and other lymphoid neoplasms and infiltrates by simple histologic examination. Pulmonary manifestations consist of well-delineated nodules, segmental parenchymal consolidation, or diffuse interstitial infiltration. Localized lesions are best treated by resection, whereas diffuse lesions may need immunosuppressive therapy.

Angioimmunoblastic Lymphadenopathy

Angioimmunoblastic lymphadenopathy mimics lymphomas. It is a disorder in which diffuse obliteration of the lymph node architecture occurs as a result of proliferation of small vessels and immunoblasts. Both an autoimmune mechanism and a T-cell defect leading to polyclonal B-cell activation may be responsible. The disease is systemic, and histopathologic features appear benign, although progression to lymphoma can occur. Angio-immunoblastic lymphadenopathy usually presents as generalized lymphadenopathy with hepatosplenomegaly and constitutional symptoms and mimics Hodgkin's disease. Differentiating features include polyclonal gammopathy, autoimmune hemolytic anemia, and a predilection for men older than 50 years. The chest roentgenographic features are similar to those of Hodgkin's disease, namely, hilar lymphadenopathy, interstitial infiltrates, and pleural effusion. Superior vena caval obstruction has been described.

Castleman's Disease

Originally reported as mediastinal lymph node hyperplasia resembling thymoma, Castleman's disease is also described by other terms, including angiofollicular lymph node hyperplasia, giant lymph node hyperplasia, lymph node hamartoma, benign giant lymphoma, multifollicular lymph node hyperplasia. The two histologic types of Castleman's disease are the hyaline-vascular (proliferation of hyalinized blood vessels) and plasma-cell (abundance of plasma cells) types. The former accounts for 90% of cases and is usually asymptomatic, whereas the latter is associated with systemic manifestations. The disease has no predilection for age, sex, or race. It occurs in the thoracic cage in up to 70% of cases. The most common clinical manifestation is the well-defined and lobulated enlargement of anterior mediastinal lymph nodes adjacent to thymus and tracheobronchial tree. Symptoms are caused by compression of the tracheobronchial tree by enlarged lymph nodes and may include cough, dyspnea, and hemoptysis. Intrapulmonary lesions, nodules, and pleural effusion are uncommon. Computed tomography shows vascular lesions that are well rounded and lobulated. Surgical resection is curative if the disease is limited to resectable lymph nodes.

POEMS Syndrome

POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) syndrome, also known as Crow–Fukase syndrome, is a rare variant of plasma cell dyscrasia with multisystemic manifestations. Multiple lung tumorlets have been described. Greatly raised vascular endothelial growth factor has been observed in this syndrome. This perhaps is responsible for the acute arterial obliteration described in several patients. Pulmonary hypertension has been described in this syndrome.

Lymphocytic Interstitial Pneumonitis

Lymphocytic interstitial pneumonitis is characterized by pulmonary parenchymal infiltrates that consist predominantly of small lymphocytes and variable numbers of plasma cells and transformed lymphocytes. Many patients with lymphocytic interstitial pneumonitis have developed lymphomas. Indeed, all cases of lymphocytic interstitial pneumonitis are thought to represent low-grade lymphomas. It is not clear whether the lymphocytic infiltrative lung diseases are premalignant, initially neoplastic, or caused by a hypersensitivity reaction, with neoplasia developing subsequently. They comprise a poorly defined group that includes lymphocytic interstitial pneumonitis, immunoblastic lymphadenopathy, plasma cell interstitial pneumonitis, lymphomatoid granulomatosis, and benign lymphocytic angiitis and granulomatosis. The diseases associated with lymphocytic interstitial pneumonitis are listed in Table 2. Many of these demonstrate similar histologic features, but involvement of the central nervous system, skin, kidneys, and lymph nodes outside the thorax varies, with a course that may be slow or rapidly fatal.

Hodgkin's lymphoma
Non-Hodgkin's lymphoma
Lymphomatoid granulomatosis
Chronic lymphocytic leukemia
Waldenstrom's macroglobulinemia
Angioimmunoblastic lymphadenopathy
Sézary syndrome
Pseudolymphoma
Sjögren's syndrome
Acquired immunodeficiency syndrome (AIDS)
Children of mothers at high risk for AIDS
Graft-versus-host disease
Congenital agammaglobulinemia
Chronic active hepatitis
Primary biliary cirrhosis
Crohn's regional enteritis
Nontropical sprue
Myasthenia gravis
Autoimmune hemolytic anemia
Systemic lupus erythematosus
Chronic thyroiditis
Idiopathic

TABLE 2. *Differential diagnosis of lymphocytic interstitial pneumonitis*

The occurrence of lymphocytic interstitial pneumonitis in patients with AIDS is well recognized. Lymphocytic interstitial pneumonitis occurs frequently in children of mothers who are at high risk for developing AIDS.

Low-grade lymphoid malignancies respond well to therapy. The treatments, however, may lead to acute, subacute, or chronic pulmonary complications. A literature analysis of 2269 patients with low-grade lymphoid malignancies who received more than 7547 cycles of fludarabine noted that 3% of patients developed opportunistic infections; among the latter group, 97% of infections occurred in patients who were pretreated with alkylating regimens or corticosteroids, and 45 (2%) of these were of respiratory origin and associated with a 56% mortality rate.

PLASMA CELL DISORDERS

Amyloidosis

Amyloidosis is a plasma cell disorder of unknown etiology, characterized pathologically by the extracellular deposition of acellular fibrils derived from the light chain of a monoclonal immunoglobulin. In primary amyloidosis, 35% to 70% of cases show roentgenographic evidence of amyloid deposition in the lung, whereas in secondary amyloidosis, pulmonary involvement is rare. A review, in 1983, of 126 reported cases of primary localized amyloidosis of the lower respiratory tract revealed the following pulmonary abnormalities: hilar or mediastinal lymphadenopathy in 5%, tracheobronchial multifocal submucosal plaques in 45%, tracheobronchial amyloid tumor-like masses in 8%, discrete nodules in the pulmonary parenchyma in 44%, and diffuse alveolar septal amyloidosis in 3%. A review in 1996 observed that 35 of 55 patients with pulmonary amyloidosis had primary systemic amyloidosis that presented roentgenologically as an interstitial or reticulonodular pattern with or without pleural effusion. The median survival after diagnosis was 16 months. Nodular pulmonary “amyloidomas” (nodular amyloid lesions) were not associated with systemic disease and were associated with a benign prognosis. Despite its localized nature, tracheobronchial amyloid deposition may be asymptomatic or may result in significant morbidity from obstructive phenomena. Pleural effusion is uncommon unless it is caused by congestive cardiac failure.

Pulmonary amyloidosis may be classified as shown in Table 3. Macroglossia associated with amyloidosis has been reported to cause airway obstruction and sleep apnea. Laryngeal and subglottic deposition of amyloid may contribute to the airway obstruction (Fig. 14). Diffuse tracheobronchial submucosal plaques result in generalized narrowing of the tracheobronchial tree and cause progressive stridor, dyspnea, cough, atelectasis, and hemoptysis. Bronchoscopic examination reveals submucosal elevation of the tracheobronchial mucosa, pale, shiny ridges, and areas of stenoses with various degrees of luminal narrowing. A deep submucosal bronchoscopic biopsy of the submucosa yields the diagnosis.

Type	Pulmonary symptoms
Macroglossia	Sleep apnea
Laryngeal and subglottic (localized, stenotic)	Stridor, dyspnea
Diffuse tracheobronchial (submucosal plaques)	Stridor, dyspnea, hemoptysis
Localized tracheobronchial (mass-like lesions)	Stridor, dyspnea, hemoptysis
Diffuse nodular (parenchymal)	Mild symptoms, bronchiectasis, cavitation in 30%
Solitary nodular (parenchymal; amyloidoma)	Rare, minimal symptoms, incidental finding
Diffuse parenchymal (septal or interstitial)	Progressive dyspnea, hemoptysis
Mediastinal and hilar lymphadenopathy[a]	Seen in 5% of all amyloidoses
Secondary[b]	Incidental (biopsy or autopsy finding, asymptomatic)
Senile	Incidental (autopsy or biopsy finding, asymptomatic)
Malignancy associated[c]	Incidental

[a] Sometimes associated with multiple myeloma.
[b] Associated with tuberculosis, syphilis, bronchiectasis, and hypergammaglobulinemia.
[c] Pulmonary malignancy, carcinoid, and amyloid associated with medullary thyroid carcinoma.

TABLE 3. *Pulmonary amyloidosis*

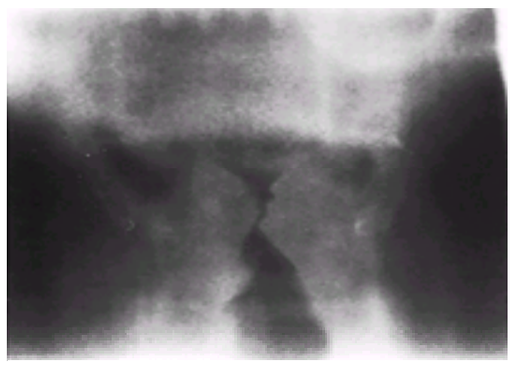

FIG. 14. Tracheal tomogram demonstrates amyloidosis involving subglottic and upper trachea.

Tracheobronchial amyloidosis is an indolent form of disease. However, hemoptysis and stridor can pose life-threatening emergencies. In contrast to the submucosal variety, localized tracheobronchial amyloidosis will exhibit, on bronchoscopy, endobronchial tumor-like amyloid masses that are usually polypoid and solitary and occur only in major bronchi. Secondary changes may include atelectasis, obstructive emphysema, obstructive pneumonitis, or bronchiectasis. Fatal hemorrhage has been described.

The lower respiratory tract often is involved in systemic primary amyloidosis, and, occasionally, disease is restricted to lungs. Chest roentgenographs may exhibit nodular changes or diffuse infiltrations. Amyloid nodules in the pulmonary parenchyma are peripheral and grow slowly, may be solitary (amyloidoma) or multiple (Fig. 15), and cavitate in one-third of patients. Calcification of the nodule can occur.

FIG. 15. Localized amyloidosis (amyloidoma) of right lower lobe treated by surgical resection.

The diffuse alveolar septal form of pulmonary parenchymal amyloidosis usually is associated with systemic amyloidosis and carries the worst prognosis of all types of pulmonary amyloidosis (Fig. 16). Progressively restrictive lung dysfunction abnormality, severely diminished diffusing capacity of lung for carbon monoxide, and significant hypoxemia are common. Lung biopsy shows diffuse deposition of amyloid in interstitium and alveolar walls (Fig. 17). Electron microscopic studies have shown that deposition of amyloid is confined to the interstitial space of alveolar septa and that capillaries are involved in the later stages. Involvement of pulmonary vasculature in amyloidosis may lead to medial dissection of pulmonary arteries and hemoptysis. Congestive cardiac failure with secondary pulmonary edema may contribute to the pulmonary distress.

FIG. 16. Diffuse parenchymal amyloidosis showing basal interstitial infiltrates.

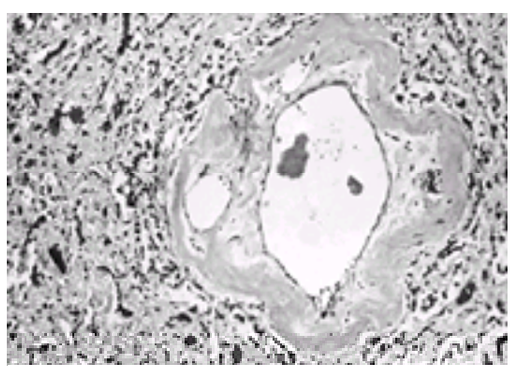

FIG. 17. Amyloid deposits surrounding pulmonary blood vessels in primary amyloidosis.

The prognosis is much better for the nodular pulmonary parenchymal type than for the tracheobronchial obstructive or diffuse interstitial forms of amyloidosis. The latter often lead to death from respiratory insufficiency. Localized tracheobronchial amyloidosis may respond to repeated bronchoscopic Nd:YAG or carbon dioxide laser photoresection, although the treatment is often unsatisfactory. Although it has been suggested that tracheobronchopathia osteoplastica is the end result of tracheal amyloidosis or other metabolic diseases, the literature fails to support this contention. Diaphragmatic myopathy from amyloidosis infiltration may result in respiratory failure. Secondary localized amyloidosis of the lower respiratory tract has been noted in tuberculosis, syphilis, hypogammaglobulinemia, malignancies (usually pulmonary), and carcinoid.

Waldenström's Macroglobulinemia

Waldenström's macroglobulinemia is an uncommon disorder characterized by monoclonal IgM gammopathy, anemia, and lymphocytic or plasmacytic infiltration of bone marrow. Pleuropulmonary involvement is relatively common. Five of 20 patients exhibited abnormalities, asymmetric nodular lesions in four and pleural effusion in one; biopsies showed infiltration of lungs by lymphocytes and plasmacytes in four, and roentgenograms demonstrated resolution of abnormalities. Characteristically, the chest roentgenogram shows a diffuse reticulonodular pattern and, occasionally, local homogeneous consolidation (Fig. 18). Pleural effusion is present in nearly 50% of patients. Chylothorax is rare.

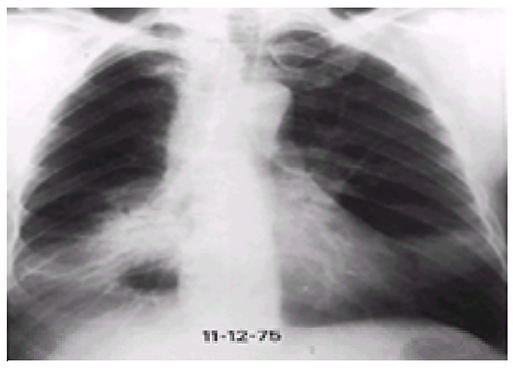

FIG. 18. Bilateral lower-lung infiltrates associated with a large right pleural effusion in Waldenstrom's macroglobulinemia.

In a 1980 literature review of pulmonary complications of Waldenström's macroglobulinemia documented by biopsy of pleura or lung (or both) in 44 patients (26 men; ages 33 to 84 years, median age 64 years), mass lesions were noted in 50%, infiltrates in 70%, and pleural effusions in 43%. Mediastinal lymphadenopathy was associated with pulmonary disease in 25%. Fifty-five percent of patients had two or more of these manifestations. Dyspnea (54%), nonproductive cough (33%), and chest pain (7%) were the main pulmonary symptoms, and 15% of patients were asymptomatic. Many had pulmonary manifestations at the time of initial disease. Respiratory involvement appeared 2 to 67 months after the diagnosis of Waldenström's macroglobulinemia in two-thirds. Bronchoalveolar lavage studies in a patient with diffuse pulmonary involvement from Waldenström's macroglobulinemia have shown abnormal plasma cells (10% to 47%), lymphocytes (60%), and myeloma protein.

Pulmonary manifestations respond to alkylating agents, corticosteroids, and radiation and do not appear to affect prognosis adversely. In one study, 19 of the 31 patients responded to chlorambucil given alone or with corticosteroids.

Multiple Myeloma

A malignant neoplasm of plasma cells, multiple myeloma is manifested primarily by widespread skeletal destruction and frequently is associated with anemia, hypercalcemia, and renal dysfunction. Pulmonary manifestations are rare. The chest roentgenographic finding of a plasmacytoma is typically that of a homogeneous mass associated with an osteolytic rib lesion, with the mass normally protruding into the thoracic cage (Fig. 19). Pulmonary parenchymal involvement by the abnormal plasma cells is unusual. Diffuse pulmonary infiltration by neoplastic plasma cells occasionally produces interstitial changes on the chest roentgenograph.

FIG. 19. Multiple myeloma involving right upper ribs with protrusion of the bony tumor into the chest cavity.

Solitary plasmacytoma of the upper respiratory tract or the pulmonary parenchyma may occur. Primary tracheal plasmacytoma, when present, appears as a solitary or multiple mass of homogeneous density. Unusual manifestations include nonosseous pleural lesions, pleural effusions, chylothorax, and pulmonary parenchymal calcification. Alveolar hemorrhage has been described as a presenting feature of myeloma. Metastatic pulmonary calcification that resolved with therapy is described in a patient with multiple myeloma.

Transfusion and the Lung

The use of blood and blood products, even under the best circumstances, carries considerable risk for the recipient. Immediate pulmonary reactions include dyspnea, bronchospasm, and pulmonary edema. It should be emphasized that pulmonary edema following blood transfusion need not be the result of overloading the circulation. In addition to the blood and blood products, patients receive crystalloid solutions and other drugs via the intravenous route. Transfusion-related acute lung injury and the postperfusion syndrome are discussed here.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is a form of noncardiogenic pulmonary edema. Passive transfusion of granulocyte or lymphocyte antibodies, or both, in donor sera is the most common setting for this unusual reaction. The antibodies in the donor serum may activate granulocytes and complements. The use of therapeutic or prophylactic granulocyte transfusion has been associated with the development of cytomegalovirus pneumonia. Granulocyte transfusion in association with amphotericin B or in the setting of endotoxemia has been associated with acute respiratory failure.

The incidence of TRALI may be underestimated. One review of 36 cases over a 2-year period indicated an incidence of 0.02% per unit and 0.16% per patient transfused. The clinical features are dramatic. Acute respiratory distress within 4 hr after transfusion (in most cases, after 2 hr) is the *sine qua non* of this syndrome.

Other features include acute onset of chills, fever, tachycardia, nonproductive cough, and blood eosinophilia. Roentgenograms show patchy opacities in the perihilar and lower-lung regions (Fig. 20). Although recovery is rapid and complete in 81%, some form of respiratory support may be required in more than two-thirds of the patients. Pulmonary infiltrates and hypoxemia have persisted for 7 days in 17% of patients. Granulocyte antibodies in the serum of at least 1 unit of donor blood were demonstrated in 89% of cases, whereas lymphocytotoxic antibodies were present in 72%.

FIG. 20. Diffuse bilateral soft nodular infiltrates as a result of transfusion-related acute lung injury.

Postperfusion Syndrome

Pulmonary complications following prolonged cardiopulmonary bypass have been termed postperfusion syndrome, pump lung, perfusion lung, or postperfusion atelectasis. The etiology remains unknown, although immunologic mechanisms have been suggested. After prolonged maintenance on cardiopulmonary bypass, patients develop progressive pulmonary insufficiency, which is manifested by cyanosis, hypoxemia, increased work of breathing as a result of severely diminished compliance, and widening of the alveolar–arterial oxygen tension gradient. Chest roentgenograms reveal patchy, diffuse alveolar infiltrates that resemble pulmonary edema. Pathologic changes are similar to those seen in the respiratory distress syndrome, namely diffuse alveolar damage.

Factors that contribute to the postperfusion lung syndrome include hypoxia, interruption of blood supply to pulmonary tissues (especially to alveolar cells), loss of surfactant, interaction of homologous blood with a pump gas exchanger, and an underlying pulmonary disease process.

Prevention of the postperfusion syndrome is important because treatment is not promising. Corticosteroids given early may help, but the results are similar to those seen in the respiratory distress syndrome from other causes.

Langerhans-Cell Histiocytosis

Langerhans-cell histiocytosis is also known as pulmonary eosinophilic granuloma or primary pulmonary histiocytosis X. It is a granulomatous disease of unknown etiology characterized by abnormal proliferation of histiocytes and an unpredictable natural history, although the disease usually exhibits a slowly progressive course. Langerhans-cell histiocytosis belongs to the group of diseases collectively known as *histiocytic reticulocytosis* or *histiocytic reticuloendotheliosis;* the latter category of disorders includes Letterer–Siwe disease (acute disseminated histiocytosis X), Hand–Schuller–Christian disease (chronic disseminated histiocytosis X), and localized histiocytosis X or eosinophilic granuloma. The main discussion here is on the pulmonary form of Langerhans-cell histiocytosis.

Pathologic Features

The etiology of pulmonary Langerhans-cell histiocytosis is unknown. An immune mechanism has been suggested because of the presence of circulating immune complexes and granular IgG and complement components in alveolar walls and pulmonary capillaries. Macrophage colony-stimulating factor and platelet-derived factor may have a role in initiating and/or maintaining pathologic lesions. The most striking association, however, is between pulmonary Langerhans-cell histiocytosis and tobacco smoking; a history of tobacco smoking has been observed in more than 95% of patients with the disorder.

The effector cells, generally referred to as histiocytes, are a combination of pigment-laden alveolar macrophages and histiocytosis X cells (H-X cells), which are closely related to Langerhans cells in normal skin. A Langerhans cell is seldom seen in normal lungs. The H-X cells are judged to be reactive or activated Langerhans cells, and therefore, pulmonary Langerhans-cell histiocytosis is considered to represent a pathologic proliferation of Langerhans cells. Electron microscopy shows a common marker organelle (X-body or Birbeck granule) in the H-X cell. These pentalaminar cytoplasmic inclusion bodies are not specific for the disorder. They are present also in nearly one-fourth of patients with idiopathic pulmonary fibrosis and hypersensitivity pneumonitis but absent in inorganic pneumoconioses, pulmonary lymphangioleiomyomatosis, and sarcoidosis.

Bronchoalveolar lavage can be used to establish the diagnosis. The H-X cells are not normally present in the alveolar wall and rarely are seen in the bronchiolar wall but may constitute 2% to 20% of the effector cells in Langerhans-cell histiocytosis. Langerhans cells express surface antigen identified by the monoclonal antibody OKT6 or positive immunoperoxidase staining for S-100 protein. Even though S-100 protein staining is non-specific, OKT6-reactive cells are more specific for Langerhans-cell histiocytosis.

Gross morphologic features in the early phase of the disease show subpleural nodules that measure 2 to 10 mm or more and small, irregular cystic lesions. The nodules contain a wide variety of cells, including cells with large vesicular nuclei, cells with vacuolated cytoplasm, giant cells, histiocytes, lymphocytes, eosinophils, and polymorphonuclear leukocytes, and the degree of lymphocytic and plasma cell infiltration, extent of eosinophilia, number of foam cells, and amount of necrosis or fibrosis vary considerably from lesion to lesion (Fig. 21 and Fig. 22). The histiocytes fuse to form multinucleate giant cells, which results in the accumulation of so-called foam cells, vacuolated histiocytes with sudanophilic material in the cytoplasm. Langerhans bodies and fibrils are apparent also in cytoplasm. The H-X cells are seen in large numbers in acute and active forms of the disease, decreasing in number as the disease becomes chronic. Fibrosis eventually replaces the granulomatous process, and formation of characteristic honeycomb cysts occurs.

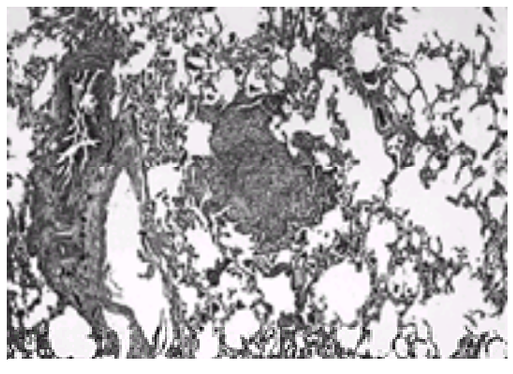

FIG. 21. The earliest lesions of pulmonary eosinophilic granuloma are central lobular proliferations of cells along small bronchioles and alveolar ducts, seen here as a small parenchymal nodule.

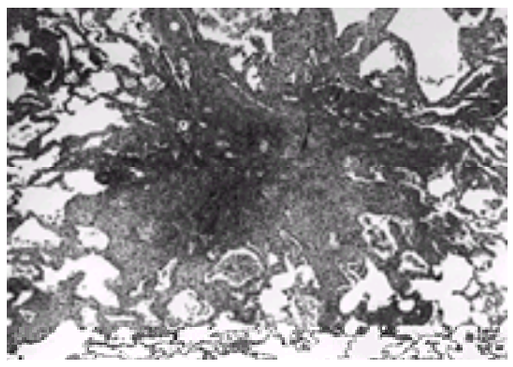

FIG. 22. In established cases of pulmonary eosinophilic granuloma, the classic lesion is a stellate nodule with central pigmentation and scarring and peripheral cellularity in which Langerhans histiocytes can be found.

Clinical Features

Pulmonary Langerhans-cell histiocytosis usually is a disease of adults and is more commonly limited to the lungs or the bones or both. The incidence of the disease is unknown. More than 1000 cases have been reported, and more than 300 of these have displayed diffuse abnormalities on chest roentgenography and an interstitial pulmonary process on pathologic examination. Most patients are 20 to 40 years old, and the male-to-female ratio is approximately equal, although most series have shown a slight male predominance. The disorder occurs most frequently in Caucasians and is rare in blacks. Familial incidence has been reported in one instance.

One-fourth to one-third of patients with pulmonary disease are asymptomatic, the disease being uncovered by a routine chest roentgenogram. One-third of patients complain of fatigue, fever, and weight loss. The most common symptom is a nonproductive cough, observed in 65% of patients. Dyspnea and chest pain are present in 40% and 25% of patients, respectively. Chest pain may be secondary to a spontaneous pneumothorax or an osteolytic rib lesion.

Commonly, pulmonary functions are only minimally abnormal even when the chest roentgenogram shows significant abnormalities. Up to 15% of patients will demonstrate normal lung functions. In contrast, in one study of the disorder in children, 13% of patients with Langerhans-cell histiocytosis had abnormal pulmonary functions even though chest roentgenograms were normal. The most common pulmonary function abnormality is a restrictive defect with decreased lung volumes, normal flow rates, and diminished diffusion capacity of lung for carbon monoxide. Significant obstructive airways disease is present in up to 20% of patients with advanced disease. These patients present with symptoms of severe airways disease. Tobacco smoking, peribronchial fibrosis with compression of airways by the cystic lesions, and obliterative bronchiolitis from infiltration of bronchial walls by cells and granulomas may contribute to airways obstruction.

Chest roentgenologic abnormalities in Langerhans-cell histiocytosis usually are diffuse, bilateral, and most pronounced in the upper two-thirds of the lung fields. Initially, a nodular pattern with lesions ranging from 1 to 12 mm in diameter is found (Fig. 23). Later on, a reticulonodular pattern and honeycomb appearance, with cysts varying from 5 to 30 mm and averaging less than 1 cm, is typical. The honeycomb pattern in upper lung zones is highly suggestive of Langerhans-cell histiocytosis. Spontaneous pneumothorax is the first indicator of this condition in up to 20% of patients (Fig. 24). The sparing of costophrenic angles, a common finding, is considered to indicate good prognosis. Pleural reaction, effusion, or thickening are uncommon, even in patients with recurrent pneumothoraces. Uncommon pulmonary symptoms include hemoptysis and wheezing. Unusual roentgenologic features include hilar prominence (in fewer than 25%), hilar vascular prominence, alveolar consolidation, solitary nodules, cavitation of nodules, and mediastinal masses with development of cavitation within the mass, mass lesions of the anterior chest wall, and tracheobronchial lesions.

FIG. 23. Pulmonary eosinophilic granuloma with diffuse reticulonodular pattern and honeycombing. Upper-lung distribution of the infiltrates is noteworthy.

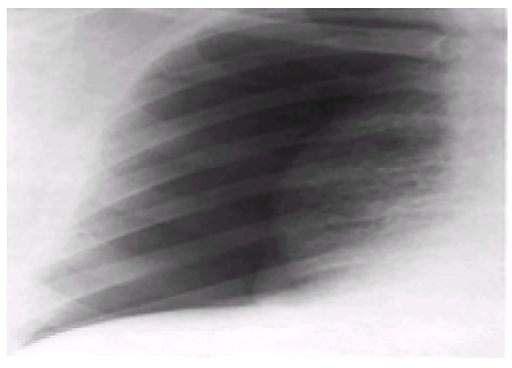

FIG. 24. Spontaneous pneumothorax in pulmonary eosinophilic granuloma. Fine honeycombing can be seen in the partially collapsed lung.

Nonpulmonary manifestations of Langerhans-cell histiocytosis include diffuse maculopapular skin nodules, solitary or multiple bony lesions, diabetes insipidus (seen in 20% of patients), head and neck lesions, otologic involvement, periodontal disease, gynecologic disease, renal disease, hepatic nodules, and hepatic cirrhosis. Two examples are reported of the disorder presenting as lymphadenopathy and confined to lymph nodes.

Diagnosis

High-resolution computed tomography (HRCT) of the chest is very useful in diagnosing pulmonary Langerhans-cell histiocytosis (Fig. 25). A study of 18 patients by HRCT revealed the following abnormalities: thin-walled cysts in 94%, nodules in 78%, cavitated nodules in 17%, thick-walled cysts in 39%, reticulation in 22%, ground-glass opacities in 22%, and irregular interfaces in 22%. The lesions were most often diffuse (89%), with a predominant distribution in the upper or middle lung zones in nine patients (50%). Comparison of HRCT and chest roentgenograms showed that small and large cysts and micronodules were better detected by HRCT. Longitudinal studies in some patients suggested that HRCT patterns progressed from nodules to cavitated nodules, thick-walled cysts to cysts, and distinct cysts to confluent cysts. Similar studies have shown that many small nodules are distributed in the centers of secondary lobules around small airways and that HRCT findings correlate better with the diffusing capacity than do the chest roentgenologic findings.

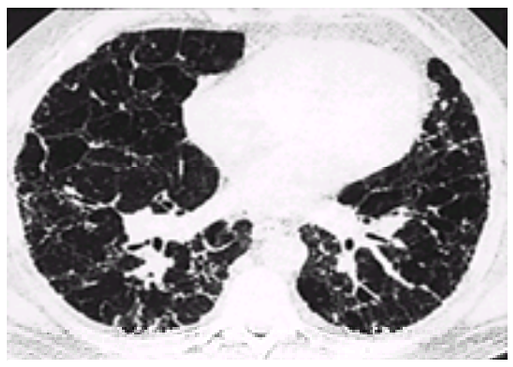

FIG. 25. High resolution computed tomogram of lung in advanced stages of pulmonary eosinophilic granuloma shows extensive cystic changes.

The diagnosis of Langerhans-cell histiocytosis is made on the basis of typical clinical features, chest roentgenologic findings, HRCT of the thorax, bronchoalveolar lavage, and bronchoscopic lung biopsy. Not every patient requires each of these diagnostic procedures. In the proper clinical setting, diagnosis can be made on the basis of clinical features and HRCT of chest. For instance, a young man who presents with a spontaneous pneumothorax and in whom the chest roentgenogram reveals diffuse honeycombing or a reticulonodular process is assumed to have pulmonary Langerhans-cell histiocytosis unless proved otherwise. The pulmonary examination is usually normal unless obstructive lung disease is present. Clubbing may occur in patients with advanced disease and chronic hypoxia. Lymphadenopathy and hepatosplenomegaly are conspicuously absent in patients with isolated pulmonary disease. Routine hematologic and serologic data are generally normal, and sedimentation rate is either normal or only minimally elevated. Peripheral eosinophilia is not a feature of Langerhans-cell histiocytosis (eosinophilic granuloma).

Bronchoalveolar lavage shows the Langerhans cells (Fig. 26). The cells obtained from bronchoalveolar lavage should be analyzed to detect surface antigens using OKT6 monoclonal antibodies, antibodies to S-100 protein, or antibodies to the HLA-DR protein. As noted above, the presence of OKT6 monoclonal antibody is more specific for the diagnosis. Electron microscopy of lung biopsy or lavage effluent reveals cytoplasmic Langerhans-cell inclusion bodies (Birbeck granules or X bodies).

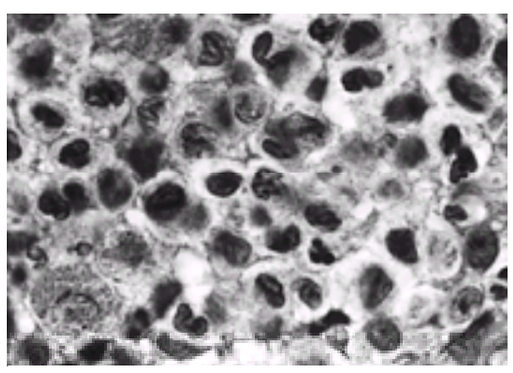

FIG. 26. Langerhans cells of pulmonary eosinophilic granuloma have delicate folded and indented nuclei and are distinct from pulmonary alveolar macrophages. An eosinophil with cytoplasmic granules is seen at lower left.

Letterer–Siwe Disease

Letterer–Siwe disease is almost always limited to infants and children. The disease becomes manifest before the age of 2 years and is characterized by extensive systemic dissemination and a fulminating, fatal course. However, Letterer–Siwe disease has been reported in 26 adult patients, with involvement of the lungs in half of them. If the symptoms appear after the age of 2 years, the 10-year survival rate is 85%, and in those who develop symptoms earlier, 10-year survival is 40%.

Hand–Schuller–Christian Disease

Patients with Hand–Schuller–Christian disease may manifest one or all of the classic three signs: exophthalmos, diabetes insipidus, and osteolytic lesions of the skull. The characteristic triad, however, is observed in only 10% of children with multifocal Langerhans-cell histiocytosis. Hand–Schuller–Christian disease usually becomes apparent during later childhood or adolescence and progresses slowly, so that most patients reach adulthood. It has been suggested that the Hand–Schuller–Christian triad is nonspecific and that the term *multifocal eosinophilic granuloma* be used to describe the abnormalities in various organs.

Treatment and Prognosis

Pulmonary Langerhans-cell histiocytosis in adults demonstrates a fluctuating course and frequent tendency toward spontaneous resolution. Asymptomatic patients and those with stable chest roentgenologic abnormalities may be observed without specific therapy. Smoking cessation should be stressed. Progressive disease may require prolonged high-dose corticosteroid therapy (prednisone, 0.75 to 1.0 mg/kg per day for 6 to 12 months). In refractory cases, a therapeutic trial of vinca alkaloids (vinblastine or vincristine) has been tried. In children, therapy using vinca alkaloids with or without corticosteroid has proved to be equally efficacious. Expanding or symptomatic bone lesions are treated with steroids, excision and curettage, or radiation. Radiation is not indicated in disease limited to the lungs. Since the Langerhans-cell is of hemopoietic origin, it has been suggested that Langerhans-cell histiocytosis is perhaps curable by ablating the patient's hemopoietic system and replacing it with donor bone marrow by bone marrow transplantation.

The overall prognosis is good in adults with pulmonary Langerhans-cell histiocytosis, with mortality rates of less than 5%. The prognosis is poor in patients with extensive cysts, large bullous type lesions, severe honeycombing, progressive obstructive airways disease, multiple pneumothoraces, severe hypoxemia, secondary pulmonary hypertension, markedly decreased diffusing capacity of lung for carbon monoxide, extensive multisystem disease, prolonged constitutional disturbance. Radiation therapy and chemotherapy to treat Langerhans-cell histiocytosis are associated with a 50% chance of inducing lung cancer and pulmonary lymphoma.

MISCELLANEOUS HEMATOLOGIC DISORDERS

Chronic anemia, in addition to its effects on cardiovascular hemodynamics, is known to produce a reduction in diffusing capacity of the lung for carbon monoxide. The diffusing capacity decreases approximately 7% for each gram per 100 mL decrease in hemoglobin. Before carbon monoxide diffusing capacity can be used to evaluate lung function, a correction for significant anemia should be made. Anemic patients demonstrate higher extraction of oxygen from blood, presumably as a result of increased work by the heart.

Paroxysmal nocturnal hemoglobinuria is a hematopoietic stem-cell disorder characterized by an increased sensitivity of blood cells to complement-mediated lysis. Vascular thrombosis of pulmonary vasculature and pulmonary hypertension have been described.

Autoimmune hemolytic anemia has been shown to be associated with pulmonary fibrosis in two patients, and a possible relationship between autoimmune hemolysis and fibrosing alveolitis has been suggested. Primary pulmonary hypertension has been described in association with microangiopathic hemolytic anemia and thrombocytopenia.

Bare lymphocyte syndrome is characterized by the absence of cell surface HLA-A, HLA-B, and sometimes HLA-C antigens and is a form of immunodeficiency in infants. The adult form of this syndrome, complicated by chronic sinusitis and bronchiectasis, has been described.

Hematopoiesis (extramedullary) in the thoracic cage may present as mediastinal process. A case of hematopoiesis occurring in bronchus has been described. Acute and rapidly fatal respiratory failure from pulmonary interstitial extramedullary hematopoiesis associated with myelofibrosis has been described. A Tc-99m sulfur colloid

bone marrow scan may show diffuse replacement of pulmonary interstitium with bone marrow, and bronchoscopic lung biopsy has shown interstitial involvement with increased numbers of megakaryocytes and other panhematopoietic staining elements.

Thoracic splenosis may present as a nodular or mass-like density in the thoracic cage or lung parenchyma. Past abdominal injuries in which splenic trauma is followed by migration of splenic fragments into the chest cage is usually responsible for this finding. The spleen is absent, usually due to splenectomy, and peripheral blood smear may be indicative of splenectomy.

Hereditary stomatocytosis is rare familial disorder of erythrocytes. Nine cases have been described with documented thrombotic complications after splenectomy. Three patients became severely ill with pulmonary hypertension.

PULMONARY DIAGNOSTIC PROCEDURES

The diagnostic approach to immunocompromised patients with pulmonary manifestations is discussed in detail in Chapter 55. Chest roentgenograph and computed tomography of the chest are invaluable in assessing the pulmonary complications in hematologic diseases. Specific findings on high-resolution computed tomography (HRCT) of the chest can be seen in pulmonary Langerhans-cell histiocytosis and bronchiolitis obliterans with organizing pneumonia. Computed tomography is frequently helpful in staging Hodgkin's and non-Hodgkin's lymphomas. Bronchoscopic needle aspiration of subcarinal, hilar, and paratracheal lymph nodes is facilitated by computed tomographic identification of the lymph nodes.

In patients with hematologic diseases who develop lung infiltrates, bronchoscopic examination is very useful to identify infectious organisms. A prospective study of 90 patients with hematologic malignancies (57 acute leukemias, six Hodgkin's disease, 15 non-Hodgkin's lymphomas, 12 other diseases) with fever (>38.4°C) and newly developed lung infiltrates employed bronchoscopy to obtain culture specimens. The results reveled that pneumonias caused by gram-negative bacteria (n = 38) and fungi (n = 34) were most frequent; sensitivity of bronchoscopy in diagnosing infectious episodes was 66%, but only four of 13 noninfectious lung infiltrates could be identified. Bronchoscopy was most effective in the diagnosis of *Pneumocystis carinii* and herpesvirus pneumonia, whereas sensitivity and specificity to detect fungal and bacterial pneumonia were low. Empiric antibiotic therapy was confirmed by evaluation of bronchoscopic samples in 25 of 90 cases, and treatment was changed in 34 of 90 cases. Early identification of causative pathogens had a significant impact on survival.

Bronchoscopy and diagnostic bronchoalveolar lavage are safe in patients with severe thrombocytopenia, other coagulopathies, and alveolar hemorrhage. Unless a bronchoscopic lung biopsy is planned, reversal of bleeding diathesis by transfusion of platelets, fresh frozen plasma, and vitamin K is usually unnecessary to obtain bronchoalveolar lavage. These procedures can be performed, with appropriate preparations and administration of supplemental oxygen, even in patients with significant hypoxemia.

Hypoxaemia in patients with hyperleukocytosis: true or spurious, and clinical implications. *Leukemia Res* 1993;17:915–919. *Description of two patients with extremely high leukocyte counts with true hypoxemia. The authors conclude that methemoglobinemia may be at least in part responsible for the low* P_aO_2. *They also state that pulse oximetry was completely unreliable in our patients because of the elevated met-hemoglobin levels.*

Godeau B, Schaeffer A, Bachir D, Fleury-Feith J, Galacteros F, Verra F, Escudier E, Vaillant JN, Brun-Buisson C, Rahmouni A, Allaoui AS, Lebargy F. Bronchoalveolar lavage in adult sickle cell patients with acute chest syndrome: value for diagnostic assessment of fat embolism. *Am J Respir Crit Care Med* 1996;153:1691–1696. *The presence of fatty macrophages recovered by bronchoalveolar lavage was used to diagnose fat embolism in 20 consecutive adult sickle cell patients with acute chest syndrome. A cutoff of >5% of alveolar macrophages containing fat droplets was determined for the diagnosis of fat embolism. The authors conclude that their study supports the diagnostic yield of BAL for fat embolism, which can be incriminated in 60% of cases of acute chest*

syndrome in adults.

Guinee D Jr, Jaffe E, Kingma D, Fishback N, Wallberg K, Krishnan J, Frizzera G, Travis W, Koss M. Pulmonary lymphomatoid granulomatosis. Evidence for a proliferation of Epstein–Barr virus infected B lymphocytes with a prominent T-cell component and vasculitis. *Am J Surg Pathol* 1994;18:753–764. *This study analyzed ten cases of pulmonary lymphomatoid granulomatosis by immunohistochemistry with* in situ *hybridization for Epstein–Barr virus, CD20, and CD45RO and hypothesized that most cases of lymphomatoid granulomatosis involving the lung represent a proliferation of Epstein–Barr virus-infected B cells with a prominent T-cell reaction and vasculitis, distinguishing these cases from angiocentric "T-cell lymphomas" in other sites, such as the head and neck.*

Hogg JC, Hegele RG. Adenovirus and Epstein–Barr virus in lung disease. *Semin Respir Infect* 1995;10:244–253. *A review of the role of the adenovirus, Epstein–Barr virus, and other viruses in the etiology and pathogenesis of lymphoproliferative disorders.*

Housini I, Tomashefski JF Jr, Cohen A, Crass J, Kleinerman J. Transbronchial biopsy in patients with pulmonary eosinophilic granuloma. Comparison with findings on open lung biopsy. *Arch Pathol Lab Med* 1994;118:523–530. *Evaluation of bronchoscopic lung biopsy specimens compared to open-lung biopsy specimens from 12 patients with Langerhans-cell histiocytosis showed that the diagnosis of Langerhans cell is possible on bronchoscopic lung biopsy but requires a high index of suspicion and that the demonstration of Langerhans cells by immunohistochemical staining for S-100 protein is a useful adjunct. The authors conclude that low diagnostic yield for Langerhans-cell histiocytosis on bronchoscopic biopsy results from inadequate sampling and from the nonspecific appearance of discrete lesions in small tissue samples.*

Jones D, Weinberg DS, Pinkus GS, Renshaw AA. Cytologic diagnosis of primary serous lymphoma. *Am J Clin Pathol* 1996;106:359–364. *A report of seven cases of primary serous lymphoma or "body-cavity" lymphoma. All were large-cell lymphomas (five B-cell types, two T-cell types). Three distinct clinical presentations were seen: four patients had the rapid onset of pleural effusions without an associated mass in the setting of immunodeficiency (three with AIDS, one with Castleman's disease). Cytologic examination of the effusion was positive in all cases for B-cell lymphoma. All four patients died of their disease in less than 6 months.*

Katsumura Y, Ohtsubo K. Incidence of pulmonary thromboembolism, infarction and hemorrhage in disseminated intravascular coagulation: a necroscopic analysis. *Thorax* 1995;50:160–164. *This postmortem study of 87 patients whose illnesses were complicated by disseminated intravascular coagulation showed that in addition to fibrin thrombosis, macroscopic thromboembolism and hemorrhage were the main pathologic findings in the lungs. The frequency of pulmonary infarction increased in proportion to the frequency of thromboembolism.*

Koss MN. Pulmonary lymphoid disorders. *Semin Diag Pathol* 1995;12:158–171. *A detailed review, with over 100 references, of the pleuropulmonary manifestations in lymphoproliferative disorders. Discussion includes both B- and T-cell diseases as well as lymphomatoid granulomatosis.*

Lund MB, Kongerud J, Boe J, Nome O, Abrahamsen AF, Ihlen H, Forfang K. Cardiopulmonary sequelae after treatment for Hodgkin's disease: increased risk in females? *Ann Oncol* 1996;7:257–264. *A study of 116 patients with Hodgkin's disease (mean age 37 years; 67 men) examined 5 to 13 years after mediastinal irradiation with or without chemotherapy observed that cardiopulmonary complications occurred in 75% of the women and in 41% of the men (*$p < 0.001$*). Nearly 30% of the patients had dyspnea on exertion and reductions in total lung capacity, forced vital capacity, forced expiratory volume in 1 sec, and gas transfer. Female gender was a significant risk factor for cardiac and/or pulmonary sequelae, whereas age, follow-up period, smoking habits, histology, bulky mediastinal disease, radiation dose, and chemotherapy were not.*

Malpas JS, Norton AJ. Langerhans cell histiocytosis in the adult. *Med Pediatr Oncol* 1996;27:540–546. *A study of 47 well-documented patients with Langerhans cell histiocytosis showed a slight female preponderance, with onset as late as the ninth decade. The skin was the most common site of presentation, but pulmonary and bone involvement was frequent. Patients with single-site disease did best. The worst prognosis was seen in the elderly or those with organ dysfunction. A high incidence of associated malignant disease was seen, which could precede, be coincidental with, or occur after a diagnosis of Langerhans-cell histiocytosis.*

Maschmeyer G, Link H, Hiddemann W, Meyer P, Helmerking M, Eisenmann E, Schmitt J, Adam D. Pulmonary infiltrations in febrile patients with neutropenia. Risk factors and outcome under empirical antimicrobial therapy in a randomized multicenter study. *Cancer* 1994;73:2296–2304. *A randomized multicenter study (of 295 patients entered, 91.2% were evaluable) of patients with neutropenia caused by hematologic malignancies and fever (>38.5°C) associated with new lung infiltrates. Patients were randomized for various initial antiinfection therapies, and nonresponders were given empiric amphotericin B plus 5-fluorocytosine beginning on day 4, day 5, or day 6. Only 27.1% of patients achieved a complete response by antibiotic therapy without additional antifungal therapy. Fungal infections were associated with a poorer outcome compared with bacterial pneumonias.*

Morrison VA, McGlave PB. Mucormycosis in the BMT population. *Bone Marrow Transplant* 1993;11:383–388. *In a 17-year consecutive series of patients with bone marrow transplant, 13 (0.9%) of 1500 patients developed mucormycosis; ten were allogeneic and three autologous transplant recipients. Seven patients were neutropenic. Six infections occurred within 90 days of transplant, and six occurred at or within several days of autopsy; death from mucormycosis occurred in ten of 13 (77%) patients.*

Thrombo-embolic disease after splenectomy for hereditary stomatocytosis. *Br J Haematol* 1996;93:303–310. *A description of nine cases of hereditary stomatocytosis with documented thrombotic complications after splenectomy. Three patients became severely ill with pulmonary hypertension.*

Tamura K, Yokota T, Mashita R, Tamura S. Pulmonary manifestations in adult T-cell leukemia at the time of diagnosis. *Respiration* 1993;60:115–119. *A report on pulmonary complications in 35 consecutive patients (18 male, 17 female) with adult T-cell lymphoma noted that over one-third presented with respiratory symptoms and 14 (40%) patients had significant findings on chest radiographs on the first admission; reticulonodular shadows were predominant in ten patients. Bacterial pneumonia and pneumocystosis were experienced in over two-thirds of the patients during the clinical course, and more than half of the patients died of pulmonary complications.*

Urban BA, Fishman EK, Goldman SM, Scott WW Jr, Jones B, Humphrey RL, Hruban RH. CT evaluation of amyloidosis: spectrum of disease. *Radiographics* 1993;13:1295–1308. *Computed tomographic studies of 90 patients with biopsy-proved primary or secondary amyloidosis demonstrated a wide spectrum of disease in the cardiothoracic, gastrointestinal, genitourinary, and musculoskeletal systems. Amyloid deposition simulated both inflammatory and neoplastic conditions. Amorphous or irregular calcifications were occasionally identified within the amyloid deposit.*

Utz JP, Swensen SJ, Gertz MA. Pulmonary amyloidosis. The Mayo Clinic experience from 1980 to 1993. *Ann Intern Med* 1996;124:407–413. *A retrospective review observed that 35 of 55 patients with pulmonary amyloidosis had primary systemic amyloidosis that presented radiographically as an interstitial or reticulonodular pattern with or without pleural effusion. The median survival after diagnosis was 16 months. Nodular pulmonary "amyloidomas" (nodular amyloid lesions) were not associated with systemic disease and were associated with a benign prognosis.*

Vichinsky E, Williams R, Das M, Earles AN, Lewis N, Adler A, McQuitty J. Pulmonary fat embolism: a distinct cause of severe acute chest syndrome in sickle cell anemia. *Blood* 1994;83:3107–3112. *Among 27 patients with sickle cell disease and acute chest syndrome who underwent bronchoalveolar lavage, 12 had pulmonary fat embolism; all these patients experienced bone pain, and 11 of 12 had chest pain. In contrast, only six of 15 patients without embolism had bone or chest pain. These results indicated that when embolism is associated with acute chest syndrome, it is characterized by*

a distinct clinical course, and that bronchial lavage is a safe and useful test.

Villa MP, Rotili PL, Santamaria F, Vania A, Bonci E, Tancredi G, Ronchetti R. Physical performance in patients with thalassemia before and after transfusion. *Pediatr Pulmonol* 1996;21:367–372. *A study of flow–volume curves, blood gas exchange, and cardiorespiratory responses to exercise in 12 patients with thalassemia major before and 24 hr after transfusions showed that these patients had significantly lower pretransfusion cardiorespiratory function than controls and the transfusion worsened relative hypoventilation at the maximum workload only in the subgroup with a history of airway obstruction.*

von Eiff M, Zuhlsdorf M, Roos N, Thomas M, Buchner T, van de Loo J. Pulmonary infiltrates in patients with haematologic malignancies: clinical usefulness of non-invasive bronchoscopic procedures. *Eur J Haematol* 1995;54:157–162. *A prospective study of 90 patients with hematologic malignancies with fever (>38.4°C) and newly developed lung infiltrates employed bronchoscopy to identify the causative organisms. Pneumonias caused by gram-negative bacteria and fungi were most frequent. Sensitivity of bronchoscopy in diagnosing infectious episodes was 66%, but only four of 13 noninfectious lung infiltrates could be identified. Empiric antimicrobial therapy was verified by bronchoscopy in 25 of 90 cases, and therapy was changed in 34 of 90 cases. Early identification of causative pathogens had a significant impact on survival.*

Weiss SM, Hert RC, Gianola FJ, Clark JG, Crawford SW. Complications of fiberoptic bronchoscopy in thrombocytopenic patients. *Chest* 1993;104:1025–1028. *A prospective study of 58 patients with thrombocytopenia (platelets <100,000/ml) who underwent bronchoscopy and bronchoalveolar lavage showed that transnasal bronchoscopy in thrombocytopenic patients was safe, being associated with minor airway bleeding in three of 37 patients.*

Wiley JS, Firkin FC. Reduction of pulmonary toxicity by prednisolone prophylaxis during all-*trans* retinoic acid treatment of acute promyelocytic leukemia. Australian Leukaemia Study Group. *Leukemia* 1995;9:774–778. *All*-trans *retinoic acid induces complete remission in most cases of acute promyelocytic leukemia. Its use, however, is associated with potentially fatal pulmonary toxicity in approximately 25% of patients in the setting of a rapidly rising peripheral blood white cell count. This prospective multicenter study documents the efficacy of oral corticosteroid for prophylaxis against pulmonary toxicity.*

Willis B, Ablin A, Weinberg V, Zoger S, Wara WM, Matthay KK. Disease course and late sequelae of Langerhans' cell histiocytosis: 25-year experience at the University of California, San Francisco. *J Clin Oncol* 1996;14:2073–2082. *An analysis of clinical features in 71 patients with a pathologic diagnosis of Langerhans-cell histiocytosis showed the following: skin-only disease in nine, monostotic disease in 22, polyostotic disease in 12, multisystem disease in 24 patients. Treatment included surgery in 17 and chemotherapy and/or radiotherapy in 54 patients. Recurrences were seen in 35 patients, with the highest rate in the polyostotic group. Ten patients died. The overall estimated survival rates at 5, 15, and 20 years are 88%, 88%, and 77%, respectively, with an estimated event-free survival rate of only 30% at 15 years.*

CHAPTER

57 Renal Diseases

Udaya B.S. Prakash

U.B.S. Prakash: Pulmonary and Critical Care Medicine, Mayo Medical School and Mayo Medical Center, Rochester, Minnesota 55905.

INTRODUCTION

The respiratory and renal systems together maintain normal acid–base equilibrium. Failure of one system promptly elicits a compensatory response from the other. This close relationship is maintained not only in health but also in certain pathologic states. For example, in Goodpasture's syndrome, the alterations that occur in the alveolar basement membrane disease represent the reaction to the immunologic process that affects the glomerular basement membrane. Similar relationships exist for many of the disorders classified under the umbrella of “pulmonary–renal” syndromes. Many of the serious respiratory complications of kidney diseases described in the past are now uncommon because of the early diagnosis and treatment of renal disorders. The successful treatment, however, of renal failure by hemodialysis, peritoneal dialysis, and renal transplantation has led to several complications related to these treatments themselves. Elucidation of the basis for the pulmonary pathology in chronic hemodialysis has led to an understanding of some of the factors responsible for certain types of acute respiratory distress syndrome. Pulmonary complications after renal transplantation are well recognized. This chapter addresses the pleuropulmonary manifestations of kidney diseases (Table 1), renal transplantation, and pulmonary alveolar hemorrhage syndromes.

Pulmonary manifestation	Renal etiology
Hypoxemia	Hemodialysis Pulmonary edema Pleural effusion Pulmonary infections Pulmonary calcification Pulmonary–renal syndromes (see Table 2)
Pulmonary edema	Renal failure (acute and chronic) Acute glomerulonephritis Nephrotic syndrome Hemodialysis Renal transplantation
Pleural effusion	Renal failure (acute and chronic) Nephrotic syndrome Acute glomerulonephritis Hemodialysis Peritoneal dialysis Ureteral obstruction Hydronephrosis Perinephric abscess Pulmonary embolism Pulmonary–renal syndromes Renal transplantation
Pleuritis	Uremia
Pulmonary calcification	Hemodialysis Hemodialysis Transplantation
Sleep apnea	Chronic renal failure Chronic renal failure Hemodialysis, peritoneal dialysis
Infections	Hemodialysis Transplantation (Renal failure (Renal transplantation
Lymphoma, lung cancer	(Renal transplantation
Pulmonary–renal syndromes	(See Table 2)

TABLE 1. *Pulmonary complications in renal diseases*

RENAL FAILURE

Pulmonary Edema

Pulmonary changes may be associated with either acute or chronic renal failure. Pulmonary edema is the most serious complication of renal failure. The roentgenographic manifestations—variously referred to as *uremic lung, uremic pneumonia,* and *butterfly shadows* or *bat-wing shadows*—are manifestations of pulmonary edema. Similar features can occur in patients with left ventricular failure or noncardiogenic edema from various causes.

In chronic renal failure, pulmonary edema may develop without uremia, in part from sodium retention and increased blood volume. The pathogenesis of pulmonary edema in renal failure is unknown. Fluid overload, left ventricular failure, and increased capillary permeability from uremia are among the likely etiologic factors. Increased endothelial permeability to sodium and water and increased alveolar permeability to technetium-99m-labeled compounds before and during hemodialysis have been shown. Edema fluid sampled by endotracheal aspiration has shown an elevated protein content, suggesting increased vascular permeability to plasma proteins in renal failure. However, some studies have reported that there is no evidence of increased pulmonary endothelial permeability to the plasma protein transferrin in patients with pulmonary edema caused by renal failure.

The morphologic features of acute pulmonary edema caused by renal failure include septal swelling and edema, proteinaceous fluid in alveoli, and, in some cases, hyaline membrane formation. Lung in chronic pulmonary edema associated with renal failure shows round hyaline structures in alveolar septa that are well circumscribed and coated by a single layer of flat endothelial cells and organized casts of alveoli, alveolar ducts, and bronchioles, many revealing marked cellularity. Repeated episodes of uremic pulmonary edema may result in interstitial fibrosis and deposition of hemosiderin in the alveoli.

Pulmonary edema (Fig. 1) does not occur consistently in uremic patients, and its occurrence is unpredictable and cannot be correlated with the degree of azotemia. However, the clearing of chest roentgenographic abnormalities is usually paralleled by a reduction in total body fluid. Even when physical signs in the lungs are scant in comparison with the roentgenographic evidence of pulmonary edema caused by renal failure, the correction of fluid imbalance results in rapid symptomatic improvement in respiratory symptoms. The chest roentgenogram typically exhibits bilaterally symmetric densities extending laterally from the hilum, leaving clear apices and peripheral zones (Fig. 1 and Fig. 2). The reason for the central concentration of the abnormal shadows is unclear, but the severity of the changes increases with the degree of azotemia and acidosis. In acute glomerulonephritis, children may die so rapidly from pulmonary edema that the diagnosis may be made only at

postmortem.

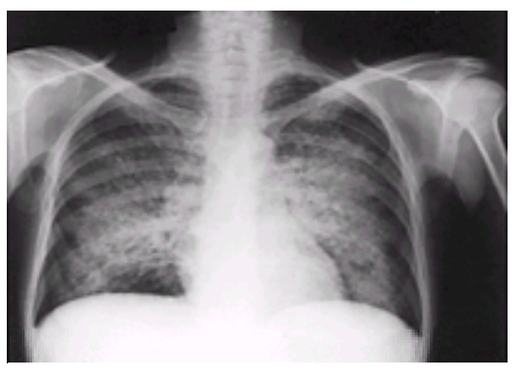

FIG. 1. Typical bat-wing (outer one-third of lungs) or butterfly (inner two-thirds of lungs) appearance in uremic pulmonary edema. Note sparing of both costophrenic angles.

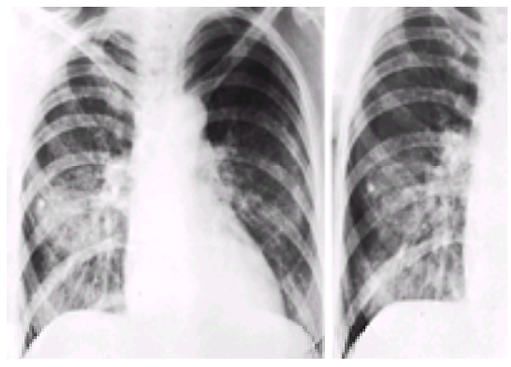

FIG. 2. Bilateral but asymmetric pulmonary edema in acute renal failure *(left).* Close-up shows clear demarcation of normal and abnormal lung.

Lung function studies in patients with severe renal failure have revealed significant decreases in diffusing capacity of lung for carbon monoxide (D_LCO), presumably from pulmonary edema. Improvement in midexpiratory flow and reduction in air trapping after hemodialysis have been described, and it has been suggested that these changes could be attributed to alleviation of peribronchial edema. The degree of restrictive lung dysfunction depends on the chronicity and severity of the renal failure. Muscle weakness, myopathy, and reduced aerobic muscle function are common in chronic renal failure and contribute to pulmonary dysfunction. Furthermore, diaphragmatic weakness caused by phrenic neuropathy is a frequent complication of uremia, and this contributes to the restrictive pulmonary dysfunction. Pulmonary function tests performed at least 12 hrs after the preceding hemodialysis in one group of patients revealed significantly reduced D_LCO, even after correction for anemia; there appeared to be no correlation between anemia and the severity of reduction in D_LCO.

Pleural Effusion

Pleural effusion is a common complication of renal diseases (Table 1). Hemodialysis, peritoneal dialysis, and renal transplantation are frequently associated with pleural effusion. Although hemodialysis can be associated with pleural effusion, the pleural effusion also resolves with hemodialysis (Fig. 3). Pleural effusion occurs in nearly half the children who develop acute glomerulonephritis. The effusions probably are secondary to hypervolemia and raised capillary hydrostatic pressures, and they are usually transudative. Many of these patients also exhibit edema and cardiomegaly.

FIG. 3. Pulmonary edema and pleural effusion before **(A)** and after **(B)** hemodialysis for renal failure.

Nephrotic syndrome is one of the common causes of pleural effusion. The main factor leading to pleural transudation is the diminution of the plasma oncotic pressure, allowing easier transport of protein-poor fluid into the pleural space. The pleural fluid is usually a transudate with a low protein content. Pleural and pericardial effusions are seen in 20% to 25% of patients with the nephrotic syndrome. Usually bilateral and sometimes massive, the pleural effusions may produce significant respiratory distress. A peculiar feature of pleural effusions in patients with uremic syndrome is that the effusion tends to remain subpulmonic in location. A reason for this is that the pleuritis associated with uremia is reported to cause areas of adhesion between the parietal diaphragmatic pleura and the visceral pleura, thereby preventing the fluid from pushing the lung upward. Roentgenologically, subpulmonic effusions do not produce obliteration of the costophrenic angle (Fig. 4). The chest roentgenogram may show only an elevated hemidiaphragm on the side of pleural effusion. A lateral decubitus chest roentgenogram is often necessary to demonstrate free layering of the fluid (Fig. 4). Occasionally, pleural effusions are complicated by infections; fibrosing uremic pleuritis complicated by empyema has been described. Medical or surgical pleurodesis may be required in patients with recurrent or symptomatic effusions.

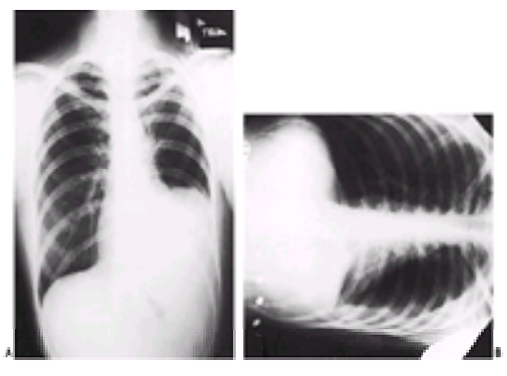

FIG. 4. Subpulmonic left pleural effusion on chronic renal failure demonstrates (A) maintenance of sharp costophrenic angle on the left and (B) free layering of the pleural effusion in the lateral decubitus position.

Fibrinous pleuritis is an uncommon but distinct entity and possibly a specific manifestation of uremia, although episodes of fibrinous pleuritis have been noted in patients on chronic hemodialysis. Clinical features consist of recurrent episodes of pleuritic chest pain, dyspnea, and low-grade fever. Pleural friction rubs are commonly heard on auscultation. In many patients, the fluid is an exudate containing high levels of protein and lactate dehydrogenase.

Patients undergoing chronic hemodialysis occasionally develop pleural effusions. The fluid usually is serosanguineous as a result of heparinization for the dialysis procedure. Correction of fluid balance by continued hemodialysis and improved renal function results in gradual clearing of the effusion. There are rare case reports of hemorrhagic effusion that resulted in fibrinous pleuritis and pulmonary restriction and required pulmonary decortication.

Ureteral obstruction from calculi, ureteral valves, malignancy, and gravid uterus may result in extravasation of urine into the pleural space and produce “urinothorax” or “urinoma.” Occasionally, retroperitoneal extravasation of urine as a result of hydronephrosis may lead to intrapleural urinomas and mediastinal widening. Urologic procedures, such as placement of ureteral stents, may cause pleural effusion. Perinephric abscess may be complicated by pleural effusions resulting from inflammation of the adjacent pleura. These rarely become infected. The pleural fluid in uninfected urinothorax is a transudate with a pH <7.30 and a creatinine concentration that is greater than serum creatinine.

The possibility that the pleural effusion is instigated by pulmonary embolism has to be considered because renal vein thrombosis is a known complication in nephrotic syndrome. One study observed pulmonary embolism in 22% (eight patients) of 36 adult patients with nephrotic syndrome.

The hemolytic–uremic syndrome may involve the respiratory system, and pleuritis and pericarditis associated with this syndrome have been described.

Although chylous ascites is known to be associated with nephrotic syndrome, chylous pleural effusion is rare. The edema of the intestines with resultant lacteal leakage or malabsorption may be responsible. Chylous pleural effusion has been described in a patient with nephrotic syndrome.

Pulmonary Calcification

Calcification of soft tissues can occur as “metastatic” calcification in which calcium salts are deposited in previously normal tissue or as “dystrophic calcification,” in which calcification occurs at anatomic sites altered by pathologic processes. The lung is the primary target of metastatic calcification in chronic renal failure and in patients on chronic hemodialysis. Although the pathogenesis of pulmonary calcification is not fully understood, some investigators have suggested that the disorder occurs when the product of calcium and phosphate ions exceeds the solubility constant in the blood (the product of plasma calcium and phosphate being greater than 75 mg/dl). Others have concluded that the product of calcium and phosphorus is more relevant to the *in vivo* situation.

Crystallographic, spectroscopic, and chemical studies have demonstrated two distinct types of calcium phosphate in tissues of patients with chronic renal failure. Calcifications found in the lungs are microcrystallites of magnesium, whitlockite, or an immediate precursor whose formation is promoted by the presence of magnesium. Preferential calcification of the upper lung zones may be induced by the higher ventilation–perfusion ratio in the apical regions of lung relative to the basal regions, resulting in a lower alveolar carbon dioxide tension and higher tissue pH (blood pH at the apex is approximately 7.51, compared with 7.39 at the base). The resultant relative alkalinity may favor precipitation of calcium phosphate. Chronic renal failure is complicated by the development of secondary hyperparathyroidism with hypercalcemia. The incidence of pulmonary calcification is greater in patients with hypercalcemia induced by secondary hyperparathyroidism of renal failure. Although pulmonary calcification is considered to be a common occurrence with chronic renal diseases, it usually is sparse and identifiable only on histologic examination of the lungs (Fig. 5). On the other hand, the pulmonary calcification that occurs in association with chronic hemodialysis is clinically more apparent (see below).

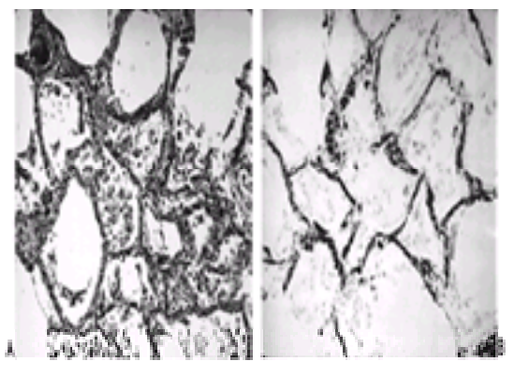

FIG. 5. Metastatic calcification associated with chronic renal failure or in patients on long-term hemodialysis. **(A)** Calcium is seen as deposits of dark and platelike material diffusely in alveolar walls. **(B)** A von Kossa stain for calcium shows diffuse black staining of calcium in alveolar walls.

The clinical manifestations of pulmonary calcification associated with chronic renal failure are nonspecific. Chest roentgenograms show calcifications that are either localized or diffuse. In most cases, they are identical to roentgenographic opacities produced by pneumonia or pulmonary edema, but sometimes definite punctate calcifications may be seen (Fig. 6). Upper lung zones are more commonly affected. A study of metastatic pulmonary calcification in seven patients (chronic renal failure in four, T-cell leukemia in one, multiple endocrine neoplasia type I syndrome in one, and idiopathic hypercalcemia in one) exhibited the following features in the computed tomographic scans of the chest: nodules were predominant in the upper lung zone in three cases, diffuse in three cases, and predominant in the lower lung zone in one case; calcification of the nodules was evident on the CT scans in four of the seven cases, and calcification of vessels in the chest wall was evident in six of seven cases. Even when pulmonary calcification cannot be demonstrated with certainty, the possibility should be considered in any case of renal failure if pulmonary infiltrates remain persistent. Pulmonary function tests may demonstrate a restrictive defect. Bone-seeking radionuclide (^{99m}Tc diphosphonate) lung scans have been used to establish an early diagnosis of pulmonary calcification (Fig. 7), especially in high-risk patients. An unusual form of focal, nodular pulmonary calcification has been reported in a patient with renal failure resulting from polycystic kidney disease.

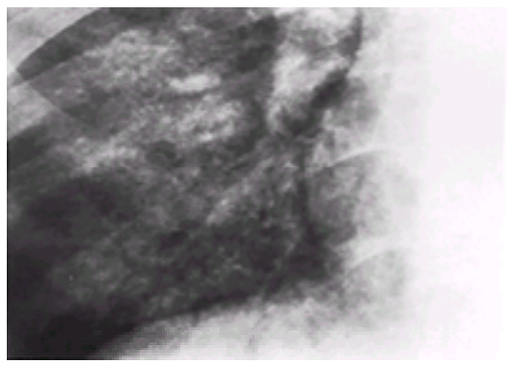

FIG. 6. Diffuse punctate clarification of pulmonary parenchyma in the right lower-lung zone in inadequately treated chronic renal failure.

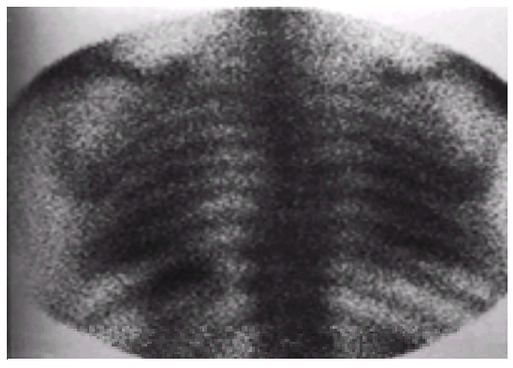

FIG. 7. A posterior view of ^{99m}Tc scan of lung in a patient with pulmonary calcification shows marked uptake of radionuclide by both lungs and the stomach (seen below the left lung).

HEMODIALYSIS

Hypoxemia

Hemodialysis-induced hypoxemia has been studied extensively. More than 85% of patients exhibit a 5 to 35 mmHg reduction in P_aO_2 from baseline as soon as the procedure is begun. This phenomenon persists for up to 60 min after the dialysis is terminated. The P_aO_2, however, seldom drops to below 70 mmHg. Several mechanisms are responsible for this phenomenon. Pulmonary arterial microembolization from certain types of the dialyzer membranes has been implicated in some studies. Dialysis membranes also can activate complement cascade, and the complement- and leukocyte-mediated leukostasis is capable of causing hemodialysis-induced hypoxemia. Cuprophane membrane activates complement cascade more than polyacrylonitrile or cellulose membranes. Larger falls in P_aO_2 have been associated with cuprophane dialysis membrane than with other types of membranes. The interaction of the dialysate and the dialysis membrane activates the alternate complement pathway by generating C3a and C5a within minutes of the dialysis procedure. The deposition of the complement fragments on the dialysis membrane induces aggregation of platelets and leukocytes on the membrane, from where they migrate to the pulmonary circulation to produce microembolization and hypoxemia. The hypoxemia occurs at the same time as the leukocyte sequestration in the pulmonary vasculature. Histologic analysis of lung tissue from animals undergoing hemodialysis have revealed severe pulmonary vessel leukostasis and interstitial edema. This pathologic process was prevented by preinactivation of complement but was reproduced by infusions of plasma in which complement was activated by zymosan. In a study of 34 patients undergoing dialysis, 15 were shown to have leukostasis or sequestration of leukocytes within the pulmonary vessels; leukopenia and impaired pulmonary function also were noted. The leukostasis-induced hypoxemia contributes minimally (<10%) to the development of hemodialysis-induced hypoxemia.

The main reason for the hemodialysis-induced hypoxemia appears to be the occurrence of dialysis-induced hypoventilation. Alveolar hypoventilation (compensatory hypoventilation) results from the substantial loss of carbon dioxide across the dialyzer membrane as well as a decrease in metabolic CO_2 production. Consumption of carbon dioxide in the oxidative metabolism of acetate has also been suggested as a mechanism for hypoventilation and hypoxemia. A study of patients undergoing hemodialysis with acetate as the dialysate found significant hypoxemia and diminished alveolar ventilation. Some studies have indicated that hypoxemia and reduced CO_2 production are most pronounced during acetate dialysis and are minimally affected during bicarbonate dialysis. Others have opined that whether acetate or bicarbonate is used in the dialysate does not seem to make a difference in dialysis-induced hypoxemia.

One study in hemodialysis patients has shown the occurrence of hypoxemia as a result of decreased minute ventilation without hypercapnia. It is hypothesized that the diminished minute ventilation is unrelated to alterations in traditional chemoreceptor output, which depends on changing arterial oxygen tension. Some have suggested that hypoventilation, localized ventilation– perfusion abnormalities related to changes in the pulmonary vascular volume during dialysis, and increases in arterial pH contribute variably to dialysis-induced hypoxemia.

Does the hemodialysis-induced hypoxemia have any clinical significance? The above discussions should be considered in the context of the timing of the detection of hypoxemia. Almost all studies on this topic were performed during hemodialysis. Almost every patient who undergoes hemodialysis is relatively immobile during the procedure because of the need to remain connected with the dialysis machine. Such a patient rarely exerts, physically that is, sufficiently to increase the work of breathing. Therefore, complaints of new or acute dyspnea or clinical detection of it is unusual in patients when they are undergoing hemodialysis. A clinical caveat is that arterial blood gas analysis should be avoided during active hemodialysis unless the patient develops respiratory symptoms and signs during the procedure. In patients with preexisting hypoxemia from diseases such as chronic obstructive pulmonary disease, cellulose or polyacrylonitrile filters and a bicarbonate bath are likely to minimize hemodialysis-induced hypoxemia.

A decreased D_LCO has been noted in both acetate-treated and bicarbonate-treated groups. Leukocyte sequestration in the pulmonary capillary network is perhaps one of the reasons for this phenomenon. A study of 25 uremic patients observed that hemodialysis-induced reductions in D_LCO in the majority of patients resulted from reduced pulmonary capillary volume brought on by hemodialysis. Another study recorded a significant fall in peak respiratory flow during the first 30 min of dialysis in 30% of patients. The improvements in flow rates ($FEF_{25–75}$) after hemodialysis suggested that peribronchial edema, which was present before hemodialysis, was responsible for the small airway dysfunction. Pulmonary dysfunction and eosinophilia have been noted in patients undergoing cuprophane dialysis.

Erythropoietin is effective in the treatment of anemia of chronic renal failure. In spite of improved hemoglobin concentration and quality of life following treatment with erythropoietin, peak oxygen uptake after erythropoietin therapy is not improved. In a study of eight patients with chronic renal failure undergoing regular hemodialysis, pre- and posterythropoietin tests suggested that this discrepancy results from two factors: first, the increase in hemoglobin produced by erythropoietin therapy is accompanied by a significant reduction in peak blood flow to exercising muscle, which limits the gain in oxygen transport; and second, even after restoration of hemoglobin, oxygen conductance from the muscle capillary to the mitochondria remains considerably below normal.

Pulmonary Calcification

The low rate of clinical occurrence and significance of metastatic pulmonary calcification in patients with chronic renal failure was discussed above. On the other hand, metastatic calcification of lungs in patients on long-term hemodialysis occurs more commonly and may cause clinically significant disease, including respiratory failure. Pulmonary calcification occurs more commonly in patients on chronic hemodialysis than in patients who undergo chronic peritoneal dialysis. Biochemical analysis of pulmonary parenchyma in patients with pulmonary calcification has shown the presence of magnesium whitlockite [$(CaMg)_3(PO_4)_2$] as the main constituent.

Ultrastructural studies of the lung parenchyma have shown linear or finely granular localization of the calcification along the alveolar septa. The extent of metastatic pulmonary calcification usually reflects the duration of hemodialysis (Fig. 6 and Fig. 7). Many patients who develop pulmonary calcification have been undergoing hemodialysis for more than 6 to 8 years. In a prospective study of 31 patients, of whom 15 died, postmortem studies revealed metastatic pulmonary calcification in nine. Such calcification has also occurred in patients with hyperphosphatemia who are being treated with a dialysate high in calcium.

The chest roentgenographs may not reveal obvious abnormalities in patients with pulmonary calcifications. Hazy, punctate, or speckled areas of density in upper and midlung zones may indicate pulmonary calcification. A pattern of persistent lung infiltrates despite adequate hemodialysis and normalization of fluid balance should suggest the possibility of metastatic pulmonary calcification. A high-resolution computed tomographic (HRCT) scan of the lung, as discussed above, may help in the diagnosis. As also noted above, a bone-seeking radionuclide (^{99m}Tc-diphosphonate) lung scan has been used to detect pulmonary parenchymal calcification. In a study of 18 children on maintenance dialysis without evidence of pulmonary calcification on chest roentgenograms, 22% had positive technetium bone scans. There were no significant differences between the groups with and without positive bone scans with respect to serum levels of calcium, phosphorus, bicarbonate, magnesium, and calcium–phosphorus product as well as parathyroid hormone and vitamin D levels. However, the two factors that influenced the presence of pulmonary calcification were the long-term duration of dialysis and high serum aluminum levels.

A literature review in 1979 noted that seven of 13 patients with pulmonary calcification died of respiratory failure.

Sleep Apnea

Hemodialysis is reported to increase the risk for developing sleep apnea. The association between end-stage renal failure and sleep apnea remains highly significant, though the cause for it remains unclear. This association seems not to be altered acutely by conventional hemodialysis treatment. In a report of 29 male patients maintained on outpatient hemodialysis, 12 had clinical features suggestive of sleep apnea, and polysomnography in eight of these patients documented obstructive

sleep apnea in six. In another study, sleep apnea was noted in nine of 15 patients on peritoneal dialysis and eight of 15 patients on hemodialysis; the incidence and severity of sleep apnea were similar in patients with end-stage renal disease being treated with chronic peritoneal dialysis and hemodialysis.

Autonomic neuropathy encountered in some patients with chronic renal failure may contribute to the occurrence of sleep-disordered breathing. Progressive dialysis encephalopathy as well as spells of sudden respiratory arrest, in close association with the episodic electroencephalographic abnormalities characteristic of the syndrome, have been reported.

Hemodialysis-Induced Asthma

Asthmatic episodes have been observed during hemodialysis, and some believe that bronchial reactivity is more pronounced in this group of patients. Hemodialysis-induced asthma has been attributed to the bronchospasm caused by acetate in the dialysate. Replacement of acetate by bicarbonate in the dialysate has resulted in resolution of this unusual problem. Others have inferred that hemodialysis does not commonly result in bronchial hyperactivity. In one study of six nonasthmatic patients who underwent histamine challenge testing before and after hemodialysis, no change was observed in reactivity, suggesting that hemodialysis does not commonly result in bronchial hyperreactivity in nonasthmatic individuals.

Asthmatic patients who take theophylline as a bronchodilator and are also hemodialysis-dependent need special care during dialysis. A shortened half-life of theophylline, from 5.7 hr to 1.6 hr, during hemodialysis has been described. However, hemodialysis clearance of theophylline varies substantially and may be dependent on the dialysis system, blood flow rate, and dialyzer used.

Pulmonary Embolism

Occlusion of the hemodialysis fistulas is a relatively common complication that requires therapy with thrombolysis and or thrombectomy. Pulmonary embolism is a potential consequence. A study of 31 patients with 43 acutely thrombosed hemodialysis fistulas observed perfusion lung scan abnormalities consistent with the diagnosis of pulmonary embolism in 59% of 22 patients studied. However, clinical signs or symptoms were absent in the majority of the patients.

Renal vein thrombosis is a known complication in nephrotic syndrome. Therefore, the risk of pulmonary embolism is increased. A study of 36 adults with nephrotic syndrome detected pulmonary embolism in eight patients (22%).

Pulmonary emboli (tumor emboli) from malignant tumors of the kidneys result from the extension of the tumor into the renal vein, from where the cancer cells exfoliate and travel to the pulmonary arterial bed. In a patient with renal cell carcinoma, onset of rapidly progressive dyspnea and diffuse interstitial pulmonary infiltrations with formation of Kerley's B-lines on chest roentgenographs of the chest should indicate the possibility of tumor emboli. Acute to subacute onset of secondary pulmonary hypertension can result from tumor emboli.

Postmortem studies in dialysis patients have shown a high incidence of pulmonary atherosclerosis, indicating chronic elevations in pulmonary artery pressure. However, clinical pulmonary hypertension is uncommon in patients with chronic renal failure or in those on chronic dialysis.

Miscellaneous Problems in Dialysis

The risk of infections caused by *Legionella* species is increased in patients on chronic hemodialysis. In some cases, these infections were believed to result from infection of the dialysis fistula by *Legionella* species. Patients receiving hemodialysis and renal transplant recipients are at an increased risk of developing pneumonia caused by *Legionella pneumophila.* The hemodialysis fistula can become infected by such organisms and cause *Legionella* pneumonia.

Tuberculosis

The risk of tuberculosis is increased in renal failure. A report from the United Kingdom estimated the risk to be nearly 70 times higher in non-Europeans with chronic renal failure than in the native population. The incidence of tuberculosis is also higher in patients on maintenance dialysis. Active tuberculosis occurs in 3.7% to 6.0% of patients followed longitudinally while on dialysis, an infection rate that is 12 to 15 times higher than normal. One study of 25 patients on dialysis detected tuberculosis in 28%; the majority were women, and extrapulmonary tuberculosis was common.

Isoniazid therapy to treat tuberculosis in patients with renal failure or those who are dialysis-dependent may be complicated by the enhanced risk of isoniazid-induced neurotoxicity. The increased sensitivity of the dialysis-dependent patients to isoniazid neurotoxicity results mainly from abnormal metabolism of pyridoxine, which results in low serum levels of the active metabolite, pyridoxal phosphate. The rapid clearance of pyridoxal phosphate by hemodialysis results in a pronounced deficiency of this active metabolite. In order to prevent the neurotoxicity associated with isoniazid therapy, a pyridoxine dose of 100 mg/day is recommended in hemodialysis patients who require isoniazid therapy.

PERITONEAL DIALYSIS

Many of the pulmonary complications associated with peritoneal dialysis are similar to those described for hemodialysis. However, several complications are peculiar to this group of patients. Chronic ambulatory peritoneal dialysis essentially produces iatrogenic ascites and the latter's attendant effects on pulmonary function. Acutely, the dialysate volumes of 2 to 3 liters will result in mild reductions in vital capacity and total lung capacity. The filling of the peritoneal cavity with the dialysate induces, in both the supine and upright positions, significant reductions in the maximal inspiratory pressure and diminished lung volumes. The diaphragmatic dysfunction observed during peritoneal dialysis is most likely the result of physical alterations resulting from infusion of the dialysate into the peritoneal cavity. The acute changes usually return to baseline within 2 weeks of initiation of the procedure as a result of the adaptation of the diaphragmatic and abdominal mechanics. A study of patients on continuous ambulatory peritoneal dialysis for more than 6 weeks indicated that the diaphragm may be capable of an adaptive rightward shift in its force–length relationship when it is chronically lengthened by continuous ambulatory peritoneal dialysis.

Patients on long-term peritoneal dialysis may develop extrapulmonary restrictive ventilatory defects. The D_LCO seems to diminish in patients who receive continuous ambulatory peritoneal dialysis. A study of 26 patients with chronic renal failure and continuous ambulatory peritoneal dialysis assessed the effects of the renal diseases on respiratory muscle function (P_{Imax} and P_{Emax}) before dialysis, 4 hr after the administration of 2 liters of dialysate into the peritoneal cavity, and just after the next drainage and concluded that respiratory muscle strength was preserved in the majority of the patients with chronic renal failure treated with continuous ambulatory peritoneal dialysis. However, lung volumes and respiratory muscle function, not strength, were decreased during dialysis.

The overall effect of long-term peritoneal dialysis on pulmonary function is minimal, even in the presence of mild lung disease from other causes. On the other hand, peritoneal instillation of large amounts of dialysate fluid in patients with severe chronic obstructive pulmonary disease may aggravate respiratory distress. The common occurrence of phrenic neuropathy in chronic renal failure may aggravate respiratory distress in patients with severe obstructive lung disease who undergo peritoneal dialysis.

Pleural effusion occurs in some patients who undergo peritoneal dialysis. A review of the literature noted 33 cases of pleural effusion associated with peritoneal dialysis. Interestingly, 28 of these cases occurred in women. Detection occurred within 48 hr of acute peritoneal dialysis. All cases were unilateral, and all but one were right-sided. The mechanism of fluid accumulation is similar to that in ascites. Instillation of large volumes of fluid intraperitoneally will further stretch the diaphragmatic defects and enable the dialysate to enter the pleural cavity. The pleural fluid can accumulate acutely and rapidly, within hours of initiating peritoneal dialysis, and produce respiratory distress. The effusions tend to recur on reinstitution of peritoneal dialysis. Massive hydrothorax occurring during continuous ambulatory peritoneal dialysis is a rare complication that may appear at any time during the course of the treatment. A case is reported in which peritoneopleural scintigraphy showed a rapid accumulation of the diagnostic agents over the right hemithorax, leading to the suspicion that a macroscopic diaphragmatic defect was responsible for the respiratory complication.

Disordered sleep occurs more frequently in patients receiving chronic peritoneal dialysis and hemodialysis than in the normal population. In a prospective study of 11 patients on chronic peritoneal dialysis, six were found to have obstructive sleep apnea; the amount of dialysate drained in the morning was negatively correlated with the minimum arterial oxygen saturation during the night. The association between dialysis and sleep apnea is discussed above.

Severe shifts in systemic pH that occur in patients undergoing peritoneal dialysis are usually acidemic shifts resulting from inadequate replacement of the kidney's ability to excrete acid and regenerate bicarbonate. Hypercapnia and acute respiratory acidosis have resulted from an increased carbohydrate load associated with peritoneal dialysis; lipogenesis following a carbohydrate load in patients with renal failure is associated with a respiratory quotient of 8.0, reflecting the much greater production of carbon dioxide per unit of oxygen consumed.

RENAL TRANSPLANTATION

Pulmonary problems in recipients of solid-organ transplants are a result of the transplant rejection process and the immunosuppressive therapy. The reader is referred to Chapter 55 for more detailed discussions regarding the respiratory complications of organ transplantation. A South African study of pulmonary complications in 110 consecutive renal transplant recipients on cyclosporine and low-dose steroid immunosuppression observed the following complications: acute pulmonary edema in 19 patients, pneumonia in 18, tuberculosis in nine, acute pulmonary embolism in five, and lung abscess in one. There were no pulmonary complications in 69 (63%) patients, and 69% of the complications occurred in the first 4 months after the transplant and were the most common cause of death in the first 3 years after the transplant.

Pulmonary infections are common in renal transplant recipients and are, as a group, the major cause of death. These infections may be caused by unusual bacteria or fungi, possibly favored by suppression of immune mechanisms by drugs and corticosteroids. The incidence of cytomegalovirus infection in cadaveric renal transplant patients is reported to be as high as 43% to 92%. Although many renal transplant patients remain asymptomatic during cytomegalovirus infection, pulmonary dysfunction is common. One report demonstrated that a decreased $D_L CO$ is common in virtually every patient with cytomegalovirus infection. An interesting finding was activation of the complement system (C3d and C3a) in many of these patients, suggesting a causal relationship between complement activation and diminished $D_L CO$. Earlier studies questioned whether cytomegalovirus played any role in the development of pneumonia among renal transplantation patients, but other reports show that cytomegalovirus pneumonia has become a leading cause of death in this patient group.

Study of pneumonia in renal transplant patients disclosed single-organism involvement by type 3 *Streptococcus pneumoniae, Staphylococcus aureus, Pseudomonas aeruginosa,* and *Escherichia coli.* Nosocomial pneumonia caused by *Legionella pneumophila* has been described in renal transplant recipients. Systemic fungal infections with pulmonary involvement, particularly candidiasis and aspergillosis, are also common after renal transplantation.

Pneumocystis carinii infection carries a high mortality in renal transplant recipients. This infectious complication appears to be more common in older patients and unrelated to immunosuppressive therapy in them. A study compared 28 renal transplant recipients with *Pneumocystis carinii* pneumonia with a control group of 27 renal transplant recipients without any episodes of *Pneumocystis carinii* pneumonia. The mean age was higher in the former group (50 versus 38 years). No differences were in observed in basic immunosuppressive and rejection treatment or in antibiotic consumption, number of hospitalization days, and incidence of infection caused by cytomegalovirus. A study of seven renal transplant recipients who developed *Pneumocystis carinii* pneumonia noted a mean duration of 150 days before the diagnosis of the infection; six had at least one episode of acute graft rejection, and cytomegalovirus pneumonia was diagnosed in six of the patients. Overall mortality was 43%.

Prophylactic therapy to prevent *Pneumocystis carinii* pneumonia usually consists of long-term oral administration of trimethoprim–sulfamethoxazole. Up to 20% of patients, however, develop intolerance to this drug combination. A retrospective review of 17 kidney transplant recipients, all of whom were unable to take trimethoprim–sulfamethoxazole, reported that when aerosolized pentamidine was used for prophylaxis against *Pneumocystis carinii,* the aerosolized pentamidine was not only well tolerated but was also highly effective in the prevention of *Pneumocystis carinii* infection.

The increased rate of occurrence of tuberculosis in patients with chronic renal failure and those on chronic hemodialysis was alluded to above. Renal transplant recipients also are at increased risk of developing tuberculosis, which occurs in them as an opportunistic infection. The infection occurs with higher frequency in areas with high prevalence of tuberculosis. In a series of 400 transplant patients in a developed country, only five developed tuberculosis. A South African study of 857 renal transplant recipients noted 21 cases of confirmed or presumed *Mycobacterium tuberculosis* infections; the median time from transplantation to diagnosis of tuberculosis was 14 months. The chest roentgenographic findings included consolidation, miliary pattern, pleural effusion, tuberculoma, cavitation, and hilar lymphadenopathy; disseminated disease was less common than reported elsewhere. Several cases of pulmonary infection caused by *Mycobacterium xenopi* have been reported. Simple gastric aspirates are reported to be adequate in the diagnosis of pulmonary tuberculosis in renal allograft recipients. In a study of more than 200 renal allograft recipients suspected to have tuberculosis, gastric aspirates were more helpful than bronchoalveolar lavage in the identification of acid-fast bacilli; the acid-fast bacillus positivity was significantly greater than that in patients with abnormal chest roentgenographs compared with patients with normal chest roentgenographs.

The early diagnosis of pulmonary infections in renal transplant recipients is important so that optimal therapy is promptly instituted. Bronchoalveolar lavage is an important diagnostic procedure in renal transplant recipients who develop respiratory symptoms or chest roentgenographic abnormalities. A study of 70 renal transplant recipients among whom 48 patients underwent 58 bronchoalveolar lavages identified 39 etiologic organisms in 32 patients, with six patients having more than one infection; bronchoalveolar lavage was negative in 22 patients. Overall, the results of bronchoalveolar lavage altered therapy in more than 70% of cases.

Pulmonary calcification, at times fatal, also is seen in renal transplant recipients. One patient developed extensive pulmonary calcification 6 days after renal transplantation and died from respiratory failure on the seventh day. In a study of 17 pediatric patients, four developed pulmonary calcification and respiratory failure within 3 to 5 days of renal transplantation. Common clinical features included poor allograft function with persistent uremia requiring dialysis and evidence of moderate to severe hyperparathyroidism. Three patients had markedly elevated calcium–phosphorus product, to peak values of 122 to 147 mg/dl. This increase was noted at the time of onset of respiratory failure. All patients died of respiratory failure 5 to 58 days after transplantation.

Chronic immunosuppressive therapy in patients with renal transplants increases the risk of developing B-cell lymphoma and carcinoma of the lung. Non-Hodgkin's lymphoma has been observed in up to 2.5% of renal transplant recipients. Although rare, pulmonary involvement from Kaposi's sarcoma has been described in recipients of renal transplants.

Abnormal pulmonary function, particularly a reduced $D_L CO$, seems to persist even after renal transplantation. Subclinical pulmonary edema present in the pretransplantation period is presumed to progress to fibrosis before transplantation.

The incidence of pulmonary thromboembolism is increased in renal transplant recipients. Pulmonary embolism was the most frequent complication among 227 renal transplant recipients, observed in 60% of those with a noninfectious pulmonary process.

ALVEOLAR HEMORRHAGE SYNDROMES

Pulmonary alveolar hemorrhage syndromes are discussed in this chapter because many belong to the group of diseases sometimes referred to as *pulmonary–renal syndromes,* to denote simultaneous occurrence of pulmonary and renal diseases, usually by the same pathologic process. Indeed, it is now clear that many of the systemic vasculitides commonly involve the kidneys and the lungs. Because pulmonary alveolar hemorrhage is a common feature in most of the pulmonary–renal syndromes, the term *lung purpura* also has been used to describe these entities (Table 2). The mechanism of alveolar bleeding may vary from disease to disease. For instance, the bleeding in Goodpasture's syndrome is believed to be the result of pulmonary capillary wall damage caused by the destruction of type IV collagen by autoantibodies. The alveolar hemorrhage in mitral stenosis is the result of stress failure of the capillary wall, caused by a tremendous increase in capillary pressure. In vasculitic syndromes, capillaritis secondary to direct involvement by the vasculitic process leads to hemorrhage into the alveoli.

Goodpasture's syndrome
Churg–Strauss vasculitis
Wegener's granulomatosis
Polyarteritis nodosa
Microscopic polyangiitis
Systemic lupus erythematosus
Lymphomatoid granulomatosis
Henoch–Schönlein purpura
Hemolytic–uremic syndrome
Scleroderma
Rheumatoid arthritis
Mixed connective tissue disease
Drug-induced vasculitis
Granulomatous (giant-cell) arteritis
Hypocomplementemic urticarial vasculitis
Idiopathic rapidly progressive glomerulonephritis
Essential mixed cryoglobulinemia

TABLE 2. *Pulmonary–renal syndromes*

The common physiological defect in these disorders is the diminished alveolar gas volumes evidenced by reduced total lung capacity and vital capacity. Airflow

limitation is not a feature. Interestingly, D_LCO can be elevated if fresh alveolar hemorrhage is present. Theoretically, D_LCO may show a continual rise if measured repeatedly in a patient with continued alveolar hemorrhage because of the increased uptake of carbon monoxide by the erythrocytes newly introduced into the alveoli. This test has been used in anecdotal cases and is reported to be a sensitive and useful indicator of the presence or absence of recurrent intrapulmonary hemorrhage. My own experience in several patients has shown that repeated measurement of D_LCO for this purpose is unreliable. Furthermore, repeated testing is impractical because most patients with alveolar hemorrhage are markedly ill and may not be able to withstand the testing.

Quantitative measurement of macrophage hemosiderin content in the bronchoalveolar lavage effluent has been suggested as a useful test to determine the degree of alveolar hemorrhage. A better diagnostic test perhaps is the estimation of the percentage of siderophages (hemosiderin-laden macrophages) among the total alveolar macrophages recovered by bronchoalveolar lavage. A study of 240 bronchoalveolar lavages, stained by Prussian blue, performed in 194 immunocompromised patients diagnosed alveolar hemorrhage in 87 (36%) of the samples; the study considered the test to be positive for alveolar hemorrhage when the siderophages constituted at least 20% of the cells. Pulmonary alveolar hemorrhage was significantly associated with four parameters: thrombocytopenia (<50,000/mm^3), presence of other abnormal coagulation parameters, renal failure (creatinine ³2.5 mg/dl), and a history of heavy smoking. During bronchoalveolar lavage, incremental increase in the bloody discoloration of alveolar effluent is one strong indicator of alveolar hemorrhage. However, the possibility of bleeding induced by the procedure itself should be considered.

The antineutrophil cytoplasmic antibody (ANCA) test may aid in differentiating the various vasculitic syndromes (see Chapter 54). However, more data suggest that some patients with Goodpasture's syndrome also may exhibit perinuclear ANCA (see below).

Although the common feature of alveolar hemorrhage syndromes is the bleeding into alveolar spaces (Fig. 8), the disorders are diverse in etiology. However, many are immunologically mediated or belong to broad categories of vasculitides or collagenoses. Differential diagnoses of alveolar hemorrhage syndrome (with or without renal involvement) are listed in Table 3.

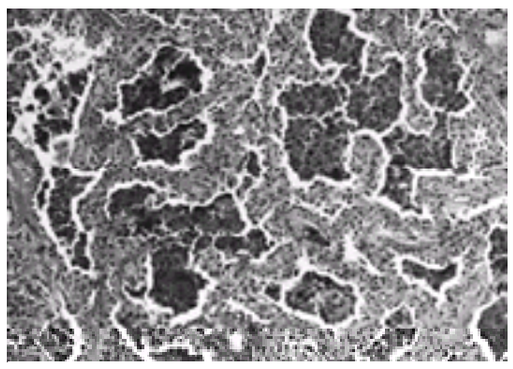

FIG. 8. Chronic pulmonary alveolar hemorrhage, regardless of cause, is seen as increased hemosiderin-filled alveolar macrophages associated with mild thickening and reactive changes in the surrounding alveolar walls.

TABLE 3. *Causes of pulmonary alveolar hemorrhage*

Goodpasture's Syndrome

Also known as antiglomerular basement membrane (anti-GBM) antibody disease, Goodpasture's syndrome is a typical example of the cytotoxic antibody-mediated (type II) reaction. It is an autoimmune disease causing rapidly progressive glomerulonephritis and pulmonary hemorrhage. The clinical manifestations are caused by autoantibodies that bind to a constituent, termed the Goodpasture autoantigen, of alveolar and glomerular basement membranes. This primary target antigen in glomerular and alveolar basement membranes is the a_3 chain of type IV collagen. The gene, COL4A3, has been encoded and localized to the q35–37 region of chromosome 2. In a postmortem study of a patient who died from Goodpasture's syndrome, the specificity of circulating, kidney-bound, and lung-bound autoantibodies against a variety of purified basement membrane constituents was studied. The results showed that the primary target for the circulating and tissue-bound autoantibodies is the NC1 domain of the a_3(IV) chain of type IV collagen; all the antibodies recognized a cryptic epitope(s) on the a_3(IV)NC1 hexamer. The results also indicated that tissue-bound and circulating antibodies compete with one another for overlapping epitopes on the antigen. Although the primary target of the antibodies to this antigen is the glomerular basement membrane of kidney, the lungs are affected by cross-reactivity.

Goodpasture's syndrome is characterized by the presence of circulating antiglomerular basement membrane (anti-GBM) antibodies and characteristic linear deposits of IgG and complement along the basement membranes of alveoli and glomerular basement membrane. The clinical manifestations correlate well with the presence of circulating anti-GBM autoantibodies.

Is the presence of anti-GBM antibody specific to Goodpasture's syndrome? This antibody has been described in patients without classic features of Goodpasture's syndrome. Indeed, some authors use the term *anti-GBM disease* to describe the syndrome when the clinical characteristics do not fit the classic Goodpasture's syndrome. In one study of 37 patients who tested positive for anti-GBM antibody or had linear IgG depositions, only 20 had typical Goodpasture's syndrome; 13 had anti-GBM glomerulonephritis alone, whereas two patients suffered solely from pulmonary hemosiderosis. Anti-GBM antibody has been detected in systemic lupus erythematosus, polyarteritis nodosa, Henoch–Schönlein purpura, hydrocarbon exposure, and following therapy with penicillamine.

The finding of ANCA with myeloperoxidase specificity in patients with Goodpasture's syndrome and other vasculitides (see Chapter 54) has introduced some confusion into the understanding of Goodpasture's syndrome and other alveolar hemorrhage syndromes. As a result, there is no universally accepted exact definition of Goodpasture's syndrome.

The etiology of Goodpasture's syndrome is unknown, but influenza virus, hydrocarbon exposure, penicillamine, and unknown genetic factors are known to stimulate anti-GBM antibody production. A review of the literature analyzed the data on 31 patients with hydrocarbon exposure and anti-GBM antibody-mediated nephritis and concluded that a causal relationship was present. Further, inadvertent exposure to hydrocarbons has resulted in the exacerbation of Goodpasture's syndrome. Goodpasture's syndrome has been described in identical twins. It is noteworthy, as noted above, that anti-GBM antibody has been detected in systemic lupus erythematosus, polyarteritis nodosa, Henoch–Schönlein purpura, hydrocarbon exposure, and penicillamine sensitivity. Azathioprine hypersensitivity, which depends on the nitroimidazole moiety of the drug, has been reported to mimic the pulmonary manifestations of Goodpasture's syndrome.

Tobacco smoking appears to have an association with Goodpasture's syndrome. In patients who develop Goodpasture's syndrome, a history of active cigarette smoking increases the risk of alveolar hemorrhage. In a study of 51 patients with glomerulonephritis related to anti-GBM antibody, 43 had pulmonary hemorrhage; of these, 37 were smokers, and all had pulmonary hemorrhage, as opposed to only two of ten nonsmokers. There was no significant difference between the titers of circulating anti-GBM antibody in smokers and nonsmokers.

Short-term exposure to certain solvents, such as halogenated hydrocarbons, petroleum distillates, ethylene glycol, ethylene glycol ethers, and diethylene glycol, may cause renal tubular necrosis, and tubular lesions with metabolic acidosis have been reported in addicts inhaling solvent vapor such as toluene. Goodpasture's syndrome may be induced by acute or subacute exposure to such solvents. Although adequate proof is lacking to suggest that repeated exposure to nonsubstituted organic solvents may lead to the development of different types of chronic glomerulonephritis and, possibly, Goodpasture's syndrome, the epidemiologic data suggest such an association. A fatal relapse of Goodpasture's syndrome 3 years after plasmapheresis has been described in a smoker who had been exposed to hydrocarbon solvents. Occult pulmonary hemorrhage followed by anti-GBM antibody-induced glomerulonephritis with normal renal function presenting as severe anemia was described in young woman who worked as a hairdresser; her exposure to chemicals in the products used for permanent waving of hair was considered to be responsible for the disease. Withdrawal of the suspected toxic hair spray was followed by both clinical remission and disappearance of the linear deposits of immunoglobulin from the renal glomeruli.

Penicillamine and carbimazole therapies for the treatment of rheumatoid arthritis and other diseases have been associated with Goodpasture's syndrome, circulating anti-GBM antibodies, and focal necrotizing glomerulonephritis with crescents. A study of 39 patients with anti-GBM antibody-mediated glomerulonephritis has suggested that HLA-B7-associated genes influence the severity of the renal disease but not that of the lung disease. In patients with Goodpasture's syndrome, a careful search should be made to ascertain the possibility of drug and toxin exposure.

A review in 1985 observed that since 1919, nearly 400 cases of Goodpasture's syndrome were published. Patients with anti-GBM antibody-mediated nephritis demonstrate two principal patterns of disease—young men presenting in their 20s with Goodpasture's syndrome (glomerulonephritis and lung hemorrhage) and elderly patients, especially women, presenting in their 60s with glomerulonephritis alone. In the classic form (in younger patients) of Goodpasture's syndrome, men are affected more often than women (male–female ratio 7:1), and the average age of onset is approximately 27 years. Recurrent hemoptysis, pulmonary insufficiency, renal involvement with hematuria and renal failure, and anemia are the classic features. Pulmonary hemorrhage almost always precedes renal manifestations. Frequent initial clinical features include hemoptysis, hematuria, proteinuria, and elevated serum creatinine.

Chest roentgenograms typically reveal bilateral, diffuse, symmetric perihilar infiltrates with sparing of the costophrenic angles and apices (Fig. 9). The diagnosis is made by correlating the clinical features, chest roentgenographic abnormalities, and characteristic renal pathology. Lung biopsy also will demonstrate the characteristic linear deposition of immunofluorescent material along the alveolar basement membrane (Fig. 10). Bronchoscopic lung biopsy has been used for diagnosis, but the diagnostic yield is approximately 30%.

FIG. 9. Extensive dense alveolar infiltrates secondary to pulmonary alveolar hemorrhage in Goodpasture's syndrome. The costophrenic angles are spared.

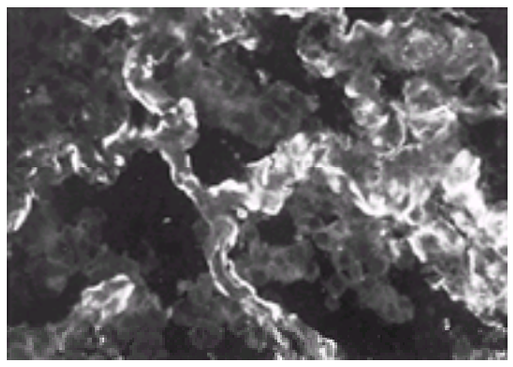

FIG. 10. Immunofluorescent staining of lung tissue in Goodpasture s syndrome reveals the characteristic linear deposits of IgG along alveolar basement membrane.

Plasmapheresis is the treatment of choice in patients with Goodpasture's syndrome. Although complete recovery can be expected in most patients who are treated with systemic corticosteroids, immunosuppressive agents, or plasmapheresis, relapses occur in up to 7% of patients.

Long-term follow-up data on 29 patients disclosed that 31% recovered totally and remained symptom-free with normal renal function for a mean of 206 weeks. In summary, the earlier therapy is associated with better outcome. Patients presenting early with a serum creatinine <200 µmol/L and without severe glomerular alterations gain the most benefit from therapy, indicating that outcome may be improved by early diagnosis.

Renal biopsies have been shown to be extremely valuable in predicting the progress and outcome of the disease. One study looked into the factors that affected the clinical course of 22 patients with Goodpasture's syndrome with renal impairment and reported that the most important features associated with a bad prognosis were total anuria or a very high percentage (>85%) of glomeruli showing crescents in the initial renal biopsy. In a retrospective study of 20 patients with Goodpasture's syndrome, indicators of poor prognosis were creatinine greater than 600 µmol/liter and crescent formation in more than 50% of the glomeruli on renal biopsy; the initial antibody titer and cigarette smoking were without predictive value. Recurrent Goodpasture's syndrome occurs in some patients. A fatal relapse 3 years after plasmapheresis has been described in a smoker who had been exposed to hydrocarbon solvents. A patient with Goodpasture's syndrome who was successfully treated with cytotoxic drugs, steroids, and plasma exchange exhibited, after an absence of 3 years, circulating anti-GBM antibodies. Long-term pulmonary function studies in patients who were treated for anti-GBM disease have found that a prior history of pulmonary hemorrhage significantly reduced the diffusing capacity of the lung for carbon monoxide without affecting other parameters of pulmonary function.

Glomerulonephritis

Rapidly progressive glomerulonephritis is a major cause of pulmonary alveolar hemorrhage. This disease is more common than reported, and more than 50% of cases are composed of Wegener's granulomatosis and microscopic polyarteritis. Additionally, rapidly progressive glomerulonephritis can occur in patients with Goodpasture's syndrome (anti-GBM antibody disease), lupus nephritis (immune complex disease), and pauci-immune and other vasculitides or idiopathic nephritis. In a series of 1500 renal biopsies demonstrating glomerulonephritis with crescent formation, 44% had immune complex deposition, 5% had anti-GBM antibody, and 51% had a pauci-immune pattern. In another review of alveolar hemorrhage syndrome associated with nephritis in 45 patients, the etiologies included anti-GBM disease (18%), a systemic vasculitis (56%), idiopathic glomerulonephritis (27%), and a variety of acute pulmonary complications, the most common being acute respiratory failure (29%); 7% died from fulminant lung hemorrhage. Follow-up studies in 22 patients 6 months after initial presentation indicated that although respiratory symptoms (14%) or pulmonary roentgenographic abnormalities (23%) were uncommon, the majority (73%) of patients had residual abnormalities on pulmonary function testing. Interstitial lung disease has occurred in association with glomerulonephritis caused by unusual vasculitic disorders such as Takayasu's arteritis. Other vasculitic syndromes—for instance, giant cell arteritis—can produce pulmonary problems without alveolar hemorrhage. Pulmonary hemorrhage is common in Behçet's disease.

Antineutrophil cytoplasmic antibodies (ANCA) have been detected in patients with idiopathic crescentic glomerulonephritis and alveolar hemorrhage syndrome. The presence of these antibodies may be associated with necrotizing vascular injury in the kidneys and the lungs. A study of 40 patients with biopsy-verified glomerulonephritis and overt hemoptysis or pulmonary infiltrates compatible with lung hemorrhage observed that 90% of patients exhibited antineutrophil cytoplasm antibodies (PR3-ANCA, myeloperoxidase-ANCA, or both in 27 patients, anti-GBM antibodies in nine). Among the patients with anti-GBM antibodies, the clinical

outcome was very poor (five irreversible renal failure; three deaths). On the other hand, despite no significant difference in clinical features or renal morphology when compared to patients with anti-GBM antibodies, 19 patients (70%) with ANCA recovered completely following treatment.

Intravenous immune globulin infusions have produced dramatic improvements in the necrotizing vascular injury produced by antineutrophil cytoplasmic autoantibodies, and a rapid reduction in the levels of these autoantibodies levels following intravenous immune globulin infusion has been observed in most patients.

Immunoglobulin A (IgA) nephropathy is rarely associated with pulmonary complications. The occurrence of fatal pulmonary hemorrhage in patients with IgA nephropathy is even rarer. An autopsy report described two patients with asymptomatic IgA nephropathy and a third patient with chronic renal failure caused by IgA nephropathy, all of whom died from an illness characterized by acute onset of dyspnea, hemoptysis, and pulmonary infiltrates. No infectious agent was identified, and in all three patients, the diagnoses of IgA nephropathy, idiopathic pulmonary hemorrhage, heavy alveolar hemosiderin-laden macrophages, and capillaritis were documented.

Collagenoses and Vasculitides

The disorders classified as collagenoses and vasculitides are two of the most important causes of pulmonary alveolar hemorrhage syndrome. In the former category, systemic lupus erythematosus is noteworthy, whereas in the latter, Wegener's granulomatosis and other vasculitic syndromes are significant. As a group, the vasculitic disorders are important in the etiology of alveolar hemorrhage syndrome. The clinical aspects of alveolar hemorrhage associated with these diseases are discussed in Chapter 53 and Chapter 54.

Idiopathic Pulmonary Hemosiderosis

It has become increasingly difficult to separate idiopathic pulmonary hemosiderosis from other causes of alveolar hemorrhage syndrome. The confusion stems from the inclusion of idiopathic pulmonary hemosiderosis with Goodpasture's syndrome and other causes of alveolar hemorrhage. Development of systemic vasculitis has been described several years after the diagnosis of idiopathic pulmonary hemosiderosis. For instance, the alveolar hemorrhage caused by microscopic polyarteritis (not to be confused with polyarteritis nodosa), associated with pauci-immune glomerulonephritis in combination with systemic small-vessel vasculitis but without granulomatous inflammation, has been labeled idiopathic pulmonary hemosiderosis. Furthermore, some have suggested that the term *idiopathic pulmonary hemorrhage* be used instead of idiopathic pulmonary hemosiderosis. Currently, idiopathic pulmonary hemosiderosis is a diagnosis of exclusion. The discussion here pertains to the traditional description of idiopathic pulmonary hemosiderosis.

Idiopathic pulmonary hemosiderosis is an uncommon disorder characterized pathologically by recurrent intrapulmonary hemorrhage, and clinically by the triad of hemoptysis, iron-deficiency anemia, and transient roentgenographic infiltrates. The etiology remains unknown, even though its origin has been attributed to several factors, including a heritable defect, an immunologic mechanism based on the presence of antibodies to cow's milk (Heiner's syndrome), cold agglutinins, and increased serum IgA, viral infections, a primary disorder of airway epithelial cells, and a structural defect of pulmonary capillaries. Familial occurrence has also been noted. Idiopathic pulmonary hemosiderosis has been described in association with idiopathic thrombocytopenic purpura and autoimmune hemolytic anemia. A significant number of patients with idiopathic pulmonary hemosiderosis and nontropical sprue (celiac disease) have been described. The implication of these associations is unclear, although an immunologically mediated mechanism has been proposed. More recently, a pediatric form of pulmonary hemosiderosis, presumed to be caused by the toxins of a spore growing in humid basements, has been described.

The clinical findings are extremely variable. Although most patients previously described have been children or young adults, the condition has been recognized in older adults. Hemoptysis may be massive, with dyspnea, cough, and cyanosis, and recurrent bleeding may result in hypochromic anemia. Chest roentgenographic abnormalities include poorly defined, coarse infiltrates, more common in the lower lobes bilaterally. Cessation of symptoms correlates with roentgenographic clearing. Intrathoracic lymphadenopathy is seen in up to 25% of cases. The clinical course is characterized by remissions and relapses. Anemia results from sequestration of iron in the lung parenchyma, often in alveolar macrophages. Because they cannot be mobilized for synthesis of hemoglobin, usable body iron stores become depleted, but they can be mobilized and excreted by the use of synthetic chelating agents. Development of pulmonary fibrosis accounts for the chronic respiratory insufficiency evident in many patients with long-standing idiopathic pulmonary hemosiderosis.

Diagnosis is based on the clinical and roentgenographic features and the presence of significant number of hemosiderin-laden macrophages in the sputum or bronchoalveolar lavage (see above). Microscopically, there is marked capillary dilation with degeneration and hyperplasia of alveolar epithelial cells (see Fig. 8). Corticosteroid and immunosuppressive therapy have been utilized with varying results. Several cases of idiopathic pulmonary hemosiderosis that resolved with cyclophosphamide or chloroquine therapy have been reported. Resolution of idiopathic pulmonary hemosiderosis after institution of a gluten-free diet in patients with idiopathic pulmonary hemosiderosis and nontropical sprue has been reported.

Malignant Disease

Alveolar hemorrhage is an important complication of pulmonary malignancies, being more common in patients who develop hematogenous pulmonary metastasis, tumor emboli, or leukemic lung infiltrates. Autopsy studies in patients with leukemia frequently show alveolar hemorrhage that is occult during life. Twelve percent of focal and 78% of diffuse pulmonary infiltrates have been attributed to alveolar hemorrhage in leukemic patients. The alveolar hemorrhage is frequently related to other complications such as invasive aspergillosis or zygomycosis, which result from immunosuppression. Occasionally, nonfungal infections can also produce alveolar hemorrhage. In the majority of the documented cases, thrombocytopenia (platelet count of fewer than 20×10^9/L) has been noted. Irrespective of the etiology, alveolar hemorrhage usually is not suspected or diagnosed before death; hemoptysis occurs in fewer than one-fourth of patients. Many patients develop an immunocompromised state as a result of infections, neoplasms, cytotoxic chemotherapy, or for unknown reasons. The incidence of alveolar hemorrhage in this group of patients varies from 3% to 8%.

Pulmonary alveolar hemorrhage is also common in certain nonhematologic malignancies. In one study of 23 patients with bronchopulmonary Kaposi's sarcoma, occult alveolar hemorrhage was present in 16 (70%). Hematogenous malignancies with tumor emboli in the pulmonary vessels also cause alveolar hemorrhage (Fig. 11). Right atrial myxoma has caused pulmonary hemorrhage.

FIG. 11. Diffuse alveolar-nodular infiltrates caused by hematogenous tumor emboli originating in a hypernephroma resulted in clinically significant alveolar hemorrhage.

Bone Marrow Transplantation

Pulmonary alveolar hemorrhage is a significant cause of respiratory disease in recipients of bone marrow transplant (see Chapter 55). This serious complication occurs in up to 21% of patients, with a mortality ranging from 50% to 80%. A high incidence of alveolar hemorrhage has been noted in patients with Hodgkin's and non-Hodgkin's lymphoma treated with high-dose radiation and chemotherapy and autologous bone marrow transplantation. Acute respiratory failure secondary to alveolar hemorrhage occurred within 2 weeks after bone marrow transplantation in 26% of 77 consecutive patients thus treated; the mortality was 100%.

Hemoptysis is unusual in most cases of alveolar hemorrhage. The majority of patients exhibit clinical and roentgenologic signs of infection, including high fever, dyspnea, nonproductive cough, hypoxemia, and diffuse or focal alveolar infiltrates. The initial roentgenologic abnormalities develop within the first 2 weeks and precede the clinical diagnosis by an average of 3 days.

Mitral Stenosis

Although mitral valve disease is now an uncommon cause of alveolar hemorrhage in the developed countries as a result of prompt surgical therapy, it remains an important etiology of hemoptysis and alveolar hemorrhage in other countries. Earlier publications indicated that hemoptysis in mitral stenosis is caused by the rupture of dilated and varicose bronchial veins. Hemoptysis from this mechanism usually occurs early in the course of mitral stenosis and may be the presenting symptom. Other studies suggest that alveolar hemorrhage is the result of stress failure of pulmonary capillaries; the capillary wall stresses greatly increase when the capillary pressure is raised, and wall damage occurs at pressures of 40 mm Hg and higher. Recurrent episodes of alveolar hemorrhage may result in pulmonary calcification and even true ossification. Pulmonary fibrosis may be seen in some patients.

Toxic Alveolar Hemorrhage

D-Penicillamine

Alveolar hemorrhage is a rare manifestation of penicillamine toxicity. Several anecdotal case reports have suggested D-penicillamine as a cause of Goodpasture's syndrome. The daily dose of the drug was high (0.75 to 2.0 g) in almost all cases, and the duration of therapy preceding toxicity ranged from 10 months to 3 years. Uniformly severe alveolar hemorrhage occurred with glomerulonephritis, but other organs were not affected, and four deaths were recorded in a review of the subject in 1984. Immunopathologic features in these cases suggest immune-complex drug-induced disease with a granular pattern of immunofluorescence and with none of the hallmarks of Goodpasture's syndrome.

Trimellitic Anhydride

Trimellitic anhydride is a component of epoxy resin used in the manufacture of epoxy resin coatings, plastics, and paints. Inhalation of fumes or powder can lead to several clinical syndromes, among which pulmonary alveolar hemorrhage is the most serious. Workers exposed to this chemical have developed allergic-type lung disease as well as alveolar hemorrhage. Presence of antibodies against haptenized erythrocytes and human serum albumin suggests an immunologic basis. The illness is characterized by cough, hemoptysis, dyspnea, weakness, and nausea or vomiting. Anemia is a common finding; hence, the term *pulmonary disease–anemia syndrome* is sometimes used to describe this entity. A series of seven young men exposed to trimellitic anhydride developed typical symptoms, but all recovered quickly without treatment; light and electron microscopic studies of lung tissue showed extensive bleeding into alveoli, but no basement membrane deposits or anti-GBM antibodies were observed.

Isocyanates

Hemoptysis, dyspnea, and bilateral pulmonary opacities have been described in a patient who was exposed to spray paint that contained hexamethylene diisocyanate and toluene diisocyanate; high levels of IgG and IgE antibodies were detected against these isocyanates.

Anticoagulants

A case of rodenticide-induced diffuse alveolar hemorrhage has been reported in a patient who consumed brodifacoum (D-Con), a derivative of warfarin. Therapeutic use of anticoagulants is unlikely to cause alveolar hemorrhage unless the pulmonary parenchyma suffers trauma. Three cases were described in 1975, and the clinical features included dyspnea, unexplained acute anemia, and alveolar infiltrates, but hemoptysis was conspicuously absent; one patient died from massive pulmonary alveolar hemorrhage.

Lymphangiography

Lymphangiography has been complicated by pulmonary alveolar hemorrhage. Hemoptysis has been estimated to occur in only one in 3000 cases and is limited to blood-tinged sputum. A 1984 review of alveolar hemorrhage syndromes noted three reported cases of severe alveolar bleeding occurring 2, 5, and 10 days after the procedure, and one patient died.

Other Causes of Alveolar Hemorrhage

Ventilator-associated pneumonia is known to produce alveolar hemorrhage. A study of autopsy findings and premortem roentgenologic features of 69 patients with ventilator-associated pneumonia observed alveolar hemorrhage in 38% of cases; roentgenograms exhibited multiple air bronchograms in 29% and bilateral alveolar infiltrates in 30% of patients.

Pulmonary lymphangioleiomyomatosis is an uncommon cause of alveolar hemorrhage syndrome. Hemoptysis occurs as a presenting symptom in 7% of cases and in half the patients during the course of their illness. Alveolar hemorrhage is the result of venous obstruction and capillary hemorrhage caused by proliferation of muscle in the walls of the pulmonary veins.

Pulmonary venoocclusive disease is an uncommon disease. Alveolar hemorrhage occurs in a significant number of patients with this rare disorder. *Anticardiolipin antibody syndrome* (see Chapter 53) is another cause of alveolar hemorrhage.

Immunocompromised patients develop a variety of infectious and noninfectious pulmonary complications, as discussed in Chapter 55. Among the noninfectious respiratory manifestations, alveolar hemorrhage is an important consideration. Coexisting thrombocytopenia and invasive fungal infections greatly increase the risk of alveolar bleeding. Clinical features include progressive dyspnea, cough, and hypoxemia. Hemoptysis is distinctly uncommon. Chest roentgenologic abnormalities vary (Fig. 12 and Fig. 13).

FIG. 12. Marked alveolar infiltrates in the right lung with only a patchy area of infiltrate in left midlung. Significant hemoptysis in this patient was caused by systemic lupus erythematosus complicated by renal failure. Not all cases of diffuse alveolar hemorrhage show bilaterally symmetric chest roentgenologic abnormalities.

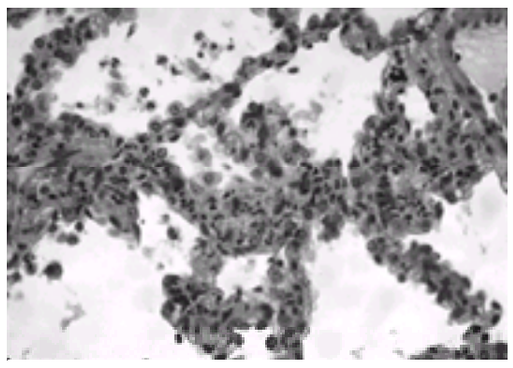

FIG. 13. Acute pulmonary alveolar hemorrhage showing infiltrates of neutrophils in the alveolar septa. The pattern here is nonspecific and could be seen in Goodpasture's syndrome, Wegener's granulomatosis, collagenoses, or vasculitis. In this particular case, a specific diagnosis could not be made.

MISCELLANEOUS RENAL DISEASES

Hemorrhagic diathesis associated with renal failure is the result of azotemia-induced platelet dysfunction. The platelet count is normal, but the bleeding time is abnormally elevated. This hemorrhagic diathesis is a relative contraindication to invasive pulmonary diagnostic procedures. When the serum creatinine level exceeds 3.0 mg/dl or serum urea exceeds 45 mg/dl, bronchoscopic lung biopsy carries an approximately 40% risk of bleeding.

Nephrobronchial fistula is a rare sequel of perinephric abscess and other inflammatory renal diseases. There are reports of nephrolithiasis and pyelonephritis complicated by obstruction leading to pyonephrosis, perinephric abscess, and nephrobronchial fistula that were treated successfully by nephrectomy. Inflammatory renal diseases may involve the perirenal space and spread contiguously to other organs in the abdomen as well as to the adjacent pleural space.

Acute respiratory distress has been described in a patient undergoing *nephrolithotripsy.* Absorption of a large volume of irrigating fluid during the procedure was responsible for this complication.

Pulmonary alveolar microlithiasis is an uncommon disease of unknown etiology, characterized by deposition of tiny calcispherites in the alveolar spaces. Although there is no relation between this disorder and nephrolithiasis, a case of pulmonary alveolar microlithiasis with pleural calcification and nephrolithiasis has been reported.

Renal cell carcinoma is one of the common tumors that produce endobronchial metastasis. Clinically, patients may present with segmental or lobar atelectasis, cough, hemoptysis, and expectoration of endobronchial tumor tissue. Pulmonary parenchymal metastases, usually the result of hematogenous spread of the tumor, may present as rounded nodules, frequently referred to as cannonball lesions. Resection of multiple bilateral pulmonary metastatic nodules is recommended by some. A study reported that in select patients with renal cell carcinoma with pulmonary metastasis who do not respond to nonsurgical therapy, surgical resection of residual metastatic disease may prolong life. The detection of such lesions may require computed tomography of chest. In a study, however, of 120 patients with renal cell carcinoma who underwent chest roentgenography and computed tomography of the chest, a follow-up at 24 months showed no significant impact as a result of the disagreement between the two imaging methods on the therapeutic decision or ultimate outcome. The study also indicated that in patients with a relatively small tumor (stage T_1), normal chest roentgenography suffices for pulmonary staging of the lung metastasis, and the indications for computed tomography of chest include a solitary nodule on chest roentgenograph before salvage resection of metastasis, respiratory symptoms suggestive of endobronchial metastasis, or extensive regional disease.

Interleukin-2 (IL-2) aerosolization therapy has been reported to be effective in controlling the progression of pulmonary metastases from renal cell carcinoma. In a study of 15 patients with pulmonary metastases from renal carcinoma, a trial of high-dose long-term inhalation of IL-2 (90% of IL-2 dose) demonstrated that none of the pulmonary metastases progressed during treatment; one complete response, eight partial responses, and six cases of stable disease were achieved in the lungs.

Renal metastases from primary lung cancer occur much more uncommonly than pulmonary metastases from renal cancer. Several cases of primary lung cancer with metastasis to kidney with resultant acute renal failure have been described, however. The renal changes included extensive bilateral parenchymal infiltration and replacement accompanied by tissue destruction, widespread vascular invasion and thrombosis resulting in ischemia, histologic evidence for foci of distal intratubular obstruction and pyelonephritis, and lymphatic renal metastases. Common findings in all six reported cases included bilaterally enlarged kidneys and progressive oliguria or anuria despite correction of prerenal or postrenal conditions.

Angiomyolipoma of the kidneys occurs commonly in patients with pulmonary lymphangioleiomyomatosis. In one study of 17 consecutive patients with pulmonary lymphangioleiomyomatosis, eight (47%) had renal angiomyolipomas that were found either at surgery or on computed tomographic scans of the abdomen. Therefore, patients with pulmonary lymphangioleiomyomatosis should undergo either ultrasonography or computed tomography of the kidneys. Furthermore, serial follow-up by ultrasonography or CT scanning is recommended to identify and monitor patients with renal lesions larger than 4 cm because such lesions present an increased risk for hemorrhage.

Rounded atelectasis, also known as *folded-lung syndrome* or *atelectatic pseudotumor,* has been described in patients with end-stage renal disease. It is usually caused by chronic pleural effusion or pleural disease. Uremic pleurisy or recurrent small pleural effusion associated with chronic renal disease may lead to rounded atelectasis.

Pulmonary fibrosis was reported in four of 19 patients with renal tubular acidosis. The explanation for the pathogenesis of this association is unclear. Hypoxemia and hemoptysis with life-threatening consequences have occurred after lithotripsy as a result of shock-wave–induced pulmonary contusion. Hemothorax has occurred as a complication of percutaneous renal biopsy.

Kinetics of pulmonary leukocyte sequestration in man during hemodialysis with different membrane-types. *Int J Artif Organs* 1990;13:729–736. *Description of 13 patients with chronic renal failure who underwent lung scintigraphy (with administration of isolated autologous leukocytes labeled with 99m-technetium) during hemodialysis with different dialyzer membranes. Authors conclude that pulmonary sequestration of leukocytes takes place in the initial phase of hemodialysis and appears to be strongly dependent on the type of dialysis membrane.*

Lai FM, Li EK, Suen MW, Lui SF, Li PK, Lai KN. Pulmonary hemorrhage. A fatal manifestation in IgA nephropathy. *Arch Pathol Lab Med* 1994;118:542–546. *Description of two patients with asymptomatic IgA nephropathy and a third patient with chronic renal failure caused by IgA nephropathy, all of whom died from an illness characterized by acute onset of dyspnea, hemoptysis, and pulmonary infiltrates. No infectious agent was identified, and in all three patients, the diagnoses of IgA nephropathy and idiopathic pulmonary hemorrhage were established at postmortem examination.*

Leatherman J. Autoimmune diffuse alveolar hemorrhage. *Clin Pulm Med* 1994;1:356–364. *A detailed review of alveolar hemorrhage syndromes including Goodpasture's syndrome, idiopathic pulmonary hemosiderosis, vasculitides, and glomerulonephritides.*

Lechleitner P, Defregger M, Lhotta K, Totsch M, Fend F. Goodpasture's syndrome. Unusual presentation after exposure to hard metal dust. *Chest* 1993;103:956–957. *An unusual case of Goodpasture's syndrome in a 26-year-old man with occupational exposure to hard metal dust is described. The patient developed a life-threatening interstitial lung disease that was followed by a rapidly progressive glomerulonephritis 2 months later.*

Lepage S, Bisson G, Verreault J, Plante GE. Massive hydrothorax complicating peritoneal dialysis. Isotopic investigation (peritoneopleural scintigraphy). *Clin Nucl Med* 1993;18:498–501. *A case of massive hydrothorax complicating peritoneal dialysis is described; isotopic peritoneopleural scintigraphy showed a rapid accumulation of the radiopharmaceutical over the right hemithorax, leading to the suspicion that a macroscopic diaphragmatic defect was responsible.*

Levy JB, Lachmann RH, Pusey CD. Recurrent Goodpasture's disease. *Am J Kidney Dis* 1996;27:573–578. *Goodpasture's disease is usually a monophasic illness that can be successfully treated in a large proportion of patients. This report describes a case of Goodpasture's disease in which recurrent pulmonary hemorrhage and glomerulonephritis were observed over 12 years.*

Lim DJ, Carter MF. Computerized tomography in the preoperative staging for pulmonary metastases in patients with renal cell carcinoma. *J Urol* 1993;150:1112–1114. *In this 24-month follow-up study of 120 patients with renal cell carcinoma who underwent chest roentgenography and computed tomography of chest, survival data showed no significant impact as a result of the disagreement between the two imaging methods on the treatment decision or ultimate outcome. The authors conclude that in patients with a relatively small tumor (stage* T_1*), a normal chest radiograph suffices for pulmonary staging.*

Lombard CM, Colby TV, Elliott CG. Surgical pathology of the lung in anti-basement-membrane antibody-associated Goodpasture's syndrome.*Hum Pathol* 1989;20:445–451. *This publication describes four of five patients with anti-basement-membrane antibody-associated Goodpasture's syndrome in whom pulmonary capillaritis with hemorrhage was found on lung biopsy, confirming that pulmonary capillaritis can be found in Goodpasture's syndrome. All five patients had evidence of injury at the level of the alveolar wall, manifested by hyaline membranes and widening of alveolar walls by edematous connective tissue.*

Manning EC, Belenko MI, Frauenhoffer EE, Ahsan N. Acute renal failure secondary to solid tumor renal metastases: case report and review of the literature. *Am J Kidney Dis* 1996;27:284–291. *The occurrence of pulmonary metastasis from renal cell carcinoma is much more common than lung cancer metastasis to the kidneys. This publication describes six cases of primary lung cancer with metastasis to kidney with resultant acute renal failure.*

Marrades RM, Roca J, Campistol JM, Diaz O, Barbera JA, Torregrosa JV, Masclans JR, Cobos A, Rodriguez-Roisin R, Wagner PD. Effects of erythropoietin on muscle O_2 transport during exercise in patients with chronic renal failure. *J Clin Invest* 1996;97:2092–2100. *In this study, eight patients with chronic renal failure undergoing regular hemodialysis were studied pre- and posterythropoietin therapy to assess the reason for the lack of peak oxygen uptake after erythropoietin therapy despite improved hemoglobin concentration and the quality of life. In spite of a 68% increase in Hb, peak* VO_2 *increased by only 33%. The authors conclude that the increase in Hb produced by erythropoietin is accompanied by a significant reduction in peak blood flow to exercising muscle, which limits the gain in oxygen transport, and even after restoration of Hb,* O_2 *conductance from the muscle capillary to the mitochondria remains considerably below normal.*

Merkel F, Pullig O, Marx M, Netzer KO, Weber M. Course and prognosis of anti-basement-membrane antibody (anti-BM-Ab)-mediated disease: report of 35 cases. *Nephrol Dial Transplant*

1994;9:372–376. *Retrospective study in which 35 patients with anti-GBM antibody were followed up for at least 6 months; 20 (57%) patients had Goodpasture's syndrome, 13 (37%) had anti-GBM glomerulonephritis alone, whereas two patients suffered solely from pulmonary hemosiderosis. Indicators of poor prognosis included a serum creatinine >600 µmol/liter and crescent formation in more than 50% of the glomeruli on renal biopsy.*

Moinard J, Guenard H. Membrane diffusion of the lungs in patients with chronic renal failure. *Eur Respir J* 1993;6:225–230. *The diffusing capacity of the lung for carbon monoxide was measured in 15 patients hemodialyzed three times a week for 1 to 10 years. Based on the results, the authors concluded that progressive development of hemodialysis-induced chronic lung disease may be related to a mechanism of complement activation by a bioincompatible membrane such as Cuprophane.*

Montseny JJ, Meyrier A, Kleinknecht D, Callard P. The current spectrum of infectious glomerulonephritis: experience with 76 patients and review of the literature. *Medicine* 1995;74:63–73. *Among 76 adults with infectious or postinfectious proliferative glomerulonephritis, ten had endocarditis; staphylococci and gram-negative strains were commonly responsible. The origin of sepsis was the lung in 14 patients. Poor prognostic factors included age over 50 years, purpura, endocarditis, and glomerular extracapillary proliferation.*

O'Brien JD, Ettinger NA. Nephrobronchial fistula and lung abscess resulting from nephrolithiasis and pyelonephritis. *Chest* 1995;108:1166–1168. *A description of an unusual complication of nephrobronchial fistula and lung abscess resulting from nephrolithiasis and pyelonephritis.*

Prezant DJ, Aldrich TK, Karpel JP, Lynn RI. Adaptations in the diaphragm's *in vitro* force–length relationship in patients on continuous ambulatory peritoneal dialysis. *Am Rev Respir Dis* 1990;141:1342–1349. *Measurements of functional residual capacity, maximum inspiratory and transdiaphragmatic pressure, and diaphragm length and radius of curvature (roentgenographic methods) in patients on continuous ambulatory peritoneal dialysis for more than 6 weeks indicated that the diaphragm may be capable of an adaptive rightward shift in its force–length relationship when it is chronically lengthened by continuous ambulatory peritoneal dialysis.*

Richardson J, Slovis B, Miller G, Dummer S. Development of pulmonary alveolar microlithiasis in a renal transplant recipient. *Transplantation* 1995;59:1056–1057. *A description of the unusual occurrence of pulmonary alveolar calcification in a renal transplant recipient. Metastatic pulmonary calcification is a well-recognized, albeit uncommon, complication following kidney transplantation.*

Saukkonen K, Garland R, Koziel H. Aerosolized pentamidine as alternative primary prophylaxis against *Pneumocystis carinii* pneumonia in adult hepatic and renal transplant recipients. *Chest* 1996;109:1250–1255. *This retrospective review of medical records of 17 kidney transplant recipients, all of whom were sensitive to trimethoprim–sulfamethoxazole, aerosolized pentamidine was used (for 5.7 months) for prophylaxis against* Pneumocystis carinii. *The results disclosed that aerosolized pentamidine is well tolerated and may be an effective alternative to prevent* Pneumocystis carinii *infection in adult kidney transplant recipients intolerant to trimethoprim–sulfamethoxazole.*

Saxena R, Bygren P, Arvastson B, Wieslander J. Circulating autoantibodies as serological markers in the differential diagnosis of pulmonary renal syndrome. *J Intern Med* 1995;238:143–152. *This study of 40 patients with biopsy-verified glomerulonephritis and overt hemoptysis or pulmonary infiltrates compatible with lung hemorrhage observed that the presence of antineutrophil cytoplasm antibodies is a predominant feature of pulmonary–renal syndromes; 90% of patients possessed one or more of these autoantibodies.*

Siafakas NM, Argyrakopoulos T, Andreopoulos K, Tsoukalas G, Tzanakis N, Bouros D. Respiratory muscle strength during continuous ambulatory peritoneal dialysis (CAPD). *Eur Respir J* 1995;8:109–113. *This study of 26 patients with chronic renal failure and continuous ambulatory peritoneal dialysis assessed the effects of the renal diseases on respiratory muscle function (*P_{Imax} *and* P_{Emax}*) before dialysis, 4 hr after the administration of 2 liters of dialysate into the peritoneal cavity, and just after the next drainage. Respiratory muscle strength was preserved in the majority of the patients with chronic renal failure treated with continuous ambulatory peritoneal dialysis. Lung volumes and respiratory muscle function, however, were decreased during dialysis.*

Siskind MS, Thienemann D, Kirlin L. Isoniazid-induced neurotoxicity in chronic dialysis patients: report of three cases and a review of the literature. *Nephron* 1993;64:303–306. *In this report of three patients with chronic renal failure who also were on isoniazid antituberculous therapy, an increased incidence of neurotoxic side effects was observed; the toxicity was observed only in those patients receiving pyridoxine supplements of less than 100 mg/day.*

Sleijfer S, van der Mark TW, Schraffordt Koops H, Mulder NH. Enhanced effects of bleomycin on pulmonary function disturbances in patients with decreased renal function due to cisplatin. *Eur J Cancer* 1996;32A:550–552. *The authors examined whether cisplatin-induced nephrotoxicity augmented bleomycin-induced pulmonary toxicity in patients with testicular cancer treated with etoposide and cisplatin with or without bleomycin. Before and at 3-week intervals during chemotherapy, creatinine clearance and lung functions were measured. The authors conclude that toxic effects of bleomycin on the lung are enhanced when bleomycin therapy is combined with cisplatin.*

Sternberg RI, Baughman RP, Dohn MN, First MR. Utility of bronchoalveolar lavage in assessing pneumonia in immunosuppressed renal transplant recipients. *Am J Med* 1993;95:358–364. *A retrospective study of 70 renal transplant recipients among whom 48 patients underwent 58 bronchoalveolar lavages identified 39 etiologic organisms in 32 patients, with six patients having more than one infection. Bronchoalveolar lavage was negative in 22 patients, eight of whom were clinically believed to have a volume overload state. Authors conclude that BAL is a useful procedure in the diagnosis of an infectious process in immunosuppressed renal transplant patients and that initial results can alter therapy in more than 70% of cases.*

Stetter M, Schmidl M, Krapf R. Azathioprine hypersensitivity mimicking Goodpasture's syndrome. *Am J Kidney Dis* 1994;23:874–877. *A report of a 21-year-old male patient with anti-GBM disease who developed end-stage renal failure and required two renal allografts at the ages of 23 and 27 years. He received three courses of azathioprine: one for glomerulonephritis caused by anti-GBM disease and two courses for rejection episodes. Each course was followed within 4 to 7 days by symptoms compatible with Goodpasture's syndrome and all signs and symptoms resolved completely on discontinuation of azathioprine.*

Swan TL, Smyth SH, Ruffenach SJ, Berman SS, Pond GD. Pulmonary embolism following hemodialysis access thrombolysis/thrombectomy. *J Vasc Interven Radiol* 1995;6:683–686. *This study of 31 patients, with 43 acutely thrombosed polytetrafluoroethylene hemodialysis fistulas, who were treated with thrombolysis/thrombectomy, observed perfusion lung scans that were consistent with the diagnosis of pulmonary embolism in 59% of 22 patients, but no clinical signs or symptoms were present in 95%.*

Turner AN, Rees AJ. Goodpasture's disease and Alport's syndromes. *Annu Rev Med* 1996;47:377–386. *This review encompasses Goodpasture's syndrome and Alport's syndrome, an inherited degenerative disorder that affects specific basement membranes; the two diseases are linked by the involvement of type-IV collagen (basement membrane collagen) in their pathogenesis.*

Wadhwa NK, Mendelson WB. A comparison of sleep-disordered respiration in ESRD patients receiving hemodialysis and peritoneal dialysis. *Adv Perit Dial* 1992;8:195–198. *Sleep apnea was noted in nine of 15 patients on peritoneal dialysis and eight of 15 patients on hemodialysis. The authors conclude that the incidence and severity of sleep apnea are similar in patients with end-stage renal disease treated with long-term chronic peritoneal dialysis or hemodialysis.*

Walshaw MJ, Lim R, Ahmad R, Hind CR. Bronchial reactivity in patients undergoing long-term hemodialysis for chronic renal failure. *Blood Purif* 1991;9:70–73. *This study performed histamine challenge testing in six nonasthmatic patients before and after hemodialysis and observed no change in reactivity, suggesting that hemodialysis does not commonly result in bronchial hyperreactivity in nonasthmatic individuals.*

West JB, Mathieu Costello O. Stress failure of pulmonary capillaries: role in lung and heart disease. *Lancet* 1992;340:762–767. *The authors propose that stress failure of pulmonary capillaries results in a high-permeability form of edema, or even frank hemorrhage in mitral stenosis, neurogenic pulmonary edema, and high-altitude pulmonary edema and that stress failure also occurs if the type IV collagen of the capillary wall is weakened by autoantibodies, as in Goodpasture's syndrome.*

CHAPTER

58 Gastroenterologic Diseases

Udaya B.S. Prakash

U.B.S. Prakash: Pulmonary and Critical Care Medicine, Mayo Medical School and Mayo Medical Center, Rochester, Minnesota 55905.

INTRODUCTION

The common embryologic origin of the upper gastrointestinal tract and the tracheobronchial tree is responsible for their close anatomic proximity throughout life. The pathologic importance of this proximate relationship is evident in the knowledge that some diseases of the esophagus affect the tracheobronchial tree and vice versa. Furthermore, the intimate relationship between the tracheobronchial tree and the esophagus is evident in several congenital and developmental disorders including tracheoesophageal fistula, laryngotracheoesophageal cleft abnormalities, and incomplete development of the trachea and the esophagus. Among the acquired diseases, the aspiration of gastric contents as a result of gastroesophageal reflux into the respiratory system is an excellent example of the close relationship between the airways and the esophagus. Malignant neoplasms originating in the esophagus frequently invade or compress the tracheobronchial tree and cause respiratory embarrassment. Further, there is evidence to suggest the existence of local neuronal esophagolaryngotracheal reflexes in humans. Pulmonary involvement in hepatic and pancreatic diseases is well known. Respiratory manifestations in other gastroenterologic diseases, however, are less common and hence are not very familiar to all. This chapter discusses pulmonary manifestations in the common as well as the uncommon gastroenterologic diseases. The role of alcohol on lung function and disease also is included.

ESOPHAGEAL DISORDERS

Fistulas

Tracheoesophageal and bronchoesophageal fistulas may be congenital or acquired. Congenital fistulas are more commonly tracheal than bronchial. In 90% of congenital cases, there is a proximal blind-ending esophagus and usually a connection between the distal esophagus and the trachea (Fig. 1). In the remaining 10% of cases, an H-type fistula is seen. This latter congenital anomaly may remain undetected until adulthood, especially if the communication is small enough to prevent aspiration of large amounts of solids or liquids through the fistulous tract. Aspiration of small amounts of esophageal contents through the anomalous communication may lead to chronic cough, asthma-like symptoms, and recurrent respiratory infections. A fistula at a more distant site, such as an esophagobronchial fistula, can lead to recurrent infections and ultimately to the development of bronchiectasis. Occasionally, surgical resection of a chronically infected bronchiectatic segment of lung may disclose the presence of a previously undiagnosed fistula between the esophagus and the airway.

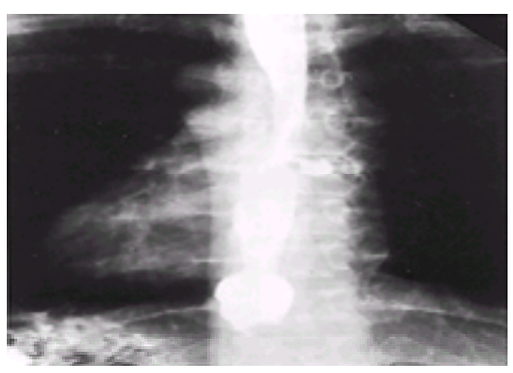

FIG. 1. Situs inversus and congenital fistula between esophagus and proximal left mainstem bronchus, presenting in adulthood as asthma and cough induced by ingestion of liquids.

Acquired tracheoesophageal fistulas as a result of malignancy in the trachea, esophagus, and mediastinum account for approximately 60% of fistulas in adults. The remainder are a consequence of infections, mediastinal granuloma secondary to histoplasmosis, broncholithiasis, silicotic lymph nodes, chemical corrosives, and trauma. Esophageal instrumentation (iatrogenic) is an important cause of tracheoesophageal fistula and acute mediastinitis. Esophagoscope and dilation procedures, inadvertent intubation of the esophagus during endotracheal intubation, rigid bronchoscopic procedures, and endoluminal laser therapy of tracheoesophageal lesions also may lead to the development of fistula. Radiation necrosis of malignancies involving the tracheoesophageal interphase is a relatively common cause of tracheoesophageal fistula. An uncommon cause of acquired tracheoesophageal fistula is Crohn's disease, which affects the esophagus in 0.3% of patients with the disease. Esophagography in patients with Crohn's disease of the esophagus has demonstrated stricture in 38% and ulceration in 32%; tracheoesophageal fistula has been observed in 6% of patients.

Symptoms depend on the location and size of the fistula, but, characteristically, there is coughing on swallowing liquids. Hemoptysis, recurrent pulmonary infection, wheezing, and bronchiectasis also are commonly encountered. A wrong diagnosis of chronic bronchitis or asthma is not uncommon. Diagnosis is documented by demonstrating, in the fistulous tract, contrast material introduced through the esophagus. Esophagoscope and bronchoscopy also are valuable in assessing the location and size of the fistula as well as in obtaining a biopsy from the edges of the fistula to exclude malignancy. Furthermore, bronchoscopy and esophagoscope are important in the insertion of a tracheobronchial or esophageal prosthesis (stent) to treat the fistula.

The possibility of satisfactory surgical correction depends on the cause and location of the fistula. Benign fistulous communications are amenable to surgical therapy. In patients with malignant fistulas, repeated aspiration and pneumonia lead to rapid deterioration and death. The prognosis is dismal, and curative resections and surgical bypass have been associated with 25% to 60% mortality. Insertion of endoprostheses (stents) by endoscopic methods carries perioperative mortality of 15% in these patients.

Gastroenteric Cysts

Gastroenteric cysts develop from the foregut and represent a failure of the originally solid esophagus to become a hollow tube. The cysts occur in the paraspinal region of the posterior mediastinum and usually are round or oval and homogeneous in density (Fig. 2). The majority of these cysts are detected incidentally when chest roentgenographs are obtained. The typical roentgenologic presentation is in the form of a mediastinal mass. Computed tomography helps in the diagnosis. It is uncommon for these cysts to enlarge greatly. Although the overwhelming majority of patients with gastroenterogenous cysts are asymptomatic, surgical resection is routine in most patients.

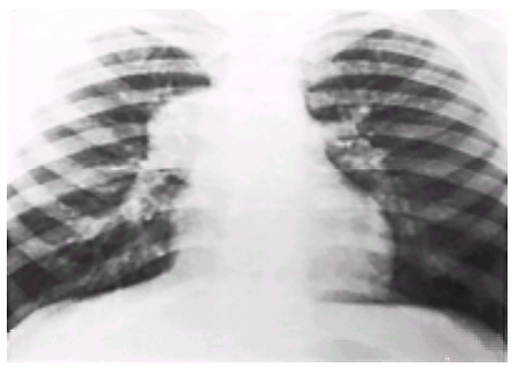

FIG. 2. A large gastroenteric cyst presenting as a posterior mediastinal mass. This was asymptomatic and was discovered during a routine examination.

Zenker's Diverticulum

A pharyngoesophageal diverticulum of Zenker may be large enough to be wrongly identified as a superior mediastinal mass on chest roentgenograms. Symptoms include dysphagia, chronic cough caused by aspiration, and recurrent aspiration pneumonia (Fig. 3).

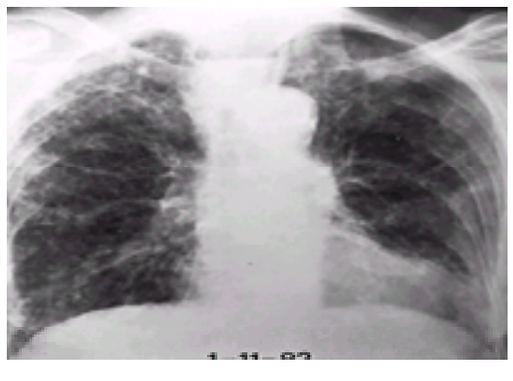

FIG. 3. Acute respiratory failure caused by aspiration from a large pharyngoesophageal diverticulum. Note the air–fluid level in the upper esophagus, just above the aortic arch.

Achalasia

Esophagomegaly (megaesophagus) secondary to achalasia can encroach on the upper airway and cause obstruction to airflow during the expiratory phase. It is not unusual for the enlarged esophagus in achalasia to appear as mediastinal widening or density on routine chest roentgenograms (Fig. 4). Aspiration pneumonia is a serious complication of achalasia and may lead to acute respiratory distress syndrome. Esophagobronchial fistula has been described in a patient with chronic achalasia.

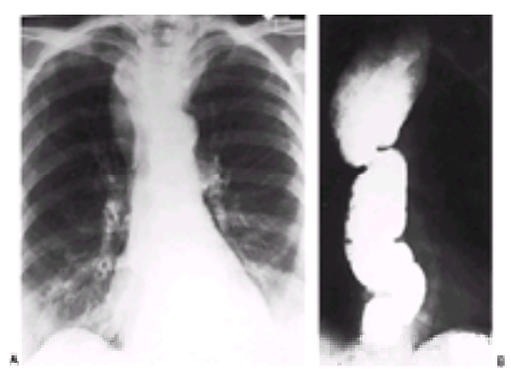

FIG. 4. Achalasia presenting as a superioposterior mediastinal mass. Posteroanterior chest roentgenogram **(A)** and barium contrast study **(B)** demonstrate the megaesophagus.

Mycobacterial infections caused by rapidly growing mycobacteria (*M. fortuitum, M. chelonae,* and others) occur more frequently in patients with achalasia and other esophageal disorders. This complication is more likely if lipoid pneumonia develops as a result of recurrent aspiration. Therapy of both the esophageal disease and mycobacterial infection may be necessary in patients who develop progressive respiratory problems.

Chagas' Disease

Chagas' disease, or American trypanosomiasis, is an infection caused by *Trypanosoma cruzi* and is characterized by an acute, often asymptomatic, illness with a prolonged latent period and chronic cardiac and gastrointestinal sequelae. In patients with predominantly esophageal involvement (chagasic megaesophagus), the pleuropulmonary problems include pleural effusion in 36%, pulmonary embolism in 22%, pneumonia in 35%, and aspiration pneumonia in a small percentage. All these complications are more common in patients with chagasic megaesophagus and cardiomyopathy than in those without esophageal involvement.

Esophageal Perforation

The majority of esophageal perforations are iatrogenic, and fewer than 15% represent spontaneous rupture. Esophagoscope, especially in the removal of foreign bodies, is the most common cause of iatrogenic perforation (Fig. 5). Other causes are the insertion of esophageal tubes, trauma, carcinomas of the esophagus or a Mallory-Weiss tear, Boerhaave's syndrome, mediastinal malignancy, radiation necrosis of the esophagus, foreign bodies, and external trauma.

FIG. 5. Instrumental perforation of anterior midesophagus demonstrated by Gastrografin extravasation into the mediastinum.

Acute mediastinitis occurs as the most serious complication of esophageal perforation. Approximately 60% of patients with esophageal perforation develop pleural effusion, and nearly 25% will exhibit a pneumothorax. Pleural effusion usually is left-sided, and analysis will reveal a high protein content, high amylase level, low pH, and the presence of squamous epithelial cells and, occasionally, food particles. The amylase is derived from the salivary juices leaking into the pleural space. The extremely low pH results from the increased leukocytic and mesothelial metabolism as well as the localized acidosis. The diagnosis of esophageal perforation is made by the clinical findings of chest pain, severe back pain, dysphagia, acute fever, subcutaneous emphysema, and documentation of the tear by Gastrografin contrast studies of the esophagus. Boerhaave's syndrome and Mallory–Weiss tear of the esophagus can lead to acute mediastinitis.

Sclerotherapy of Esophageal Varices

Sclerotherapy of the esophageal varices is one therapeutic method used to control variceal hemorrhage. Either sodium morrhuate or ethanolamine oleate is used as the sclerosant and is injected into the varices under direct vision via the esophagoscope. Within 6 hrs of the injection, some patients develop mediastinal widening, presumably from chemical mediastinitis. The overall incidence of intrathoracic complications includes pleural effusion (0% to 50%), mediastinitis (63%), atelectasis (16%), bronchitis (8%), pneumonia (0% to 5%), and esophagopleural fistula (1% to 2%). Other complications such as esophagobronchial fistula, empyema, acute respiratory distress syndrome, pulmonary infarction, and late expectoration of sclerosant are described but rare. Acute pulmonary edema leading to respiratory distress syndrome within 8 to 36 hrs of sclerotherapy has been described. A study of 223 patients who underwent 390 esophageal variceal sclerotherapy procedures with either ethanolamine oleate or tetradecyl sulfate evaluated the pulmonary complications and reported the following: retrocardiac or mediastinal widening in 35%, pleural effusion in 27%, atelectasis in 12%, and pulmonary infiltrates in 9% of procedures. Respiratory insufficiency was noted after 14 sclerotherapy procedures. Most thoracic manifestations after variceal sclerotherapy are likely caused by a local inflammatory response to the sclerosant.

Injection of sodium morrhuate in sheep causes marked but transient pulmonary hypertension and an increased flow of relatively protein-poor lymph. The constituent unsaturated fatty acids may be responsible for the pathogenesis of pulmonary edema. The edema from sodium morrhuate may be another example of hydrostatic (low lymph protein) pulmonary edema caused by abrupt pulmonary hypertension without an increase in pulmonary capillary wedge pressure. Use of a Sengstaken tube immediately after sclerotherapy may increase the risk of pulmonary complications. On the other hand, acute respiratory failure resulting from sclerotherapy has resolved after aspiration of air via a Sengstaken tube.

The reductions in P_aO_2 and vital capacity soon after sclerotherapy have been attributed to pulmonary embolization of the sclerosant even though significant occurrence of pulmonary embolism has not been described.

Pleural effusion after endoscopic variceal sclerotherapy is reported in 50% of patients. The incidence of pleural effusion is related to the amount of sclerosant injected. The effusions are usually small; they are bilateral in a third, right-sided in a third, and left-sided in a third. They usually are exudative and transient. The pleural effusion is secondary to mediastinal pleuritis caused by the sclerosant. Chylothorax also has ensued after sclerotherapy.

GASTROINTESTINAL ENDOSCOPY

Transmission of infection by gastrointestinal endoscopy can occur if endoscopy instruments are contaminated. Organisms include *Salmonella* species, *Pseudomonas aeruginosa,* and *Helicobacter pylori.* A review of the literature disclosed 180 isolates causing disease in 67 cases and death in two as a result of infection transmitted by gastrointestinal endoscopy. Pulmonary aspiration is a fairly common complication during emergency upper gastrointestinal endoscopy. In a study of 30 patients who underwent upper gastrointestinal endoscopy for diagnosis and treatment of acute bleeding, six (20%) developed new pulmonary infiltrates after the procedure, and all but one exhibited fever, leukocytosis, and oxygen desaturation below 90%.

Percutaneous endoscopic gastrostomies for feeding have become the preferred method of providing enteral nutritional support. Pneumonia is a known sequel of this procedure and is reported to occur with an incidence of 10% at 30 days and 56% at 11 months. A study used 24-hr monitoring to demonstrate an increased prevalence of gastroesophageal reflux in patients who developed pneumonia following placement of percutaneous endoscopic gastrostomies.

GASTROESOPHAGEAL REFLUX

Gastroesophageal reflux is an extremely common phenomenon, occurring on a daily basis in 10% and intermittently in 50% of healthy individuals. Gastroesophageal reflux disease (GERD) is a syndrome that manifests as heartburn and the sequelae of esophagitis, ulceration, stricture, or Barrett's epithelium. Gastroesophageal reflux and GERD have assumed importance in the pathogenesis of certain lung diseases, particularly laryngospasm, chronic cough, and asthma. Strong evidence suggests that both reflux-induced asthma and otolaryngologic complications including subglottic stenosis, laryngitis, pharyngitis, or cancer can occur without esophagitis. Mechanical reflux of gastric acid into the tracheobronchial tree is another mechanism responsible for the pulmonary complications. A study of patients with chronic persistent cough or asthma suspected to be caused by reflux used distal and proximal pH monitoring to identify those with reflux-induced pulmonary problems and concluded that 17% of patients whose pulmonary symptoms responded to antireflux therapy would not have been recognized as having abnormal reflux if proximal pH

monitoring had not been done; indeed, the antireflux therapy achieved good to excellent success in relief of pulmonary symptoms in 71% of patients with reflux. Esophageal pH testing is of diagnostic significance if intermittent symptoms can be shown to be regularly associated with a decrease in the intraesophageal pH to less than 4.0 during testing.

Vagally mediated local neuronal esophagolaryngotracheal reflexes have assumed an important role in the etiology of many respiratory complications associated with GERD. Normal vagal reflexes in the respiratory tract include cough, laryngeal closure, forced inspiration, respiratory suppression, bronchoconstriction, and mucus secretion. Abnormal reflexes consist of laryngospasm, prolonged apnea, bronchospasm, and singultus (hiccup). There remains the question of whether gastroesophageal reflux is primary or secondary to the pulmonary disease. It is common knowledge that continuous coughing causes retching and vomiting. However, a study of 12 patients with chronic obstructive pulmonary disease employed esophageal manometry, 24-hr pH monitoring, esophageal acid clearance, and pulmonary function tests to determine that these patients do not have a bronchoconstrictive reflex to distal esophageal acidification and that their esophageal function was normal.

Reflux Laryngitis

The association of gastroesophageal reflux with chronic hoarseness and posterior laryngitis has been referred to as *reflux laryngitis* or *Cherry–Donner syndrome.* Twenty-four-hour esophageal pH monitoring has revealed that as many as 75% of patients with chronic hoarseness will exhibit an abnormal amount of gastroesophageal reflux. In a group of 33 patients referred for hoarseness, gastroesophageal reflux was found in almost 80%. Abnormal laryngeal reflexes can be elicited by acidic (pH < 4.5) solutions. GERD also contributes to the development of chronic throat clearing, cough, sore throat, contact ulcer and granuloma, globus pharyngeus, cervical dysphagia, subglottic stenosis, and cricoarytenoid arthritis.

Cough

Controlled studies have shown that chronic persistent cough that remains after a diagnostic evaluation is associated with increased episodes of otherwise asymptomatic gastroesophageal reflux. Four to 21% of chronic cough is estimated to be secondary to gastroesophageal reflux. Reflux should be considered an etiologic possibility in subjects with chronic persistent cough that remains unexplained after a standard diagnostic assessment. The adjusted odds ratio for the presence of gastroesophageal reflux in adults with unexplained chronic cough has been estimated to be 4.4. Indeed, cough may be the sole presenting manifestation of gastroesophageal reflux. Prolonged exposure of esophageal mucosa to gastric acid may cause cough by stimulating esophagolaryngotracheal reflexes. It has been suggested that in those with gastroesophageal reflux, a self-perpetuating mechanism may exist whereby acid reflux causes cough via a local neuronal esophageal–tracheobronchial reflex, and the cough in turn amplifies reflux via increased transdiaphragmatic pressure or by inducing transient lower esophageal sphincter relaxation. Impaired clearance of esophageal acid has been documented by 24-hr ambulatory monitoring of esophageal pH in patients with chronic cough. Postnasal drip also may irritate the receptors located in the pharynx and larynx and contribute to cough; this phenomenon should be excluded in patients who have nocturnal cough and gastroesophageal reflux. Cough caused by tobacco smoke may be aggravated by the lowered esophageal sphincter tone induced by the tobacco smoke.

Asthma

The association of asthma with GERD is well documented. As many as 45% to 65% of adults with asthma have been estimated to have gastroesophageal reflux. Both animal and clinical data suggest that gastroesophageal reflux serves as a trigger of bronchospasm, potentiates the bronchomotor response to additional triggers, or both. Patients with reflux-associated asthma may manifest symptoms of gastroesophageal reflux, either classic or atypical, but approximately 25% to 30% have clinically silent reflux. A questionnaire-based survey of 109 asthmatic patients recorded the presence of heartburn, regurgitation, and swallowing difficulties in 77%, 55%, and 24% of patients, respectively; at least one antireflux medication was required by 37% of asthmatics, and none of the asthma medications were associated with an increased likelihood of symptomatic gastroesophageal reflux. It is, however, important to recognize that asthmatic patients who take theophylline may develop gastroesophageal reflux because the drug is known to decrease lower esophageal sphincter tone and predispose to reflux. In addition, theophylline increases gastric acid secretion.

There is evidence that microaspiration does not play a significant role in esophageal acid-induced bronchoconstriction. The mechanism of bronchospasm in the setting of gastroesophageal reflux is unclear. Although reflux of acid into the airways is well known to produce bronchospasm, not all individuals with gastroesophageal reflux develop asthma. Asthma and gastroesophageal reflux are more common during sleep, but studies have shown that gastroesophageal reflux does not aggravate nocturnal asthma. It has even been questioned whether esophageal reflux is caused by asthma because treatment of asthmatics with esophageal reflux has resulted in diminished reflux symptoms. Nonetheless, compared to bronchitic patients with gastroesophageal reflux, asthmatics have exhibited more episodes and a shorter duration of gastroesophageal reflux.

One study provided the results of long-term experience (average follow-up of 7.9 years) with a group of 44 asthmatic patients with gastroesophageal reflux who underwent Nissan fundoplication: the gastroesophageal reflux cleared in 42 patients (95%), asthma was markedly improved or cured in 18 (41%), and the reflux improved in 29 (66%). There was a significant association between cure of asthma after fundoplication and the presence of nocturnal attacks, nocturnal tracheitis, intrinsic tracheitis, intrinsic asthma, or a clear history of reflux symptoms preceding the onset of asthmatic symptoms. A clinically useful finding was that the positive response to a trial of medical treatment helped identify patients who would be cured.

An opposite view of the role of gastroesophageal reflux in asthmatics was presented in a report on 90 nonasthmatic patients with adult-onset wheezing. A 90% prevalence of gastroesophageal reflux was noted during a study in which the patients were assigned randomly to receive cimetidine or a placebo for a 6-month trial. Those assigned to cimetidine or surgical therapy of gastroesophageal reflux improved significantly. The intake of pulmonary medicine for wheezing decreased significantly. Others have reported that antireflux treatment will provide only small improvements in asthma control in patients with a history of gastroesophageal reflux. Unfortunately, there is no acceptable diagnostic method to confirm the presence of gastroesophageal reflux-induced asthma, and controversy about this issue is likely to continue.

Although the otolaryngologic manifestations usually respond to antisecretory medications, reflux-induced asthma responds convincingly only to antireflux surgery. A number of studies have documented excellent long-term results of surgical treatment for reflux-induced asthma. However, such therapy should be reserved for cases of severe asthma poorly controlled by medications and complicated by severe reflux that leads to ulcerative esophagitis.

Aspiration Pneumonia

Aspiration pneumonitis caused by gastroesophageal reflux is a serious acute medical problem and may lead to acute respiratory distress syndrome. The risk of developing significant aspiration pneumonia increases when the volume of gastric contents aspirated exceeds 50 ml and the pH of the aspirate is below 2.5. Although the initial pathologic features are directly related to the damaging effects of gastric acid, aspiration pneumonia frequently is complicated by bacterial pneumonitis. Community-acquired aspiration pneumonia is extremely uncommon except in alcoholics, those with poor dental hygiene, and debilitated individuals. Nosocomial aspiration pneumonia is more likely to be complicated by bacterial pneumonitis. Debility and prolonged supine posture predispose to this complication. Studies using technetium-99 sulfur colloid labeling of gastric contents and subsequent measurements of endobronchial secretions in patients on mechanical ventilation have shown that the supine position, and particularly the length of time the patient is kept in this position, are potential risk factors for aspiration of gastric contents. The same microorganisms were isolated from stomach, pharynx, and endobronchial samples in 32% of studies done while patients were semirecumbent and in 68% of studies done while patients were in the supine position.

Alkalinization of gastric contents also can predispose to bacterial pneumonia, and gastric colonization by microorganisms is related to the degree of gastric alkalinization. A gastric pH exceeding 4.0 seems to be the most important factor favoring gastric colonization. Hospitalized patients, particularly those being mechanically ventilated, are systematically given antacids or histamine (H_2) blocking drugs, or both, to prevent the development of stress ulcers. Several studies have shown that the use of these drugs in critically ill patients is associated with a greater incidence of both nosocomial pneumonia and gastric and pharyngeal colonization. These studies also reported that the prophylactic use of a cytoprotective agent such as sucralfate does not alter gastric pH and thus prevents microbial colonization (see below). Others have shown that treatment with cimetidine is an independent risk factor for developing pneumonia in mechanically ventilated patients. Elevating the head of the bed to 45° is reported to reduce the risk of aspiration pneumonia significantly.

Many subjects who remain asymptomatic despite frequent aspiration may develop pulmonary complications after chronic aspiration. Typical examples of insidious aspiration-induced lung disease include mild basal pulmonary fibrosis and patchy infiltrates. Ingestion of oil-based compounds for laxative purposes or other reasons may result in lipoid pneumonia (Fig. 6).

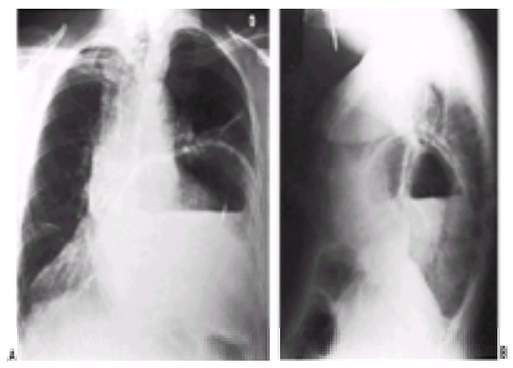

FIG. 6. A large hiatal hernia occupying most of the chest cavity. **(A)** Anterior view. **(B)** Left lateral view.

Gastric pH and Nosocomial Pneumonia

The clinical practice of neutralizing gastric acid to prevent aspiration pneumonia and nosocomial pneumonia in ventilator- and non-ventilator-dependent patients has been controversial. A gastric pH above 4.0 is crucial for overgrowth of gastric gram-negative but not gram-positive bacteria. Critically ill patients who receive ulcer prophylaxis with drugs to suppress or neutralize gastric acidity commonly demonstrate growth of intragastric gram-negative bacteria. Almost all patients receiving enteral feeding also are colonized in the stomach with gram-negative bacteria. Aspiration of these organisms is an important mechanism in the development of nosocomial pneumonia. In a study of 242 mechanically ventilated trauma patients, pneumonia occurred more frequently in patients with gram-negative retrograde colonization from stomach to trachea, even though this accounted for only 13% of all pneumonias. The presence of an endotracheal tube does not afford complete protection from aspiration of the gastric bacteria. A review of 269 articles including 63 randomized trials on the role of stress ulcer prophylaxis observed that prophylaxis with H_2-receptor antagonists decreased the incidence of overt gastrointestinal bleeding, but there was a trend toward an increased risk of pneumonia associated with H_2-receptor antagonists as compared with no prophylaxis. Sucralfate, however, was associated with a lower incidence of nosocomial pneumonia when compared with antacids and H_2-receptor antagonists. In a study of 242 patients who were randomized to sucralfate, antacid, and ranitidine, there was no statistically significant difference in pneumonia rates among the treatment groups during the first 4 days of therapy, although sucralfate appeared to decrease the incidence of nosocomial pneumonia after this period.

Other Complications of GERD

Several other complications have been described in relation to gastroesophageal reflux. These include singultus (hiccup), bronchitis, bronchiectasis, atelectasis, hemoptysis, pulmonary fibrosis, apnea, and seizures related to hypoxia. Many adults with obstructive sleep apnea suffer from gastroesophageal reflux. This may be related to lowered intrathoracic pressure caused by obstructive sleep apnea and increased arousal and repetitive body movement during sleep. Treatment of obstructive sleep apnea with nasal continuous positive airway pressure has been shown to decrease thoracic gastroesophageal reflux in these patients. The esophagus and central nervous system of asymptomatic volunteers have been shown to maintain an awareness of the presence and volume of intraesophageal acid, and the response time by the central nervous system is inversely related to acid volume. The larger volumes of acid in the esophagus are reported to create an afferent warning signal to the central nervous system to produce rapid arousal from sleep along with a shortened interval to the first swallow.

GASTRIC DISORDERS

Hiatal Hernia

In esophageal hiatal hernia, chest roentgenograms often show the herniated portion of the stomach directly behind the heart, suggesting the possibility of a posterior mediastinal mass lesion. The presence of an air–fluid level and a barium contrast study usually confirm the diagnosis. Symptoms originating from hiatal hernia may resemble those of cardiopulmonary disease; however, careful attention to the clinical history often helps in making the distinction. Occasionally, a large hiatal hernia may compromise pulmonary function by occupying a large area of the chest cavity (Fig. 7).

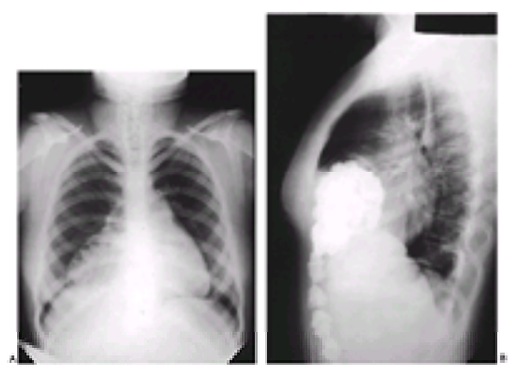

FIG. 7. (A) Foramen of Morgagni hernia presenting as an air-filled mass adjacent to the right heart border. **(B)** A left lateral chest roentgenogram shows that much of small intestine (containing barium contrast) has herniated through the foramen of Morgagni.

One of the most serious respiratory complications of hiatal hernia is the occurrence of aspiration pneumonia secondary to gastroesophageal reflux, as discussed previously. Roentgenologic and endoscopic investigations have reported that from 50% to 94% of patients with GERD have hiatal hernia. A study of 34 patients with endoscopically documented hiatal hernia recorded that, compared to normal volunteers, those with hiatal hernia had substantially higher reflux scores and reduced lower esophageal sphincter pressure.

Hernia Through the Foramina of Bochdalek and Morgagni

Hernia through the foramen of Bochdalek results from incomplete fusion of the posterolateral part of the diaphragm. Herniation is seen more frequently in children, and the abnormality is usually located on the left. Chest roentgenograms reveal a space-occupying mass lesion. Large herniations produce dyspnea, chest discomfort, and, occasionally, respiratory failure. Sometimes these hernias mimic pleural effusion, with the lateral chest roentgenogram disclosing free layering. Postmortem studies in infants with congenital diaphragmatic hernia have shown that the lungs are immature, especially the ipsilateral lung. Additionally, intraalveolar hemorrhage is reported to be a common complication of congenital diaphragmatic hernia. Hernia through the foramen of Morgagni tends to be on the right and anteriorly located. Herniation of the liver may occur, though herniation of intestinal segments is more likely (Fig. 8).

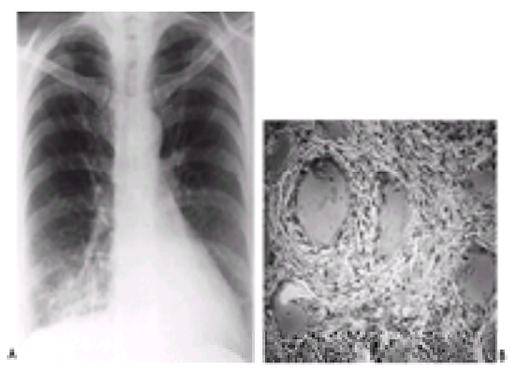

FIG. 8. (A) Chronic ingestion of mineral oil for laxative purposes resulted in an ill-defined mass in the right lower lobe. **(B)** Resected section of the abnormal lung revealed typical findings of lipoid pneumonia.

Peptic Ulcer Disease

Peptic ulcer disease has been found in 10% to 35% of study groups with chronic obstructive lung disease, contrasting with 3% in control groups. The increased incidence of ulcer disease has been explained, at least partly, by gastric hypersecretion because of increased arterial carbon dioxide tension and decreased arterial oxygen tension. This theory applies only to those who develop chronically persistent hypercarbia as a result of the lung disease. Peptic ulcers associated with chronic obstructive lung disease are more commonly duodenal than gastric. Often the peptic ulcer disease is not accompanied by pain and is recognized only after gastrointestinal hemorrhage calls attention to it. Perforation of a gastric ulcer occasionally may result in pleural effusion. Because many patients with obstructive lung disease are treated with corticosteroid preparations, the symptoms related to ulcer disease remain masked.

Acute upper gastrointestinal bleeding in patients with chronic obstructive pulmonary disease is reported to be associated with higher mortality than the upper gastrointestinal bleeding in patients without chronic obstructive pulmonary disease. A case-control study at a university teaching hospital observed that the mortality in patients with chronic obstructive pulmonary disease and ulcer bleeding was 32%, whereas for those with bleeding but without chronic obstructive pulmonary disease, mortality was 10% (odds ratio 4.3); the increased mortality was correlated to severity of chronic obstructive pulmonary disease.

Effect of Gastrectomy on Tuberculosis

Gastrectomy has an adverse effect on preexisting, active pulmonary tuberculosis, and elective surgery is best postponed until a reasonable period of antituberculous therapy has been completed. An increased incidence of pulmonary tuberculosis after subtotal or total gastrectomy and jejunal or ileal bypass has been noted. The incidence of tuberculosis after gastrectomy is estimated at 1% to 5%. The prevalence of prior gastrectomy in patients with tuberculosis has ranged from 1.7% to 20%, the higher incidence being more common in elderly patients. A poor response to treatment and an increased rate of reactivation have been noted in gastrectomy patients who develop infection caused by *Mycobacterium avium* complex. The relationship between gastrectomy and tuberculosis that develops several years later is uncertain. A plausible explanation for the increased incidence of tuberculosis in this group of patients is the decreased absorption of antituberculous drugs as a result of the gastrectomy. Pharmacokinetic studies have documented this phenomenon in anecdotal cases. All this notwithstanding, fear of tuberculosis should not be a factor in deciding on elective gastrectomy.

Total gastrectomy may predispose to the aspiration of esophageal reflux contents. A study concluded that this was the most important risk factor for recurrent pulmonary complications in patients who had undergone total gastrectomy. Among 186 patients who had undergone total gastrectomy, 16 patients had recurrent respiratory tract inflammation, and 45 had sporadic respiratory tract inflammation. The former group frequently showed symptoms related to esophageal reflux and the swallowing provocation test.

Gastrobronchial Fistula

Gastrobronchial fistula is extremely rare. A review in 1985 found only 13 cases. There are five causes for the development of these fistulas. The most common cause is the presence of a subphrenic abscess, which erodes through the diaphragm and leads to lung abscess. Traumatic rupture of the diaphragm, especially from penetrating injury, is the next most common cause. Perforated ulcer in an incarcerated hiatal hernia and necrosis of gastric tumors and areas of previous esophageal or gastric surgery are the other causes.

INTESTINAL DISEASES

Inflammatory Bowel Diseases

Both chronic ulcerative colitis and Crohn's disease (regional enteritis) are well known for their propensity to produce various extraintestinal manifestations. Pulmonary involvement is an uncommon extraintestinal manifestation of these inflammatory bowel diseases (Table 1). The pathogenesis of pulmonary disease in inflammatory bowel diseases is not known. A common systemic mechanism affecting both the bronchial and colonic epithelium may be responsible. It also has been speculated that similarities in the mucosal immune system of the lung and intestine are responsible for the bronchial hyperreactivity in some patients with active inflammatory bowel diseases. A variety of respiratory problems, including pulmonary vasculitis, apical fibrosis, chronic suppurative bronchitis, and bronchiectasis, have been reported (Fig. 9). However, in a series of 1400 patients with inflammatory bowel disease evaluated retrospectively, only three were found to have unexplained bronchopulmonary disease. In a separate review of clinical material on 1400 patients with inflammatory bowel diseases whose diagnoses were recorded in a computerized registry between 1930 and 1970, there were only six unexplained pulmonary diseases. However, publications in the 1980s and 1990s have reported higher prevalence rates of respiratory problems in inflammatory bowel diseases. For instance, abnormal pulmonary functions have been reported in 36% to 68% of patients with Crohn's disease.

TABLE 1. *Pulmonary abnormalities associated with intestinal diseases*

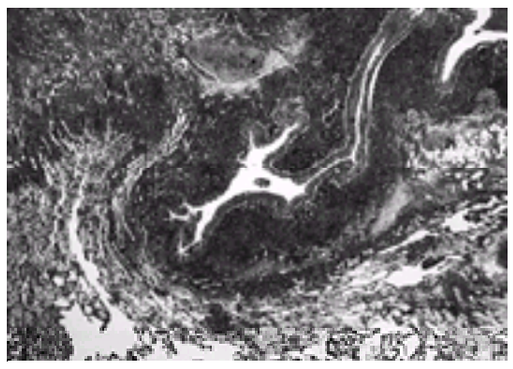

FIG. 9. Chronic bronchiectasis that was symptomatically steroid-responsive in this patient with ulcerative colitis. Dense infiltration of chronic inflammatory cells involving a small bronchus is shown.

A report on the data of an ongoing registry containing 33 cases of pulmonary complications in ulcerative colitis and Crohn's disease, of whom 23 were not on any therapy, noted that in 28 of the 33 cases, lung involvement followed the onset of intestinal diseases (eight of these 28 cases were postcolectomy), and in the others,

pulmonary features preceded the intestinal diseases. Airway manifestations included subglottic stenosis, chronic bronchitis, severe chronic bronchial suppuration, bronchiectasis, and chronic bronchiolitis. Bronchoscopy in these patients revealed exuberant inflammatory tissue and mucosal ulcerations and narrowed tracheal and/or bronchial lumen. Histologically, dense aggregates of inflammatory cells were noted. Interstitial lung disease consisted mainly of bronchiolitis obliterans with organizing pneumonia, pulmonary infiltrates, and eosinophilia. Neutrophilic necrotic parenchymal nodules were also noted. Corticosteroid therapy was more effective in resolving the parenchymal disease than in airway disease.

In another study, among ten nonsmokers with chronic ulcerative colitis, four had exertional dyspnea, four exhibited abnormal chest roentgenograms, and three had obstructive changes in their pulmonary function tests. Bronchial biopsies in four patients showed basal cell hyperplasia, submucosal inflammation, and thickening of the basement membrane, similar to the pathologic changes in the colonic mucosa. In a study of 18 patients with Crohn's disease and no pulmonary symptoms, bronchoalveolar lavage revealed lymphocytic alveolitis in 61%, with lymphocyte counts ranging from 18% to 79%. There was no apparent correlation between lymphocyte count in the lavage effluent and the pulmonary dysfunction observed in 11 patients. These studies suggest that most patients with Crohn's disease have a latent pulmonary involvement mediated by lymphocytes. In one study, 71% of patients with Crohn's disease demonstrated increased superoxide production, but the significance of this in the pathogenesis of lung disease is unclear.

Airways Disease

In one study, pulmonary function was assessed in patients with ulcerative colitis and Crohn's disease and compared with that of a healthy population, and no statistically significant differences were found among the three groups. However, in a prospective study of 58 patients with Crohn's disease and 44 patients with chronic ulcerative colitis, a high incidence of respiratory abnormalities was identified in both groups. Pulmonary function tests were abnormal in 50% of patients, with diminished flow rates (less than 50% of predicted forced expiratory volume in the first second, FEV_1) in 31% and decreased diffusing capacity (less than 75% predicted) in 26%. Abnormally low diffusing capacity was the only abnormality in 16 patients (eight with Crohn's). Four patients with Crohn's and two with colitis had interstitial processes on the chest roentgenograms.

A study disclosed that the prevalence of hay fever and asthma was raised among 242 patients with chronic ulcerative colitis and slightly higher among 45 patients with Crohn's disease. A report on 29 patients with Crohn's disease noted that the lungs are relatively unaffected by Crohn's disease. Bronchiolitis with organizing pneumonitis, sclerosing peribronchiolitis, and diffuse panbronchiolitis are the other abnormalities described in ulcerative colitis.

Ulcerative tracheobronchitis, with intense plasma cell infiltration of tracheal mucosa and submucosa and destruction of mucous glands, has occurred 4 and 8 years after total colectomy in patients with ulcerative colitis. Bronchoscopy in Crohn's disease has revealed small, diffuse, whitish granulations and erythematous mucosa, and biopsy of bronchial mucosa has shown ulcerative bronchitis and noncaseous tuberculoid granuloma.

Pulmonary Parenchymal Disease

Pulmonary function testing, in a study of 36 outpatients with inflammatory bowel diseases, revealed significantly reduced diffusing capacity for carbon monoxide (D_LCO) as compared with matched controls ($p < 0.01$). The reason for this reduction was not clear, though it was considered unlikely to be caused by sulfasalazine (salazosulfapyridine). A further study of the lung function of ten patients with Crohn's disease during and after an attack of the disease revealed that pulmonary volumes and D_LCO were not impaired but that functional residual capacity (FRC) was greater during the attack than during remission; it was also greater than in normal subjects. Disease activity, FRC values, and finger clubbing decreased concomitantly during remission. As noted above, some patients have exhibited low diffusing capacity as the only abnormality.

Although the association of apical fibrosis and ankylosing spondylitis is widely recognized, only one case has been reported in which fibrosis was associated with both spondylitis and ulcerative colitis. Dense basal pulmonary infiltrates responsive to steroid therapy have been reported in two patients: lung biopsy in one revealed changes similar to those in idiopathic pulmonary fibrosis, and the second had nondiagnostic findings. Pulmonary bullous lesions also are described in chronic ulcerative colitis. Hypoproteinemia is common in Crohn's disease. A case has been described of a 29-year-old man who presented with recurrent pulmonary edema and hypoalbuminemia. The diagnosis of Crohn's disease was made only after several episodes of pulmonary edema.

An investigation of pulmonary abnormalities in 26 children with acute or quiescent Crohn's disease revealed normal chest radiographs in all subjects. Even though no significant differences were found between acute and quiescent Crohn's for pulmonary volumes and expiratory flows, D_LCO was significantly decreased during the active phase of the disease as compared to remission (53 ± 15% versus 81 ± 19% predicted). An 11-year-old child who presented with terminal ileitis associated with pulmonary lesions showing periodic progression has been described; the initial thoracic disorder developed 2 years before roentgenographic evidence of the ileitis, the second episode coinciding with the diagnosis of the ileal lesion. Pulmonary lesions progressed simultaneously with the clinical signs of digestive tract disturbances, which eventually stabilized.

In patients with inflammatory bowel disease, biopsy of the affected segment of intestine may show granulomatous changes. Noncaseous and nonconfluent granulomas are found in 30% of patients with Crohn's disease. A report described three patients with classic chronic ulcerative colitis who developed histologically proved type III sarcoidosis during the course of their disease. A case of acute segmental inflammation of the terminal ileum in a female patient who presented with signs and symptoms of acute appendicitis is reported. The patient had associated bilateral pulmonary tuberculosis. The role of *M. tuberculosis* in the etiology of the segmental ileal disease is well known, but the relationship between tuberculosis and inflammatory bowel disease is not clear. Those with jejunal or ileal bypass exhibit an increased incidence of tuberculosis.

Other Pulmonary Complications

Pleuropericarditis may complicate ulcerative colitis and Crohn's disease. A review of the literature reveals approximately a dozen patients with ulcerative colitis and Crohn's disease who developed pleural effusions, bilateral in a third and left-sided in the rest. Many of these were associated with pericardial effusion. The pleuropericardial complications of inflammatory bowel disease may run an independent course and may be present at the time of inactive bowel disease.

Aspiration pneumonia has occurred from esophageal involvement in inflammatory bowel diseases. Crohn's disease is complicated by esophageal stricture in 38% and ulcerations in 32%. The most common presenting symptom in Crohn's disease of the esophagus is dysphagia, seen in more than two-thirds of patients. Cough and repeated bouts of pneumonia occur in a small number of patients.

Enteropulmonary fistulas may present as recurrent localized pneumonia. A case of one such fistula originating from the colon in a patient with Crohn's disease has been discussed. Esophagotracheal fistula has been described in 6% of patients. Histologic studies of these areas have shown submucosal fibrosis, lymphocytic infiltration, noncaseous granulomas, and hypertrophy of muscle.

Antineutrophil cytoplasmic antibodies (ANCA) have been reported in up to 87% of patients with primary sclerosing cholangitis with or without ulcerative colitis and in 68% of patients with only ulcerative colitis. A snow-drift-like perinuclear (p-ANCA) pattern has been described in up to 84% of patients with high disease activity in ulcerative colitis. The cytoplasmic ANCA (c-ANCA) seen in active Wegener's granulomatosis and p-ANCA with myeloperoxidase specificity seen in microscopic polyangiitis are distinctly uncommon in patients with ulcerative colitis. Nevertheless, c-ANCA positivity with typical histologic features and chest roentgenographic features of Wegener's granulomatosis has been described in a patient with ulcerative colitis who was treated with sulfasalazine. All these features resolved after the withdrawal of sulfasalazine.

Sulfasalazine, used in the treatment of inflammatory bowel diseases, is known to produce pulmonary infiltrates and dyspnea. A patient with ulcerative colitis receiving sulfasalazine therapy who developed interstitial pneumonitis and bronchiolitis has been described. Open-lung biopsy in a patient with chronic ulcerative colitis showed severe interstitial fibrosis and bronchiectasis. The pulmonary fibrosis progressed despite cessation of sulfasalazine therapy and a total colectomy. A child with chronic ulcerative colitis and hepatic cirrhosis developed progressive respiratory distress from desquamative interstitial pneumonitis despite cessation of sulfasalazine and institution of systemic corticosteroid therapy.

Mesalamine, one of the 5-aminosalicylate (5-ASA) drugs used to treat inflammatory bowel disease, has been implicated in the causation of bilateral pulmonary infiltrates, peripheral eosinophilia, and histologic findings consistent with acute pneumonitis characterized the lung injury. Nongranulomatous interstitial diffuse lung disease with an inflammatory lymphoid infiltration associated with some mild interstitial collagen fibrosis has been reported in a patient treated with mesalamine for Crohn's disease. Bilateral interstitial infiltrates and gas-exchange abnormalities were described in a patient who developed the pulmonary complication insidiously after 2 years of treatment with mesalamine.

Tobacco smoking and nicotine gum chewing are reported to have a beneficial effect on the severity of symptoms in patients with ulcerative colitis. Some reports have indicated that lifetime nonsmokers and former smokers have an increased risk of developing ulcerative colitis. In contrast, several studies have demonstrated a strong

association between Crohn's disease and smoking. The biological basis for these unusual associations remains unknown.

Nontropical Sprue

The association of nontropical sprue (celiac disease) and diffuse pulmonary disease has been reported in several cases. Although each of these disorders may be associated with abnormal immunologic phenomena, the pathogenesis remains unclear. However, studies of patients with this combination of diseases have identified avian protein precipitins in the sera. The influence of extrinsic factors seems to be prominent in cases of pulmonary fibrosis; in patients with the combination of nontropical sprue and pulmonary fibrosis, the presence of farmer's lung precipitins *(Micropolyspora faeni)* has been noted. It has been suggested that both nontropical sprue and extrinsic allergic alveolitis may be caused by a common immunologic mechanism, because extrinsic allergic alveolitis and nontropical sprue are both associated with HLA-D3, and an association has been reported between nontropical sprue and hypersensitivity pneumonitis in Europe. However, a study of 18 North American patients with nontropical sprue failed to corroborate this association. Nonetheless, a history of asthma or chronic cough was present in a higher proportion of the celiac than the control subjects, and the patients with nontropical sprue showed objective evidence of obstructive lung disease.

Interstitial lung disease has been diagnosed by lung function studies and chest roentgenograms. A case is reported of a 62-year-old woman who had celiac sprue and developed lymphocytic interstitial pneumonia followed by abdominal lymphoma. The patient presented with dyspnea, cough, weight loss, and bibasilar pulmonary infiltrates. Systemic corticosteroids resulted in improvement lasting 1 year. Whereas lymphocytic lymphomas are a well-known complication of sprue, lymphocytic interstitial pneumonitis is not. Postmortem examination of the respiratory system in a patient with nontropical sprue has revealed partial fibrous obliteration of small airways and dilation of larger airways.

Pulmonary hemosiderosis has been described in several patients with celiac disease. A study of seven patients with idiopathic pulmonary hemosiderosis revealed nontropical sprue in three patients and limitation to airflow and decreased D_LCO in five. Clinical documentation that treatment of celiac disease could lead to remission of idiopathic pulmonary hemosiderosis is worth noting. In the cases reported in the literature, six of ten patients showed improvement in both diseases with a gluten-free diet, although histopathologic improvement in the intestinal lesion was shown in only two patients. In patients with celiac disease, antibodies to reticulin and gliadin are found in 78% and 95%, respectively. It has been suggested that a positive serology for either reticulin or gliadin in a patient with idiopathic pulmonary hemosiderosis should lead to consideration of a gluten-free diet as part of the therapy.

Whipple's Disease

Whipple's disease is a chronic systemic infectious disease caused by *Tropheryma whippelii,* an organism closely related to actinomycetes. Whipple's disease typically involves the small intestine and causes malabsorption. Extraintestinal manifestations such as arthritis and fever are common and often exist before the onset of gastrointestinal symptoms. Involvement of the central nervous system can occur and lead to permanent sequelae. Weight loss, hyperpigmentation, and lymphadenopathy are frequent findings. A review of the literature demonstrates high prevalence of cardiac manifestations including constrictive pericarditis, valvular deformity, myocarditis, coronary arteritis, and congestive heart failure. The definitive diagnosis is made by biopsy of the small intestine mucosa which reveals infiltration of the lamina propria of the small intestine with periodic acid-Schiff positive macrophages. Electron microscopy reveals rod-shaped bacillary bodies which perhaps represent *Tropheryma whippelii.* Therapy with trimethoprim-sulfamethoxazole for 12 months usually results in clinical remission and an excellent prognosis. Several pulmonary complications have been described in patients with Whipple's disease.

Pleuropulmonary complications include pleuritic pain, pleural effusion, dyspnea, cough, lung infiltrates, and restrictive lung dysfunction. Respiratory involvement without other symptoms such as arthralgias and fever has occurred. Cough is noted in nearly half of these cases. Although intestinal and joint manifestations are attributed to intracellular infection, the pulmonary manifestations may be the result of an inflammatory reaction to locally deposited immune complexes containing bacterial antigens. Whipple's disease is known to simulate pulmonary sarcoidosis. One patient who developed chest roentgenographic features of sarcoidosis had noncaseous granulomas in the peripheral lymph nodes, pleura, and lung parenchyma. The pleuropulmonary disease resolved with appropriate treatment of Whipple's disease.

Endobronchial lesions and large pulmonary nodules have been described in Whipple's disease. In a 31-year-old man, Whipple's disease presented with large rapidly enlarging pulmonary nodules. A bronchoscopic examination showed several raised yellow endobronchial lesions mainly at the subcarinae of the lobar bronchi. Biopsies revealed multiple foamy macrophages that were PAS positive and diastase resistant without granulomas or giant cells. Interestingly, this patient had no gastrointestinal features. Whipple's disease presenting as pleuropericarditis in a 48-year-old woman exhibited peribronchiolar and perivascular histiocytic infiltrates in a patchy distribution with characteristic cytoplasmic bacilliform inclusions present in these cells.

Other Malabsorption Syndromes

Protein-losing enteropathy may predispose patients to developing pleural effusions, both transudative and chylous. Primary intestinal lymphangiectasia is a rare condition of uncertain etiology characterized by dilated small-bowel lymphatics and often complicated by anomalous lymphatics elsewhere, typically in the limbs. Protein-losing enteropathy secondary to intestinal lymphangiectasia has been reported to produce chylothorax.

The combination of yellow nails, lymphedema, and pleural effusions is known as the *yellow-nail syndrome.* Lymphedema can occur as a distinct entity or as a result of lymphatic obstruction or loss of chyle from various mechanisms. More than 20% of patients with primary lymphedema have a protein-losing enteropathy resulting from lymphangiectasia of the small bowel. With significant loss of protein, these patients develop hypoproteinemia as well as hypogammaglobulinemia. Persistent pleural effusions and recurrent pulmonary infections may ensue in this setting.

HEPATIC DISEASES

Diseases of the liver produce or are associated with multiple pulmonary problems (Table 2). Arterial hypoxemia in conjunction with hemoglobin desaturation, clubbing, pleural effusions secondary to ascites, hyperventilation, and platypnea-orthodeoxia are encountered in 15% to 45% of patients with cirrhosis. The pathologic mechanisms involved in these complications are varied. Pulmonary intravascular macrophages (phagocytes) are mainly responsible for the uptake of circulating particles by lung cells. Pulmonary intravascular phagocytosis has been detected in animal models of chronic biliary cirrhosis and in humans with liver diseases. In certain disease states, for instance, biliary cirrhosis, pulmonary phagocytes may develop in the pulmonary capillaries, placing the lungs at risk for pathogen localization and subsequent inflammation and respiratory distress.

TABLE 2. *Intrathoracic abnormalities in hepatic diseases*

Pleural Effusion

Pleural effusion, usually right-sided and occasionally massive and symptomatic, may occur in cirrhosis or peritonitis. Pleural effusion is found in 6% of patients who have hepatic cirrhosis associated with ascites. The fluid is usually a transudate, and its chemical characteristics are similar to those of ascitic fluid. There are three possible mechanisms for the development of pleural effusion in hepatic cirrhosis: hypoproteinemia, azygos hypertension, and transfer of peritoneal fluid to the pleural cavity via congenital defects in the diaphragm. Intraperitoneal injection of the radioisotope ^{99m}Tc-sulfur colloid has demonstrated the one-way transdiaphragmatic flow of fluid from the peritoneal to the pleural space, and thoracotomy has allowed identification of the diaphragmatic defects. In patients with massive pleural effusion secondary to ascites, drainage of pleural fluid for therapeutic purposes is usually futile because as long as the peritoneal cavity contains fluid, the pleural fluid will continue to reaccumulate. Treatment should be aimed at controlling the ascites. Pleural effusions also are seen with viral hepatitis. In a prospective Italian study of

hepatitis, 70% of 156 patients had some fluid in the pleural space.

Ascites, if large in volume, can interfere with normal pulmonary function by interfering with normal diaphragmatic excursion. Ascites and abnormal distension restrict full inflation of the lungs and thus reduce lung volume. This effect of ascites on the pulmonary system is mediated by the hydrostatic pressure exerted from within the peritoneal cavity on the diaphragm. However, this effect varies among patients and seems to be dependent on the intraabdominal hydrostatic pressure (thought of as a pressure in excess of the height of the anterior abdominal wall).

Large-volume paracentesis is a safe, rapid, and effective treatment of ascites and usually relieves respiratory symptoms caused by tense ascites. One study investigated the effect of large-volume (5 liters) paracentesis on pulmonary function parameters in eight hemodynamically stable patients with cirrhosis and tense ascites and absence of known lung disease or abnormal chest roentgenograms. Baseline lung volumes, diffusing capacity, and arterial PO_2 were reduced, but flow rates were normal. Following paracentesis, lung volumes increased significantly; diffusing capacity and arterial oxygenation did not change significantly.

Hepatopulmonary Syndrome

The hepatopulmonary syndrome denotes the arterial hypoxemia in patients with cirrhosis. Arterial hypoxemia is present in 30% to 50% of patients with hepatic cirrhosis. It also may occur in other chronic liver diseases, such as chronic active hepatitis and nonspecific hepatitis. The pathophysiological mechanisms include presence of low pulmonary vascular tone characterized by a poor or absent hypoxic pressor response, which results in a marked dilation of the pulmonary vasculature. Both the liver and the endothelial cells may play a critical role in the regulation of the pulmonary vascular tone in these patients. The abnormal pulmonary vascular tone causes *V/Q* mismatch and mild to moderate hypoxemia. As the hepatic damage progresses, the intrapulmonary venoarterial shunt becomes more severe, leading to serious limitation of oxygen diffusion and, finally, severe respiratory failure. Development of abnormal anatomic communications between pulmonary arteries and veins with bypassing of the capillary–alveolar interphase also contributes the hypoxemia. There may be other mechanisms at play in causing hypoxemia in association with liver cirrhosis. Injection of radioactive krypton into the spleen has shown definite portopulmonary anastomoses. In some instances, venous blood in the portal system may reach the left side of the heart through anastomotic channels with pulmonary veins. Intrapulmonary shunts can reach considerable proportions (20% to 70%) of the cardiac output. Blood gas analysis discloses moderate hypoxemia and respiratory alkalosis.

Orthodeoxia is hypoxemia that is produced by the assumption of an erect position and relieved by a recumbent position. Orthodeoxia in patients with hepatic cirrhosis results from the effect of the gravitational forces that increase the blood flow through intrapulmonary venoarterial shunts. When orthodeoxia is severe, patients develop increasing dyspnea while standing *(platypnea).* Although hypoxemia is common and multifactorial, severe hypoxia is unusual. In a large series of cirrhotic patients, 7% had an arterial oxygen tension of less than 60 mm Hg while breathing room air.

Chest roentgenographs in hepatopulmonary syndrome normally display bibasilar nodular or reticulonodular opacities. Conventional computed tomography reveals that these nodules portray dilated lung vessels. Imaging with ^{99m}Tc-MMA perfusion can be utilized to confirm intrapulmonary arteriovenous shunting. High-resolution computed tomography is valuable in eliminating pulmonary fibrosis as the reason for these opacities. Contrast-enhanced echocardiography appears to be the most sensitive diagnostic test for detecting intrapulmonary vascular dilations.

Therapy of hepatopulmonary syndrome with almitrine bismesylate, a somatostatin analog, indomethacin, and plasmapheresis has been disappointing. Large pulmonary arteriovenous shunts documented by pulmonary angiography have been treated by embolotherapy with improvement in hypoxemia.

Diffuse Pulmonary Disease

Diffuse interstitial lung disease, occasionally granulomatous, has been observed in patients with primary biliary cirrhosis. Primary biliary cirrhosis is a granulomatous liver disease characterized by chronic intrahepatic cholestasis. The etiology is unknown, and it is associated with the presence of non-organ-specific antibodies to mitochondria in more than 95% of patients. The frequency and nature of pleuropulmonary manifestations in primary biliary cirrhosis are poorly documented. Many of the cases of lung involvement in primary biliary cirrhosis have been characterized by lung parenchymal granuloma formation and mononuclear cell alveolitis mimicking pulmonary sarcoidosis. One study using bronchoalveolar lavage has shown an increase in the number of alveolar $CD4^+$ lymphocytes (22% versus 12% in alcoholic cirrhosis) and activated alveolar macrophages in 50% of patients. These data suggest that subclinical alveolar inflammation, involving T lymphocytes and activated alveolar macrophages and mimicking sarcoid alveolitis, is present in a high proportion of patients with primary biliary cirrhosis. Pulmonary nodules simulating pulmonary carcinomatosis and later documented to be lymphocytic interstitial pneumonitis was described in a 51-year-old woman. These changes were unrelated to the activity of primary biliary cirrhosis and underwent spontaneous resolution. Because sicca complex often is associated with primary biliary cirrhosis, part of the respiratory dysfunction noted in primary biliary cirrhosis may be related to sicca complex rather than to the liver disease.

A prospective study of hepatic and pulmonary function in 47 patients (nonsmokers) with primary biliary cirrhosis found a significant relationship between histologic stage of primary biliary cirrhosis and steady-state diffusing capacity, and between the Mayo risk score for disease severity and steady-state diffusing capacity. Progressive deterioration of steady-state diffusing capacity was associated with increasing severity of primary biliary cirrhosis. There was no relationship between pulmonary involvement and the presence of Sjögren's syndrome. No significant relationship was observed between expiratory airflow and severity of primary biliary cirrhosis.

In a prospective study of 170 patients with various types of chronic hepatic diseases, mottled pulmonary parenchymal infiltrates were noted in 6%. Decreased D_LCO was observed in 20%. Clubbing of nails seemed to occur with a higher frequency in those with liver disease and abnormal chest roentgenograms. Pulmonary edema as a result of passive congestion can be seen in patients with liver disease. There appears to be high incidence of low-pressure pulmonary edema and acute respiratory distress syndrome in patients with fulminant hepatic failure.

Pulmonary Hypertension

The association of hepatic cirrhosis and pulmonary hypertension was first observed more than three decades ago. In a study of 2459 patients with biopsy-proved cirrhosis and 1241 patients with cirrhosis diagnosed at autopsy, the incidences of idiopathic hypertensive pulmonary vascular disease were 0.6% and 0.73%, respectively, in contrast to 0.13% ($p < 0.001$) in all autopsies. The data from this study suggest an association between cirrhosis and the development of pulmonary hypertension. Whereas the prevalence of cirrhosis alone was highest in the fifth decade, the average age of the cirrhotics with pulmonary hypertension was 35 years, and they tended to be women. The mechanisms responsible for the development of pulmonary hypertension in hepatic cirrhosis are unknown. Recurrent embolization from portal to pulmonary circulation, primary vasoconstriction, *in situ* thrombosis of pulmonary vessels, increased pulmonary vascular resistance from vasoactive peptides released as a result of portal hypertension, dietary alterations, and recurrent pulmonary emboli have been implicated.

Although most cases of pulmonary hypertension have been reported in patients with cirrhosis, hepatic parenchymal disease or failure is not necessary for its development. The strongest association appears to be with portal hypertension, and portal hypertension nearly always precedes by several years the diagnosis of pulmonary vascular disease. Histologic features, including plexogenic arteriopathy, are similar to those in primary pulmonary hypertension. Autopsy studies reveal a high incidence of intravascular thrombosis in association with plexiform lesions.

Hepatitis C Virus Infection

Hepatitis C virus (HCV) infection has been suggested as a cause of idiopathic pulmonary fibrosis, based on a Japanese study in which a high prevalence of anti-HCV antibodies was detected. A British study, however, failed to confirm these results. A subsequent study observed that Italian patients with idiopathic pulmonary fibrosis recorded a 13% prevalence of HCV infection and viral replication; the prevalence of anti-HCV antibodies did not differ from that in patients with other lung diseases.

Bronchoalveolar lavage lymphocyte subsets from 13 patients (ten men) with active chronic hepatitis C virus infection, when compared with those from 13 healthy volunteers, showed no difference in total cell counts in lavage fluid between the two groups. However, lavage lymphocyte and eosinophil numbers were increased in patients with chronic hepatitis C, leading the authors to consider that HCV infection may trigger alveolitis.

Recombinant interferon-a is used to treat hepatitis C virus infection. There are many reports on the occurrence of diffuse interstitial lung infiltration, with acute respiratory failure in some, in patients with chronic hepatitis C virus infection following therapy with recombinant interferon-a. Bronchoalveolar lavage has shown an increase in lymphocytes, especially $CD8^+$ cells, and lung specimens have exhibited bronchiolitis obliterans with organizing pneumonia (BOOP). In the vast majority of patients, the pulmonary manifestations and chest roentgenographic abnormalities disappeared after interferon therapy was discontinued and corticosteroid therapy was given.

Liver Transplant

Pulmonary infections occur in 25% of transplant recipients. The organisms responsible for pulmonary infections include gram-negative bacteria, cytomegalovirus, *Candida* species, *Aspergillus* species, and *Pneumocystis carinii.* Interstitial pneumonia caused by herpes simplex virus type 1 (HSV-1) is a severe complication of orthotopic liver transplantation. Acyclovir together with mechanical ventilation and reduced immunosuppression has proved to be an effective treatment for HSV-1 pneumonia following orthotopic liver transplantation.

Cytomegalovirus (CMV) pneumonia is a relatively common occurrence in orthotopic liver transplant recipients and is associated with high mortality. A prospective analysis of 141 orthotopic liver transplant recipients observed CMV pneumonia in 13 (9%) patients during the first year posttransplant, and the mortality rate was 85% at 1 year compared with a 17% mortality in those without CMV pneumonia. Overall, a 67% mortality rate was attributed to CMV pneumonia within the first year after liver transplantation.

Noninfectious complications following orthotopic liver transplant are caused by prolonged general anesthesia, extensive upper abdominal surgery, and massive administration of blood products and colloids. Noninfectious complications include atelectasis, pleural effusion, acute respiratory distress syndrome, and pulmonary calcification. Although air embolism is common during liver transplantation, clinical sequelae are few.

Diaphragmatic paralysis that occurs after orthotopic liver transplantation may contribute to the postoperative pulmonary problems. A crush injury to the right phrenic nerve during transplantation is most likely the cause of right hemidiaphragmatic dysfunction. A prospective study of 48 adult liver transplant recipients assessed by ultrasound, pulmonary function tests pre- and postoperatively, and transcutaneous phrenic nerve conduction studies recorded right phrenic nerve injury and hemidiaphragm paralysis in 79% and 38% of patients, respectively; conduction along the right phrenic nerve was absent in 53% and reduced in 26%. Left phrenic nerve conduction and left hemidiaphragm excursion were unaffected. The abnormal findings, however, did not significantly influence either the time on the ventilator or the hospital stay. Complete recovery of phrenic nerve conduction and diaphragm function took as long as 9 months in some patients.

Metastatic pulmonary calcification (calcinosis) following orthotopic liver transplantation has been described. In a series of 91 patients who underwent orthotopic liver transplantation, chest roentgenographs of 77 patients were reviewed, and pulmonary calcification was observed in four (5%) patients. Pulmonary calcinosis is a form of dystrophic calcification. Pulmonary calcification, at times fatal, has been described in renal transplant recipients. Many of the renal transplant recipients had markedly elevated calcium–phosphorus product, to peak values of 122 to 147 mg/dl. In the four liver transplant recipients described above, significantly higher levels of serum phosphate and calcium were recorded postoperatively, and these patients had received more intraoperative platelets and other blood products containing exogenous calcium than other patients. Nonspecific and persistent pulmonary opacities should suggest the possibility of pulmonary calcification. High-resolution computed tomographic lung scan or bone-seeking radionuclide (^{99m}Tc-diphosphonate) lung scans can be used to establish an early diagnosis of pulmonary calcification.

Miscellaneous Hepatic Disorders

Pulmonary embolism caused by bile embolism is a rare, occasionally fatal complication following biliary trauma. Communications between the biliary tract and hepatic veins after biliary surgery have been shown to result in bile emboli in small pulmonary arteries. Among the nine cases reported in the literature up to 1983, five had malignancies encroaching on the biliary tree, and the rest had biliary trauma.

a_1*-Antitrypsin deficiency* predisposes to pulmonary emphysema, liver cirrhosis, and hepatocellular carcinoma. Liver disease or impaired liver function is not a clinically relevant problem in most adults with pulmonary emphysema caused by a_1-antitrypsin deficiency. Indeed, severe lung and liver disease rarely coexist in the same subject. A review of 19 adult patients with a_1-antitrypsin deficiency and chronic liver disease showed a late onset of symptomatic hepatic abnormalities; 13 patients were 60 years old or older when liver disease was discovered. Low levels of serum a_1-antitrypsin are more likely to be associated with cirrhosis of the liver in children than in adults; approximately 10% of children with PiZZ $a_1$antitrypsin deficiency develop significant liver dysfunction. Chronic liver disease in patients with a_1-antitrypsin deficiency is associated with a high prevalence of hepatic infection by viruses. It has been suggested that the viral infection of the liver, rather than the a_1-antitrypsin deficiency alone, may be the cause of the liver disease in such patients.

Hepatic amebiasis produces pleuropulmonary complications in 7% to 20% of patients with amebic liver abscesses and in 2% to 3% of those with invasive disease. The intrathoracic manifestations include sympathetic effusion over the infradiaphragmatic area of inflammation, rupture of the amebic abscess and amebic empyema, and rupture directly into the bronchial tree to produce hepatobronchial fistula (Fig. 10).

FIG. 10. Right-sided pleuropulmonary involvement by amebic abscess.

Pulmonary injury from *drugs* such as penicillamine, azathioprine, sulfasalazine, and mesalamine may occur in patients who are administered these drugs for therapy of various gastroenterologic diseases.

Alcohol and the Lung

Chronic alcohol consumption increases the risk of developing pulmonary tuberculosis, chronic bronchitis, aspiration pneumonitis, lung abscess, pulmonary complications of alcoholic cirrhosis, and pulmonary problems from alcoholic cardiomyopathy. The reported effects of alcohol on the respiratory system include diminished ciliary motion, decreased migration of alveolar macrophages, interference with surfactant production, and increased prevalence of oropharyngeal gram-negative bacilli.

Three large epidemiologic studies in the 1980s critically analyzed the effect of alcohol on respiratory function and found that alcohol has little, if any, effect on pulmonary function. The pulmonary functional abnormalities noted in earlier studies were apparently related to smoking, a common habit among subjects who consume alcohol. Further, a study of 27 alcoholic subjects in the United Kingdom concluded that the high prevalence of respiratory disease in alcoholics was largely attributable to their smoking habits and that there was no evidence of a specific pulmonary toxic effect of ethanol on the lungs. A population-based study, however, of more than 8750 persons, each of whom had consumed alcohol, 350 g/week or more, evaluated the effect of alcohol consumption on pulmonary function over a period of 5 years and reported that alcohol consumption significantly accelerated the loss of FEV_1 and forced vital capacity; these changes were comparable to the effect of smoking 15 g tobacco daily. Other reports have noted that short-term cessation of alcohol intake has no effect on pulmonary function parameters in cigarette-smoking alcoholics.

Impaired glottic reflex and cough reflex and oversedation induced by alcohol ingestion may play a role in causing community-acquired pneumonia. A case-control study concluded that high alcohol intake is the main risk factor for developing community-acquired pneumonia in middle-aged people. Compared with nonalcoholic patients, alcoholic patients with pneumonia exhibited more severe clinical symptoms, required longer intravenous therapy and longer hospital stays, and had multilobar involvement and pleural effusion as well as slower resolution of lung infiltrates. Pneumonia may also result from gastroesophageal reflux induced by alcohol ingestion. The effect of moderate amounts of alcohol (e.g., 120 mL Scotch whiskey, with 40% alcohol) on nocturnal esophageal reflux was studied in healthy volunteers. Monitoring of esophageal pH in ambulatory and supine postures revealed prolonged supine reflux episodes in 41%, whereas none in the control group had reflux. This study also found that there was a significant exposure of the distal esophagus to acid and that the normal acid clearance of the esophagus in the supine position was impaired after only moderate amounts of alcohol.

Klebsiella pneumoniae pneumonia with bacteremia is common and associated with a very high mortality in alcoholic subjects. In a study of 28 alcoholic patients (all men) with community-acquired pneumonia who were admitted to a referral medical center, all but a few were heavy smokers; bacteremic *Klebsiella pneumoniae*

pneumonia was diagnosed in 11 patients, all of whom required management and ventilatory support in the intensive care unit. Chest radiographs showed pleural effusion and roentgenographic spread of pneumonia in nearly 50% of patients. Acute renal failure and disseminated intravascular coagulation developed in six patients. Even though the overall mortality was 64%, all patients with *Klebsiella pneumoniae* died.

Acute respiratory distress syndrome (ARDS) is reported to occur with higher frequency in patients with a history of alcohol abuse. A prospective cohort study of 351 medical and surgical intensive care unit patients with one of seven at-risk diagnoses for the development of ARDS noted that the incidence of ARDS was significantly higher in patients with a history of alcohol abuse than in patients without such a history (43% versus 22%). In patients with sepsis, ARDS developed in 52% of the patients with a prior history of alcohol abuse compared with only 20% in patients without that history. In the subset of patients who developed ARDS, the in-hospital mortality rate was 65% in patients with a prior history of alcohol abuse. This mortality rate was significantly higher than the mortality rate in patients without a history of alcohol abuse.

Alcoholism is closely associated with tuberculosis, the prevalence of alcoholism being 49% in newly diagnosed tuberculous disease. Among 970 subjects in New York City with alcohol and drug addiction, the prevalence of tuberculosis was 0.91%, which was 28 times the age-matched rate for the population in the city; the screening of only those with a positive tuberculin test and cough substantially increased the yield of active tuberculosis to 7.2%, or 225 times the rate for the city. In view of the rising incidence of tuberculosis in the 1990s, screening for tuberculosis in the alcoholic population is highly recommended. A review of 23 patients with primary pulmonary sporotrichosis, presumably acquired by inhalation, revealed that this form of the disease affects middle-aged men with a history of alcoholism or chronic lung disease. Clinically and roentgenographically, the disease mimics chronic cavitary tuberculosis and histoplasmosis.

One study reported that low to moderate alcohol consumption by older persons is associated with a decreased risk of deep venous thrombosis and pulmonary embolism.

Alcohol asthma is the term applied to chest tightness and wheezing after alcohol ingestion; a small number of persons of Asian and Native American extraction have been reported to demonstrate this phenomenon.

Deficiency of IgG subclass has been reported in 70% of patients with alcoholic liver disease, and the deficiency was reported to be closely correlated with the number and type of bacterial respiratory infections.

PANCREATIC DISEASES

Pleural Effusion

Pleural effusion occurs in 4% to 17% of patients with acute pancreatitis. Roentgenographic abnormalities include free or loculated pleural effusion, elevation of a hemidiaphragm, and basilar atelectasis. The effusions are predominantly left-sided. Characteristically, the fluid is an exudate, contains elevated amylase level, and is hemorrhagic in 30% of patients. Massive pleural effusions can occur in association with asymptomatic pancreatic disease.

Pleuropancreatic fistula may produce chronic massive pleural effusions. Chronic massive pancreatic pleural effusion also may develop weeks, months, or years after an episode of acute pancreatitis, and, in most of these patients, there is no history of pancreatitis. Patients may present with dyspnea, cough, and chest pain. The pleural fluid amylase content is always markedly elevated. Chronic massive pancreatic pleural effusion is caused by posterior disruption of the pancreatic duct into the retroperitoneal space, with tracking of secretions from the pancreas along the esophagus or aorta upward into the mediastinum. The fluid can occasionally collect in the mediastinum and produce a mediastinal pseudocyst. Pericardial effusion and tamponade have been described. Very high levels of pleural fluid amylase also can be seen in pleural effusion secondary to esophageal perforation. The amylase in this situation results from leakage of salivary amylase.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is the most serious complication of pancreatitis and is reported to occur in 20% to 50% of patients. A prospective study to assess the incidence of pulmonary infiltrates in acute pancreatitis observed this complication in 26% of patients, but not all patients had ARDS. Pancreatitis-induced ARDS usually is attributed to the release of active enzymes and vasoactive substances from the pancreas. The mechanism of injury is unknown, but it is believed to be related to defective surfactant production. Lecithin is a main constituent of the pulmonary surfactant dipalmitoyl lecithin. The surfactant is split by a lecithinase, which is increased in acute pancreatitis. An experimental study suggests that pancreatic elastase plays a major role, by direct deleterious action on the pulmonary vasculature, in the development of pulmonary vascular injury after acute pancreatitis. In another experimental model, pancreatitis induced by injection of trypsin and sodium taurocholate into the pancreas, pulmonary injury was prevented by pretreatment of animals with trasylol, an antiprotease drug active toward trypsin and elastase.

Thoracic duct drainage has been used to remove pancreatic enzymes and vasoactive substances before they could reach the systemic circulation and cause adult respiratory distress syndrome. This method was used to collect the lymphatic effluent in six patients with severe acute pancreatitis; moderate lymph-to-plasma gradients were noted for IL-6, lipase, and trypsin, and similar levels in plasma and lymph were recorded for the other substances. These results suggest that cytokines as well as pancreatic enzymes could contribute to the development of the lung injury and that lymphatics are potential vectors of these mediators.

Ocreotide, a synthetic analog of somatostatin, is effective in the palliative therapy of vomiting associated with intraabdominal malignancies by reducing the volume of secretions. Intravenous administration of octreotide in patients with severe necrotizing pancreatitis has been shown to significantly reduce the frequency of the adult respiratory distress syndrome, circulatory shock, and mortality.

Acute hemorrhagic pancreatitis frequently is associated with acute respiratory failure with pulmonary edema, which is generally believed to be caused by increased alveolar membrane permeability. Hypoalbuminemia seen in pancreatitis may aggravate the tendency to develop pulmonary edema.

Pancreatic pseudocysts have been complicated by large intrathoracic fluid collections. Most, but not all, chronic or persistent pleural effusions are associated with, and caused by, a fistulous tract between the pseudocyst and the pleural space. Computed tomography is helpful in detecting the fistulous communication. Subdiaphragmatic collection of fluid is common and may play a role in the accumulation of pleural effusion; ultrasonography or computed tomography is necessary to exclude such fluid collections. Other pulmonary complications of chronic pancreatitis include bibasilar atelectasis, diaphragmatic elevation caused by pleural effusion or atelectasis, and pleural calcification. Mediastinal fat necrosis is another reported complication.

GASTROINTESTINAL MALIGNANCIES

Esophageal Cancer

Gastrointestinal malignancies play a major role in respiratory diseases. This is particularly true in esophageal cancer. Metastatic pulmonary involvement by esophageal cancer occurs in 20% of patients. However, an overwhelming majority of the metastases are the result of direct spread to the tracheobronchial tree because of the anatomic proximity of the esophagus to the airways. For this reason, some routinely perform bronchoscopy before surgical resection of the esophageal cancer. An important clinical caveat is that a positive cytology from bronchoscopic secretions in patients with esophageal carcinoma does not necessarily indicate airway involvement by cancer. Rather, the abnormal cytology is often the result of aspiration of cancer cells from the esophagus into the airways.

The respiratory manifestations can vary depending on the type of esophageal lesion and the degree of pulmonary involvement. An obstructing esophageal lesion can promote retention of food proximally, which in turn can lead to cough and aspiration pneumonia. Direct extension of the cancer into the airways can result in esophagotracheobronchial fistula. This too can cause aspiration pneumonia. Hemoptysis is another symptom of this. Extrinsic compression of the tracheobronchial tree may produce respiratory difficulty. Last, surgical resection of esophageal cancer may lead to respiratory complications.

A retrospective study of 309 resections for esophageal cancer (Ivor–Lewis resection for middle thoracic lesions was done in 182 cases, and the Akiyama resection for upper thoracic lesions in 127 cases) recorded overall mortality and morbidity rates of 9% and 37%, respectively. Mortality rate was four times higher, and morbidity was twice as high, after the Akiyama procedure than after the Ivor–Lewis procedure. Respiratory complications accounted for 64% of postoperative deaths. The Akiyama procedure had more respiratory complications, especially isolated bronchopneumonia and necrosis of the trachea or of the right or left main bronchus. Respiratory complications accounted for 53% of morbidity, mainly recurrent nerve paralysis with false passages and stasis in the transplant. Another mechanism for the formation of esophagus–airway fistula is necrosis of the esophageal tissue after surgery and/or high-dose radiation therapy for cancer.

Colon Cancer

Metastatic involvement of the lungs occurred in 11.7% of 22,715 patients who underwent colectomy for carcinoma in the U.S. Veterans Administration hospital system.

Of the 2659 (11.7%) patients who had pulmonary metastases, 514 had no prior or other metastatic sites. Of the 974 patients who underwent surgery for colorectal cancer during a 20-year period in Japan, pulmonary metastasis developed in 35 (3.6%) patients. Solitary or multiple lung nodules occur more frequently than other forms of pulmonary metastasis. Thus, colorectal carcinoma should always be considered when new or undiagnosed pulmonary nodules are encountered. Obviously, a documented history of previous malignancy of the colon and rectum increases the possibility of pulmonary metastasis. Even though the therapeutic approach to nodular lung metastasis from colon cancer has varied, surgical resection of pulmonary metastases from colorectal cancer in selected patients might improve prognosis. Indeed, significantly enhanced survival can be expected in patients with only intrapulmonary metastasis documented before thoracotomy.

Several large studies of patients who underwent resection of pulmonary metastases from colorectal cancer have recorded survivals of 20% to 41% at 5 years and 20% to 30% at 10 years. In the VA study quoted above, resections of pulmonary metastases were performed in 76 (2.9%) patients; the projected 5-year survival rate was 36%, mean survival was 8 months, and 30-day mortality rate was 3%. Of the 974 patients who underwent surgery for colorectal cancer during a 20-year period in Japan, the survival rate was 53% at both 3 and 5 years after resection of pulmonary metastasis.

Predictors of longer survival include total resection of metastatic lung disease, fewer than two pulmonary metastases, and a normal prethoracotomy serum carcinoembryonic antigen (CEA) level. In one study, the estimated 5-year survival rate of patients with a normal prethoracotomy serum CEA level was 60%, as compared with 4% in patients with elevated (>5 ng/mL) serum CEA. Sex, age, site of the primary tumor (colon or rectum), disease-free interval, size of metastases, and previous resection of hepatic metastases do not appear to be statistically significant prognostic factors.

Liver Cancer

Pulmonary metastasis in liver cancer may appear as small nodular lesions or, more likely, as interstitial infiltrations. Hepatocellular carcinoma is treated by hepatic artery chemoembolization therapy. One of the therapeutic agents contains iodized oil. In a retrospective study of 336 patients with hepatocellular carcinoma who underwent transcatheter oily chemoembolization of the hepatic artery, 14 patients were administered iodized oil in excess of 20 ml. In six of these patients, pulmonary symptoms including cough, hemoptysis, and dyspnea developed 2 to 5 days after chemoembolization therapy. The chest roentgenographs demonstrated diffuse bilateral pulmonary parenchymal infiltrates; P_aO_2 on ambient air ranged from 39 to 60 mmHg. All respiratory features resolved in 10 to 28 days, and five patients survived; one patient died 10 days after the procedure as a result of respiratory arrest with a progression of pulmonary infiltrate.

Of the 154 consecutive autopsies of patients with exocrine pancreatic cancer, 13 (8%) patients were found to have pulmonary metastases without hepatic metastasis.

OTHER GASTROENTEROLOGIC DISEASES

Subphrenic Abscess

With intraabdominal problems such as a rupture or perforation of a viscus and after intraabdominal surgery, subphrenic abscess is a common complication. The incidence of involvement of either side is approximately equal, as is involvement of the anterior and posterior subphrenic spaces. Roentgenographically, evidence of subphrenic abscess appears within the lung, in the pleural space, and in the subphrenic space. Blunting of the costophrenic angle is seen in nearly 90% of patients. Retroperitoneal abscess also can cause pleural effusion.

Abdominal Surgery

Changes in respiratory function after abdominal surgery have been well documented. Intraoperative testing of lung function has shown both diminished vital capacity and diminished residual capacity. Microatelectasis, seen commonly in postoperative states, is believed to be a major cause of persistent hypoxemia. Several mechanisms have been hypothesized to explain this, including diminished production of surfactant resulting from inhalation of high oxygen concentrations or from altered ventilatory patterns; alveolar collapse from complete resorption of alveolar gas following inhalation of 100% oxygen; and peripheral airways obstruction by bronchoconstriction in response to hypocapnia.

Upper abdominal surgery is commonly followed by postoperative pulmonary complications. Laparoscopic procedures are less likely to cause respiratory complications. A case-control study of laparoscopic (37 patients) and open cholecystectomy (58 patients) observed that the incidence of postoperative pulmonary complications was 2.7% after laparoscopic cholecystectomy and 17.2% after open cholecystectomy. Increased intraabdominal pressure during laparoscopic cholecystectomy causes a significant, but fully reversible, decrease in dynamic compliance. Prospective evaluation of pre- and postoperative spirometry, arterial blood gases, and chest roentgenographs in patients undergoing laparoscopic cholecystectomy has shown that the physiological derangements that occur are sufficiently small that all but the most severely impaired patients with pulmonary disease should be able to tolerate this operation.

Pleural effusions commonly occur after abdominal procedures. The amount of fluid accumulation, however, is small. In one study, pleural fluid could be detected in 49% of 200 patients 48 to 72 hr after operation. The incidence was higher after upper abdominal surgery and in patients with atelectasis on the same side as the operation. Thoracentesis in 20 patients revealed that the fluid was an exudate in 16 of them. Almost all the effusions resolved spontaneously.

Miscellaneous Disorders

Pulmonary embolism can be triggered by the act of defecation in patients with deep vein thrombosis. One retrospective chart review estimated that defecation-induced pulmonary embolism occurred in 6.8% of all patients with the discharge diagnosis of pulmonary embolism, and, of the nine patients with this combination, six died. Increased intraabdominal pressure (from the Valsalva maneuver) during defecation, followed by a sudden decrease in the pressure (vacuum effect), is hypothesized to dislodge clots from deep veins.

Ventral hernia and other abnormalities of the abdominal wall may interfere with normal pulmonary function. Large defects such as ventral hernia may produce respiratory embarrassment and therefore require surgical correction, especially in those with chronic obstructive lung disease.

Pneumatosis coli is a rare condition characterized by multiple gas-filled cysts within the bowel wall. A review of 25 cases (mean age 59 years; 15 women) treated over a period of 30 years observed its association with chronic lung disease in 20% of patients; oxygen therapy in nine patients always relieved the symptoms.

Strongyloides stercoralis infestation is postulated to be associated with asthma. A study, however, observed that there is no statistically significant difference in the prevalence of asthma between patients with *Strongyloides stercoralis* infestation and those without parasitic infection.

compared to controls with gastrointestinal bleeding and without chronic obstructive pulmonary disease.

Chao Y, Wang SS, Lee SD, Shiao GM, Chang HI, Chang SC. Effect of large-volume paracentesis on pulmonary function in patients with cirrhosis and tense ascites. *J Hepatol* 1994;20:101–105. *This study on the role of large-volume paracentesis on lung function in 12 male patients with cirrhosis showed significant increases in forced vital capacity, FEV1, total lung capacity, functional residual capacity, inspiratory capacity, expiratory reserve volume, diffusing capacity, and alveolar volume following paracentesis.*

Chin K, Tabata C, Sataka N, Nagai S, Moriyasu F, Kuno K. Pneumonitis associated with natural and recombinant interferon a therapy for chronic hepatitis C. *Chest* 1004;105:939–941. *Description of three patients with chronic hepatitis C virus infection, who developed bilateral lung infiltration and acute respiratory failure following therapy with recombinant interferon-a.*

Chung JW, Park JH, Im JG, Han JK, Han MC. Pulmonary oil embolism after transcatheter oily chemoembolization of hepatocellular carcinoma. *Radiology* 1993;187:689–693. *Chemoembolization (in six of 14 patients), which included iodized oil in the injected material via the hepatic artery for the treatment of hepatocellular carcinoma resulted in symptomatic pulmonary oil embolism. Respiratory symptoms of cough, hemoptysis, and dyspnea developed 2 to 5 days after therapy, with chest radiographs showing diffuse bilateral pulmonary parenchymal infiltrate.*

Cook DJ, Reeve BK, Guyatt GH, Heyland DK, Griffith LE, Buckingham L, Tryba M. Stress ulcer prophylaxis in critically ill patients. Resolving discordant meta-analyses. *JAMA* 1996;275:308–314. *A review of 269 articles including 63 randomized trials on the role of stress ulcer prophylaxis observed that prophylaxis with histamine H_2 receptor antagonists decreases the incidence of overt gastrointestinal bleeding but there was a trend toward an increased risk of pneumonia associated with H_2 receptor antagonists as compared with no prophylaxis. Sucralfate, however, was associated with a lower incidence of nosocomial pneumonia when compared with antacids and H_2 receptor antagonists.*

Costa C, Sambataro A, Baldi S, Modena V, Todros L, Libertucci D, Coni F, Fusaro E, Revello F, Murgia A, et al. Primary biliary cirrhosis: lung involvement. *Liver* 1995;15:196–201. *Pulmonary complications in 61 consecutive patients with different stages of primary biliary cirrhosis were evaluated by static and dynamic lung volumes and diffusing capacity for carbon monoxide. No patient had respiratory symptoms. Diffusion capacity was reduced in 24 patients. Reduced diffusion capacity showed a significant correlation with the presence of complete or incomplete CREST syndrome and with the presence of circulating anticentromere antibodies.*

Dumont P, Wihlm JM, Hentz JG, Roeslin N, Lion R, Morand G. Respiratory complications after surgical treatment of esophageal cancer. A study of 309 patients according to the type of resection. *Eur J Cardiothorac Surg* 1995;9:539–543. *A retrospective study of 309 resections for esophageal cancer (Ivor–Lewis resection for middle thoracic lesions was done in 182 cases, and the Akiyama resection for upper thoracic lesions in 127 cases) recorded overall mortality and morbidity rates of 9% and 37%, respectively; mortality rate was four times higher, and morbidity was twice as high, after the Akiyama procedure than after the Ivor–Lewis procedure. Respiratory complications accounted for 64% of postoperative deaths.*

Falagas ME, Snydman DR, George MJ, Werner B, Ruthazer R, Griffith J, Rohrer RH, Freeman R. Incidence and predictors of cytomegalovirus pneumonia in orthotopic liver transplant recipients. *Transplantation* 1996;61:1716–1720. *Prospective analysis 141 orthotopic liver transplant recipients observed cytomegalovirus pneumonia in 13 (9.2%) patients during the first year posttransplant. The CMV pneumonia was associated with an 85% 1-year mortality compared with 17% 1-year mortality in those without CMV pneumonia. The mortality rate attributed to CMV pneumonia within the first year after liver transplantation was 67%.*

Fernandez-Sola J, Junque A, Estruch R, Monforte R, Torres A, Urbano-Marquez A. High alcohol intake as a risk and prognostic factor for community-acquired pneumonia. *Arch Intern Med* 1995;155:1649–1654. *A case-control study of 50 patients and 50 controls concluded that high alcohol intake is the main risk factor for developing community-acquired pneumonia in middle-aged people, and because it is associated with a worse prognosis, these patients should be treated with broad-spectrum antibiotics for a longer period.*

Fiedler F, Jauernig G, Keim V, Richter A, Bender HJ. Octreotide treatment in patients with necrotizing pancreatitis and pulmonary failure. *Intens Care Med* 1996;22:909–915. *This case-control study showed that intravenous octreotide, 100 µg three times daily for 10 days, had a beneficial effect in patients with severe necrotizing pancreatitis: the frequency of adult respiratory distress syndrome (18% versus 40%;* $p < 0.05$*) and circulatory shock (51% versus 87%;* $p < 0.05$*) was significantly lower in the treatment group. Mortality was 26% (ten of 39 patients) in the octreotide group and 61% (33 of 54 patients) in the control group (*$p < 0.01$*).*

Field SK, Underwood M, Brant R, Cowie RL. Prevalence of gastroesophageal reflux symptoms in asthma. *Chest* 1996;109:316–322. *This questionnaire-based survey of 109 asthmatic patients recorded the presence of heartburn, regurgitation, and swallowing difficulties in 77%, 55%, and 24% of patients, respectively; at least one antireflux medication was required by 37% of asthmatics (*$p < 0.001$ *versus controls). None of the asthma medications were associated with an increased likelihood of symptomatic gastroesophageal reflux.*

Garg K, Lynch DA, Newell JD. Inflammatory airways disease in ulcerative colitis: CT and high-resolution CT features. *J Thorac Imag* 1993;8:159–163. *This retrospective review of seven patients with ulcerative colitis who presented with cough and recurrent respiratory infections showed that six had diffuse mucosal erythema and edema predominantly of the proximal airways when examined by the flexible bronchoscope. Chest radiographs showed bronchiectasis in two patients and bronchial wall thickening in three. Computed tomography showed bronchiectasis in six patients, peripheral airways involvement in four, and airway stenosis in three.*

Hall JC, Tarala RA, Hall JL. A case-control study of postoperative pulmonary complications after laparoscopic and open cholecystectomy. *J Laparoendosc Surg* 1996;6:87–92. *A case-control study of laparoscopic (37 patients) and open cholecystectomy (58 patients) observed that the incidence of postoperative pulmonary complications was 2.7% after laparoscopic cholecystectomy and 17.2% after open cholecystectomy.*

Harding SM, Richter JE, Guzzo MR, Schan CA, Alexander RW, Bradley LA. Asthma and gastroesophageal reflux: acid suppressive therapy improves asthma outcome. *Am J Med* 1996;100:395–405. *A study of 30 nonsmoking adult asthmatics with gastroesophageal reflux used omeprazole in titrated acid-suppressive doses for 3 months and observed that omeprazole improves asthma symptoms and/or peak expiratory flow rates by >20%. The therapy also improved pulmonary function in 73% of asthmatics with gastroesophageal reflux after 3 months of acid-suppressive therapy.*

Irving WL, Day S, Johnston ID. Idiopathic pulmonary fibrosis and hepatitis C virus infection. *Am Rev Respir Dis* 1993;148:1683–1684. *In contrast to a report from Japan that noted increased incidence of idiopathic pulmonary fibrosis in patients with hepatitis C virus infection, this English study of 62 patients indicated that idiopathic pulmonary fibrosis is no more prevalent in patients with hepatitis C virus infection than in the general population.*

Jong GM, Hsiue TR, Chen CR, Chang HY, Chen CW. Rapidly fatal outcome of bacteremic Klebsiella pneumoniae pneumonia in alcoholics. *Chest* 1995;107:214–217. *In this study from Taiwan, 28 alcoholic patients (all men) with community-acquired pneumonia who were admitted to a referral medical center during a 3-year period showed that with few exceptions all were heavy smokers. The overall mortality was 64%, but all 11 patients with bacteremic* Klebsiella pneumoniae *pneumonia died. All 11 patients needed intensive care unit management and ventilatory support.*

Kahrilas PJ. Gastroesophageal reflux disease. *JAMA* 1996;276:983–988. *A review of the management of gastroesophageal reflux disease in adults with esophageal complications including esophagitis, stricture, adenocarcinoma, or Barrett's metaplasia or extraesophageal complications (otolaryngologic manifestations and asthma).*

Kelly CA, Egan M, Rawlinson J. Whipple's disease presenting with lung involvement. *Thorax* 1996;51:343–344. *Description of the first reported case of Whipple's disease presenting with large pulmonary nodules and endobronchial lesions in a 31-year-old man who presented with nonspecific symptoms and a chest radiograph showing rapidly enlarging pulmonary nodules. Bronchoscopic examination showed endobronchial lesions.*

King PD, Rumbaut R, Sanchez C. Pulmonary manifestations of chronic liver disease. *Dig Dis* 1996;14:73–82. *A detailed review of pulmonary manifestations in chronic hepatic diseases. Includes discussion on "hepatopulmonary syndrome," which results in hypoxemia through pulmonary vasodilation and V_A/Q mismatch, restrictive lung pattern, or pleural effusions from the development of ascites, pulmonary hypertension, and immune-mediated lung disease.*

Krowka MJ, Grambsch PM, Edell ES, Cortese DA, Dickson ER. Primary biliary cirrhosis: relation between hepatic function and pulmonary function in patients who never smoked. *Hepatology* 1991;13:1095–1100. *A prospective study of hepatic and pulmonary function in 47 patients (nonsmokers) with primary biliary cirrhosis found a significant relationship between histologic stage of primary biliary cirrhosis and steady-state diffusing capacity and between the Mayo risk score for disease severity and steady-state diffusing capacity. Progressive deterioration of steady-state diffusing capacity was associated with increasing severity of primary biliary cirrhosis.*

Kubo K, Yamaguchi S, Fujimoto K, Hanaoka M, Hayasaka M, Honda T, Sodeyama T, Kiyosawa K. Bronchoalveolar lavage fluid findings in patients with chronic hepatitis C virus infection. *Thorax* 1996;51:312–314. *Bronchoalveolar lavage lymphocyte subsets from 13 patients (ten men) with active chronic hepatitis C were*

compared with those from 13 healthy volunteers. There was no difference in total cell counts in lavage fluid between the two groups. However, lavage lymphocyte and eosinophil numbers were increased in patients with chronic hepatitis C, leading the authors to consider that HCV infection may trigger alveolitis.

Lankisch PG, Droge M, Becher R. Pulmonary infiltrations. Sign of severe acute pancreatitis. *Int J Pancreatol* 1996;19:113–115. *The incidence of pulmonary infiltrates was evaluated in 140 patients with acute pancreatitis by means of chest roentgenography within 24 hr and a contrast-enhanced computed tomography within 72 hr after admission, and Ranson's prognostic parameters were estimated within the first 48 hr. Thirty-six (26%) patients who developed pulmonary infiltrates had a significantly higher Ranson's score and pancreatic necroses more frequently than patients without this complication, plus a higher mortality rate.*

Levine JB, Lukawski-Trubish D. Extraintestinal considerations in inflammatory bowel disease. *Gastroenterol Clin North Am* 1995;24:633–646. *A detailed review of the extraintestinal manifestations in inflammatory bowel diseases. Pulmonary complications and the speculative considerations on the mechanism of lung involvement also are included.*

Libson E, Wechsler RJ, Steiner RM. Pulmonary calcinosis following orthotopic liver transplantation. *J Thorac Imag* 1993;8:305–308. *In a series of 91 patients who underwent orthotopic liver transplantation, chest roentgenographs of 77 were reviewed, and metastatic pulmonary calcification was observed in four (5.2%). The patients with pulmonary calcification had significantly higher levels of serum phosphate and calcium postoperatively and had received more intraoperative platelets and other blood products containing exogenous calcium than other patients.*

Manganelli P, Salaffi F, Subiaco S, Carotti M, Cervini C, Consigli G, Majori M, Pesci A. Bronchoalveolar lavage in mixed cryoglobulinaemia associated with hepatitis C virus. *Br J Rheumatol* 1996;35:978–982. *Bronchoalveolar lavage in 16 nonsmoking women (free of clinical pulmonary symptoms and with normal chest roentgenograms) with hepatitis C virus-associated mixed cryoglobulinemia showed lymphocytes in 20%. Even though pulmonary function tests showed significantly lower values of forced expiratory flow and D_LCO, there were no correlations between BAL results and pulmonary function tests.*

Marumo K, Homma S, Fukuchi Y. Postgastrectomy aspiration pneumonia. *Chest* 1995;107:453–456. *Among 186 patients who had undergone total gastrectomy, 16 (8.6%) patients had recurrent respiratory tract inflammation, and 45 (24.2%) patients had sporadic respiratory tract inflammation. The former group frequently showed symptoms related to esophageal reflux, and the swallowing provocation test in this group showed swallowing disturbances (prolonged latency). Authors concluded that the aspiration of esophageal reflux contents was the most important risk factor of recurrent pulmonary complications in patients with total gastrectomy.*

McAlister VC, Grant DR, Roy A, Brown WF, Hutton LC, Leasa DJ, Ghent CN, Veitch JE, Wall WJ. Right phrenic nerve injury in orthotopic liver transplantation. *Transplantation* 1993;55:826–830. *A prospective study of 48 adult liver transplant recipients who were evaluated by ultrasound and pulmonary function performed preoperatively and postoperatively and transcutaneous phrenic nerve conduction studies postoperatively observed right phrenic nerve injury and hemidiaphragm paralysis in 79% and 38%. Conduction along the right phrenic nerve was absent in 53% and reduced in another 26%.*

Meliconi R, Andreone P, Fasano L, Galli S, Pacilli A, Miniero R, Fabbri M, Solforosi L, Bernardi M. Incidence of hepatitis C virus infection in Italian patients with idiopathic pulmonary fibrosis. *Thorax* 1996;51:315–317. *Antibodies to hepatitis C virus (HCV) were evaluated in 60 patients with idiopathic pulmonary fibrosis, 130 patients with noninterstitial lung disease, and in 4614 blood donors. It was concluded that Italian patients with idiopathic pulmonary fibrosis showed a 13% prevalence of HCV infection and viral replication, but the prevalence of anti-HCV antibodies did not differ from those in other lung diseases.*

Montravers P, Chollet-Martin S, Marmuse JP, Gougerot-Pocidalo MA, Desmonts JM. Lymphatic release of cytokines during acute lung injury complicating severe pancreatitis. *Am J Respir Crit Care Med* 1995;152:1527–1533. *Thoracic duct drainage was used in six patients with adult respiratory distress syndrome complicating severe acute pancreatitis in an effort to remove active enzymes and vasoactive substances before they could reach the systemic circulation and lead to ARDS. Based on the analysis of the drainage effluent, the authors concluded that cytokines as well as pancreatic enzymes could contribute to the development of the lung injury and that lymphatics are potential vectors of these mediators.*

Moss M, Bucher B, Moore FA, Moore EE, Parsons PE. The role of chronic alcohol abuse in the development of acute respiratory distress syndrome in adults. *JAMA* 1996;275:50–54. *Prospective study of 351 medical and surgical intensive care unit patients at risk for the development of acute respiratory distress syndrome noted that the incidence of ARDS in patients with a history of alcohol abuse was significantly higher than in patients without a history of alcohol abuse (43% versus 22%), and in patients with sepsis, ARDS developed in 52% with a prior history of alcohol abuse compared with 20% of patients without such a history.*

Munck A, Murciano D, Pariente R, Cezard JP. Latent pulmonary function abnormalities in children with Crohn's disease. *Eur Respir J* 1995;8:377–380. *Investigation of pulmonary abnormalities in 26 children with acute or quiescent Crohn's disease revealed normal chest radiographs in all, and although no significant differences were found between acute and quiescent Crohn's for pulmonary volumes and expiratory flows, D_LCO was significantly decreased during the active phase of the disease as compared to remission (53 ± 15% versus 81 ± 19% predicted).*

Treatment of malignant esophagorespiratory fistulas with silicone-covered metallic Z stents. *J Vasc Intervent Radiol* 1995;6:237–242. *A prospective evaluation of the efficacy of covered metallic Z stents in the treatment of esophagorespiratory fistulas in 12 patients with severe aspiration symptoms from malignant fistulas showed that fluoroscopically guided stent placement was successful and well tolerated in all patients. Aspiration symptoms were completely relieved in eight of 12 patients, and four of 12 patients were improved and able to eat a soft diet. There were no stent-related deaths.*

Schnatz PF, Castell JA, Castell DO. Pulmonary symptoms associated with gastroesophageal reflux: use of ambulatory pH monitoring to diagnose and to direct therapy. *Am J Gastroenterol* 1996;91:1715–1718. *This study of 54 patients with chronic persistent cough or asthma suspected to be caused by reflux used pH monitoring to identify those with reflux-induced pulmonary problems; 42 patients had abnormal reflux, among whom 28 patients had abnormal proximal acid exposure. Antireflux therapy achieved good to excellent responses in pulmonary symptoms in 71% of patients.*

Short TP, Patel NR, Thomas E. Prevalence of gastroesophageal reflux in patients who develop pneumonia following percutaneous endoscopic gastrostomy: a 24-hr pH monitoring study. *Dysphagia* 1996;11:87–89. *To assess the frequency of pneumonia following percutaneous endoscopic gastrostomy, this study included 24-hr pH monitoring and observed an increased prevalence of gastroesophageal reflux in patients who developed pneumonia.*

Simpson WG. Gastroesophageal reflux disease and asthma. Diagnosis and management. *Arch Intern Med* 1995;155:798–803. *A review of diagnosis and therapy of gastroesophageal reflux disease and asthma. Gastroesophageal reflux serves as a trigger of bronchospasm, potentiates the bronchomotor response to additional triggers, or both. Patients with reflux-associated asthma may manifest symptoms of gastroesophageal reflux, either classic or atypical, but approximately 25% to 30% have clinically silent reflux.*

Tryba M, Cook DJ. Gastric alkalinization, pneumonia, and systemic infections: the controversy. *Scand J Gastroenterol* 1995;210(Suppl):53–59. *The discussion indicates that gastric alkalinization significantly increases the risk of nosocomial pneumonia in long-term ventilated patients but sucralfate may have significant protective effects. However, only specific subgroups of patients benefit from acid-independent stress ulcer prophylaxis relative to nosocomial pneumonia.*

van Halteren HK, van Geel AN, Hart AA, Zoetmulder FA. Pulmonary resection for metastases of colorectal origin. *Chest* 1995;107:1526–1531. *A retrospective study of 38 patients who underwent resection of pulmonary metastasis from colon cancer observed a 5-year disease-free survival of 31% and an overall 5-year survival of 43%. Three or fewer metastases and a short delay between detection of pulmonary metastases and resection were significantly associated with longer postthoracotomy disease-free intervals.*

Vasishta S, Wood JB, McGinty F. Ulcerative tracheobronchitis years after colectomy for ulcerative colitis. *Chest* 1994;106:1279–1281. *Description of two men with severe ulcerative colitis who developed ulcerative tracheobronchitis 4 and 8 years after total colectomy. Intense plasma cell infiltration of tracheal mucosa and submucosa and destruction of mucous glands were noted, with partial relief of symptoms with corticosteroids.*

Wade TP, Virgo KS, Li MJ, Callander PW, Longo WE, Johnson FE. Outcomes after detection of metastatic carcinoma of the colon and rectum in a national hospital system. *J Am Coll Surg* 1996;182:353–361. *A retrospective survival analysis of 22,715 patients in the VA hospital system who underwent colectomy for carcinoma observed that 2659 had pulmonary metastases, and 514 with pulmonary metastases had no prior or other metastatic sites. Pulmonary resections were done in 76 patients, and in this group, the projected 5-year survival rate was 36%, mean survival was 8 months, and 30-day mortality rate was 3%.*

Warner AE. Pulmonary intravascular macrophages. Role in acute lung injury. *Clin Chest Med* 196:17:125–135. *This publication considers a potential pathogenetic role for pulmonary intravascular phagocytosis in certain disease states, for instance, biliary cirrhosis, in which pulmonary phagocytes may develop in the pulmonary capillaries, placing the lungs at risk for pathogen localization and subsequent inflammation and respiratory distress.*

CHAPTER

59 Endocrine and Metabolic Diseases

Udaya B.S. Prakash

U.B.S. Prakash: Pulmonary and Critical Care Medicine, Mayo Medical School and Mayo Medical Center, Rochester, Minnesota 55905.

INTRODUCTION

The lung, under certain conditions, may secrete or release various humoral substances that can produce specific endocrine syndromes or otherwise influence the functions of many organ systems. Ectopic endocrine syndromes, most often occurring with pulmonary malignancies, are the best known and most dramatic. It is not commonly recognized in clinical practice that the respiratory system can be involved in many of the endocrinologic diseases. In addition to the well-known respiratory compensatory mechanisms in metabolic acidosis and alkalosis, the pulmonary system may become involved in both common and uncommon metabolic disorders. This chapter deals with the pulmonary problems resulting from or associated with various endocrine and metabolic diseases. Pulmonary effects of the reproductive organs are discussed in Chapter 63.

PITUITARY DISORDERS

Pneumomegaly

The lungs are involved in the general visceromegaly of acromegaly, and, if an excess of growth hormone is present in adult life, the lungs are capable of additional growth. Total lung capacity in acromegaly is significantly increased from predicted values measured by body plethysmography. In one study, large lungs, defined as those with a vital capacity greater than 120% of predicted normal, were noted in 34% of 35 patients with acromegaly. Studies of pulmonary function in ten male patients with acromegaly and one male pituitary giant revealed tremendous increases in all lung volumes. There was no evidence of airflow obstruction or air trapping; lung compliance was increased, but lung elastic recoil was normal. Despite the large lung volumes, diffusing capacity of lung for carbon monoxide (D_LCO) was normal. However, others have reported D_LCO greater than 120% of normal in 22% of patients with acromegaly. Further, physiological studies in acromegalic patients indicate that lung growth is achieved by an increased alveolar number rather than size. There is disagreement among reports as to whether abnormal lung growth occurs in women with acromegaly. In children with hypopituitarism, the mechanical properties of the lung are consistent with the height-related rather than age-related variations.

Airways Obstruction

Extrathoracic airway narrowing has been noted in acromegalic patients. Even though the pulmonary function tests are normal in most, reduced airflow as a result of upper airway involvement has been noted in 50% of patients. Pulmonary function testing and roentgenographic assessment of the larynx and trachea in a group of 26 acromegalic patients demonstrated upper airway obstruction in 23%, whereas laryngeal tomography revealed marked narrowing of the true and false vocal cords in 54%.

The cause of the airway obstruction in acromegaly is believed to be related to osseous and soft-tissue changes surrounding the upper airway, which lead to narrowing and subsequent collapse during sleep. Macroglossia and hypertrophy of hypopharyngeal tissues, regressive after surgical therapy, have also been noted. Flexible bronchoscopy in acromegalic patients has revealed collapsible upper airways at the level of the soft palate, whereas at the base of the tongue, little, if any, dynamic narrowing occurs. The clinical importance of these observations is that attention to laryngeal anatomy is important in acromegalic patients scheduled for tracheal intubation and anesthesia. Thickened laryngeal mucosa has caused stridor and progressive dyspnea in acromegalic patients.

Sleep Apnea

Obstructive sleep apnea is a recognized complication in acromegaly. In one series of 11 patients, five had obstructive sleep apnea. Contributing factors include the large tongue and thickened tissues in the upper airways of acromegalic patients. The reduced ratio of airway space to tissue mass increases the resistance to airflow. As noted above, obstruction of the airways by the enlarged tongue further exaggerates the airway narrowing. However, bronchoscopic examination in some patients with sleep apnea and acromegaly has shown that, on inspiration, the soft tissue of the posterior and lateral hypopharynx invaginates into the lateral vestibule before there is any posterior movement of the tongue; thus, enlargement of the tongue does not appear to be a primary factor in causing sleep apnea.

Central sleep apnea occurs with greater frequency in patients with acromegaly. In a study of 53 patients with acromegaly, central sleep apnea was the predominant type of apnea in 33% of patients. Biochemical evidence of increased disease activity was associated with the presence of central apnea rather than with the degree of sleep apnea. Another study of 21 patients with sleep apnea and acromegaly suggested that the central sleep apnea in acromegaly may result from defective respiratory drive caused by the elevated growth hormone level. The resolution of sleep apnea after treatment of acromegaly indicates that it may indeed resolve after a normal level of growth hormone is restored. The hypercapnic ventilatory response remains normal and unaffected by the level of growth hormone.

The results of a case-control study of 11 patients with treated acromegaly who underwent nocturnal sleep studies, cephalometry, and endocrinologic studies revealed that nocturnal breathing abnormalities were present in ten acromegalic patients. The predominant breathing abnormality was periodic breathing with symmetrically waxing and waning respiratory effort without a major body movement component. Treated acromegaly was the most powerful predictor of breathing abnormalities, independent of the other significant predictors, age, and body mass index.

Cardiopulmonary complications are responsible for significant mortality in acromegalic patients. In one series of 194 patients with acromegaly, there were 55 deaths,

and nearly half of these were from cardiopulmonary complications.

Results of the clinical investigations suggest that acromegalic patients with sleep apnea should be treated for their pituitary tumor to reduce growth hormone before consideration of surgery to enlarge or bypass the upper airway. In a report on seven patients with both sleep apnea and acromegaly, four were treated by transsphenoidal hypophysectomy alone with a resolution of sleep apnea syndrome. One underwent hypophysectomy followed by postoperative radiation therapy, which reduced his apnea, and surgery was unsuccessful in three patients.

Octreotide, a somatostatin analog, has been shown to improve indices of sleep apnea severity in patients with acromegaly-induced sleep apnea.

THYROID DISORDERS

Goiter

Respiratory symptoms can result from both extrathoracic and intrathoracic goiters (Table 1). Intrathoracic goiter may be defined as any thyroid enlargement that has its greater mass inferior to the thoracic inlet. Although extension of goiter into the thorax is seen in only 1% to 3% of thyroidectomy patients, thyroid masses constitute a considerable percentage of anterior mediastinal tumors. In most of these, there is a direct connection between the retrosternal mass and a palpable thyroid gland in the neck. The masses usually consist of nodular colloid goiters, and thyrotoxicosis occurs in some cases. Malignant changes are extremely uncommon even though a rare case of tracheal invasion by a papillary carcinoma in an intrathoracic goiter has been reported. The intrathoracic location of the goiter does not alone predispose it to undergo malignant changes. Up to 80% of the intrathoracic goiters arise from the isthmus or lower pole and extend into the anterior mediastinum in front of the trachea. The rest arise from the posterior aspect of the thyroid gland and extend into the posterior mediastinum, behind the trachea, and almost always on the right.

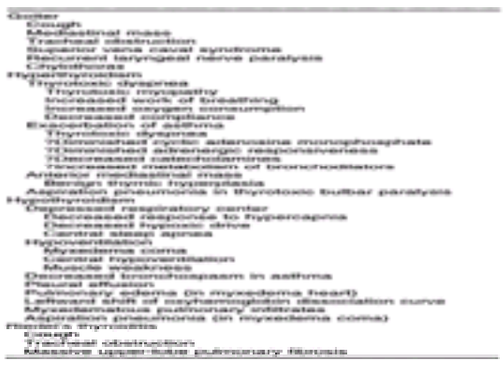

TABLE 1. *Pulmonary complications in thyroid diseases*

Of a total of 2908 goiters operated on over a 17-year period, 22 patients had severe or acute dyspnea, and four of them required immediate tracheal intubation. Chronic dyspnea without cyanosis was noted in 36 patients. In a study of 91 patients who underwent thyroidectomy, 29 had marked thyroid enlargement; 13 were unilateral (mean weight 122 g), and 16 were bilateral (mean weight 160 g). Of the 25 patients with symptoms of airway compression, 18 exhibited tracheal narrowing and/or displacement, 19 had substernal extension, and one had superior vena cava syndrome. Histologic analysis showed nodular goiter (11), adenoma (five), carcinoma (three), Graves' disease (five), and toxic multinodular goiter (five).

Most patients with intrathoracic goiters are women, and, in many, a previous history of thyroid surgery is present. From 50% to 96% of such patients have symptoms. The most common symptoms associated with intrathoracic goiters are dyspnea, stridor, dysphagia, hoarseness, coughing, wheezing, and cervical mass. A small percentage of intrathoracic goiters produce stridor and respiratory embarrassment. In a study of 273 patients with benign goiters, 33% had signs of tracheal compression, mostly from colloid goiters. Another study of 132 patients used flow–volume loops to evaluate upper airways and reported upper airway obstruction in 31% of those with goiters. The incidence of tracheoesophageal compression was higher (67%) in those with thyroiditis. Acute or subacute tracheal obstruction necessitated tracheostomy in 3% of these. Severe expiratory flow obstruction requiring surgical removal of goiter has been described. Acute life-threatening tracheal obstruction has been noted in patients with intrathoracic goiter. Histologic studies have shown that the acute problem is very likely related to the multiple foci of hemorrhage in the goiter.

Goiters may present with superior vena caval obstruction. Among 32 patients with superior vena caval syndrome, four had thyroid goiters. Recurrent laryngeal nerve paralysis is uncommon in benign goiters, having been discovered in fewer than 1% of 3279 goiters. A retrosternal goiter can compress the thoracic duct and brachiocephalic vessels and cause chylothorax. Intrathoracic goiter with hyperthyroidism, tracheal compression, superior vena cava syndrome, and Horner's syndrome has been described.

In the evaluation of chronic cough, thyroid disease usually is ignored as a cause. The close proximity of the thyroid gland to the laryngotracheal structures is occasionally responsible for distressing chronic cough. The cough usually disappears after the goiter is removed. Thyroiditis also may present with chronic cough.

Chest roentgenograms reveal a sharply defined, lobulated or smooth mass of homogeneous density displacing the trachea posteriorly and laterally if the goiter is located in the anterior mediastinum (Fig. 1). Calcification is very common (Fig. 2). The majority of intrathoracic goiters produce no symptoms and are discovered incidentally on a routine chest roentgenogram. A small percentage of patients have symptoms: inspiratory and expiratory stridor, hoarseness, and, rarely, respiratory distress. Radioisotopic studies (^{131}I thyroid scans) are diagnostic when positive, but these goiters are rarely, if ever, functioning. To evaluate the degree of tracheal obstruction caused by thyroid goiter or masses, flow–volume loops may be superior to conventional roentgenologic methods. Cine-CT and bronchoscopy provide dynamic assessment of the airway during all phases of respiration.

FIG. 1. Intrathoracic extension of thyroid goiter.

FIG. 2. Close-up view of upper middle chest demonstrating calcification within the intrathoracic goiter.

A retrospective study of 2908 goiters operated on over a 17-year period observed that the long-standing goiter did not preclude the possibility of compressive respiratory distress. Therefore, preventive removal of all large or substernal goiters should be considered. Thyroidectomy is the treatment of choice in patients with thyroid enlargement complicated by compression or displacement of the trachea. In patients who are inoperable, a bronchoscopically inserted tracheal prosthesis (stent) may provide airway patency.

Hyperthyroidism

Dyspnea at rest (thyrotoxic dyspnea) is a common symptom in patients with thyrotoxicosis. Proximal myopathy appears to play a major role because weakness of skeletal muscles has been reported in as many as 82% of thyrotoxic patients, and electromyographic evidence of myopathy is present in 93%. Significant decreases in both inspiratory and expiratory maximal pressures have been demonstrated. Reduced vital capacity and decreased compliance also may occur; however, the diffusing capacity of the lung for carbon monoxide is normal. Respiratory muscle strength is proportional to the degree of thyroid dysfunction, and the thyrotoxic myopathy is reversible with medical treatment. Thyrotoxic patients have higher ventilation than normal subjects during exercise. The increased ventilation is secondary to enhanced central drive, which is correlated to circulating thyroid hormone level, and this abnormal drive can be normalized by b-blockade. These findings suggest that the inappropriately increased ventilatory drive may be the result of enhanced adrenergic stimulation.

Dyspnea in thyrotoxic patients is also caused by decreased compliance, increased dead-space ventilation, and increased work of breathing. These are further aggravated by the greater oxygen requirement of the hypermetabolic body tissues. A study of 12 patients during hyperthyroid and euthyroid states indicated that the exercise intolerance in hyperthyroidism, despite elevated resting cardiac output, is the result of diminished work efficiency of skeletal muscles.

Hyperthyroidism occasionally may cause benign thymic hyperplasia. In most instances, the thymic enlargement is minimal and remains unnoticed. On rare occasions, thymic hyperplasia may present as an anterior mediastinal mass. The thymic enlargement associated with hyperthyroidism occasionally may produce dyspnea from extrinsic compression of the trachea, but usually the thymic hyperplasia is detected on computed tomographic scans performed for other reasons. Treatment of hyperthyroidism is followed promptly by regression of thymic hyperplasia. Bulbar palsy is a known complication of thyrotoxicosis; aspiration pneumonia and respiratory failure have been described in this setting.

Hypothyroidism

Hypothyroidism is associated with several respiratory problems because of a combination of factors, including hypoactive respiratory center, disturbed neuronal and neuromuscular transmission (hypothyroid neuropathy), respiratory muscle weakness, and changes in pulmonary alveolar capillary membranes.

Hypoventilation

Alveolar hypoventilation occurs in myxedema, and nearly 10% of patients with myxedema demonstrate diminished hypoxic drive. Myxedematous patients exhibit normal minute ventilation and oxygen and carbon dioxide tension in arterial blood. However, they demonstrate a decreased response to breathing higher concentrations of carbon dioxide. The hypoventilation is related to the depressed hypoxic ventilatory drive. This abnormal hypoventilatory response resolves with thyroid replacement therapy. A less-known mechanism is the myopathy that occurs in 30% to 40% of all hypothyroid patients. Dysfunction of diaphragm, in addition to weakness of other inspiratory and expiratory muscles, also occurs in these patients. Indeed, hypothyroidism can present as dyspnea secondary to phrenic neuropathy, which is reversible with therapy of hypothyroidism. Diminished muscle strength, as indicated by diminished maximum voluntary ventilation, has been observed in patients with hypothyroidism. Rapid resolution of hypercapnia with thyroid replacement despite persistent muscle weakness in some patients suggests that thyroid hormone deficiency is hierarchically more important than myopathy. It is also documented that the significantly diminished inspiratory and expiratory maximal strengths return to normal with thyroid replacement therapy. Prolonged hypothyroidism with gradual onset of respiratory failure and predominant hypercapnia has been described. Myxedema coma occurs usually in elderly, obese women; hypoventilation appears to be responsible for the coma in a third of the patients.

Sleep Apnea

Obstructive sleep apnea and oxygen desaturation are important complications in patients with hypothyroidism. However, in a study of 65 patients with documented obstructive sleep apnea, only two (3%) had hypothyroidism, and, among 20 patients with hypothyroidism, two showed moderate to severe obstructive sleep apnea. All hypothyroid patients in this study were snorers. Whereas obstructive sleep apnea without hypothyroidism is more common in men, obstructive sleep apnea associated with hypothyroidism is more common in women. Hypothyroidism can produce obstructive sleep apnea from the macroglossia and narrowing of the upper airways secondary to submucosal deposition of mucopolysaccharides and protein extravasation.

Central sleep apnea results from abnormalities in ventilatory control. Episodes of sleep apnea occur more frequently in hypothyroid patients who are obese than in the nonobese. The impaired respiratory drive is corrected by thyroid hormone replacement therapy. Thyroxine replacement therapy decreases apnea frequency, even without a change in body weight. Increases in the loaded respiratory effort and ventilation during thyroxine therapy have been demonstrated. Restoration of euthyroid status usually results in complete resolution of obstructive sleep apnea.

Pleural Effusion

Myxedema is an uncommon cause of pleural effusion, and the incidence of this complication in hypothyroidism is unknown. A review of the literature in 1983 revealed 13 cases, of which 11 were in women whose mean age was 52 years. The pleural effusions frequently were associated with ascites. Congestive heart failure also was noted in many patients. Usually, myxedematous patients with pleural effusion have a concomitant pericardial effusion. The pleural effusion associated with pericardial effusion is a transudate (Fig. 3). A report in 1990 reviewed the record of 60 patients with hypothyroidism and noted pleural effusion in 15 (25%), but the effusions in the majority of patients were caused by other diseases or hypothyroidism-related nonpulmonary complications. When this study was combined with another group of 13 for a total of 28 patients with pleural effusions associated with hypothyroidism, the study in 1990 found that only five patients (18%) had pleural effusions that could be ascribed to hypothyroidism; pleural fluid protein levels in four patients varied from 1.1 to 3.2 g/dl. Usually, effusions are evident only on roentgenographic examination, but rarely is one sufficiently large to cause symptoms. The observation that the pleural effusion disappears after treatment of myxedema supports an etiologic relationship with myxedema. Increased pulmonary or pleural capillary permeability may play a role in the collection of fluid in the pleural space.

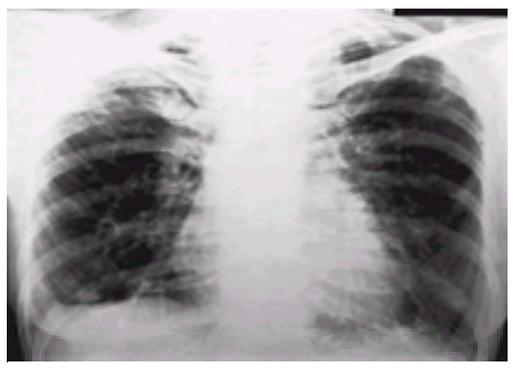

FIG. 3. Right-sided pleural effusion and pulmonary edema in a patient with severe myxedema. These findings resolved with thyroid replacement therapy.

Other Complications

A decrease in vital capacity in the absence of heart failure also has been noted in myxedema. Hypothyroidism is a good example of the leftward shift of the oxyhemoglobin dissociation curve; hence, the tissue supply of oxygen is worse than is indicated by hypoxemia alone. Soft, patchy, nodular infiltrates (myxedematous lesions) are reported to occur in myxedema. Roentgenographic clearing of these infiltrates has been reported following replacement therapy with thyroid hormone. The pathogenesis of these lesions is unknown, but studies have shown that thyroidectomized rats develop atelectasis related to decreased surfactant, and thyroxine therapy stimulates surfactant synthesis. Thyroxine is reported to promote lung maturation in fetal rabbit lungs.

Coexistence of autoimmune hypothyroidism with pulmonary hemosiderosis has been described in a patient. Pulmonary hemosiderosis has also been described in four patients with thyrotoxicosis.

Asthma and the Thyroid Gland

The relationship between thyroid function and bronchial asthma has very interesting clinical implications. However, the coexistence of asthma and thyroid diseases has been reported only sporadically. A retrospective cohort mortality study of 3696 women treated for thyrotoxicosis showed that asthma was the underlying cause of death in seven patients, compared with 2.6 expected deaths in the normal population. Another retrospective study of 1107 patients found only 12 with coexistent hypothyroidism and asthma. Treatment of hypothyroidism in three of these patients led to the worsening of their asthma. A similar experience has been described following administration of triiodothyronine for hypothyroidism. In contrast, some patients with coexistent intractable asthma and hyperthyroidism have exhibited prompt and striking improvement in asthma when their hyperthyroidism was treated. In a study, however, thyrotoxicosis that was induced by administering triiodothyronine (T_3) to subjects with mild asthma had no effect on lung function, airway responsiveness, or exercise capacity. One proposed mechanism for the worsening asthma in hyper-thyroidism is increased airways reactivity. Reduced b-adrenergic responsiveness and reduced b receptors (down-regulation of b receptors) in asthma may contribute to the worsening of bronchospasm. However, the positive therapeutic response to treatment of hyperthyroidism in asthmatic patients is not always uniform.

Nonasthmatic hyperthyroid patients exhibit an entirely opposite airway response. There appears to be an inverse relationship between the level of thyroid function and the b-adrenergic receptor responsiveness. Acute hypothyroidism has been reported to increase nonspecific bronchial reactivity in nonasthmatic subjects. However, a report on 11 hyperthyroid nonasthmatic patients concluded that hyperthyroidism actually reduced the severity of carbachol-induced changes in airways reactivity as measured by airway specific conductance (sG_{aw}).

It should be recognized that patients with hyperthyroidism may not demonstrate the therapeutic benefits of bronchodilator therapy. This is because of the accelerated metabolism of bronchodilators. b-Adrenergic blocking drugs such as propranolol used to treat thyrotoxicosis may exacerbate asthma. An asthmatic who develops hyperthyroidism should be closely monitored for deterioration of asthma. Similarly, even slow and cautious restoration of the euthyroid state in hypothyroid patients may lead to increasing problems with asthma.

Iodide-induced thyrotoxicosis is occasionally encountered after long-term administration of iodine or iodide-containing compounds to patients with preexisting thyroid disorders, particularly goiter. Interestingly, the saturated solution of potassium iodide (SSKI) was used in the past as an expectorant in asthmatic patients. Its use, in some patients, resulted in hyperthyroidism, which in turn aggravated the asthmatic condition. Currently, many clinicians use iodinated glycerol (Organidin) as a mucolytic agent in the treatment of chronic obstructive pulmonary disease; thyrotoxicosis induced by iodinated glycerol has been described.

Riedel's Thyroiditis

Riedel's thyroiditis is a rare disease characterized by extensive dense fibrosis of the thyroid gland, often extending into the strap muscles and adjacent structures in the neck. The condition is rare, 20 cases being discovered among 42,000 patients seen at a tertiary center. Respiratory symptoms result from tracheal compression. Massive fibrotic process has been described in both upper lobes of the lungs. Severe upper airway obstruction has been described in a patient with Hashimoto's thyroiditis. Lymphocytic interstitial pneumonitis has been described in four patients with autoimmune thyroiditis. The association of idiopathic pulmonary hemosiderosis and autoimmune thyroiditis has been noted.

Thyroid Cancer

Pulmonary involvement in thyroid carcinoma may be related to direct or contiguous spread with intraluminal extension into the airway, extrinsic compression of the trachea, or metastatic nodules in the lungs. The latter can be solitary or multiple. Tracheal obstruction can be life-threatening and require immediate bronchoscopically guided stent therapy or tracheostomy. Paralysis of the recurrent laryngeal nerve will increase the risk of aspiration pneumonia.

Pulmonary metastases are not uncommon in children and young adults with differentiated thyroid cancer. Metastases in the lungs may be overlooked unless near-total thyroidectomy is followed by total-body radioiodine scan in these patients. In a study of 209 patients younger than 25 years of age who were treated for thyroid cancer, 19 (9%) had pulmonary metastases at presentation, and all 19 had regional lymphadenopathy at the time of diagnosis. This study observed that the lung metastases almost always concentrate radioiodine diffusely and may be associated with a normal chest roentgenograph in almost half of the patients. Nevertheless, it is important to note that radioiodine uptake in the lung could also represent an uptake by unrelated pulmonary disease or by the breasts, or external contamination.

PARATHYROID DISORDERS

Parathyroid tumors rarely present as anterior mediastinal masses. They usually are small and encapsulated growths in the upper mediastinum. They may become large enough to widen the mediastinum, usually unilaterally. Mediastinal parathyroid tissue is identified in approximately 11% of patients who undergo surgical exploration and resection as therapy for primary hyperparathyroidism. In a study of 573 patients who underwent surgical exploration for therapy of hypercalcemia, mediastinal parathyroid glands numbered 68, of which 55 (81%) were enlarged, and 13 were of normal size. Preoperative levels of serum calcium have been observed to be higher in patients with mediastinal parathyroid tissue than in patients with hyperactive parathyroid glands in the neck. In patients who are suspected to have primary hyperparathyroidism, approximately 60% of the mediastinal glands are found on first exploration of the neck, and the rest (35%) usually require more than one surgical exploratory procedure for the detection and resection of the parathyroid tissue.

Ectopic parathyroid glands in the thoracic cavity have been detected with great accuracy with the use of sestamibi scintigraphy, whereas single-photon-emission CT (SPECT) has been helpful in distinguishing the adenomas located in the aortopulmonary recess from more common adenomas in the anterior mediastinum. Both CT and MR imaging studies also can enable this distinction.

Because most of these tumors are functioning, patients present with clinical hyperparathyroidism, which, along with hypercalcemic crises, has been reported to produce pulmonary edema. This, however, is uncommon. Hypercalcemic states also produce metastatic calcification or calcinosis (or calciphylaxis) of visceral organs. In the lungs, calcium deposits are found in bronchi, alveoli, and venous channels. A review of more than 7000 autopsies disclosed 13 cases of metastatic pulmonary calcification, and chronic renal disease and parathyroid abnormalities accounted for seven of them; the remainder were associated with malignancies. Roentgenograms in patients with metastatic pulmonary calcification reveal calcification of the bronchi and an amorphous, diffuse, and finely dispersed calcification of the lungs radiating from the hilar regions. Although primary hyperparathyroidism, malignancies, and chronic renal failure are the more common causes of the hypercalcemic state, metastatic lung calcification is seen also in recipients of renal and liver transplants and in those with hypervitaminosis D, sarcoidosis, and milk alkali syndrome as well as following intravenous calcium infusion.

In a study of 49 patients with persistent primary hyperparathyroidism caused by mediastinal parathyroid adenoma, angiographic ablation by injections of large doses of contrast material into the feeding artery was successful in long-term control of persistent primary hyperparathyroidism in 17 of 27 patients (63%); the unsuccessful cases were treated by surgical resection by median sternotomy.

Parathyroid carcinoma produces nodular metastasis in the lungs. Resection of pulmonary metastases in six patients with such lesions demonstrated that postoperative serum calcium level returned to normal after each thoracotomy in three patients who were alive and well 3, 8, and 12 years after the first thoracotomy, but the hypercalcemia persisted in the other three patients.

ADRENAL DISORDERS AND CORTICOSTEROIDS

Cushing's syndrome and long-term corticosteroid therapy can result in abnormal accumulation of fat in the upper mediastinum (mediastinal lipomatosis) and both pleuropericardial angles. Roentgenograms reveal a smooth, symmetric widening of the upper mediastinum (Fig. 4A) extending from the thoracic inlet to both hilar areas. Computed tomography (Fig. 4B) is diagnostic because of its ability to demonstrate the lipid density in the mediastinum.

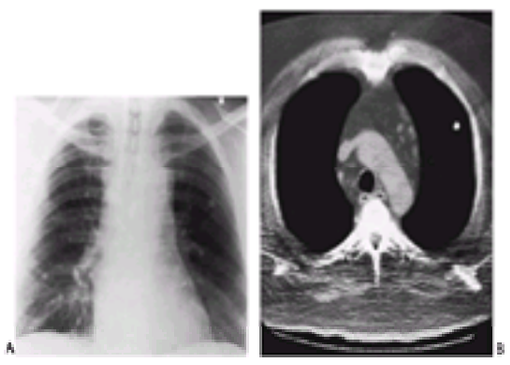

FIG. 4. (A) Cushing's syndrome with mediastinal widening. **(B)** Computed tomography in mediastinal lipomatosis reveals typical lipid density in the anterior mediastinum.

Cushing's syndrome can be the initial clinical presentation in patients with bronchial carcinoid tumors. In a study of 15 consecutive patients with Cushing's syndrome, all of whom were subsequently found to have bronchial carcinoid tumors, biochemical studies showed marked elevations of circulating corticotropin with a mean serum value of 156 ± 58 pmol/liter (normal 4 to 22 pmol/liter), hypokalemia in six patients, and glucocorticoid response to either high-dose dexamethasone or metyrapone in six of 13. These carcinoid tumors were frequently radiographically occult, with ten of 15 patients initially having normal chest roentgenographs. Computed tomography was successful in locating the lesions. Surgery resulted in complete remission in ten patients and partial remission in two; three patients continued to have symptomatic glucocorticoid excess caused by metastatic disease.

Long-term corticosteroid therapy suppresses some of the immune defense mechanisms of the body and predisposes the host to a number of unusual and opportunistic infections. Tuberculosis occurs with greater frequency in patients receiving long-term corticosteroid therapy. *Pneumocystis carinii* pneumonia is a serious complication in patients on significant doses of corticosteroid therapy for long periods. Endogenous Cushing's syndrome has been complicated by cryptococcosis. This syndrome, secondary to a hormonally active thymic carcinoid, has been noted to exist with *Pneumocystis carinii* infection. Patients with endogenous Cushing's syndrome who develop pulmonary infiltrates should be carefully evaluated to exclude the possibility of opportunistic infections.

Aerosolized corticosteroid therapy, particularly the megadose, in asthmatic patients has been of concern not only with regard to its increasing the risk of oropharyngeal candidiasis but also its ability to suppress adrenal function. In one report, it was noted that prolonged administration of 200 µg of inhaled budesonide daily to young children with severe asthma did not impair growth or pituitary–adrenal function.

Pheochromocytoma associated with a catecholamine-induced cardiomyopathy has led to the development of recurrent bilateral and unilateral pulmonary edema; special radionuclide studies indicated that oversecreted catecholamines influenced both the heart and lungs. Acute respiratory distress syndrome (ARDS) has been observed in a patient with pheochromocytoma. A surge of catecholamines from pheochromocytoma may provoke pulmonary edema in a manner similar to that in neurogenic pulmonary edema. Hemoptysis during paroxysms of hypertension caused by pheochromocytoma, and cured by surgical resection of the tumor, has been reported.

Paragangliomas (chemodectomas) are tumors of the extraadrenal paraganglion system. The most common paragangliomas are carotid body chemodectomas, the glomus jugulare tumors, and globus tympanicum. Para-ganglioma of the mediastinum is an indolent and slow-growing tumor. A review of the world literature noted 79 cases of mediastinal paraganglioma. The tumors were locally invasive and had a high local recurrence rate (56%) with a true metastatic capacity in 27%; the overall survival was 62% with a mean survival time of 98 ± 12 months. A retrospective study of 16 cases (ten men and six women; mean age 43 years) of mediastinal paragangliomas observed that 13 tumors were located in the posterior mediastinum, and three tumors were located in the anterior mediastinum. Some, however, have reported that these neoplasms usually are located in the anterior mediastinum (Fig. 5). In the thorax, these are usually located above the aortic arch near the subclavian arteries. Female preponderance, an average age at the time of diagnosis of 49 years, and an average tumor size of 7.5 cm are reported from a review of 40 patients. Nearly 50% of these patients are asymptomatic; the reported symptoms include hoarseness, cough, dysphagia, and chest pain. Distant metastasis were noted in 23% of the 40 cases reported in 1979. Surgical resection is recommended.

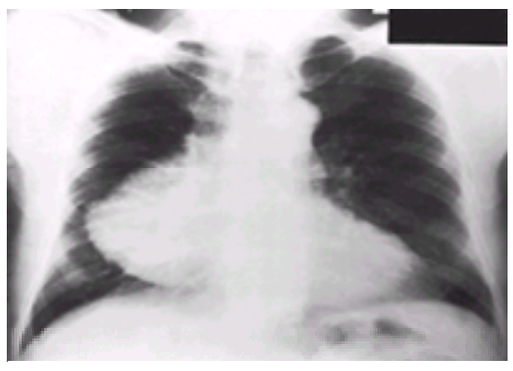

FIG. 5. Paraganglioma located in the lower anterior mediastinum.

Carney's triad is a syndrome of pulmonary chondroma, multicentric gastric epithelioid leiomyosarcoma, and extraadrenal paraganglioma. This triad has been described in over 35 patients since 1977. Several clinically important features of this unusual syndrome include the multicentricity of both the paragangliomas and the epithelioid leiomyosarcomas, the often indolent progression of metastatic leiomyosarcoma, the potential for late recurrences, and the importance of distinguishing intraadrenal from periadrenal catecholamine-producing tumors (paragangliomas). The majority of patients are women, and the average age has been 16.5 years. The most common clinical features are hematemesis and anemia as a result of the gastric lesion. Hypertension is the next most common finding. Multiple pulmonary tumors (two-thirds were uncalcified) and mediastinal widening are seen in the chest roentgenographs (Fig. 6). None of the reported patients had symptoms from the pulmonary lesions. If a new catecholamine-producing tumor is suspected, urine biochemical assays and computed tomography of the chest and abdomen are the first-choice localization procedures.

FIG. 6. Multiple pulmonary chondromas in the triad of multicentric gastric epithelioid leiomyosarcoma, functioning extraadrenal paraganglioma, and pulmonary chondroma.

The uncommon concurrence of duodenal epithelioid stromal sarcoma, pulmonary chondromatous hamartoma, and pancreatic islet cell tumor in a patient is described as a variant or an analog of Carney's triad. Gastric leiomyosarcoma and extraadrenal paraganglioma have been described in a 7-year-old child.

Adrenal carcinoma is rare. A review of the records of 24 patients with adrenal cortical carcinoma and pulmonary metastases over a 14-year period revealed that ten patients underwent pulmonary resection. The 5-year survival of seven patients in the surgical group was significantly longer than those not resected, with no one having survived for more than 3 years (median survival 11 months).

METABOLIC DISORDERS

Diabetes Mellitus

Diabetes mellitus is a common disease that often is complicated by the involvement of other “target” organs such as the eye, kidney, and peripheral nervous system. Based on the pathophysiological abnormalities observed in various studies, the lung also has been considered a “target” organ. The pulmonary pathologic changes such as thickened alveolar epithelial and pulmonary capillary basal laminae are considered to be secondary to pulmonary microangiopathy, akin to the diabetic vasculopathy encountered in retinal, renal, and other systemic vasculatures. Pulmonary complications may manifest clinically in different ways. Table 2 lists the reported complications in diabetes mellitus.

Reduced elastic lung recoil
Reduced diffusing capacity for carbon monoxide
Viral and bacterial infections
Tuberculosis
Mucormycosis
Pneumomediastinum
Pneumothorax
Acute pleuritic pain (in ketoacidosis)
Pulmonary fibrosis
Pulmonary edema (in ketoacidosis)
Mucous plugging of major airways (in ketoacidosis)
Central hypoventilation (in autonomic neuropathy)
Sleep apnea (with autonomic neuropathy)
Aspiration pneumonia (in diabetic gastroparesis)
Pulmonary xanthogranulomatosis
Respiratory alkalosis (in ketoacidosis)
Increased endogenous production of carbon dioxide

TABLE 2. *Pulmonary complications in diabetes mellitus*

Pulmonary Infections

Diabetes mellitus is often identified as an independent risk factor for developing lower respiratory tract infections. Carrier rates for aerobic gram-negative rods in pharyngeal secretions have been found to be higher for diabetics and alcoholics. Bacterial pneumonias are by far the most common type of respiratory infections. The causative agents include gram-negative organisms (*Escherichia coli, Klebsiella pneumoniae*) and gram-positive bacteria (*Staphylococcus aureus*). Infections caused by *Streptococcus pneumoniae, Legionella,* and influenza may be associated with increased morbidity and mortality. Nonbacterial lung infections (mycobacteria and *Mucor*) occur with an increased frequency.

Diabetics are particularly prone to develop tuberculosis, frequently to an advanced stage. Among 106 patients in whom both diseases occurred, the diabetes came first in 48, the tuberculosis was first in 40, and the two were diagnosed simultaneously in 18. The increased incidence of tuberculosis in patients with diabetes mellitus is paralleled by the incidence of diabetes in those with tuberculosis. Tuberculous infection of lungs in diabetics may present with infiltrates in any lobe (Fig. 7) rather than the traditional posterior-apical segments of upper lobes. A study of 20 patients with both pulmonary tuberculosis and diabetes mellitus showed lower-lobe involvement in 10% of patients.

FIG. 7. Localized lesion secondary to *Mycobacterium tuberculosis* in a young patient with type I diabetes mellitus. The pulmonary lesion is located in the superior segment of the left lower lobe.

Diabetics also have been found to be more susceptible to mucormycosis. This is particularly true of patients with poorly controlled diabetes mellitus who have multiple complications (Fig. 8). In a literature review of 255 patients with pulmonary mucormycosis, diabetes mellitus was noted in 32%. Other associated medical conditions included leukemia or lymphoma, chronic renal failure, history of organ transplantation, or a known solid tumor. The overall mortality was 80%; the most common causes of death were fungal sepsis (42%), respiratory insufficiency (27%), and hemoptysis (13%).

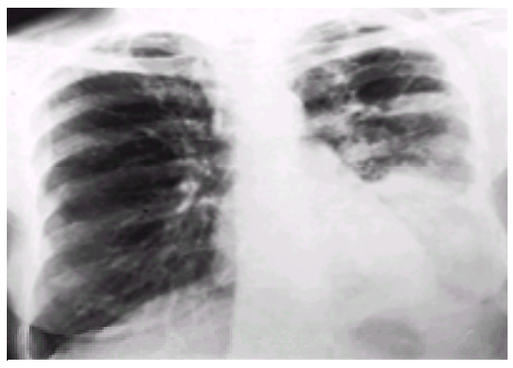

FIG. 8. Pneumonia of left lower lobe secondary to *Mucor* species in a patient with poorly controlled diabetes mellitus.

Diabetics with pulmonary mucormycosis have a striking tendency to develop lesions in major airways. Because of the propensity of the *Mucor* species to invade vascular structures, pulmonary infarction or massive hemoptysis can occur. Diagnostic features of major airways involvement include hoarseness, gross hemoptysis, or mediastinal widening on chest roentgenograms. Sudden, massive hemoptysis is a common fatal complication of endobronchial mucormycosis. The more usual roentgenographic findings of pulmonary zygomycosis represent a spectrum that comprises a normal chest roentgenograph, a lung abscess, subacute or chronic pneumonia that often evolves into a lung abscess, and rapidly progressive fatal pneumonia.

Pulmonary Dysfunction

Pulmonary dysfunction in diabetics is reported to be related to the severity of diabetes mellitus. A study of 284 diabetics reported that, on average, forced vital capacity (FVC) and FEV_1 were reduced by 334 ml and 239 ml, respectively, in insulin-treated diabetics and by 184 ml and 117 ml, respectively, in diabetics treated with oral hypoglycemic agents. An earlier study of 31,691 patients with diabetes mellitus observed pulmonary emphysema in 4.2%, asthma in 0.9%, and pulmonary fibrosis in 0.8%. Although the incidence of asthma and emphysema among diabetics was the same as in the total hospital population, the incidence of fibrosis was reported to be moderately elevated. Pulmonary function tests of 36 patients with insulin-dependent diabetes mellitus were compared with those of 40 nondiabetic controls, and the inspiratory vital capacity in the former group was found to be significantly reduced. The authors concluded that this abnormality may have been caused partly by the reduced capacity of the inspiratory muscles.

The significant lung function abnormalities have included reduced lung volumes in young (aged less than 25 years) insulin-dependent diabetic subjects, reduced pulmonary elastic recoil in both young and adult (aged greater than 25 years) diabetic subjects, and impaired diffusion caused by a reduced pulmonary capillary blood volume in the adult group. Nonenzymatic glycosylation-induced alteration of lung connective tissue is reported to be the most likely pathogenetic mechanism underlying mechanical pulmonary dysfunction in diabetic subjects, and the most tenable explanation for impaired diffusion is the pulmonary microangiopathy. Diminished total lung capacity in insulin-dependent diabetics has been ascribed to limited expansion of the ribs. The clearance of inhaled ^{99m}Tc-diethyltriaminepentaacetic acid (DTPA) aerosol from the lungs has been used to show that diabetic patients, particularly those with other diabetic complications, develop decreased epithelial permeability, which leads to pulmonary dysfunction. Other studies, however, have shown that insulin-dependent diabetes mellitus does not affect pulmonary function.

Physiological studies in juvenile diabetics have shown that the elastic lung recoil is significantly less than in normal individuals, and total lung capacity also is diminished. It is postulated that the disordered lung mechanics are manifestations of elastin and collagen abnormalities. In a study involving 40 adult insulin-dependent diabetics, all lifelong nonsmokers without evidence of lung disease and compared to a matched group of healthy controls, detailed pulmonary function tests demonstrated that the diabetics had mild abnormalities of lung elastic recoil and D_LCO as well as a reduction in pulmonary capillary blood volume. The degree of lung dysfunction was related directly to the duration of insulin-dependent diabetes mellitus.

Histopathologic studies of streptozotocin-induced diabetes in rats have shown ultrastructural alterations in the granular pneumocytes in the alveolar septum, nonciliated bronchiolar epithelial (Clara) cells, and collagen and elastin in the alveolar wall. Postmortem studies of diabetics also have documented thickening of epithelial and capillary basal laminae of alveoli, centrilobular emphysema, and diabetic microangiopathy in the capillaries of alveolar septa and the alveolar and pleural arterioles.

Diabetics with autonomic neuropathy have a higher threshold for the cough response to nebulized citric acid, thereby suggesting that vagal innervation of the bronchial tree is damaged by diabetic autonomic neuropathy. This is further supported by the observation that bronchoconstrictive response to cold air and methacholine is impaired in patients with diabetic autonomic neuropathy. Further studies in patients with diabetic autonomic neuropathy have demonstrated reduction in parasympathetic bronchomotor tone, resulting in increased basal airway caliber. Even though diaphragmatic dysfunction is reported to be common in type 1 diabetes, the impaired diaphragm function is not caused by phrenic neuropathy.

Physiological studies in insulin-dependent diabetic patients (type I diabetes) have shown that the endogenous opioid system does not respond to stress caused by breathing against fatiguing inspiratory resistive loads. Further, whereas resistive-loaded breathing caused a further increase in plasma b-endorphin concentration in the control group, absolutely no increase was found in the diabetic patients.

What are the clinical implications of these observations? Clinical experience suggests that the pulmonary parenchymal defects and pulmonary dysfunctions in insulin-dependent diabetics are insufficient to cause significant respiratory embarrassment in the vast majority of patients with diabetes mellitus. Despite the overwhelming information published in the medical literature on the subject, as is evident from the discussions here, clinically significant lung disease solely on the basis of diabetes-mellitus-induced pulmonary dysfunction is seldom encountered in clinical practice. Despite the extensive studies on pulmonary dysfunction in patients with diabetes mellitus, routine pulmonary function testing is not indicated in the absence of pulmonary symptoms or a history of smoking.

Pulmonary Edema

Pulmonary edema has been associated with diabetic ketoacidosis. It has been suggested that altered pulmonary capillary permeability is the cause of the extravascular leakage of fluids. The patient with diabetic ketoacidosis usually is administered large quantities of intravenous crystalloids over a short period. These solutions elevate the hydrostatic pressure and diminish oncotic pressure, thereby facilitating the development of pulmonary edema. Pulmonary vascular diabetic angiopathy may predispose some diabetics to pulmonary edema. Additionally, endogenous fluid shifts due to severe hyperglycemia may contribute to pulmonary edema. Recurrent episodes of acute alveolar and interstitial pulmonary edema have been noted on chest roentgenograms in anephric diabetics during periods of severe hyperglycemia. Clinical and chest roentgenographic resolution occurs immediately after insulin therapy and restoration of normoglycemia.

Disordered Sleep

Sleep-related breathing abnormalities occur with greater frequency in diabetic patients with autonomic neuropathy. The ventilatory and heart rate response to hypoxia are impaired in diabetics, whereas the ventilatory response to hypercapnia is well preserved. Although a diminished hypercapnic ventilatory response to progesterone therapy is described in a patient with diabetic autonomic neuropathy, detailed studies of the effect of this neuropathy on the respiratory system have shown that there is no difference in the ventilatory responses to hypoxemia and hypercapnia in patients with and without autonomic neuropathy. Diabetic microangiopathy of muscles, resulting in a myopathic process and muscle weakness and central hypoventilation, may cause hypercapnia and respiratory failure. Another explanation for the diminished ventilatory response to hypoxia is that medullary depression of ventilation by hypoxia is reported to be greater in diabetic patients than in control subjects. Others have reported normal breathing patterns in diabetics with severe autonomic neuropathy. A relationship has been shown between neuropathy and sleep-related breathing abnormalities in type I insulin-dependent diabetics.

Other Complications

Oxygen tension in arterial blood is usually high in patients with diabetic ketoacidosis. This is because of hyperventilation secondary to acidosis and the increased glucose load. Additionally, the production of endogenous carbon dioxide from the metabolic acidosis causes a higher respiratory quotient and thus a higher-than-expected increase in oxygen tension in arterial blood. Rarely, hypokalemic hypoventilation may complicate severe diabetic ketoacidosis.

Pleural effusion is reported to occur more commonly in diabetic patients, particularly in those with left ventricular failure. In a study of 40 patients with similar degrees of left ventricular dysfunction, pleural effusions were more common in diabetic patients, and, indeed, four of five diabetic patients who had persistent pleural effusions had no evidence of either cardiomegaly or congestive cardiac failure. Although several mechanisms, including those discussed above, were postulated to be responsible,

the exact mechanism remains unclear.

Pneumomediastinum has been reported in several cases of diabetic ketoacidosis. The cause remains obscure, although ketoacidosis is believed to change the pressure gradient within the lungs by the hyperpnea induced by acidosis, by severe vomiting, or by a combination of both. The prognosis is excellent, and the pneumomediastinum regresses promptly after correction of the ketoacidosis.

Mucous plugging of major airways has been described as a specific complication of diabetic ketoacidosis. Lethargy, altered vagal tone, and autonomic neuropathy are proposed as contributing factors responsible for occult mucous plugging. Reduced airway vagal tone and diminished cold responsiveness have been shown in nonsmoking, nonasthmatic diabetic patients with autonomic neuropathy.

Aspiration pneumonia secondary to recurrent vomiting caused by unsuspected gastroparesis has been observed in diabetic patients. This is of greater importance during anesthetic procedures.

Xanthogranulomatosis has been demonstrated in the perivascular spaces in lungs in 6% of diabetic patients (versus 2% in nondiabetics), but the effect of this abnormality on pulmonary function is unknown.

Acute pulmonary edema was observed in patients in whom hypoglycemic coma was induced as therapy (insulin shock therapy) for schizophrenia in the 1930s. In one series of seven patients treated with insulin shock, acute pulmonary edema ranked second to irreversible coma as the cause of death. Most of the patients were otherwise healthy and were younger than 35 years. Animal studies support the hypothesis that the pulmonary edema seen in hypoglycemic coma results from neurogenic causes.

Pulmonary maturation in the fetus has been linked to the level of maternal glucose control in diabetic pregnancies. Amniocentesis in pregnant diabetic women has shown that adequate glucose control may lower the risk of fetal pulmonary immaturity to that seen in the nondiabetic population.

Obesity

Pulmonary Dysfunction

Obesity, even when mild, is reported to significantly impair lung function. The most persistent pulmonary function abnormalities in obesity are decreased expiratory reserve volume and functional residual capacity (FRC). Among 144 men with mild obesity (mean weight 81.1 ± 9.0 kg), 63% exhibited diminished functional residual capacity (FRC), expiratory reserve volume, and arterial oxygen tension compared to 28 subjects of normal weight. Spirometric evaluation of lung functions in morbidly obese patients before severe weight loss programs has shown no significant abnormalities and no significant improvement in their lung functions after considerable weight loss. Several studies have reported decreases in forced expiratory flow in midcycle ($FEF_{25–75}$) and mildly decreased arterial oxygen tension. A study of 63 obese men without overt obstructive lung disease detected a subgroup with normal flow rates but significantly diminished maximum voluntary ventilation (MVV). These findings have been interpreted to show disease of the small airways.

Several studies in obese subjects have shown diminished tidal volume, vital capacity, and functional residual capacity but normal diffusing capacity. Another study has shown an increase in D_LCO in patients with weight-to-height ratios exceeding 0.6. It is postulated that the increase in D_LCO is the result of increased pulmonary blood volume, which accompanies the elevated cardiac output noted in obesity. These findings suggest that the diminished D_LCO in morbidly obese subjects indicates intrinsic pulmonary pathology. Abnormal ventilation–perfusion ratios have been demonstrated in the lung bases of obese patients with hypoxemia and low or normal carbon dioxide tension in arterial blood.

Altered respiratory function in obesity may result from a combination of mechanical impedance to breathing exerted by thoracic and abdominal fat and a ventilation–perfusion mismatch. Increased work of breathing and decreased efficiency of the respiratory system are also seen. Studies suggest greater diaphragmatic efficiency in the upright than in the supine position in a majority of obese subjects, a reversal of the normal response. Diaphragmatic overstretching may be an important mechanism in the development of hypoventilation in the morbidly obese. The overall incidence of postoperative pulmonary complications in a large group of obese patients undergoing abdominal surgery (ileojejunal bypass) was 25%.

Hypoventilation

The hypoventilation seen in obese patients with both hypoxemia and hypercapnia may result from one or more of the following proposed mechanisms: increased fat deposits around the chest wall and resultant increase in the work of breathing; extremely low ventilation–perfusion ratio at lung bases, promoted by lower expiratory reserve volume; upper airways obstruction; or a disturbance in the respiratory center itself, making it insensitive to carbon dioxide. Considerable weight loss may reverse the symptoms in many cases. However, in some instances, low arterial oxygen tension may persist, whereas in others there has been a significant reduction in the number of episodes of sleep-disordered breathing and nocturnal desaturation, lending support to the concept that obesity is the cause and not an effect of the sleep apnea syndrome in these patients.

Detailed discussions of sleep-disordered breathing in obese subjects can be found in Chapter 44.

Malnutrition

Clinically significant malnutrition is a common complication of long-term mechanical ventilation and in patients with severe emphysematous obstructive lung disease. These forms of malnutrition, as well as the malnutrition caused by starvation, affect the respiratory system. Prolonged starvation significantly alters the structure and function of the lung. Morphometric and ultrastructural changes similar to those observed in elastase-induced emphysema have been noted in hamsters subjected to starvation. Pulmonary defense mechanisms, as do those of other organ systems, depend on optimal nutritional status. Diminished respiratory clearance of microbial organisms, decreased number of pulmonary alveolar macrophages, and marked decreases in secretory IgA and other immunoglobulins (as a result of hypoproteinemia) may predispose these patients to infections caused by various organisms. Malnourished subjects also demonstrate reduced ventilatory drive from the effects of nutritional depletion on both the central nervous system and respiratory muscles. Diaphragmatic muscle mass is reduced in malnourished subjects.

The effects of starvation and renutrition on pulmonary function have been studies in patients with anorexia nervosa. In a study of 15 patients with anorexia nervosa, spirometry, lung volumes, arterial blood gases, and diaphragmatic functions were recorded on admission and days 7, 30, and 45. The mean body weight on admission was 37 ± 4.7 kg (63% ideal body weight) and increased significantly to 43 ± 4.6 kg by day 45. The VC and FEV_1 increased significantly by day 30; lung volumes were unchanged. The most significant change was in the diaphragmatic contractility, which was severely depressed initially but significantly increased with nutritional support by day 30. These results document earlier assertions that diaphragmatic function is markedly impaired in severely malnourished patients, even in the absence of lung disease, and that renutrition partially reverses the weakness.

Rachitic lung demonstrates roentgenographic abnormalities as lobar or segmental atelectasis, compression atelectasis, and interstitial pneumonitis. These changes are attributed to hypoventilation in a distorted, small chest along with chronic and recurrent pulmonary infections. Hypoventilatory failure has been described in these patients. In a study of a large group of children with vitamin A deficiency, the incidence of respiratory disease was twice that of normal children, and the risk of respiratory disease was more closely associated with vitamin A status than with general nutritional status.

Gaucher's Disease

Gaucher's disease is an autosomal recessive error of lipoprotein metabolism caused by a deficiency of glucocerebrosidase, the enzyme that catalyzes glucocerebroside metabolism. It is seen predominantly in Jewish women and occurs in a neurologic form, a visceral form, and an osseous form. Accumulation of glucocerebroside in cells of the reticuloendothelial system changes them to Gaucher's cells, which accumulate both there and in the lungs and other organs. Whereas pulmonary involvement and symptoms are common in the infantile form of Gaucher's disease, it is distinctly uncommon in the adult form (type I disease).

Pulmonary manifestations consist of interstitial infiltration of Gaucher's cells in the peribronchial, perivascular, and septal regions. Pulmonary hypertension has resulted from pulmonary capillary plugging by Gaucher's cells. Roentgenograms of the lung reveal a diffuse reticulonodular or miliary pattern. Microscopic examination indicates impressive consolidation of lung parenchyma by Gaucher's cells. Elevated levels of serum angiotensin-converting enzyme have been noted in this disease.

Of the 95 patients with type I Gaucher's disease studied in Israel, 68% had pulmonary function abnormalities; TLC was reduced in 22%, RV/TLC was elevated in 18%, and FEV_1 was reduced in one-third of the patients. Reduced FRC and transfer coefficient for carbon monoxide (KCO) were found in 45% and in 42% of the patients,

respectively. Male patients had a higher incidence of reduced expiratory flow than female subjects. Even though chest roentgenographic abnormalities were found in 17% of the patients, only 4% had significant symptoms. There was no association between abnormal pulmonary function and genotype or age.

In a patient with pulmonary involvement in type I Gaucher's disease, high-resolution CT demonstrated thickening of the interlobular septa and between four and six small nodules within secondary lobules, each probably corresponding to an acinus.

Intrathoracic extramedullary hematopoiesis in the form of a thoracic paravertebral mass is described in an asymptomatic woman with type I Gaucher's disease.

Replacement therapy with glucocerebrosidase has resulted in improved pulmonary status.

Niemann–Pick Disease

Niemann–Pick disease is characterized by an absolute or relative deficiency of the enzyme sphingomyelinase. Severe nodular pulmonary disease leading to cor pulmonale has been noted. Association of widespread pulmonary nodules, linear strands, and honeycombing has been reported. Large, multivacuolated foam cells (sea-blue histiocytes) can be found in pulmonary alveoli.

Angiokeratoma Corporis Diffusum (Fabry's Disease)

An X-linked sphingolipid storage disorder caused by the lack of a-galactosidase, Fabry's disease is reported to be associated with multiple angiomas of the tracheobronchial tree and bullous emphysema leading to hyperinflation of the lungs. Recurrent pulmonary infections and hemoptysis may indicate respiratory involvement. Bronchial inclusion bodies and alveoli filled with ceramide hexosidase have been observed in patients with obstructive lung disease secondary to Fabry's disease. The deposition of ceramide hexosidase in the bronchial tree may contribute to the intrinsic airways disease and functional airways obstruction.

Mucopolysaccharidosis

Lung involvement occurs in several mucopolysaccharidoses. Deposition of mucopolysaccharides in the tracheal wall of 56 patients with various mucopolysaccharidoses was noted to result in tracheal narrowing and airways compromise in nine patients. Pulmonary complications in 21 patients with mucopolysaccharidosis or mucolipidosis included (1) upper airway narrowing by hypertrophied tongue, tonsils, adenoids, and mucous membranes; (2) lower airway narrowing by glycosaminoglycan deposition within the tracheobronchial mucosa; and (3) decreased thoracic dimensions because of scoliosis and thoracic hyperkyphosis. The pulmonary consequences include the increased risk of developing respiratory tract infections, airway compromise during or after anesthesia or sedation, dyspnea on exertion, obstructive lung disease, obstructive sleep apnea, and cor pulmonale.

Hunter's syndrome is one of a group of heritable metabolic disorders caused by decreased activity of one or more of the lysosomal enzymes responsible for mucopolysaccharide catabolism, resulting in excessive deposition of mucopolysaccharides in skeletal and soft tissues. Airway obstruction is a frequent problem. Progressive obstruction sequentially involving the upper, mid-, and lower airway characterized by gradual deformation and collapse of the trachea (tracheobronchomalacia) has been described. Autopsy analyses have demonstrated anteroposterior flattening of the trachea and bronchi with submucosal thickening leading to structural alterations peculiar to this disease. Sleep apnea syndrome, atelectasis, recurrent pneumonia, and difficult endotracheal intubation are known to be associated with this rare disorders.

Hurler syndrome is a rare mucopolysaccharide storage disease that becomes clinically apparent during early childhood as mucopolysaccharide deposits form in skeletal and soft tissues. Progressive mucopolysaccharide deposition in the oropharynx and tracheal connective tissues leads to airway obstruction if untreated. Tonsillectomy, adenoidectomy, and tracheostomy have been utilized to provide symptomatic relief of upper airway obstruction. Treatment of tracheal lesions by carbon dioxide laser excision is an alternative method for the management of airway obstruction.

Hurler–Scheie syndrome is a genetic compound of two mucopolysaccharidoses, the Hurler and Scheie syndromes. The genetic error of metabolism caused by this syndrome produces intermediary systemic effects in the affected individuals. Lacking the enzyme a-L-iduronidase, glycosaminoglycans are deposited in the tissues, causing multiple systemic effects and airway lesions.

Morquio syndrome (mucopolysaccharidosis type IV A) is a rare inherited connective tissue disorder characterized by a distinct skeletal dystrophy (spondyloepiphyseal dysplasia), restrictive pulmonary disease, and normal intelligence. Tetraplegia secondary to subluxation of C1 over C2 because of marked odontoid dysplasia or hypoplasia is a common occurrence in these patients. Pulmonary function studies have noted the restrictive nature of the ventilatory defects. Upper airways collapse during head flexion may be an important cause of pulmonary disability in Morquio's disease.

Krabbe's leukodystrophy leading to rapidly progressive respiratory failure in an 8-week-old boy with has been described. Ultrastructural examination of lungs revealed the presence of numerous intraalveolar macrophages.

Sleep apnea is a common occurrence in patients with mucopolysaccharidoses. In the past, all reported cases of sleep apnea in these patients had been treated with tonsillectomy/adenoidectomy or tracheostomy. Some patients have been successfully treated with high-pressure nasal CPAP and supplemental oxygen. Bone marrow transplantation has resulted in effective metabolic correction as well as relief of obstructive apnea in Hurler syndrome.

Lipoid Proteinosis

A rare hereditary disorder of the autosomal recessive type, lipoid proteinosis involves multiple organs by deposition of an amorphous eosinophilic glycoprotein. Pulmonary abnormalities consist of infiltration of this anomalous glycoprotein into capillary walls. Roentgenograms reveal a diffuse reticulonodular pattern throughout both lungs.

Bronchoalveolar lavage in patients with pulmonary involvement from lipid storage disorders has shown presence of lipid-containing foamy cells, with the demonstration of both periodic acid–Schiff and Scharlach red stain-positive vacuoles in the cytoplasm of alveolar macrophages. These abnormal cells are the same cells found in bone marrow biopsy.

Lysinuric Protein Intolerance

Lysinuric protein intolerance is an autosomal recessive disorder caused by the defective transport of cationic amino acids. Pulmonary disease is a potentially fatal complication in these patients. A study of nine patients with lysinuric protein intolerance observed death in a 10-year-old patient as a result of severe respiratory insufficiency from alveolar proteinosis. The remaining patients were asymptomatic at the time of the study, although high-resolution CT scans revealed acinar nodules, inter- and/or intralobular thickening of the interstitial septa, and subpleural cysts in five of the patients. No abnormalities of pulmonary function were evident. Radionuclide studies showed an uneven distribution of perfusion and ventilation and confirmed the presence of segmental and/or diffuse pulmonary functional defects.

Acute Intermittent Porphyria

Acute intermittent porphyria results from an inborn error of metabolism. Occasionally, this entity may present as acute respiratory insufficiency or with neurologic, psychiatric, or gastrointestinal manifestations. With respiratory involvement, the mortality may be high. The pulmonary features usually are similar to those of Guillain–Barré syndrome, in which the disease process involves the respiratory muscles and produces alveolar hypoventilation. Acute intermittent porphyria should be considered in the differential diagnosis of respiratory failure.

Carcinoid Syndrome

Carcinoid tumors of the bronchus and lung are discussed fully elsewhere. The following is a review of pulmonary manifestations of the carcinoid syndrome, the classic form of which is caused by a hormonally active carcinoid tumor located most frequently in the terminal ileum. The tumor arises from the Kulchitzky (argentaffin) cells, which contain neurosecretory granules filled with serotonin (5-hydroxytryptamine). This hormone is responsible for most of the clinical features, which include episodic flushing, purplish cyanosis, diarrhea, bronchospasm, and valvular disease of the right side of the heart.

Among the 3718 cases of abdominal carcinoid tumors, 3.7% had symptomatic endocrine activity. In a Mayo Clinic series, the carcinoid syndrome was observed with

7% of gastrointestinal carcinoids and 2% of bronchial carcinoids.

Pulmonary manifestations of the syndrome may include hyperventilation and wheezing. Most frequently, however, patients do not have symptoms referable to the chest, and evidence of bronchoconstriction is found only during flushing attacks. The most prominent cardiac symptoms arise from stenosis of the pulmonic and tricuspid valves, and these lesions can lead to intractable right heart failure. Elevation of urinary 5-hydroxyindoleacetic acid is helpful in establishing the diagnosis.

Other Metabolic Disorders

Volume contraction is a common clinical problem, and its effects on pulmonary functions have been studied. During hypohydration induced by diuretics in normal volunteers, lung volumes increased significantly. In addition, peak expiratory flow rate, FEV_1, maximal voluntary ventilation, and flow rates at low lung volumes also increased but returned to normal on rehydration. D_LCO was unchanged. The mechanism is probably related to the loss of water in the airway walls or peribronchial space. The clinical significance of these findings is unclear.

Hypokalemia is a commonly encountered clinical problem. Respiratory muscle weakness may result from severe hypokalemia. Hypokalemic periodic paralysis has been associated with hypoventilation. Severe diarrhea, dehydration, and marked hypokalemia in a pediatric patient was followed by fatal respiratory failure as a result of respiratory muscle paralysis.

Hypophosphatemic states are known to produce respiratory failure secondary to muscle weakness. A decrease in the body phosphate level diminishes adenosine triphosphate and results in muscle weakness. Phosphate replacement therapy in such cases dramatically improves muscle function and reverses respiratory failure. Chronic hypophosphatemia produces a decrease in 2,3-diphosphoglycerate, which increases the affinity of oxygen for hemoglobin, thereby decreasing the delivery of oxygen to the tissues.

Hypomagnesemia may contribute to respiratory muscle weakness. Next to potassium, magnesium is the most abundant intracellular cation in the human body. It is required as a cofactor by many enzymes and is a cofactor in all transphosphorylation reactions. The incidence of hypomagnesemia varies from 30% in alcoholics to 2% in normal individuals. In patients with respiratory muscle weakness, hypomagnesemia should be sought as an etiologic factor because magnesium replacement therapy has been shown to improve all the indices of muscle power measured after treatment.

Hypermagnesemia as a result of excessive ingestion of antacids, bowel obstruction, and renal failure may be followed by respiratory depression and coma. These features can be reversed by lowering the magnesium level.

Metabolic alkalosis is a common acid–base disorder in hospitalized patients. The compensatory hypoventilation may lead to atelectasis, deterioration in the ventilation–perfusion relationship, and an increased alveolar–arterial oxygen tension difference. The resultant hypoxia can be corrected significantly by reversing alkalosis with administration of hydrochloric acid.

High carbohydrate loads have led to acute respiratory failure. This is a potential problem in those receiving total parenteral nutrition. The infused glucose is used as the primary energy source, which leads to substantial increases in carbon dioxide production and respiratory quotient. Respiratory failure is more likely to occur in patients with limited pulmonary reserve.

Total parenteral nutrition increases carbon dioxide production in patients on ventilation who cannot match their carbon dioxide excretion to the carbon dioxide load, leading to increased arterial carbon dioxide tension. This risk can be minimized by increasing minute ventilation before total parenteral nutrition is begun.

Hyperlipidemia is reported to produce falsely low D_LCO measurements as a result of interference with a hemoglobin-combining coefficient. This is of no clinical significance in healthy subjects.

Glycogen storage diseases predispose patients to bacterial infections. Staphylococcal infections may produce lung abscesses and pneumatoceles (Fig. 9).

FIG. 9. Glycogen storage disease in an infant complicated by *Staphylococcus aureus*-induced abscesses in the right upper lobe.

Gouty tophi of the larynx and vocal cords have been described, with accompanying stridor, hoarseness, and signs of extensive gouty disease.

Different features of pulmonary metastases in differentiated thyroid cancer: natural history and multivariate statistical analysis of prognostic variables. *J Nucl Med* 1993;34:1626–1631. *A study of 134 patients with differentiated thyroid cancer and pulmonary metastases. All were treated with total or near-total thyroidectomy, radioiodine and* L*-thyroxine. The results showed that early (preradiologic) scintigraphic diagnosis and* ^{131}*I therapy of lung metastases were the most important elements in obtaining both a significant improvement in survival rate and a prolonged disease-free time interval.*

Chertow BS, Kadzielawa R, Burger AJ. Benign pleural effusions in long-standing diabetes mellitus. *Chest* 1991;99:1108–1111. *Intractable pleural effusions in five patients with long-standing diabetes mellitus were studied. The incidence of pleural effusions in diabetics was 83% and 14% in nondiabetic patients. Authors conclude that pleural effusions occur more commonly in diabetic than nondiabetic patients and may be related to left ventricular dysfunction and possibly other factors.*

Conn JM, Goncalves MA, Mansour KA, McGarity WC. The mediastinal parathyroid. *Am Surg* 1991;57:62–66. *Of 573 patients explored for primary hyperparathyroidism, parathyroid tissue was found in the mediastinum in 64 (11.2%). Age, sex, symptoms, gland mass, and pathologic diagnoses did not differ significantly from those of all patients with primary hyperparathyroidism. Mean preoperative serum calcium values were higher for patients with mediastinal parathyroid tissue than for all patients with primary hyperparathyroidism.*

Cooper BG, Taylor R, Alberti KG, Gibson GJ. Lung function in patients with diabetes mellitus. *Respir Med* 1990;84:235–239. *Lung function was assessed in 35*

nonsmoking adults with insulin-dependent diabetes mellitus and 34 matched control subjects. The TLC in the diabetics was lower than that in the controls, but there were no significant differences in respiratory muscle strength between the groups. The older patients (over 35 years) showed a lower transfer factor for CO.

Doherty GM, Doppman JL, Miller DL, Gee MS, Marx SJ, Spiegel AM, Aurbach GD, Pass HI, Brennan MF, Norton JA. Results of a multidisciplinary strategy for management of mediastinal parathyroid adenoma as a cause of persistent primary hyperparathyroidism. *Ann Surg* 1992;215:101–106. *In this study of 49 patients with persistent primary hyperparathyroidism caused by mediastinal parathyroid adenoma, hypercalcemia was effectively treated by either angiographic ablation or median sternotomy. Angiographic ablation with large doses of contrast material into the artery that selectively perfused the adenoma was successful in long-term control of persistent primary hyperparathyroidism in 17 (63%) of 27 patients.*

Donnelly PM, Grunstein RR, Peat JK, Woolcock AJ, Bye PT. Large lungs and growth hormone: an increased alveolar number? *Eur Respir J* 1995;8:938–947. *Measurements of pulmonary distensibility (an index of alveolar size), elastic recoil, single-breath CO transfer factor and CO transfer coefficient, pulmonary capillary blood volume, and alveolar membrane diffusing capacity, together with chest width, were compared in nonsmoking acromegalic and normal men and women, with and without an increased lung size. The normal values for pulmonary distensibility found in all individuals with large lungs, including acromegalic patients, suggested that lung growth was achieved by an increased alveolar number rather than size.*

Farina J, Furio V, Fernandez-Acenero MJ, Muzas MA. Nodular fibrosis of the lung in diabetes mellitus. *Virchows Arch* 1995;427:61–63. *Autopsies of 61 diabetic and 50 nondiabetic patients observed statistically significant differences in the incidence of chronic obstructive lung disease and pulmonary hemorrhage. There were no differences in the incidence of fibrosis of the alveolar walls or intimal and medial thickening of small vessels. A specific type of nodular fibrosis not previously reported was found that the authors believe to be typical of diabetes.*

Effect of triiodothyronine-induced thyrotoxicosis on airway hyperresponsiveness. *J Appl Physiol* 1991;71:438–444. *Airway responsiveness, lung function, and exercise capacity, when measured in a randomized double-blind placebo-controlled trial before and after liothyronine (triiodothyronine,* T_3*)-induced thyrotoxicosis in 15 patients with mild asthma, did not change significantly. It was concluded that mild* T_3*-induced thyrotoxicosis of 4 weeks' duration had no effect on lung function, airway responsiveness, or exercise capacity in subjects with mild asthma.*

Kahaly G, Hellermann J, Mohr-Kahaly S, Treese N. Impaired cardiopulmonary exercise capacity in patients with hyperthyroidism. *Chest* 1996;109:57–61. *Using cardiopulmonary exercise testing, 12 consecutive women with Graves' disease and 18 euthyroid women were evaluated. Analysis of respiratory gas exchange showed marked alterations of cardiopulmonary exercise capacity in hyperthyroid patients.*

Kerem E, Elstein D, Abrahamov A, Bar-Ziv Y, Hadas-Halpern I, Melzer E, Cahan C, Branski D, Zimran A. Pulmonary function abnormalities in type I Gaucher disease. *Eur Respir J* 1996;9:340–345. *Of the 95 patients with type I Gaucher's disease, 68% had pulmonary function abnormalities; reduced FRC and transfer coefficient for CO* (KCO*) were found in 45% and in 42% of the patients, respectively. The TLC was reduced in 22% of the patients,* FEV_1 *in one-third, and elevated RV/TLC in 18% of the patients. Male patients had a higher incidence of reduced expiratory flow than female subjects. Chest radiographic abnormalities were found in 17% of the patients, although only 4% had severe changes.*

Kim SJ, Hong YP, Lew WJ, Yang SC, Lee EG. Incidence of pulmonary tuberculosis among diabetics. *Tubercle Lung Dis* 1995;76:529–533. *Longitudinal (1988–1990) epidemiologic study of diabetic and nondiabetic civil servants in Korea observed that pulmonary tuberculosis developed in 170 patients (including 37 smear and eight culture positives) among 8015 diabetics and in 4935 (including 538 smear and 342 culture positives) among 806,698 control subjects. Relative risks of developing pulmonary tuberculosis of all types and bacteriologically confirmed cases were 3.47 times and 5.15 times, respectively, in the diabetics than in the matched controls.*

Kimura H, Kawagoe Y, Kaneko N, Fessler HE, Hosoda S. Low efficiency of oxygen utilization during exercise in hyperthyroidism. *Chest* 1996;110:1264–1270. *Cardiorespiratory variables were measured in 12 patients during both hyperthyroid and euthyroid state. The results indicated that hyperthyroidism decreases the work efficiency of skeletal muscles, leading to limitation in exercise tolerance.*

Kwauk S, Burt M. Pulmonary metastases from adrenal cortical carcinoma: results of resection. *J Surg Oncol* 1993;53:243–246. *A review of the records of 24 patients with adrenal cortical carcinoma and pulmonary metastases over a 14-year period revealed that ten patients underwent pulmonary resection, 12 received chemotherapy, and two no therapy. In the pulmonary resection group, treatment consisted of wedge resection in eight patients and lobectomy in two. For the ten patients undergoing resection of their pulmonary metastases, the 5-year survival was 71% (median not reached at 5 years). This was significantly longer than those not resected, with no one alive at 3 years (median survival 11 months).*

Lamy AL, Fradet GJ, Luoma A, Nelems B. Anterior and middle mediastinum paraganglioma: complete resection is the treatment of choice. *Ann Thorac Surg* 1994;57:249–252. *A review of the world literature noted 79 cases of mediastinum paraganglioma. The tumors were locally invasive and had a high local recurrence rate (56%) with a true metastatic capacity in 27%; the overall survival was 62% with a mean survival time of 98 ± 12 months.*

Lin CC, Tsan KW, Chen PJ. The relationship between sleep apnea syndrome and hypothyroidism. *Chest* 1992;102:1663–1667. *This polysomnographic study of 65 patients with proven sleep apnea syndrome and 20 hypothyroid patients noted that only two (3.1%) of 65 sleep apnea patients had thyroid hypofunction, and of the 20 patients with hypothyroidism, two showed moderate to severe sleep apnea and three had mild sleep apnea. Patients with both hypothyroidism and sleep apnea had impaired respiratory drive, but this was corrected by thyroid hormone therapy.*

McElvaney GN, Wilcox PG, Fairbarn MS, Hilliam C, Wilkins GE, Pare PD, Pardy RL. Respiratory muscle weakness and dyspnea in thyrotoxic patients. *Am Rev Respir Dis* 1990;141:1221–1227. *A study of 12 thyrotoxic patients and 12 control subjects measured lung volumes, compliance, elastic recoil, respiratory muscle strength, maximal exercise performance, and the intensity of breathlessness at various levels of exercise. The respiratory muscles were weaker in patients than in controls. This weakness improved in treated patients with concomitant increases in VC, IC, and TLC. Despite this, no differences were noted in breathlessness intensity scores between patients and controls or in patients before and after successful antithyroid therapy.*

Madjar S, Weissberg D. Retrosternal goiter. *Chest* 1995;108:78–82. *During a 22-year period, the authors resected the goiter in 40 of 44 patients with intrathoracic multinodular goiter. The indications for resection included compression of adjacent structures, prevention of future complications, and obtaining a diagnosis. Cervical incision was nearly always adequate, with few exceptions, such as very large posterior goiter, mediastinal blood supply, or carcinoma necessitating mediastinal dissection.*

Margulies KB, Sheps SG. Carney's triad: guidelines for management. *Mayo Clin Proc* 1988;63:496–502. *A review of 28 patients with at least two of the three tumors (gastric leiomyosarcoma, pulmonary chondroma, and extraadrenal paraganglioma) described with Carney's triad. Discussion includes clinical features, diagnosis, and guidelines for management.*

Martinez FJ, Bermudez-Gomez M, Celli BR. Hypothyroidism. A reversible cause of diaphragmatic dysfunction. *Chest* 1989;96:1059–1063. *This study of three patients with hypothyroidism presenting with fatigue, dyspnea, exercise limitation, and, in two, chronic alveolar hypoventilation* (P_aCO_2 *of 51 and 75 mm Hg) before and after thyroid hormone replacement showed that in patients with hypothyroidism, diaphragmatic dysfunction occurs more frequently than has been suspected and might be of varying severity, and this dysfunction reverses with adequate hormone replacement.*

McHenry CR, Piotrowski JJ. Thyroidectomy in patients with marked thyroid enlargement: airway management, morbidity, and outcome. *Am Surg* 1994;60:586–591. *Of the 91 patients who underwent thyroidectomy, 29 had marked thyroid enlargement: 13 unilateral (mean weight 122 g), and 16 bilateral (mean weight 160 g). Symptoms of airway compression were noted in 25 patients; 18 exhibited tracheal narrowing and/or displacement, 19 had substernal extension, and one had superior vena cava syndrome. Pathology consisted of nodular goiter (11), adenoma (five), carcinoma (three), Graves' disease (five), and toxic multinodular goiter (five).*

Melliere D, Saada F, Etienne G, Becquemin JP, Bonnet F. Goiter with severe respiratory compromise: evaluation and treatment. *Surgery* 1988;103:367–373. *Of a total of 2908 goiters operated on over a 17-year period, 22 patients had severe or acute dyspnea, and four of them required immediate tracheal intubation. Chronic dyspnea without cyanosis was present in 36 patients. This retrospective study observed that long-standing tolerance of goiter did not preclude the possibility of compressive respiratory distress and that preventive removal of all large or substernal goiters should be considered.*

Mickelson SA, Rosenthal LD, Rock JP, Senior BA, Friduss ME. Obstructive sleep apnea syndrome and acromegaly. *Otolaryngol Head Neck Surg* 1994;111:25–30. *Description of the results of treatment in seven patients with both sleep apnea and acromegaly. Four patients were treated by transsphenoidal hypophysectomy alone, with resolution of sleep apnea syndrome. One underwent hypophysectomy followed by postoperative radiation therapy, which reduced his apnea. Three patients underwent unsuccessful uvulopalatopharyngoplasty.*

Morris JT, Seaworth BJ, McAllister CK. Pulmonary tuberculosis in diabetics. *Chest* 1992;102:539–541. *A retrospective chart review of all patients with a diagnosis of diabetes and pulmonary tuberculosis admitted to a health care facility revealed that multiple lobe involvement was the predominant chest roentgenographic finding in both diabetics and nondiabetics with pulmonary tuberculosis.*

Murciano D, Rigaud D, Pingleton S, Armengaud MH, Melchior JC, Aubier M. Diaphragmatic function in severely malnourished patients with anorexia nervosa. Effects of renutrition. *Am J Respir Crit Care Med* 1994;150:1569–1574. *Diaphragmatic function was studied in 15 patients with anorexia nervosa (mean body weight 37 kg) on admission and days 7, 30, and 45 after starting feeding. Body weight and lean muscle mass significantly increased by day 45. Diaphragmatic contractility was severely impaired at admission but significantly improved after renutrition.*

Obara T, Okamoto T, Ito Y, Yamashita T, Kawano M, Nishi T, Tani M, Sato K, Demura H, Fujimoto Y. Surgical and medical management of patients with pulmonary metastasis from parathyroid carcinoma. *Surgery* 1993;114:1040–1048. *Pulmonary metastases from parathyroid carcinoma in six patients were treated by unilateral thoracotomy for a single pulmonary lesion in two and multiple lesions in four patients. The postoperative serum calcium level returned to normal after each thoracotomy in three patients but persisted in the other three patients.*

Pelttari L, Polo O, Rauhala E, Vuoriluoto J, Aitasalo K, Hyyppa MT, Kronholm E, Irjala K, Viikari J. Nocturnal breathing abnormalities in acromegaly after adenomectomy. *Clin Endocrinol Oxf* 1995;43:175–182. *A case-control study of 11 patients with treated acromegaly and two control groups that underwent nocturnal sleep studies, cephalometry, and endocrinologic studies. Nocturnal breathing abnormalities were present in ten acromegalics, and the predominant breathing abnormality was periodic breathing with symmetrically waxing and waning respiratory effort without a major body movement component.*

Piper JM, Langer O. Does maternal diabetes delay fetal pulmonary maturity? *Am J Obstet Gynecol* 1993;168:783–786. *Fetal pulmonary maturity testing before delivery in diabetic patients showed that pregnant women with poorly controlled diabetes had a significantly higher risk of immature fetal lung profiles at amniocentesis than did pregnant women without diabetes. Pregnant women with well-controlled diabetes were not significantly different from the nondiabetic population.*

Sahebjami H, Gartside PS. Pulmonary function in obese subjects with a normal FEV_1/FVC ratio. *Chest* 1996;110:1425–1429. *This prospective study of 63 consecutive obese male subjects (body mass index >27.8 kg/m^2) without obstructive lung disease identified a subgroup of subjects with a more severe lung dysfunction, the marker of which was the low maximum voluntary ventilation (MVV). The authors conclude that peripheral airway abnormalities may be responsible for this finding.*

Sandler M. Is the lung a “target organ” in diabetes mellitus? *Arch Intern Med* 1990;150:1385–1388. *This review considers the lung as a target organ in diabetes mellitus and discusses the pulmonary pathologic changes, including thickened alveolar epithelial and pulmonary capillary basal laminae, and the abnormal pulmonary functions such as reduced lung volumes in young (age less than 25 years) insulin-dependent diabetic subjects, reduced pulmonary elastic recoil in both young and adult (age greater than 25 years) diabetic subjects, and impaired diffusion because of a reduced pulmonary capillary blood volume in the adult group.*

Sandler M, Bunn AE, Stewart RI. Cross-section study of pulmonary function in patients with insulin-dependent diabetes mellitus. *Am Rev Respir Dis* 1987;135:223–229. *In this study of 40 insulin-dependent diabetics and 40 healthy subjects (all lifelong nonsmokers with no past respiratory disease), lung functions showed that there was no association between abnormal pulmonary function and the presence of other diabetic complications. Authors concluded that there are mild, duration-related abnormalities of lung elastic recoil and* D_LCO *and a reduction in pulmonary capillary blood volume in insulin-dependent diabetics.*

Santamaria F, Parenti G, Guidi G, Rotondo A, Grillo G, Larocca MR, Celentano L, Strisciuglio P, Sebastio G, Andria G. Early detection of lung involvement in lysinuric protein intolerance: role of high-resolution computed tomography and radioisotopic methods. *Am J Respir Crit Care Med* 1996;153:731–735. *A study of nine patients with lysinuric protein intolerance observed death in a 10-year-old patient as a result of severe respiratory insufficiency from alveolar proteinosis. The remaining patients were asymptomatic at the time of the study, although HRCT scans revealed acinar nodules, inter- and/or intralobular thickening of the interstitial septa, and subpleural cysts in five of the patients. No abnormalities of pulmonary function were evident.*

Semenza GL, Pyeritz RE. Respiratory complications of mucopolysaccharide storage disorders. *Medicine* 1988;67:209–219. *Pulmonary complications in 21 patients with mucopolysaccharidosis or mucolipidosis included (1) upper airway narrowing by hypertrophied tongue, tonsils, adenoids, and mucous membranes; (2) lower airway narrowing by glycosaminoglycan deposition within the tracheobronchial mucosa; and (3) decreased thoracic dimensions as a result of scoliosis and thoracic hyperkyphosis.*

Siafakas NM, Milona I, Salesiotou V, Filaditaki V, Tzanakis N, Bouros D. Respiratory muscle strength in hyperthyroidism before and after treatment. *Am Rev Respir Dis* 1992;146:1025–1029. *A study of 20 thyrotoxic patients and 20 normal subjects; global respiratory muscle strength was assessed before and 3 months after treatment. Results showed that both maximal pressures were significantly reduced before treatment in thyrotoxic patients, and they increased significantly after treatment. Lung volumes were significantly reduced before and increased significantly after therapy. Authors conclude that in thyrotoxicosis, muscle weakness affects both inspiratory and expiratory muscles*.

Siafakas NM, Salesiotou V, Filaditaki V, Tzanakis N, Thalassinos N, Bouros D. Respiratory muscle strength in hypothyroidism. *Chest* 1992;102:189–194. *Measurements of global respiratory muscle strength before and 3 months after therapy in 43 hypothyroid patients showed that the mean value of* P_{Imax} *and* P_{Emax} *increased after treatment. A highly statistically significant linear relationship was found between* P_{Imax} *and TSH and between* P_{Emax} *and TSH as well as between* P_{Imax} *and* T_3 *and* P_{Emax} *and* T_3.

Siafakas NM, Sigalas J, Filaditaki B, Tsirogiannis K. Small airway function in acromegaly. *Bull Eur Physiopathol Respir* 1987;23:329–334. *Small airway function was studied in 21 acromegalic patients (13 female, eight male) and quantitated as the maximal expiratory flow at 25% and 50% of vital capacity* (V_{Emax25}, V_{Emax50}). *Authors conclude that abnormal small airway function observed in acromegalics could either be due to obstruction, or, more likely, to an exaggeration of abnormal lung growth.*

Small D, Gibbons W, Levy RD, de Lucas P, Gregory W, Cosio MG. Exertional dyspnea and ventilation in hyperthyroidism. *Chest* 1992;101:1268–1273. *This study of 11 hyperthyroid patients and 11 controls assessed lung functions and incremental exercise test. Hyperthyroid patients showed higher ventilation than normal subjects during exercise; this increased ventilation was secondary to increased central drive. Hyperthyroid patients were more dyspneic than controls, and the increased drive could be normalized by b-blockade. Authors concluded that the main ventilatory abnormality in hyperthyroid patients is an inappropriate increase in respiratory drive, possibly secondary to increased adrenergic stimulation.*

Trotman-Dickenson B, Weetman AP, Hughes JM. Upper airflow obstruction and pulmonary function in acromegaly: relationship to disease activity. *Q J Med* 1991;79:527–538. *Pulmonary function and disease activity were assessed in acromegalics (19 men and 16 women). Large lungs (VC > 120%) were detected in six of 19 men and six of 16 women. Extrathoracic airflow obstruction was the most common abnormality, and significant intrathoracic airflow obstruction occurred in eight of 35 patients. Ten of the 12 patients with elevated VC had active disease. Upper airways obstruction was more common in men (13 of 18, compared to four of 16 women).*

Vassilopoulou-Sellin R, Klein MJ, Smith TH, Samaan NA, Frankenthaler RA, Goepfert H, Cangir A, Haynie TP. Pulmonary metastases in children and young adults with differentiated thyroid cancer. *Cancer* 1993;71:1348–1352. *Of 209 patients younger than 25 years of age who were treated for thyroid cancer, 19 (9%) had pulmonary metastases at presentation, and all 19 had regional lymphadenopathy at the time of diagnosis. All but two had intense, diffuse radioiodine uptake in the lungs. The chest radiograph was normal in eight of 17 (42%) patients with abnormal radioiodine scans.*

Wanke T, Formanek D, Auinger M, Popp W, Zwick H, Irsigler K. Inspiratory muscle performance and pulmonary function changes in insulin-dependent diabetes mellitus. *Am Rev Respir Dis* 1991;143:97–100. *A study of pulmonary functions and inspiratory muscle performance in 36 patients with insulin-dependent diabetes mellitus observed a highly significant reduction in inspiratory vital capacity among diabetic patients; inspiratory muscle performance was also restricted. The results did not correlate with either the duration of diabetes or the quality of metabolic control.*

Wanke T, Lahrmann H, Auinger M, Merkle M, Formanek D, Ogris E, Irsigler K, Zwick H. Endogenous opioid system during inspiratory loading in patients with type I diabetes. *Am Rev Respir Dis* 1993;148:1335–1340. *The activity of the endogenous opioid system in six male and five female patients with insulin-dependent diabetes mellitus during ventilatory stress was assessed by means of breathing maneuvers against fatiguing inspiratory resistive loads and plasma b-endorphin levels. The results showed that the endogenous opioid system in diabetics does not respond to stress caused by breathing against fatiguing inspiratory resistive loads.*

Wanke T, Paternostro-Sluga T, Grisold W, Formanek D, Auinger M, Zwick H, Irsigler K. Phrenic nerve function in type I diabetic patients with diaphragm weakness and peripheral neuropathy. *Respiration* 1992;59:233–237. *A study of the phrenic nerve latency in 14 male type I diabetic patients with impaired diaphragm function and in 14 healthy control subjects showed that the diabetics showed significantly decreased values for inspiratory vital capacity and FEV_1 compared with the control subjects. All other lung function parameters were similar in both groups. The phrenic nerve latencies turned out to be normal, indicating absence of a neuropathic disorder.*

Wieshammer S, Keck FS, Schauffelen AC, von Beauvais H, Seibold H, Hombach V. Effects of hypothyroidism on bronchial reactivity in nonasthmatic subjects. *Thorax* 1990;45:947–950. *Bronchial reactivity was assessed by measuring specific airways conductance (sG_{aw}) after increasing doses of inhaled carbachol in 11 nonasthmatic patients with hyperthyroidism and after they became hypothyroid. It was concluded that acute hypothyroidism increases nonspecific bronchial reactivity in nonasthmatic subjects.*

Zimran A, Kay A, Gelbart T, Garver P, Thurston D, Saven A, et al. Gaucher disease. Clinical, laboratory, radiologic, and genetic features of 53 patients. *Medicine* 1992;71:337–353. *A detailed description of clinical, laboratory, roentgenologic, and genetic features of 53 patients with Gaucher's disease.*

CHAPTER

60 Neurologic Diseases

Udaya B.S. Prakash

U.B.S. Prakash: Pulmonary and Critical Care Medicine, Mayo Medical School and Mayo Medical Center, Rochester, Minnesota 55905.

INTRODUCTION

The central and peripheral nervous systems play significant roles in the normal functioning of the respiratory system. The central component of the respiratory system resides mainly in the respiratory centers located in the medulla oblongata. Internuncial pathways connect these centers with higher brain centers, which also play a role in the normal breathing mechanism. The peripheral nervous system is responsible for normal functioning of the respiratory musculature. Depending on the type and extent of injury to either the central or peripheral nervous system, the respiratory system may exhibit various abnormalities. In this chapter, the pulmonary manifestations of disease processes at various levels of the nervous system are discussed.

NEUROGENIC BREATHING DISORDERS

The most common respiratory feature noted in intracranial disorders is a change in the breathing pattern. Elevation of intracranial pressure is the main pathologic event responsible for the breathing abnormalities. When damage is limited to one hemisphere, breathing is often normal. In contrast, acute bilateral hemispheric injury commonly elicits abnormal pattern of breathing. Abnormal breathing patterns have been related to prognosis after brain damage. Abnormal breathing is equally common in each of three large groups of patients: those with head injury, intracranial tumor, or subarachnoid hemorrhage. Depending on the anatomic location of brain injury, patients may demonstrate hypoventilation, hyperventilation, or both at different times during their illness. In one report of 100 consecutive patients with severe head injuries who arrived at a major trauma center, hypoxia was noted in 30% and hypercapnia in 4%. Abnormalities in the rate and depth of respiration occur in approximately 40% of cases of cerebral hemorrhage. Extensive lesions, such as massive cerebral hemorrhage, major cerebral embolism, and those caused by severe head trauma, are accompanied by a higher incidence of abnormalities in breathing pattern.

Several types of breathing abnormalities, including periodic breathing, irregular breathing, and tachypnea, have been described in patients with central nervous system trauma, tumor, or cerebrovascular accidents. In one report of 227 patients with these types of abnormalities, 60% demonstrated some type of abnormal breathing. All patients with medullary lesions demonstrated respiratory abnormalities, whereas pontine lesions were associated with respiratory abnormalities in 60%–70% of patients. Poor prognosis was associated with respiration exceeding 25 breaths per minute and an arterial carbon dioxide tension ($PaCO_2$) of <30 mmHg (see discussion of hyperventilation below).

Cheyne-Stokes Breathing

Cheyne-Stokes breathing is characterized by regularly alternating phases of hyperventilation and apnea and usually persists for long periods. It occurs in approximately 25% of cases of cerebral embolism and nearly 10% of cases of cerebral infarction. This respiratory dysrhythmia is also seen in other clinical conditions, including lactic acidosis, diabetic ketoacidosis, and uremic coma. Instability of the ventilatory control system is the main cause of Cheyne-Stokes breathing. Another possible cause is

abnormal sensitivity of respiratory neurons to carbon dioxide, resulting in hyperventilation that is unduly prolonged by impairment of forebrain ventilatory inhibition. Patients with Cheyne-Stokes respiration exhibit a progressively increased tidal volume during the hyperpneic phase, with subsequent decreases without change in respiratory rate.

Patients with Cheyne-Stokes breathing in whom respiratory alkalosis develops have a higher mortality. Cardiac and pulmonary monitoring in 44 patients admitted within 48 hours of onset of stroke disclosed that the presence of intermittent Cheyne-Stokes breathing or tachypnea, seen in 88%, was associated with increased mortality. In one study reporting on 11 patients with a $PaCO_2$ of <35 mm Hg and a pH of >7.46, only one patient survived.

Ataxic Breathing

Ataxic breathing, sometimes known as *chaotic breathing,* comprises periodic hypoventilation, slow regular breathing, Biot's respiration, apneusis-like inspiratory pauses, and inspiratory gasps. Ataxic breathing is seen in lower pontine and medullary disorders, morphine poisoning, hypercapnic stupor, infarcts of the brainstem, meningitis, and tumors of the central nervous system.

Biot's respiration is another term that was employed in the past to describe some abnormal breathing patterns. The terms *ataxic breathing* and *Biot's breathing* are often used synonymously. The breathing pattern consists of irregular cycles of uniformly deep or shallow breaths separated by apnea. Biot's breathing can be seen in patients with lower pontine and medullary disorders, meningitis, lesions in the posterior fossa, morphine poisoning, and hypercapnic stupor.

Apneustic breathing refers to prolonged inspiratory “cramps” with cessation of breathing in the inspiratory phase. It is a rare clinical entity. Dissociation of cerebral pathways is believed to cause this. A report on five patients with achondroplasia, all of whom demonstrated apneustic breathing, speculated that compression of the lower medullary respiratory centers and afferent pathways in the spinal cord was responsible for the breathing abnormality. Apneustic breathing can be seen in patients with lower pontine and medullary disorders, brainstem infarction, hypercapnic stupor, meningitis, and hypoglycemia. A classic example of apneustic breathing has been described in a patient with Dandy-Walker syndrome, in which hydrocephalus associated with a cystic fourth ventricle, hypoplasia or agenesis of the cerebellar vermis, and atresia of the foramina of Luschka and Magendie are noted. Although the breathing pattern may revert to normal after a shunt procedure, respiratory failure is the major complication leading to death in infants with this syndrome.

Cluster breathing is characterized by clusters of normal breaths separated by irregular pauses. Cluster breathing is seen in patients with high medullary or low pontine lesions.

In *respiratory inhibitory apraxia,* the patient is unable to stop breathing voluntarily. However, voluntary spontaneous respiration is unaffected. This abnormal breathing pattern is often associated with other forms of apraxia or motor impersistence. Respiratory inhibitory apraxia has been described in association with lesions in the internal capsule and areas supplied by the middle cerebral artery.

Neurogenic Hyperventilation

A rare phenomenon, neurogenic hyperventilation is characterized by very regular, rapid breathing (24 to 38 breaths per minute, a rate three to six times greater than normal) for hours or days at a time. The diagnosis of central hyperventilation is based on the presence of normal PaO_2 (80 mmHg) and a volume of breathing that is increased out of proportion and beyond body needs. Lesions in the region of the midbrain and upper pontine tegmentum—as seen in brainstem infarctions, acute encephalitis, hypoglycemia, severe sustained anoxia, trauma, and carbon monoxide poisoning—may cause central neurogenic hyperventilation. The mortality is very high when central neurogenic hyperventilation or Cheyne-Stokes breathing is associated with respiratory alkalosis.

The mechanism of respiratory alkalosis in central neurogenic hyperventilation is unclear. Lessened sensitivity of peripheral chemoreceptors to hypoxia may allow the PaO_2 to fall to 45 mmHg, at which point central hypoxic drive produces hyperventilation and respiratory alkalosis. The presence of hyperventilation itself has been used as a diagnostic aid in patients with partial complex seizures. In a study of a large number of patients with partial complex seizures, hyperventilatory maneuvers evoked abnormal electroencephalographic discharges and clinical seizures in 11%. Central neurogenic hyperventilation has never been induced experimentally, and it is rare even in patients with severe neurologic problems.

Neurogenic Hypoventilation

Hypoventilation is defined as elevation in $PaCO_2$ of 45 mmHg. Neurogenic hypoventilation can be either central or peripheral in origin. The direct depressant effects of overdoses of narcotic medication are a well-known cause of centrally induced hypoventilation. Cerebral trauma, vascular accidents, and infections also may result in alveolar hypoventilation. Neurogenic hypoventilation, as result of microinfarctions of basal ganglia, has been described in patients with familial hemiplegic migraine. Patients with severe cerebrovascular disease show a reduced steady-state ventilatory response to hypercapnia. The mechanism for this phenomenon is unknown.

Ondine's curse or “true” central alveolar hypoventilation (i.e., hypoventilation without any neurologic, cardiopulmonary, or metabolic disorder) is extremely rare, with only a few cases having been reported. If, however, disorders such as syringomyelia, Parkinson's disease, schizophrenia, and mental retardation are included, approximately 50 cases of central alveolar hypoventilation have been described. Clinical features in these patients included cyanosis in all, polycythemia in one third, somnolence in one third, and headache in 25%. Frequent findings noted among these patients have included pulmonary hypertension and congestive cardiac failure. Bilateral phrenic nerve pacing has been tried with varying success. Pharmacologic agents, including medroxyprogesterone acetate and nocturnal administration of oxygen, have been used to stimulate respiration in patients with central hypoventilation.

Neurogenic Pulmonary Edema

The clinical occurrence of neurogenic pulmonary edema is uncommon. In a report of 2100 patients with serious head injuries and 132 with serious cervical spinal cord or spinal column injuries, there were only two clear examples of neurogenic pulmonary edema. In contrast, an autopsy study of 100 soldiers dying of combat wounds in Vietnam revealed pulmonary edema and alveolar hemorrhage in 89%, most commonly in those who died within 1 week of injury. Respiratory disease was discovered frequently, whether or not thoracic injury was present. Furthermore, pulmonary edema is a common postmortem finding in patients with bulbar poliomyelitis, hydrocephalus, tumors of the central nervous system, intracerebral hematomas, intraventricular and subarachnoid hemorrhages, and especially trauma to the central nervous system.

Sustained acute elevation of intracranial pressure is probably the most important factor in the pathogenesis of neurogenic pulmonary edema. Elevation of intracranial pressure stimulates hypothalamic centers, resulting in massive a-adrenergic sympathetic discharge. Damage to the hypothalamus probably initiates the response just discussed; indeed, the postchiasmatic area has been referred to as the *edematogenic center.* These events result in severe vasoconstriction of the systemic and pulmonary vessels. Additionally, increases in microvascular pressure attributed to changes in the distribution of lung perfusion are believed to play a major pathogenic role in pulmonary edema (Fig. 1). These hemodynamic events occur within seconds after injury to the central nervous system. The stiffening of the left ventricle further contributes to the development of pulmonary edema. Pulmonary edema develops during these hemodynamic alterations and persists after the vascular pressures return to normal. The persistence of edema is a consequence of pulmonary capillary endothelial damage caused by the abrupt changes in pressure and volume within the pulmonary vasculature. Protein also leaks into the alveoli.

FIG. 1. Mechanism of neurogenic pulmonary edema. [Modified from Robin TJ, ed. Speculations on neurogenic pulmonary edema (NPE). *Am Rev Respir Dis* 1976;113:405.].

Head trauma is one of the most common causes of severe but nonfatal neurogenic pulmonary edema. Analysis of a large autopsy database and head-injured patient database showed the incidence of neurogenic pulmonary edema in patients with isolated head injury dying at the scene to be 32%; in patients with isolated head injury dying within 96 hrs, the incidence was 50%. The implication of these findings is that neurogenic pulmonary edema begins very early following head injury. In a retrospective clinical and pathologic analysis of 78 cases of fatal subarachnoid hemorrhage, a pathologic diagnosis of pulmonary edema was made in 71%, and 31% of this group had a clinical diagnosis of pulmonary edema. Neurogenic pulmonary edema after subarachnoid hemorrhage carries a poor prognosis, and postmortem studies indicate the presence of pulmonary edema in 33%–71% of patients with fatal subarachnoid hemorrhage.

Severe cerebral hypoxia of any cause can lead to neurogenic pulmonary edema. The overall frequency of postictal edema is low; the literature yields approximately 100 cases. Postictal pulmonary edema has recurred in the same patient. It shows a predilection for young epileptic patients. It may develop immediately after an epileptic seizure or several hours later. Electric shock therapy for seizure disorder has resulted in fatal pulmonary edema. Guillain-Barré syndrome, old poliomyelitis, and meningitis have caused neurogenic pulmonary edema. In a report of the pathologic findings in 200 cases of fatal meningococcal meningitis, pulmonary edema was noted in 60%. Neurogenic pulmonary edema has followed trigeminal blockade.

The clinical features of neurogenic pulmonary edema include the obvious evidence of damage to the central nervous system, progressive respiratory distress, and chest roentgenographic distribution of asymmetric alveolar infiltrates (Fig. 2), although a generalized pattern has been observed in most cases. Delayed onset of edema is unusual, but it has been observed in a number of cases.

FIG. 2. Neurogenic pulmonary edema. Bilateral alveolar infiltrates with air bronchograms are noted.

ABNORMAL STATES OF CONSCIOUSNESS

Unconsciousness and Coma

Unconsciousness and coma predispose to the development of aspiration pneumonitis, nosocomial pneumonia, hypoventilatory respiratory failure, and pulmonary thromboembolism. Neurogenic pulmonary edema also is seen in these patients. Abnormal breathing patterns are common, especially at the lowest level of consciousness. However, no significant association has been found between a particular abnormal pattern and level of consciousness. The unconscious patient breathes more rapidly and regularly than a conscious patient. Increasing regularity of respiration correlates well with deepening coma and accurately reflects ultimate outcome, even when other clinical signs remain unchanged.

Aspiration pneumonia and nosocomial pneumonia resulting from infection with gram-positive, gram-negative, and anaerobic organisms are the major causes of morbidity and mortality in this group of patients. Approximately 50% of patients who are unconscious or comatose aspirate. Aspiration is significantly associated with reduced pharyngeal sensation, dysphagia, and stroke severity. Aspiration is common in the early period following acute stroke. Therefore, each patient admitted with acute stroke should be carefully tested for disordered pharyngeal sensation. Even though aspiration is a transient phenomenon in most cases of acute stroke, it is associated with a high incidence of lower respiratory tract infection. In a prospective study of 60 consecutive patients with acute stroke, videofluoroscopy detected aspiration in 42% of patients within 72 hours of stroke onset, and aspiration had resolved in all but three patients after 3 months. Aspiration was closely related to the presence of dysphagia, which itself resolved within 2 weeks in all but the persistent aspirators. Lower respiratory tract infection was more common in aspirators than in nonaspirators. In an analysis of 125 patients with closed head injury, development of early pneumonia was noted in 48% of the patients. Patients in whom early pneumonia developed were found to have a lower score on the Glasgow Coma Scale (5). In a study of 441 patients with recent stroke, videofluoroscopic barium swallow detected aspiration of thin liquids in 84 patients (19%), and aspiration pneumonia developed in 12% of this group.

Head Trauma

Neurogenic pulmonary edema and other complications also can result from closed head injury. The pulmonary complications depend on the degree of trauma, level of consciousness, and involvement of other organs. Closed head injury commonly requires endotracheal intubation and mechanical ventilation. A study of 109 initially comatose patients with isolated closed head injuries who were ventilated for 24 hours or more showed that closed head injury is associated with a high incidence of pneumonia and that pneumonia occurs earlier in patients with closed head injury than in other patient groups. Pneumonia usually does not occur after the first week of hospitalization in this group of patients.

Barbiturates are commonly administered to patients with cerebral edema. A prospective study in mechanically ventilated patients with brain edema discovered that the rate of nosocomial pneumonia was significantly higher in patients receiving barbiturates than in the control group, with those receiving higher doses being at greater risk for development of pneumonia. Colonization of the respiratory tract was observed in all barbiturate-treated patients and in 70% of the control group.

Epilepsy

Short periods of apnea almost always occur in *petit mal* seizures. Prolonged apnea also has been noted. Apneic periods have been observed in partial epilepsy, especially the temporal lobe type. However, respiratory changes only rarely appear to be the principal and important components of the seizure. Several cases of respiratory failure as a seizure phenomenon have been reported. The sudden death of epileptic patients, unexplained by autopsy, is reported to be relatively frequent. Such deaths have been attributed to acute functional disturbances in cardiorespiratory centers as a result of seizure discharges. It is theorized that acute respiratory failure develops from the propagation of seizure discharges that lead to brainstem dysfunction.

Laryngospasm has been noted as a presenting symptom in patients with temporal lobe seizures. Severe hypoxia and acidosis after local anesthetic-induced convulsions have been reported; the convulsions were induced by topical application of bupivacaine. Neurogenic pulmonary edema also occurs following epileptic seizures. Prolonged spasm of the respiratory muscles leading to ventilatory problems has been reported in patients with status epilepticus.

Phenytoin, used in the therapy of epilepsy, has been noted to predispose to immune deficiency (IgA) and frequent symptoms of respiratory disease. Phenytoin also is reported to cause mild lymphadenopathy.

Exaggerated vagal response has been described in 58 children in whom reflex anoxic seizures secondary to provoked cardiac inhibition (also known as *white breath-holding attacks*) were diagnosed. The seizures were diagnosed initially as epileptic in nature; however, it appears that these seizures resulted from vagally mediated reflex cardiac arrest.

SPINAL CORD DISORDERS

Damage to the cervical spinal cord can interfere with both afferent and efferent spinal pathways concerned with respiratory function. Transection or other severe injury to the cervical spinal cord at a high level causes weakness of the respiratory muscles and may result in ventilatory failure. Transection of the cord below the level of the fifth cervical vertebra results in intercostal muscle paralysis. In such an instance, although the accessory neck muscles of respiration are affected, diaphragmatic function is preserved, and so hypoventilation is rare. However, the work done by the diaphragm (work of breathing) is significantly exaggerated, and therefore most

patients with transection of the spinal cord experience dyspnea.

The term *hemiplegia* denotes loss of neuromuscular function on one side of the body, usually owing to a cerebrovascular accident on the contralateral side. The functional classification of spinal cord injuries includes *pentaplegia, quadriplegia* (*tetraplegia*), and *paraplegia.* In quadriplegia, the C4-8 levels are involved, with motor and sensory loss in the arms and legs. In respiratory quadriplegia, the spinal cord is involved at the second through third cervical vertebral levels, and findings include motor and sensory loss of the arms, legs, and diaphragm. Pentaplegia results when the lesion is located in the brain-stem to the first cervical vertebral level, with resultant motor and sensory loss of the neck, arms, legs, and diaphragm. In paraplegia, sensory and motor loss is noted in the legs as a result of involvement of the spinal cord between the levels of the first thoracic and first sacral vertebrae.

Quadriplegia (Tetraplegia)

In quadriplegic patients, the vital capacity (VC) is approximately two thirds of normal and the maximal breathing capacity is half of normal. A mean decrease in VC to 42% of the predicted value has been reported. The impaired ventilatory function in quadriplegic patients is caused by the elimination of supraspinal control of respiratory muscles innervated by spinal segments below the level of the lesion. The spastic paralysis results in decreased compliance of the chest wall and reduction of both inspiratory and expiratory reserve volumes. The decrease in VC is also caused by altered body posture. Duration of quadriplegia does not seem to alter the response to pulmonary function testing. In the early stages of quadriplegia, the intensity of the compensatory respiratory function of the sternomastoid muscle varies, and its development to full strength as an auxiliary force in the act of breathing may require some time and the use of systematic exercises. Indeed, the role of another accessory muscle, the pectoralis major, is such that its causes dynamic airway compression during expiratory efforts in a substantial proportion of tetraplegic subjects.

The most conspicuous feature of the respiratory mechanics of the supine quadriplegic patient is the paradoxical inward movement of the rib cage during inspiration. This results in functional deformity of the chest wall and increased work of breathing. In the sitting posture, the paradoxical inward motion disappears in the lower rib cage, whereas it is decreased but still present in the upper rib cage. The disappearance of paradoxical motion of the upper rib cage with time in quadriplegics has been attributed to the development of spasticity of the intercostal muscles, with better support of the rib cage preventing it from drawing in during inspiration.

The work done by the diaphragm in quadriplegic patients is estimated to be nine times greater than that in normal individuals. This increased work of breathing is associated with dyspnea, which is minimized by a decrease in the respiratory rate to an inadequate level, which is the basis for the chronic alveolar hypoventilation seen in such cases. Tracheostomy in these patients has been associated with a higher mortality. Radiofrequency electrophrenic respiratory pacing has been used to support quadriplegic patients in whom hypoventilation develops. Milder degrees of hypoventilation may respond to noninvasive ventilatory therapies, such as continuous positive airway pressure (CPAP). Mechanical ventilatory assistance is required in many.

A study evaluating the airway responsiveness to methacholine in subjects with spinal cord injury reported that smokers and former smokers with quadriplegia are hyperresponsive to methacholine and that the response is comparable with that found in persons who have never smoked. The airway hyperresponsiveness in these subjects is thought to represent loss of sympathetic innervation of the lung, leaving bronchoconstrictor cholinergic activity intact and unopposed.

Bronchorrhea (mucous secretion in excess of 100 mL/d) or bronchial mucous hypersecretion is reported to occur in 20% of quadriplegic patients, with the quantity of mucus produced occasionally exceeding 1.0 L/d. The sudden onset of and spontaneous recovery from quadriplegic bronchorrhea is probably a consequence of disturbed neuronal control of bronchial mucous gland secretions and the initial disappearance and later reappearance of peripheral sympathetic nervous system tone.

Most deaths that follow soon after acute quadriplegia are caused by pulmonary complications. Respiratory problems include hypoventilation, recurrent infections resulting from aspiration and ineffective cough, neurogenic pulmonary edema in the acute quadriplegic state, and an increased incidence of thromboembolic phenomena. In a prospective study of 22 consecutive patients with quadriplegia, a high mortality was noted during the first months; a 15%–40% mortality was seen in the first year. Most deaths were related to respiratory failure. A retrospective analysis of 22 quadriplegic patients showed a 41% mortality within 5 years after quadriplegia. With time, respiratory function improved in the survivors, especially diaphragmatic function.

Hemiplegia

In hemiplegia, spastic paralysis or weakness of the affected side of the body may affect the diaphragm and intercostal muscles. However, respiratory complications ordinarily are not regarded as a complication of hemiplegia, even though ipsilateral diaphragmatic dysfunction occurs frequently. The left diaphragm is more commonly involved in left hemiplegia than is the right hemidiaphragm in right hemiplegia. Forced vital capacity (FVC) and forced expiratory volume may be decreased to 60% of normal. Ventilatory failure becomes imminent when the VC is reduced to 25% or less of the predicted normal value. Spirometry has shown reduction of FVC and forced expiratory volume in 1 second (FEV_1) to approximately 60% and 70%, respectively, of the predicted values. Also, a mild restrictive pulmonary dysfunction occurs in patients with hemiplegia. The lack of significant clinical symptoms is attributed to the physical inactivity.

Paraplegia

Paraplegia usually is accompanied by a slight ventilatory restriction. Lung function tests have shown both VC and maximal voluntary ventilation (MVV) in the ranges of 60%–100% of predicted normal values. One study reported a VC diminished to 60% in patients with high thoracic transections and to 78% in patients with low thoracic lesions.

DIAPHRAGMATIC PARALYSIS

The diaphragm is the most important muscle of respiration, and therefore diaphragmatic paralysis can cause significant respiratory abnormalities. The paralysis can be unilateral or bilateral, transient or permanent. It may result from interruption of the nerve supply, from muscular atrophy, or transiently from diaphragmatic pleurisy. Acute unilateral diaphragmatic paralysis usually results from interruption of the phrenic nerve by bronchogenic carcinoma or another tumor in the mediastinum, whereas chronic unilateral paralysis usually is idiopathic. Unilateral or bilateral paralysis can be caused by motor neuron disease, paralytic poliomyelitis, high cervical cord injuries, infectious polyneuritis of Guillain-Barré, or peripheral neuritis associated with measles, tetanus, typhoid, or diphtheria. Diaphragmatic involvement is often a late manifestation of generalized neuromuscular disease. Diaphragmatic weakness has also been noted in patients with Charcot-Marie-Tooth disease. Diaphragmatic paralysis has been associated with Erb's palsy, which is a well-circumscribed complication of birth trauma to the shoulder and neck, with thoracotomy, and as a complication of central venous alimentation.

Unilateral phrenic nerve paralysis occurs in 2%–10% of patients who undergo cardiac procedures, most frequently with Blalock-Taussig shunts. Hypothermic cardioplegia, induced by placing ice around the heart before open heart surgery, is complicated by transient unilateral phrenic nerve palsy (“frost-bitten” phrenic nerve) that lasts for 6 to 8 weeks. In recipients of orthotopic liver transplants, crush injury to the right phrenic nerve during transplantation is most likely the cause of right hemidiaphragmatic dysfunction. A prospective study of 48 adult recipients of liver transplants recorded right phrenic nerve injury and hemidiaphragmatic paralysis in 79% and 38% of patients, respectively. Complete recovery of phrenic nerve conduction and diaphragmatic function took as long as 9 months in some patients.

The etiology of diaphragmatic paralysis remains undetermined in more than two thirds of cases. The majority of patients studied in clinical investigations were asymptomatic and remained so on follow-up examination. Approximately 25% of them regained diaphragmatic function after a period of several months to 3 years. In another study, of 247 patients with diaphragmatic paralysis, a cause was found in 42.5% of the cases, whereas no reason for the paralysis could be identified in the remaining 57.5% (142 patients). Among this group, left-sided paralysis was seen in 58%, right-sided involvement in 41%, and bilateral involvement in 1%. Intrathoracic malignant lesions were subsequently diagnosed in 3.5%, and progressive neurogenic atrophy was seen in one patient. During a 1-year period, two cases of bilateral diaphragmatic paralysis were found among 360 prospectively studied patients who underwent hypothermic cardioplegia; both patients had insulin-dependent diabetes mellitus. Phrenic nerve isolation and protection from hypothermia during surgery resulted in no case of phrenic paralysis in a group of 76 control patients, compared with an 18% incidence in 76 patients whose phrenic nerves were exposed to cold.

Parsonage-Turner syndrome, also referred to as *paralytic brachial neuritis, neuralgic amyotrophy,* or *brachial plexus neuropathy,* is characterized by sudden onset of pain in shoulder, chest, or upper arm followed by paresis of the shoulder girdle or upper arm. Although rare, both unilateral and bilateral diaphragmatic paralysis has been described in this syndrome. The diseases associated with diaphragmatic paralysis are listed in Table 1.

Cerebral hemispheric stroke
Spinal cord disorders
Trauma to the cervical spinal cord
Syringomyelia
Poliomyelitis
Motor neuron diseases
Peripheral neuropathies
Trauma to the phrenic nerve (surgery, radiation, tumor)
Phrenic nerve compression by tumor
Landry-Guillain-Barré syndrome
Brachial plexus neuritis
Nutritional or alcoholic neuropathy
Lead neuropathy
Postinfectious neuropathies
Diphtheria
Tetanus
Typhoid
Measles
Myasthenia gravis
Muscular disorders
Myotonic dystrophies
Duchenne muscular dystrophy
Metabolic myopathies
Polymyositis
Idiopathic

TABLE 1. *Causes of diaphragmatic paralysis*

Unilateral Diaphragmatic Paralysis

A diagnosis of unilateral diaphragmatic paralysis often is difficult to establish with certainty. Study of the motion of the abdominal wall and rib cage in the supine position with magnetometry has failed to show paradoxical movements of the abdomen in unilateral paralysis. This is in contrast to the findings in bilateral diaphragmatic paralysis, in which the anterior abdominal wall moves inward paradoxically with inspiration. Measurement of transdiaphragmatic pressure using two balloon catheters has shown that at rest and expiration, when the diaphragm is relaxed, the transdiaphragmatic pressure is zero. During maximal inspiration, the change in pressure exceeds 25 cm H_2O in normal individuals, whereas in patients with weakness of the diaphragm, this pressure is 6 cm H_2O.

Symptoms of unilateral phrenic paralysis are orthopnea and difficulty in inspiration. Significant arterial oxygen desaturation can occur in the supine position but is unusual. Carbon dioxide retention also is unusual. Roentgenographic findings include elevation of the diaphragm; diminished, absent, or paradoxical movements on inspiration; mediastinal shift on inspiration; and paradoxical movements of the diaphragm under conditions of augmented load, such as sniffing. Paradoxical motion of the affected diaphragm during a “sniff test” under fluoroscopic guidance is a widely accepted test to establish the diagnosis (Fig. 3). However, it should be noted that nearly 6% of normal people may demonstrate paradoxical movement of one hemidiaphragm or the other. It should be noted, however, that nearly 6% of normal people may demonstrate paradoxic movement of either hemidiaphragm. If paradoxical excursion during sniffing exceeds 2 cm and involves the whole leaf of the diaphragm as seen on the oblique view, it probably is pathologic, provided that the abdominal muscles are relaxed during the test. Measurement of transdiaphragmatic pressure or diaphragmatic electromyography are more reliable for the diagnosis. The diagnostic evaluation of respiratory muscle weakness primarily involves the assessment of diaphragmatic function. An algorithmic approach is depicted in Fig. 4.

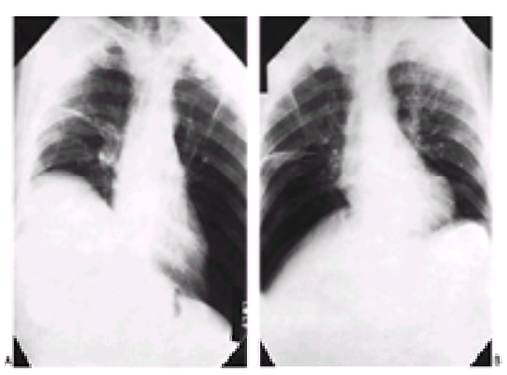

FIG. 3. Diaphragmatic motion in diaphragmatic paralysis. **A:** Paradoxical upward motion of the paralyzed right diaphragm during sudden inspiratory breathing. **B:** Paradoxical downward motion during expiration.

FIG. 4. Algorithm for approach to assessment of respiratory muscles. An incremental approach is used for most patients. For the remainder, comprehensive specialized tests are indicated. *VC,* vital capacity; *MIP,* maximal inspiratory pressure; *MEP,* maximal expiratory pressure; *SNIP,* sniff nasal inspiratory pressure; *Qs,* quadriceps; *MVC,* maximal voluntary contraction force. (Reproduced with permission from Polkey MI, Green M, Moxham J. Measurement of respiratory muscle strength. *Thorax* 1995;50:1131–1135.)

Pulmonary function studies in patients with unilateral diaphragmatic paralysis have shown total lung capacity (TLC) to be decreased by 37%, and VC and MVV to be decreased by 20%. The effects of posture on lung volume, airway closure, and gas exchange studied in eight patients with hemidiaphragmatic paralysis showed the mean VC in the sitting position to be 81% of the predicted normal value; in the supine posture it decreased by a further 19% in right-sided paralysis but by only 10% in left-sided paralysis. Diffusing capacity for carbon monoxide (D_LCO) was normal in all cases. Overall pulmonary function in the sitting position in 17 subjects with hemidiaphragmatic paralysis revealed VC, MVV, and FEV_1 to be reduced by an average of approximately 25%. Studies of regional lung function in the same body position have shown a considerable decrease in perfusion (19%), ventilation (20%), and lung volume (7%) in the diseased side as compared with reference values obtained in healthy volunteers.

Ipsilateral diaphragmatic dysfunction occurs frequently in hemiplegia. As stated previously, the left hemidiaphragm is more commonly involved in left hemiplegia than is the right hemidiaphragm in right hemiplegia. FVC and FEV_1 may be decreased to 60% of normal values in these patients. Ventilatory failure becomes immanent when the VC is reduced to 25% or less of the predicted normal value. Determination of maximal inspiratory and expiratory pressures is helpful in assessing respiratory muscle strength. Serial measurements aid in recognizing respiratory muscle fatigue or recovery of muscle strength. Unilateral diaphragmatic paralysis is associated with an abnormal pattern of use of the respiratory muscles during quiet breathing, characterized by the use of intercostal and accessory inspiratory muscles or compensatory use of abdominal expiratory muscles. A detailed physiologic study in one patient with right hemidiaphragmatic paralysis has suggested that to compensate for paralysis of a hemidiaphragm, a new pattern of inspiratory muscle recruitment develops, involving more rapid contraction of the remaining inspiratory muscles.

Bilateral Diaphragmatic Paralysis

Bilateral diaphragmatic paralysis is not as common as unilateral paralysis. Acute bilateral paralysis can be life-threatening. Bilateral paralysis or severe weakness of the diaphragm alone does not lead to respiratory failure unless weakness of other respiratory muscles is present. The most striking clinical feature is severe orthopnea in the absence of heart and lung disease. The VC is reduced to 50% of the predicted normal value in upright posture, with further decrease in the supine position accompanied by orthopnea. Lung compliance is reduced, especially in the supine posture, perhaps because of atelectasis. Although the $PaCO_2$ is usually normal in the

erect position, in some cases an elevated $PaCO_2$ in the supine position as well as during sleep has been observed. Bilateral diaphragmatic paralysis leads to chronic respiratory failure, with worsening of hypoxemia and hypercapnia during sleep.

An increased alveolar-arterial oxygen tension difference [$P(A\text{-}a)O_2$] and further mismatch of ventilation-perfusion relationships occur when the supine posture is assumed. The increased incidence of respiratory infection may be caused by chronic atelectasis and impaired mucociliary clearance. Radiofrequency electrophrenic pacing has been used successfully in some patients. Nocturnal ventilatory support, nasal CPAP, and chest cuirass have been used as therapies.

MYONEURAL AND MUSCULAR DISORDERS

Among these disorders are various neuromyopathies, demyelinating diseases, motor neuron diseases, and dystrophic muscle disorders. Although the etiology, pathogenesis, and nonrespiratory manifestations vary greatly in these diverse diseases, the main pulmonary problem relates to respiratory muscle weakness and chronic hypoventilation. In fact, respiratory failure may be the presenting symptom in many of these diseases (Table 2), and in their later stages, respiratory failure is common and frequently the cause of death.

Inherited muscular disorders
Muscular dystrophy
Duchenne muscular dystrophy
Myotonic dystrophy
Facioscapulohumeral muscular dystrophy
Limb girdle dystrophy
Oculopharyngeal dystrophy
Congenital myopathies
Nemaline (rod) myopathy
Centronuclear myopathy
Metabolic myopathies
Acid maltase deficiency
Mitochondrial myopathies
Periodic paralysis
Acquired myopathies
Inflammatory myopathies (polymyositis and dermatomyositis)
Systemic lupus erythematosus
Endocrine myopathies
Hyperthyroidism
Hypothyroidism
Hyperadrenocorticism and corticosteroid therapy
Acute steroid myopathy
Electrolyte disorders
Rhabdomyolysis

TABLE 2. *Myopathic diseases associatedwith respiratory dysfunction*

Myasthenia Gravis

Several pulmonary complications occur in myasthenia gravis. They can be categorized as complications of the disease itself and respiratory complications associated with therapy (Table 3). The respiratory muscles are involved in approximately 10% of patients with myasthenia gravis; the resultant respiratory failure may require prolonged ventilatory assistance. The risk for respiratory insufficiency is increased by surgery, infectious diseases, and the administration of corticosteroids or antimicrobial drugs. Untreated myasthenic patients show decreases in VC, TLC, dynamic lung volumes, and functional residual capacity (FRC), as well as in maximal inspiratory and expiratory forces. Patients with myasthenia gravis may have severe respiratory muscle involvement even when peripheral muscle weakness is mild. Repetitive surface electrode stimulation of the phrenic nerves is a useful and noninvasive method for identifying patients with myasthenia gravis in whom weakness of the diaphragm is suspected.

Reduced global respiratory muscle strength (reduced $P_{I_{max}}$ and $P_{E_{max}}$)
Reduced vital capacity (VC) as a result of
inspiratory muscle weakness, resulting in a reduction in inspiratory capacity
expiratory muscle weakness, resulting in a reduction in expiratory reserve volume
Fall in VC of >25% in supine position with severe diaphragmatic weakness
Increased residual volume (RV) in some patients
Decreased functional residual capacity (FRC)
Decreased transpulmonary pressure at FRC
Decreased maximal transdiaphragmatic pressure (Pdi_{max})
Rapid shallow breathing
Blunted ventilatory response to hypercapnia
Acute changes after anticholinesterase therapy
Improved global respiratory muscle function (increased $P_{I_{max}}$ and $P_{E_{max}}$)
Increased FRC because of greater respiratory muscle tone
Increased static compliance
Increased maximal transdiaphragmatic pressure
Minimal change in lung volumes
Improved ventilatory response to hypercapnia

$P_{I_{max}}$, maximal inspiratory pressure; $P_{E_{max}}$, maximal expiratory pressure.

TABLE 3. *Effects of myasthenia gravison the respiratory system*

The patient with myasthenia gravis undergoing thymectomy presents special problems during and after anesthesia. In a study of 24 myasthenic patients who underwent thymectomy, assessment of four factors—duration of myasthenia, presence or absence of respiratory disease, pyridostigmine dosage, and VC—made it possible to predict in which patients postoperative mechanical ventilation would be needed and in which extubation could readily be performed. In addition, bulbar symptomatology and a prior history of respiratory failure should be considered in identifying patients who will need mechanical ventilation. Previous reports advocated tracheostomy in all instances to deal with complications in postoperative myasthenic patients. Others recommend that tracheostomy be performed if bulbar weakness is present, if the patient has a history of respiratory and myasthenic crises, or if the VC is 2 L. One study reported that repeated measurements of VC and blood gas parameters do not help to identify those in whom respiratory failure eventually develops. The anesthetic management of patients with myasthenia gravis is complicated by their increased sensitivity to nondepolarizing myoneural blocking drugs and resistance to depolarizing neuromuscular blocking drugs. Consequently, it is common practice to leave the endotracheal tube in place for 24 to 48 hours after surgery, and usually the patient's response to doses of anticholinesterase drugs is used as a guide to the progress of myasthenia after surgery. The major problems in myasthenic patients undergoing general anesthesia involve maintenance of adequate ventilation and provision of adequate relaxation and clearance of secretions.

Studies of the effect of administration of an anticholinesterase agent (pyridostigmine) on lung mechanics in eight patients with myasthenia gravis demonstrated impaired respiratory muscle function; the average VC increased by 14% after therapy. Pyridostigmine did not seem to modify specific airway conductance or the relationship between static lung recoil pressure and maximal expiratory flow. It did, however, markedly increase the peak expiratory flow and maximal inspiratory flow. This study suggested that the changes observed in patients were related solely to the increase in respiratory muscle force, and the major effect of the drug was an increase in the ability to inflate the lungs. Further studies using edrophonium chloride (Tensilon) have shown that this drug reduces the VC as well as the maximal inspiratory flows. Hence, the use of edrophonium chloride may be limited in patients with myasthenic crisis, especially those with obstructive lung disease. The increased airways resistance signals the limits of drug quantity that can be administered, especially in myasthenic patients who also have obstructive lung disease.

Plasmapheresis, immunosuppressive therapy, and thymectomy may prove effective in improving the respiratory function of some patients with myasthenia gravis. In a study of 22 patients who required prolonged mechanical ventilation because of respiratory failure secondary to myasthenia gravis, the most frequent cause of respiratory failure was surgery, and the most common type of procedure was thymectomy. All but one of the patients were weaned from the ventilator after 1 to 32 days of respiratory support.

Myasthenic Syndrome

Also known as *Eaton-Lambert syndrome,* myasthenic syndrome is a disorder of neuromuscular transmission in which the presence of IgG antibodies to presynaptic calcium channels causes them to be downregulated, thereby reducing the calcium-dependent, nerve impulse-evoked release of acetylcholine. Nearly 70% of patients with this syndrome have an underlying small-cell carcinoma of lung. In approximately half of all cases of myasthenic syndrome, a tumor is not detectable. The syndrome is characterized by proximal muscle weakness, tendency to fatigue, and progressive respiratory failure.

Myotonic and Progressive Muscular Dystrophy

Myotonic dystrophy and progressive muscular dystrophy can lead to insidious, chronic respiratory failure. This complication develops in approximately 10% of patients with myotonic dystrophy. Myotonic patients demonstrate decreased minute ventilation, hypoxemia, hypercapnia, and pulmonary hypertension, whereas patients with

nonmyotonic dystrophy exhibit a greater decrease in VC and maximal breathing capacity. FVC and MVV were decreased to 67% of predicted values and peak expiratory flow rate was reduced to 72% in 14 men with pseudohypertrophic muscular dystrophy. Pulmonary involvement in the form of respiratory muscle weakness is frequently observed in patients with limb girdle muscular dystrophy and occurs early in the disease. Children with nonmyotonic muscular dystrophy of the Duchenne type normally have well-preserved diaphragmatic function, but they commonly die of respiratory failure or pulmonary infection. Blunted respiratory drive is occasionally seen in congenital myopathies. Chronic alveolar hypoventilation has been reported in all major forms of muscular dystrophy. Studies of lung mechanics in patients with severe respiratory muscle weakness have shown that both maximal transpulmonary pressure and static expiratory compliance are low. The low compliance results from either microatelectasis or a generalized alteration of alveolar elastic properties.

Patients with muscular dystrophies face the same problems as those with other neuromyopathic diseases—namely, aspiration pneumonia, hypoventilation, and, in patients with dystrophic myocardial involvement, cardiomyopathy and pulmonary edema. The VC improves following vigorous respiratory therapy, including breathing exercises and intermittent positive-pressure therapy. A study of seven patients with mild myotonic dystrophy showed a consistently decreased hypoxic ventilatory response with a varying hypercapnic response. The high incidence of respiratory failure in such patients is most likely related to the decreased hypoxic ventilatory response, which occurs because of an underlying neurogenic deficit.

Daytime hypersomnolence is frequently reported by patients with myotonic dystrophy, and they often exhibit hypoxia during sleep. Obese patients with myotonic dystrophy are particularly at risk for the development of sleep apnea. These patients may demonstrate central apnea, an obstructive type of apnea, or a combination of the two. Detailed sleep studies in six young male patients with mild myotonic dystrophy and excessive daytime sleepiness showed evidence of sleep apnea syndrome, with high apnea indices in all. Other studies have shown no relation between hypoxic and hypercapnic ventilatory responses during wakefulness and sleep apnea indices. Both hypoxemia and hypercapnia worsen considerably during rapid-eye-movement (REM) sleep. Pulmonary and systemic arterial pressures are increased during sleep in these patients.

Ventilatory aids and mechanical respiratory assistance have been used in a domiciliary setting to support the respiratory function of such patients. They can have a meaningful life even though they require continuous mechanical ventilatory assistance. Spinal stabilization is one of the therapies available for patients with Duchenne muscular dystrophy. A retrospective study of 17 boys with Duchenne muscular dystrophy who underwent spinal stabilization found that the procedure altered neither the decline in pulmonary function nor survival. On the other hand, a study of 16 patients with spinal muscular atrophy who underwent surgical spinal stabilization demonstrated not only a reversal in the decline in lung function seen preoperatively but also a significant improvement at final follow-up.

Friedreich's Ataxia

Friedreich's ataxia is characterized by cardiac myopathy with decreased ventricular compliance, varying degrees of hypertrophy, and less frequently obstruction to ventricular outflow. Cardiopulmonary dysfunction is a primary cause of death in patients in whom the disease develops at a young age (average of 28 years). Progression of the neuromuscular disease leads to total respiratory failure. Three mechanisms contribute to the eventually fatal outcome: (1) Severe scoliosis, common in these patients, leads to respiratory failure; (2) neuromuscular dysfunction decreases the efficiency of the respiratory muscles; and (3) pulmonary edema occurs secondary to cardiomyopathy. Pulmonary function shows decreases in TLC and VC with elevation of the residual volume (RV) and FRC. Scoliosis itself may cause most of the respiratory difficulty in patients with Friedreich's ataxia.

A follow-up and a study repeated 3 years later in a group of 15 patients with classic Friedreich's ataxia showed striking decreases in RV and FRC. These changes could not be attributed entirely to the progression of scoliosis, as RV has been shown to be independent of the degree of scoliosis. Hence, it was concluded that the deterioration of cardiopulmonary function was multifactorial and that neuromyopathy appeared to be the main contributing factor to the deterioration in cardiopulmonary function, which is exacerbated by scoliosis and cardiomyopathy of varying degrees of severity. Another unusual feature in these patients is the low incidence of pulmonary infections.

Steinert's Myotonic Dystrophy

Steinert's myotonic dystrophy is a genetically transmitted (autosomal dominant) neuromuscular disease in which premature death is caused by cardiopulmonary complications. Both acute and chronic respiratory failure develop. Acute respiratory insufficiency is first diagnosed by the failure to generate the first postnatal breath, leading to a requirement for ventilatory support in the neonatal period. In adults with Steinert's dystrophy, acute respiratory disease can be precipitated during recovery from general anesthesia. Chronic respiratory complications include pneumonia, weakness of the respiratory muscles and hypoventilation, increased work of breathing, and altered central control of respiration. Both the blunted chemical drive of breathing and the respiratory muscle weakness have been cited in the pathophysiology of premature death in these patients. Studies have shown that the sensitivity of chemoreceptors in the respiratory centers is well preserved; however, the output to breathing is modulated by the impaired ventilatory mechanics, which causes tachypnea even in the absence of restricted lung volume.

Demyelinating Diseases

Multiple sclerosis, a relatively common demyelinating disease in Western countries, may lead to several types of respiratory complications (Table 4). The pulmonary complications, however, tend to be mild in the majority of patients. In a report of the natural history of multiple sclerosis in 840 patients, it was noted that involvement of the vital centers of the central nervous system was rare and confined to patients with acute disease who died within a few months of onset. This series included three deaths caused by respiratory failure, one of which occurred within 3 months of onset.

Abnormality	Anatomic localization	Clinical findings at bedside
Paralysis of voluntary respiration	Bilateral corticospinal tracts, brainstem, or upper cervical cord	Inability voluntarily to increase tidal volume or hold breath, automatic respirations intact
Paralysis of automatic respiration	Dorsomedial medulla, nucleus ambiguus, and medial lemnisci	Apnea during drowsiness, normal voluntary control of respiration while awake
Diaphragmatic paralysis (unilateral or bilateral)	Upper cervical cord (C1-4 level)	Paradoxical movements of chest wall and abdomen, use of accessory muscles, orthopnea
Apneustic breathing	Lower brainstem	Inspiratory apneusis, voluntary control between episodes
Paroxysmal hyperventilation	Lower brainstem	Apneic pauses after hyperventilation with or without bulbar "tonic spasms"
Obstructive sleep apnea	Tegmentum of medulla	Snoring, sleep apnea with or without hiccups
Neurogenic pulmonary edema	Medulla in region of nucleus tractus solitarii and floor of fourth ventricle	Pulmonary edema without signs of heart failure

Reproduced with permission from Carter JL, Noseworthy JH: Ventilatory dysfunction in multiple sclerosis. *Clin Chest Med* 1994;15:693–700.

TABLE 4. *Patterns of respiratory involvement in multiple sclerosis*

In a report of four cases of respiratory failure associated with multiple sclerosis, the presence of lesions in high segmental sensory levels was emphasized. In these patients, respiratory failure was secondary to demyelinating lesions involving the bulbar area (especially the region of the respiratory center) and pyramidal tracts bilaterally and possibly the anterior horns. Severe involvement of the spinal cord by the demyelinating process may be complicated by respiratory failure. Hyperventilation, decreased response to carbon dioxide, irregular breathing, and sleep-induced apnea have been noted. Three cases of spontaneous pneumothorax were noted among 141 patients identified as incidence cases of spontaneous pneumothorax in an epidemiologic study. This occurrence was reported to be unlikely on the basis of chance alone. A statistically low incidence (less than expected) of pulmonary embolism has been noted. A study of 40 patients with multiple sclerosis concluded that descriptive clinical indices and clinical assessment were superior to spirometry as predictors of clinical illness; however, determination of MVV uncovered subtle respiratory muscle weakness.

Other Neuropathies

Charcot-Marie-Tooth disease encompasses a collection of chronic degenerative neuropathic conditions and includes cases of hereditary motor and sensory neuropathies. The major clinical feature is slowly progressive weakness, predominantly of the distal lower limbs. Diaphragmatic dysfunction has been described in several patients with this disease. Neuropathic changes characteristic of the disease have been observed in phrenic nerves.

Other Myopathies

Metabolic Myopathiesmaltase

Acid deficiency, also called *Pompe's disease,* is a type II glycogen storage disease known to cause respiratory failure. The deficiency of the enzyme acid maltase leads to engorgement of cellular vacuoles with glycogen excess. Acid maltase deficiency can present with respiratory failure. Proximal myopathy and weakness as well as diaphragmatic dysfunction occurs; isolated diaphragmatic paralysis also has been noted. Acid maltase deficiency classically affects infants and children, with a few sporadic cases appearing in adults.

Respiratory involvement, including ventilatory failure and diaphragmatic paralysis, has been described in various types of myopathies, including centronuclear myopathies (congenital myotubular myopathy), progressive congenital myopathy with type I fiber atrophy, Isaac's syndrome (myokymia, generalized muscular stiffness, and decreased tendon reflexes), and Kearns-Sayre syndrome (also known as *oculocraniosomatic neuromuscular disease,* characterized by a combination of all or some of the following: ptosis, external ophthalmoplegia, retinal degeneration, axial muscle weakness, deafness, ataxia, pyramidal tract abnormalities, small stature, mental retardation, endocrine abnormalities, and cardiac conduction defects). Mitochondrial myopathy leading to chronic respiratory failure with the need for mechanical ventilation has been described.

The porphyrias (acute intermittent porphyria, porphyria variegata, and hereditary coproporphyria) are disorders of porphyrin metabolism. Each of these may be associated with ascending paralysis and respiratory failure. The neuropathy in these diseases probably is caused by the toxic effect of the accumulated porphyrin precursors aminolevulinic acid and porphobilinogen.

Muscular weakness and respiratory failure have been noted in rhabdomyolysis (myoglobinuria), hypophosphatemia, hypokalemia, polymyositis-dermatomyositis, and familial periodic paralysis.

Toxic Myopathies

Organic phosphate poisoning is a common occurrence in certain regions of the world where these compounds are used as agricultural insecticides. Accidental or suicidal ingestion can lead to serious respiratory problems as a result of muscarinic and nicotinic effects. Organic phosphates cause muscle paralysis by inhibiting acetylcholinesterase. The pulmonary features include rhinorrhea, excessive bronchial secretions, pulmonary edema, laryngospasm, bronchospasm, respiratory muscle paralysis, and paralysis of the respiratory centers. In a report of 107 subjects in Taiwan exposed to organic phosphate or carbonate, respiratory failure developed in 40%, and 51% died. The use of pralidoxime did not reduce the incidence of respiratory failure. Importantly, aggressive treatment within the first 96 hours resulted in prevention of respiratory failure.

Botulism is a disorder of the neuromuscular junctions caused by the binding of neurotoxins elaborated by the bacterium *Clostridium botulinum.* Botulism characteristically causes multiple cranial motor neuropathies. Clinical findings include blurred vision, paralysis of pupillary muscles, ileus, dry mouth, and descending paralysis involving extraocular and bulbar muscles, with frequent progression to respiratory muscle weakness. Muscle weakness of the upper airways may result in dysphonia and nasal regurgitation. In a study of six patients with botulism, weakness of the ventilatory muscles was noted early in the course of poisoning in all patients, but recovery was the rule, although it took several months. Long-term follow-up in 13 patients revealed that residual symptoms, including dyspnea and fatigue, were common at 2 years after intoxication, even though lung function had returned to normal in all.

Summary of Respiratory Problems in Myoneural and Muscular Disorders

The main respiratory complications in neuropathies and dystrophic muscular diseases include hypoventilation with progressive respiratory failure, restrictive pulmonary dysfunction, aspiration pneumonia, recurrent infection, and cardiopulmonary problems in patients with cardiomyopathy-associated muscular dystrophies. Pulmonary embolism also occurs with greater frequency. Depending on the severity of the underlying disease, patients may have symptoms of anxiety, lethargy, headaches, dyspnea, and occasionally a sensation of suffocation. Severe hypoventilation leads to confusion, coma, cyanosis, severe hypoxemia, hypercapnia, and death. In patients with severe, protracted respiratory muscle weakness, marked alterations develop in the static mechanical properties of the lungs. Alveolar collapse produces low pulmonary compliance. Spirometric evaluation of lung function and assessment of respiratory muscle function by measurement of inspiratory and expiratory pressures aid in gauging the severity of respiratory involvement. A step-by-step approach to the evaluation and diagnosis of respiratory muscle weakness is important in the management of these patients (Fig. 4).

DISEASES OF PERIPHERAL NERVES AND ANTERIOR HORN CELLS

Poliomyelitis

Poliomyelitis is a typical example of an anterior horn cell disease that can lead to respiratory failure. Respiratory involvement from poliomyelitis may go undetected. Indeed, many patients remain in a state of chronic hypoventilation. Pulmonary function studies in patients who have recovered from poliomyelitis but who have residual muscle weakness have demonstrated that the majority experience exertional dyspnea and recurrent respiratory tract infections. Late onset of respiratory failure and polycythemia have been described in a significant number of patients with previous poliomyelitis. Respiratory failure is more common in poliomyelitis patients who have kyphoscoliosis and diaphragmatic paralysis. In a study of 55 patients with previous poliomyelitis, VC was reduced to approximately 20%–40% of the predicted normal values and TLC was correspondingly reduced in the majority of patients, but RV was within normal limits. The PaO_2 is usually normal despite severe reduction in VC. However, 60% of patients with a VC that is <50% of the predicted value have exhibited a PaO_2 of <80 mmHg. Hypercapnia is seen at some stage in 35% of patients. The decreased VC is a consequence of diminished compliance of the chest wall and lung parenchyma.

In patients with previous poliomyelitis and severe respiratory failure, long-term ventilatory assistance is required. Four years after the epidemic of poliomyelitis in Copenhagen in 1952, in which 264 patients underwent tracheostomy and 232 were treated with positive-pressure ventilation, 24 of 138 survivors were considered to be chronically respirator-dependent. Nine of these died during the next 17 years. Among the 24 chronically respirator-dependent patients, 13 were alive in 1975 and were receiving constant ventilatory assistance.

Guillain-Barré Syndrome

Guillain-Barré syndrome (acute polyneuritis) is the most common cause of acute paralysis and neuromuscular ventilatory failure. Guillain-Barré syndrome is probably the most common neuromuscular cause of acute respiratory failure. It is a demyelinating disease of motor neurons, and it is manifested clinically as symmetric ascending paralysis and a lack of cellular response in the cerebrospinal fluid despite an increase in protein concentration. A typical patient is younger than 26 years or between 45 and 60 years of age. Seasonal clustering (late summer and autumn) is a feature. However, atypical clinical features may make Guillain-Barré syndrome difficult to diagnose, and therefore a process of exclusion is necessary. Respiratory complications develop in nearly half the patients. The diaphragmatic and intercostal muscular paralysis produce progressive alveolar hypoventilation. The patient frequently is not disturbed by this weakness because of its gradual onset and slow progression. Indeed, significant respiratory muscle insufficiency can be present without being detected clinically. Paralysis of the ninth and tenth cranial nerves may lead to dysphagia, laryngeal paralysis, and aspiration. Neurogenic pulmonary edema has occurred in patients with Guillain-Barré syndrome.

The clinical course of Guillain-Barré syndrome is variable, but complete recovery can be expected in most cases. Systemic corticosteroids have been used as treatment, but because of the extremely variable course of the disease, it is difficult to evaluate their role. Treatment with plasma exchange and immune globulins has decreased the duration of mechanical ventilation by half. Respiratory failure requires mechanical ventilatory support in 10%–30% of patients. In a series of 79 patients with acute Guillain-Barré syndrome, 27% required admittance to the respiratory intensive care unit for 14 to 105 days, and nasotracheal intubation followed by tracheostomy and mechanical ventilation were required in 18%. The mortality was 4%. Repeated measurements of VC have been used as predictive parameters of the need for mechanical ventilation and weaning success. Up to 10% of patients remain seriously disabled, and approximately 5% die as a result of complications. Most deaths are caused by cardiopulmonary complications.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis is the most common motor neuron disease in the United States. Destruction of the anterior horn cells in the spinal cord leads to atrophy and muscle weakness. The loss of anterior horn cells is most marked in the cervical, lumbosacral, and lower thoracic spinal segments. Most patients with amyotrophic lateral sclerosis exhibit progressive neurologic deterioration without remission, with an average life expectancy of 4 years after the onset of symptoms.

Respiratory muscle involvement can be detected in most patients before respiratory symptoms begin, and respiratory failure occurs as the initial manifestation in some. However, patients who have respiratory symptoms, decreased FVC, and an abnormal $PaO_2/PaCO_2$ ratio are more likely to exhibit increased phrenic nerve latencies or absent response than are patients with amyotrophic lateral sclerosis who have no respiratory problems. Irreversible hypoventilation leading to fatal respiratory failure is common in the later stages of the disease. Hypopnea during sleep as the presenting symptom has been described. Sleep and breathing were assessed in 18 patients with amyotrophic lateral sclerosis involving the bulbar muscles involvement and 10 controls. The patients had more arousals per hour, more stage 1 sleep, a shorter

total sleep time, and mild sleep-disordered breathing with a greater apnea-hypopnea index than did the control subjects. Eight patients had sleep-disordered breathing consisting of periods of hypoventilation, predominantly during REM sleep. No obstructive sleep apnea was observed.

Among 218 patients with amyotrophic lateral sclerosis, indications of abnormal lung function were detected in 94%. Decreased MVV and FVC were the significant findings. Severe diminutions of maximal inspiratory and expiratory pressures as well as MVV is observed in most, and the majority of patients have low lung volumes and unaltered RV volume and FRC. Some studies have found that TLC is well preserved even in an advanced stage of the disease, provided that diaphragmatic function is not grossly compromised. Obstructive pulmonary disease, although clinically not well recognized, has been noted in up to 19% of patients. Repetitive aspiration caused by bulbar incoordination perhaps is responsible.

The second major problem is aspiration pneumonia, as 25% of patients with amyotrophic lateral sclerosis have bulbar paralysis, which aggravates the problem of aspiration (Fig. 5). Respiratory insufficiency in patients with amyotrophic lateral sclerosis also may be a consequence of unilateral or bilateral diaphragmatic paralysis.

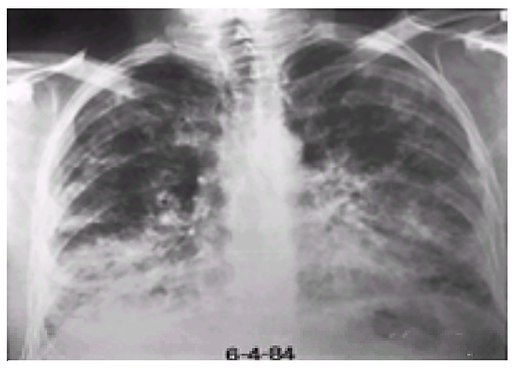

FIG. 5. Recurrent episodes of aspiration pneumonia secondary to bulbar involvement in amyotrophic lateral sclerosis.

The prognosis in the motor neuron diseases depends on the rapidity with which the underlying disorder progresses and the degree of respiratory muscle involvement. Aggressive, long-term ventilatory assistance and tracheostomy usually are not recommended because of the relentless progression of the disease. Selected patients, those who demonstrate slow progression of disease, are occasionally treated using CPAP or tracheostomy with ventilator assistance. In one study of 18 patients with amyotrophic lateral sclerosis, significantly prolonged survival was demonstrated in subjects who elected to receive noninvasive mechanical ventilation: In one study of 18 patients with amyotrophic lateral sclerosis, significantly prolonged survival was demonstrated in subjects who elected to receive noninvasive mechanical ventilation: 80 days for patients who had therapy versus 19 days for patients who did not. Prevention of aspiration pneumonia and nonaggressive palliative therapy are the prudent goals.

DYSKINETIC DISORDERS

Extrapyramidal diseases, such as parkinsonian syndrome, may produce severe, prolonged spasm of the respiratory musculature and consequent respiratory insufficiency. Respiratory abnormalities described in extrapyramidal diseases are now believed to involve the nigrostriatal dopaminergic system. In addition, these patients have episodes of respiratory spasms or tics associated with grunting, snorting, or puffing. It is postulated that the respiratory dyskinesias are related to destruction of mesencephalic and pontine respiratory centers governing the lower bulbar regions.

Parkinson's Disease

Parkinson's disease is a common dyskinetic disorder, and although pulmonary involvement is frequent and considered to be the common cause of death, it rarely is recognized clinically. Pneumonia and pulmonary embolism are the two most frequent causes of overall mortality in Parkinson's disease. Parkinson's disease is associated with pathologic changes in the reticular formation of the brainstem, and hence the afferent or efferent pathways involved in the control of respiration may be affected. More than 85% of patients have impaired ventilatory function, which is related to the severity of disease rather than to underlying lung disease. Patients with more severe disease tend to exhibit more pronounced pulmonary dysfunction. In a detailed study of 63 patients with Parkinson's disease, a restrictive ventilatory defect was noted in 54 patients, all of whom had an FEV_1/FVC ratio that was >80% of predicted.

The more common pulmonary function abnormality, however, is the obstructive type. It is been postulated that the obstructive lung disease in Parkinson's disease may be related to increased parasympathetic tone and infection. It is more likely that the airway abnormalities reflect involvement of the upper airway musculature.

Upper airways obstruction is relatively common in patients with Parkinson's disease. Among 31 patients with Parkinson's disease who underwent detailed pulmonary function testing, evidence of obstructive pulmonary function was identified in one third; lung function did not improve after therapy with levodopa. However, significant abatement of symptoms of Parkinson's disease was noted, and hence it was concluded that the obstructive pulmonary disease did not result from the Parkinson's disease. In contrast, 10 patients in another study exhibited a significant improvement in MVV following therapy with levodopa, but no correlation was found between clinical and pulmonary functional improvement.

An abnormal flow-volume loop contour is a frequent finding in patients with Parkinson's disease (Fig. 6). A study of the maximal inspiratory and expiratory flow-volume curves in 63 patients with different stages of Parkinson's disease, of whom 59 were undergoing treatment, showed that 31 patients (49%) had abnormal flow-volume curves. Physiologic evidence of upper airway obstruction was observed in three cases. The clinical aspects and duration of disease did not influence the pattern of the curve.

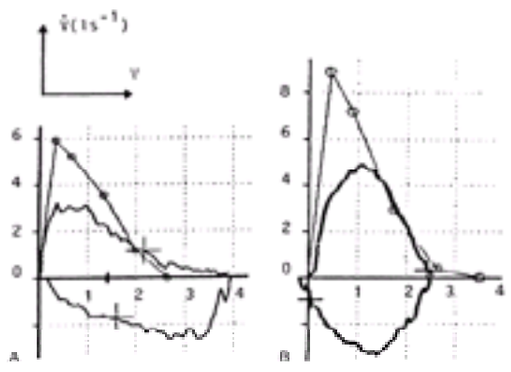

FIG. 6. Flow-volume loops described in patients with Parkinson's disease. **A:** Loop exhibits “saw-toothing” of both inspiratory and expiratory limbs, thought to result from rapid changes in laryngeal and supraglottic diameter. **B:** Loop exhibits a delay in achieving peak flow and a decrease in peak flow. (Reproduced with permission from Bogaard JM, Hovestadt A, Meerwaldt J, et al. Maximal expiratory and inspiratory flow-volume curves in Parkinson's disease. *Am Rev Respir Dis* 1989;139:610.)

Erratic breathing, also known as *chaotic breathing,* is common. The ventilatory defect is caused by rigidity and weakness of the respiratory muscles, which abate with treatment.

Levodopa is commonly used to treat Parkinson's disease. In patients with neuroleptic-induced tardive dyskinesia or levodopa-induced dyskinesia, acute dyspnea and chest pain may develop secondary to severe, involuntary muscle incoordination. Bromocriptine has been used in the treatment of Parkinson's disease. In a review of 123 patients treated with bromocriptine, six had pleurisy accompanied by effusion, pleural thickening, and pulmonary infiltrates. The daily dose of bromocriptine ranged from 20 to 90 mg, and the duration of treatment ranged from 6 to 27 months. Three of the patients were also taking levodopa with benserazide, from 400 to 800 mg/d. The pleuropulmonary complications are believed to have been caused by bromocriptine rather than levodopa. Similar complications have been noted in a patient

receiving cabergoline. Bromocriptine-induced myocardial infarction and secondary pulmonary edema should be considered in any patient using this drug, because bromocriptine is reported to cause coronary vasospasm and myocardial infarction; 24 such cases have been identified in the literature.

Respiratory Dyskinesia

The term *respiratory dyskinesia* has been used to describe extrapyramidal dysfunction with dyspnea that is not related to Parkinson's disease. It may mimic chronic psychogenic hyperventilation syndrome, and so it has been called *pseudopsychogenic hyperventilation.* Respiratory dyskinesia is probably related to destruction of mesencephalic and pontine respiratory centers governing the lower bulbar regions. When these areas of the brainstem are affected by pathologic process, irregular respiratory movements result. In both respiratory dyskinesia and chronic hyperventilation syndrome, abnormal respiratory movements worsen with stress and disappear with sleep.

In patients with respiratory dyskinesia, speech is interrupted by involuntary sounds or grunts, snorting, and puffing; respiration is awkward, and the patient appears distressed and anxious even when pain or dyspnea is absent. In a report of four patients with severe involuntary respiratory dyskinesia, respiratory findings included irregular respiratory rate, shortness of breath, and discomfort in the chest. Three of these patients had neuroleptic-induced tardive dyskinesia, and one had levodopa-induced dyskinesia. Many of these initially were believed to have cardiopulmonary disorders. Dopaminergic manipulation was successful in correcting the subjective discomfort and respiratory abnormalities in all these patients. Reserpine was used in three patients, and the dose of levodopa was lowered in another.

Tardive Dyskinesia

Tardive dyskinesia is a syndrome of involuntary movement characterized by facial involvement and temporal association with ingestion of neuroleptic drugs. Respiratory dyskinesia may well be a part of tardive dyskinesia syndrome. Patients with subjective tardive dyskinesia should undergo an assessment of respiratory function. Stiff-man syndrome is reported to be associated with progressive respiratory failure.

Respiratory tardive dyskinesia (clinical evidence of irregular respiration) was observed in 2% of a large group of continuously hospitalized patients with tardive dyskinesia and psychiatric illness. The prevalence of respiratory irregularities was significantly greater in patients with an organic mental disorder (11%) than in those without. None had respiratory symptoms.

CEREBELLAR DISORDERS

Arnold-Chiari Malformation

Arnold-Chiari malformation is a congenital anomaly characterized by caudal displacement of the inferior cerebellar vermis, kinking of the medulla oblongata, a small posterior fossa, a low tentorium cerebelli, and displacement of the fourth ventricle into the spinal canal. Coexistence of spina bifida, hydrocephalus, and other anomalies of the neural axis is common. The most common respiratory problem is the dramatic onset of laryngeal stridor, which appears precipitously and is closely correlated with increased intracranial pressure. Three vagally mediated mechanisms have been postulated: brainstem disease, compression of the vagus nerves at the level of the foramen magnum, and traction of the vagus nerves by caudal displacement of the brainstem. Respiratory obstruction and apnea with bilateral abductor vocal cord paralysis also has been described. Depressed ventilatory response to carbon dioxide has been observed. However, physiologic studies have shown that patients with uncomplicated Arnold-Chiari malformation have normal respiratory function.

Respiratory abnormalities, such as respiratory distress, apnea, vocal cord paralysis, and inability to swallow, are known complications of Arnold-Chiari malformation. Hemorrhages in the medulla oblongata in addition to compression or traction of the vagus and other lower cranial nerves may cause these symptoms. Respiratory problems result from impaired function of the ninth, tenth, and twelfth cranial nerves. In a study of 14 children who had Arnold-Chiari malformation, vascular lesions resulting in hemorrhage, hemorrhagic necrosis, or bland infarcts in the tegmentum of the medulla oblongata were found in 12 children with clinical abnormalities of respiratory function and dysfunction of the lower cranial nerves. Surgical decompression of the posterior fossa has been shown to relieve respiratory symptoms in some cases. Respiratory problems frequently cause death or markedly shorten the life expectancy of affected children.

Joubert's Syndrome

Joubert's syndrome, caused by agenesis of the cerebellar vermis, is characterized by abnormal eye movements, ataxia, retardation, and episodic hyperpnea. An abnormal respiratory pattern—namely, persistent tachypnea from birth—is the clinical hallmark of Joubert's syndrome and may be detectable *in utero,* thus permitting prenatal diagnosis. Peak respiratory rates in excess of 200 breaths per minute during wakefulness and of 150 breaths per minute with tachypneic episodes lasting up to 150 seconds have been described. Apneic episodes in non-REM sleep lasting 10 to 20 seconds, with a maximal duration of 45 seconds, have been observed.

PERIPHERAL CHEMORECEPTORS

Carotid Body Resection

Respiratory hypoxic drive is controlled primarily by peripheral chemoreceptors situated in the carotid bodies. Although the carotid bodies initiate the hyperpneic response to hypoxia, they have no part in ventilatory control in normal persons at sea level, either at rest or after exercise. Therapeutic carotid body resection has been advocated for bronchial asthma, but beneficial effects have not been proved. Bilateral carotid endarterectomy may abolish compensatory hyperventilation and cause hypoxemia. Furthermore, bilateral carotid body resection may preclude compensatory ventilation when hypoxemia develops. However, it has been reported that in patients who underwent bilateral carotid body resection for asthma, the ventilatory response to increased $PaCO_2$ was reduced, but hypoventilation did not occur. A patient with cough syncope has been described who was found to have carotid sinus hypersensitivity and mixed cardioinhibitory and vasodepressor responses. The cough syncope improved after denervation of the more hypersensitive carotid sinus.

Sympathectomy

Dorsal sympathectomy is performed for a wide spectrum of vascular diseases. Most patients have some shortness of breath during the first days after the operation. Pulmonary function tests in a group of 15 patients before and 1 to 3 months after upper dorsal sympathectomy showed significant decreases in all lung volumes and maximal expiratory flows. The reasons for these include a loss of diaphragmatic tone as a result of the surgical procedure, surgical transection of the scalenus anticus muscle leading to impairment of maximal inspiration and decreases in TLC and VC, and pulmonary constriction caused by sympathetic denervation.

DISORDERS OF THE AUTONOMIC NERVOUS SYSTEM

Familial Dysautonomia (Riley-Day Syndrome)

The term *dysautonomia* denotes autonomic dysfunction. Both acquired and familial dysautonomia can lead to respiratory problems. Central and obstructive sleep apnea both occur in patients with dysautonomia. Familial dysautonomia is a mendelian recessive disease associated with a relative unresponsiveness to hypoxia and hypercapnia, believed to result from a defect in the carotid body. Breath-holding attacks have been seen in 66% of 210 children with familial dysautonomia, and fleeting episodes of hyperventilation followed by profound hypoxia have been observed. Hyperventilation followed by hypoxia, attributed to incoordinated central depression consequent to reduced cerebral blood flow, has been reported in these patients. Familial dysautonomia in 13 patients was associated with abnormal sleep patterns (decreased amounts of REM sleep and increased REM latencies) in all patients; the average number of apneic spells was 73 per night.

Acquired Dysautonomia

Dysautonomia is acquired as a result of diabetic autonomic neuropathy, amyloidosis, Shy-Drager syndrome, Arnold-Chiari malformation, botulism, generalized neuropathy, neoplasms, Parkinson's disease, bilateral cervical cordotomy, and bulbar poliomyelitis. A 6-year-old girl in whom sleep-induced hypoventilation and apnea with diffuse dysautonomic changes developed died 2 years later during sleep; detailed pathologic analysis revealed a ganglioneuroma originating in the sympathetic ganglia. This type of acquired progressive dysautonomia is rare. Dysautonomia can be associated with respiratory failure resulting from inability of the chemoreceptors to respond to hypoxia.

Aspiration pneumonia is a significant complication in patients with diabetic autonomic neuropathy. Studies of gastric volume and pH have shown solid, undigested food particles to be present more often in the gastric contents of diabetic patients with autonomic neuropathy than in diabetic patients without autonomic neuropathy.

MISCELLANEOUS NEUROLOGIC DISORDERS

Alzheimer's Disease

Pulmonary complications are being recognized more frequently in patients with progressive or advanced Alzheimer's disease. A prospective study of 25 patients with moderate or severe Alzheimer's disease employed videofluoroscopy to assess the incidence of oropharyngeal swallowing abnormalities. Six patients (28.6%) exhibited aspiration, and only four patients showed unequivocally normal performance. Swallowing abnormalities were associated significantly with duration of dementia, eating dependency, and abnormal oral praxis. A trend toward a higher incidence of aspiration in patients with more severe dementia was noted.

Cerebral Palsy

Patients with cerebral palsy are predisposed to respiratory infection because respiratory neuromotor control is affected. In one study of dynamic and static lung volumes in children with cerebral palsy, total capacity was significantly reduced, averaging 85% of the predicted normal values; a 50% decrease in VC was noted in subjects with dyskinesia, and a 67% decrease in patients with spasticity. The features of lung disease in these children were similar to those of chronic obstructive pulmonary disease. Breathing exercises in a study of 10 children with spastic cerebral palsy showed a mean increase in VC to 30% of pretest values, and this increase in VC nearly matched the normal predicted levels.

Migraine

Severe hyperventilation occasionally encountered in patients with migraine has led to diagnostic difficulties. In the reported cases, hyperventilation occurred at the peak of the migraine, making the attack seem worse to the patient. It is speculated that in these cases the migraine was exacerbated by the vasoconstrictor effect of hyperventilation. The term *pulmonary migraine* was suggested to describe a localized atelectasis of the lung associated with migraine headaches in a 14-year-old girl. Neuropathologic findings included deep areas of microinfarction in the basal ganglia and a remarkable sparing of brainstem nuclei associated with respiratory function.

Dystonia

Dystonia is a rare disorder characterized by involuntary sustained muscle contractions that frequently cause twisting and repetitive movements or abnormal postures. The disorder can be primary or secondary and may affect any muscle.

A combination of upper airway and diaphragmatic dysfunction has been described in these patients. The results of a study of 26 patients with dystonia indicated that dyspnea in dystonia appeared to be caused by excessive and/or desynchronized contractions of the upper airways and/or diaphragm, with usually normal gas exchange.

Reye's Syndrome

Reye's syndrome is characterized by encephalopathy and fatty accumulation in visceral organs, especially in children. Excessive lipolysis and mobilization of fat occur in this disorder, which has been shown to be associated with hypoxemia, hypocapnia, and tachypnea as well as interstitial pneumonitis, thickening of the alveolar walls, and the presence of intraalveolar foamy histiocytes.

Krabbe's Globoid Cell Leukodystrophy

Krabbe's globoid cell leukodystrophy is a hereditary degenerative brain disease caused by lack of the enzyme galactosylceramide galactosidase. The disease is characterized by the progressive development of retardation, failure to thrive, seizures, spasticity, and blindness, culminating in death by the age of 2 to 3 years. Symptoms begin at 4 to 8 months of age. In an 8-week-old boy who presented with rapidly progressive respiratory failure and died shortly thereafter, lung biopsy revealed numerous intraalveolar and a few interstitial macrophages containing intracellular structures that stained positively with periodic acid-Schiff.

Pulmonary Effects of Electroconvulsive Therapy

Electroconvulsive therapy is used in the treatment of major depressive disorders, schizophrenia, mania, and other conditions. Aspiration may occur, especially in elderly patients. Neurogenic pulmonary edema following electroconvulsive therapy has been observed in these patients.

Pulmonary Effects of Ventriculoatrial Shunt

Ventriculoatrial and ventriculoperitoneal shunts are placed to treat high-pressure hydrocephalus. The catheter tips occasionally become blocked or infected. Recurrent discharge of the proteinaceous debris from the catheter tip into the pulmonary circulation can produce recurrent embolic phenomena and secondary pulmonary hypertension. The onset of pulmonary hypertension in these patients is insidious and invariably leads to right ventricular failure. Empyema has been described as a complication of ventriculoperitoneal shunt.

Pulmonary Embolism in Neurologic Diseases

Pulmonary embolism is a common occurrence in patients with neurologic disorders and in those who undergo neurosurgery. A major etiologic factor is venous thromboembolism, especially in the lower extremities, as a result of stasis caused by significant immobilization. The risk for venous thromboembolism and pulmonary embolism is higher in patients with head trauma, stroke, spinal cord injury, brain tumor, and subarachnoid hemorrhage, and in patients who have undergone neurosurgical operations. In one study, spinal cord injury accounted for 31% of all pulmonary embolisms in the total trauma population of 2525 patients. Subacute or chronic neurologic disorders also are associated with a higher risk for pulmonary embolism. For instance, a review of the results of 60 complete autopsies performed in patients with parkinsonian syndrome revealed that pulmonary embolism was second only to pneumonia as the most common cause of overall mortality.

Anticoagulant therapy in patients with intracranial diseases is fraught with the risk of causing or aggravating hemorrhage in the brain or other areas within the cranium. Excessive anticoagulation has resulted in fatal intracerebral hemorrhage in patients with brain tumors. The risk for pulmonary embolism, however, exceeds the risk for severe or fatal bleeding from prophylactic or therapeutic anticoagulation. Studies have noted that prophylactic insertion of a filter in the inferior vena cava is effective in preventing pulmonary emboli in these patients.

Severe hypercapnia after low-flow oxygen therapy in patients with neuromuscular disease and diaphragmatic dysfunction. *Mayo Clin Proc* 1995;70:327–330. *In a retrospective review of 118 consecutive adult patients with a diagnosis of neuromuscular disease who underwent phrenic nerve conduction studies during a 5-year period, the mean $PaCO_2$ increased 28.2 ± 23.3 torr after low-flow oxygen treatment. The authors concluded that in patients with neuromuscular disease and diaphragmatic dysfunction, even low-flow supplemental oxygen should be administered with caution.*

Gozal D, Marcus CL, Shoseyov D, Keens TG. Peripheral chemoreceptor function in children with the congenital central hypoventilation syndrome. *J Appl Physiol* 1993;74:379–387. *This study of five children with congenital central hypoventilation syndrome and five controls concluded that peripheral chemoreceptor function, as assessed by acute hypoxia, hyperoxia, or hypercapnia, is present and intact in children with congenital central hypoventilation syndrome who are able to sustain adequate ventilation during wakefulness.*

Hamilton MG, Hull RD, Pineo GF. Venous thromboembolism in neurosurgery and neurology patients: a review. *Neurosurgery* 1994;34:280–296. *An extensive review of thromboembolism, a common problem in neurosurgery and neurology patients, including a discussion of the principles of prophylaxis, diagnosis, and clinical management of venous thromboembolic disease in neurosurgery and neurology patients.*

Hanly PJ, Zuberi-Khokhar NS. Increased mortality associated with Cheyne-Stokes respiration in patients with congestive heart failure. *Am J Respir Crit Care Med* 1996;153:272–276. *Overnight polysomnography in 16 male patients (nine had Cheyne-Stokes respiration during sleep and seven did not) with chronic, stable congestive heart failure showed that the former group had a higher apnea-hypopnea index (41/h vs. 6/h) and experienced greater sleep disruption. Mortality was also higher in this group. The authors suggest that Cheyne-Stokes respiration itself accelerates the deterioration in cardiac function.*

Harvey LA, Ellis ER. The effect of continuous positive airway pressures on lung volumes in tetraplegic patients. *Paraplegia* 1996;34:54–58. *Ten recently injured but otherwise healthy tetraplegic patients with lesions between the fourth and eighth cervical segments underwent lung function tests before, during, and after 32 minutes of zero end-expiratory pressure and CPAP at 5 and 10 cm H_2O. The authors concluded that CPAP at 5 and 10 cm H_2O increases FRC in healthy tetraplegic individuals but that these increases are rapidly lost with the subsequent removal of CPAP.*

Holas MA, DePippo KL, Reding MJ. Aspiration and relative risk of medical complications following stroke. *Arch Neurol* 1994;51:1051–1053. *A prospective, longitudinal cohort study of 114 consecutive inpatients admitted for stroke rehabilitation estimated that the relative risk for development of pneumonia was 6.95 times greater for those patients who aspirated compared with those who did not, 5.57 times greater for those who aspirated silently compared with those who coughed during aspiration or who did not aspirate, and 8.36 times greater for those who aspirated ³10% on one or more barium test swallows compared with those who aspirated 10% or did not aspirate.*

Horner J, Alberts MJ, Dawson DV, Cook GM. Swallowing in Alzheimer's disease. *Alzheimer Dis Assoc Disord* 1994;8:177–189. *In a prospective case series study of 25 patients with moderate or severe Alzheimer's disease, videofluoroscopy was used to assess the incidence of oropharyngeal swallowing abnormalities; aspiration occurred in 6 of 25 (28.6%). Only four patients showed unequivocally normal performance. Swallowing abnormalities were associated significantly with duration of dementia, eating dependency, and abnormal oral praxis. A trend toward a higher incidence of aspiration in patients with more severe dementia was noted.*

Horner J, Brazer SR, Massey EW. Aspiration in bilateral stroke patients: a validation study. *Neurology* 1993;43:430–433. *In a study of 38 patients with bilateral stroke, the authors observed that abnormal gag reflex and impaired voluntary cough accurately predicted radiographically verified aspiration. Patients were grouped into three risk strata: low risk of 14% (cough and gag normal), moderate risk of 46%–51% (one of two behaviors abnormal); and high risk of 87% (cough and gag abnormal).*

Ishihara H, Singh H, Giesecke AH. Relationship between diabetic autonomic neuropathy and gastric contents. *Anesth Analg* 1994;78:943–947. *Autonomic function as well as gastric volume and pH were measured in 36 patients with diabetes mellitus and 15 nondiabetic patients at induction of general anesthesia for elective ambulatory surgery. Solid, undigested food particles were found more often in the gastric contents of diabetic patients with autonomic neuropathy. These findings support observations by others that delayed gastric emptying secondary to diabetic autonomic neuropathy is a recognized risk factor for aspiration pneumonitis.*

Izquierdo-Alonso JL, Jimenez-Jimenez FJ, Cabrera-Valdivia F, Mansilla-Lesmes M. Airway dysfunction in patients with Parkinson's disease. *Lung* 1994;172:47–55. *Maximal inspiratory and expiratory flow-volume curves in 63 patients (59 under treatment) at different stages of Parkinson's disease showed that 31 patients (49%) had abnormal flow-volume curves. The clinical profile and duration of the disease did not influence the pattern of the curve. A restrictive ventilatory defect (FEV_1/FVC 80%) was observed in 54 patients (85%). The authors conclude that abnormal flow-volume loops probably reflect involvement of the upper airway musculature.*

Johnson ER, McKenzie SW, Sievers A. Aspiration pneumonia in stroke. *Arch Phys Med Rehabil* 1993;74:973–976. *Among a total population of 304 patients with acute stroke, aspiration pneumonia developed within 1 year in 29 of 60 patients referred for videofluoroscopic evaluation of poststroke dysphagia. The presence of vallecular pooling, piriform pooling, or bolus penetration to or through the true vocal cords on videofluoroscopy did not correlate with the development of aspiration pneumonia.*

Kaplan LM, Hollander D. Respiratory dysfunction in amyotrophic lateral sclerosis. *Clin Chest Med* 1994;15:675–681. *The discussion includes a detailed review of respiratory complications in amyotrophic lateral sclerosis, a progressive and currently incurable neurodegenerative disorder of the voluntary motor system. The authors provide details of the clinical features and diagnosis, and offer guidelines for the management of respiratory failure.*

Karaaslan T, Meuli R, Androux R, Duvoisin B, Hessler C, Schnyder P. Traumatic chest lesions in patients with severe head trauma: a comparative study with computed tomography and conventional chest roentgenograms. *J Trauma* 1995;39:1081–1086. *Among 47 consecutive patients with severe craniocerebral trauma who underwent CT of the head and prospective limited CT examination of the thorax, nine patients had pneumothorax (bilateral in one). Thirty-one areas of pulmonary parenchymal contusions were seen in 19 subjects, and rupture of thoracic aorta and right diaphragmatic rupture each in one patient. The limited CT examination of the chest supplied additional information (compared with chest roentgenography) in 30% of patients.*

Kennedy JD, Staples AJ, Brook PD, Parsons DW, Sutherland AD, Martin AJ, Stern LM, Foster BK. Effect of spinal surgery on lung function in Duchenne muscular dystrophy. *Thorax* 1995;50:1173–1178. *In a retrospective study, 17 boys with Duchenne muscular dystrophy who had undergone spinal stabilization at a mean age of 14.9 years (surgical group) were compared with 21 boys having Duchenne muscular dystrophy who had not had surgery (nonsurgical group). No difference was found between spinal stabilization (surgical group) and the nonsurgical group in the rate of deterioration of % FVC, which was 3%–5% per year. Spinal stabilization in Duchenne muscular dystrophy did not alter the decline in pulmonary function, nor did it improve survival.*

Khan Y, Heckmatt JZ. Obstructive apnoeas in Duchenne muscular dystrophy. *Thorax* 1994;49:157–161. *The evolution of sleep hypoxemia with age was studied in 21 patients with Duchenne muscular dystrophy and compared with that in 12 age-matched normal male subjects. Among patients, 13 had hypoxemia below 90% during sleep, and 12 of the 13 had discrete hypoxemic dips in association with episodes of apnea; 60% of all episodes of apnea were obstructive in nature. The hypoxemic periods became more frequent with increasing age.*

Kidd D, Lawson J, Nesbitt R, MacMahon J. Aspiration in acute stroke: a clinical study with videofluoroscopy. *QJM* 1993;86:825–829. *During prospective clinical evaluations, bedside water-swallowing tests, and videofluoroscopy performed within 72 hours of stroke in 60 consecutive patients admitted to a hospital within 24 hours of their first symptomatic stroke, it was observed that 25 patients (42%) aspirated at videofluoroscopy. Aspiration was significantly associated with reduced pharyngeal sensation, dysphagia, and severe stroke.*

Kidd D, Lawson J, Nesbitt R, MacMahon J. The natural history and clinical consequences of aspiration in acute stroke. *QJM* 1995;88:409–413. *In a prospective, 3-month study of 60 consecutive patients with acute stroke, videofluoroscopy was used to identify aspiration in 25 patients (42%) within 72 hours of stroke onset, and aspiration had resolved in all but three patients (8%) after 3 months. It was closely related to the presence of dysphagia, which itself resolved within 2 weeks in all but the persistent aspirators. Lower respiratory tract infection was more common in aspirators (68%) than in nonaspirators (6%).*

Lyager S, Steffensen B, Juhl B. Indicators of need for mechanical ventilation in Duchenne muscular dystrophy and spinal muscular atrophy. *Chest* 1995;108:779–785. *In a nonrandomized, prospective, descriptive study of 11 patients with spinal muscular atrophy type II and 14 patients with Duchenne muscular dystrophy, the authors observed that the seven patients who needed mechanical*

ventilation were those with Duchenne muscular dystrophy who had the greatest disability and the smallest values for FVC (% FVC 30).

Cardiac injury associated with neurogenic pulmonary edema following subarachnoid hemorrhage. *Neurology* 1994;44:815–820. *In this study of five patients (none had heart disease) who sustained acute subarachnoid hemorrhage, the authors observed that a reversible form of cardiac injury may contribute to cardiovascular instability and aggravate neurogenic pulmonary edema.*

McCool FD, Tzelepis GE. Inspiratory muscle training in the patient with neuromuscular disease. *Phys Ther* 1995;75:1006–1014. *In this review of seven studies evaluating respiratory muscle training in a total of 75 patients with varied neuromuscular disorders, the adverse effects of respiratory muscle weakness on pulmonary mechanics are discussed, and the role of inspiratory muscle training in reversing pulmonary dysfunction in patients with neuromuscular disease is examined.*

Mosewich RK, Rajput AH, Shuaib A, Rozdilsky B, Ang L. Pulmonary embolism: an underrecognized yet frequent cause of death in Parkinsonism. *Mov Disord* 1994;9:350–352. *In this review of the results of 60 complete autopsies performed on patients with parkinsonian syndrome, pulmonary embolism is second only to pneumonia as the most common cause of death overall.*

Mulvey DA, Aquilina RJ, Elliott MW, Moxham J, Green M. Diaphragmatic dysfunction in neuralgic amyotrophy: an electrophysiologic evaluation of 16 patients presenting with dyspnea. *Am Rev Respir Dis* 1993;147:66–71. *Report of a study of 16 adult men (ages 41 to 75 years) with neuralgic amyotrophy (Parsonage-Turner syndrome) who presented with dyspnea caused by involvement of the diaphragm. Breathlessness developed in all patients after a prodrome of acute severe neck and shoulder pain. Bilateral diaphragmatic paralysis was confirmed in 12 patients and unilateral diaphragmatic paralysis in four.*

Perez A, Mulot R, Vardon G, Barois A, Gallego J. Thoracoabdominal pattern of breathing in neuromuscular disorders. *Chest* 1996;110:454–461. *This study assessed abnormalities in the thoracoabdominal pattern of breathing in 31 patients with spinal muscular atrophy and 19 patients with myopathy (mean age, 10 years). Marked abnormalities in the thoracoabdominal pattern of breathing were noted in the former group.*

Polkey MI, Green M, Moxham J. Measurement of respiratory muscle strength. *Thorax* 1995;50:1131–1135. *This editorial review discusses an algorithmic approach to the measurement of respiratory muscle strength. The steps include bedside clinical tests, imaging methods, physiologic measurements, sniff test, and electrical and magnetic stimulation of the diaphragm.*

Quevedo JF, Buckner JC, Schmidt JL, Dinapoli RP, O'Fallon JR. Thromboembolism in patients with high-grade glioma. *Mayo Clin Proc* 1994;69:329–332. *In a retrospective analysis of 64 patients enrolled in two prospective clinical trials of therapy for newly diagnosed high-grade glioma, venous thromboembolism occurred in 18 of the 64 patients (28%); 11 had deep venous thrombosis of a lower extremity, five had pulmonary emboli, and two had superficial thrombophlebitis. A paretic arm or leg or a history of thromboembolism before the diagnosis of glioma was more common in patients with thromboembolism than in those without thromboembolism.*

Rich MW, Radwany SM. Respiratory dyskinesia. An underrecognized phenomenon. *Chest* 1994;105:1826–1832. *An extensive review of various types of dyskinesia and their pulmonary manifestations; includes review of six other studies that have addressed the prevalence of respiratory dyskinesia in patients with tardive dyskinesia.*

Rieder P, Louis M, Jolliet P, Chevrolet JC. The repeated measurement of vital capacity is a poor predictor of the need for mechanical ventilation in myasthenia gravis. *Intensive Care Med* 1995;21:663–668. *Repeated measurements of arterial blood gases and VC (at least every 4 hours) during ten episodes of acute respiratory failure caused by decompensated myasthenia gravis in five patients showed no difference in these parameters between patients eventually requiring mechanical ventilation (four episodes) and those in whom mechanical ventilation was not necessary (six episodes).*

Rogers FB, Shackford SR, Trevisani GT, Davis JW, Mackersie RC, Hoyt DB. Neurogenic pulmonary edema in fatal and nonfatal head injuries. *J Trauma* 1995;39:860–866. *A large autopsy database and database of head-injured patients were analyzed. Results showed that the incidence of neurogenic pulmonary edema in patients with isolated head injury dying at the scene was 32%. In patients with isolated head injury dying within 96 hours, the incidence of neurogenic pulmonary edema was 50%. The authors conclude that neurogenic pulmonary edema begins early in the clinical course.*

Roth EJ, Nussbaum SB, Berkowitz M, Primack S, Oken J, Powley S, Lu A. Pulmonary function testing in spinal cord injury: correlation with vital capacity. *Paraplegia* 1995;33:454–457. *In 52 patients with recent acute traumatic spinal cord injury, complete pulmonary function testing revealed that VC was significantly correlated with* FEV_1*, FRC, RV, TLC, inspiratory capacity, expiratory reserve volume, and RV/TLC ratio, but not with either* Pe_{max} *or* Pi_{max}*. The authors conclude that the excellent correlations between VC and nearly all the other pulmonary function tests support the use of VC as a single global measure of overall ventilatory status in patients with spinal cord injury.*

Sherman MS, Paz HL. Review of respiratory care of the patient with amyotrophic lateral sclerosis. *Respiration* 1994;61:61–67. *This article reviews the physiology of respiratory compromise in amyotrophic lateral sclerosis and techniques of monitoring respiratory function. Treatment options, including pharmacologic interventions, precautions to prevent aspiration, and invasive and noninvasive modes of mechanical ventilation, are reviewed.*

Stanghelle JK, Festvag L, Aksnes AK. Pulmonary function and symptom-limited exercise stress testing in subjects with late sequelae of poliomyelitis. *Scand J Rehabil Med* 1993;25:125–129. *In this study, 68 consecutive subjects with a presumptive postpolio syndrome underwent pulmonary function and symptom-limited exercise stress testing. Moderately reduced lung function of a restrictive type and a pronounced reduction in maximal oxygen uptake (*$\dot{V}O_{2max}$*) were seen, the latter especially in women. The authors conclude that considerable cardiorespiratory deconditioning occurs in most of their subjects with postpolio syndrome.*

Stubgen JP, Ras GJ, Schultz CM, Crowther G. Lung and respiratory muscle function in limb girdle muscular dystrophy. *Thorax* 1994;49:61–65. *Standard lung and respiratory muscle function tests in 20 patients (mean age, 41 years) with limb girdle muscular dystrophy and 20 healthy subjects revealed evidence of unilateral paresis of the diaphragm in three patients. Respiratory muscle weakness was common but mild. Expiratory muscle function was more impaired than inspiratory muscle function.*

Teasell RW, McRae M, Marchuk Y, Finestone HM. Pneumonia associated with aspiration following stroke. *Arch Phys Med Rehabil* 1996;77:707–709. *A review of 441 consecutive patients admitted to a rehabilitation unit within 4 months of stroke during an 8-year period. Videofluoroscopic barium swallow in patients suspected of aspirating detected aspiration of thin liquids in 84 patients (19%), and pneumonia developed in 12 (2.7%) of 441 patients. The incidence of pneumonia among proven aspirators was 11.9% (10/84).*

Teitelbaum JS, Borel CO. Respiratory dysfunction in Guillain-Barré syndrome. *Clin Chest Med* 1994;15:705–714. *A detailed review of pulmonary complications in Guillain-Barré syndrome, the most common cause of acute paralysis and neuromuscular ventilatory failure. The authors state that a good clinical outcome depends to a large extent on anticipation and management of ventilatory failure and its complications. The role of plasma exchange and immune globulins is discussed.*

Wilson JT, Rogers FB, Wald SL, Shackford SR, Ricci MA. Prophylactic vena cava filter insertion in patients with traumatic spinal cord injury: preliminary results. *Neurosurgery* 1994;35:234–239. *A retrospective, 5-year review of 111 patients with traumatic spinal cord injury; eight pulmonary emboli were documented in seven patients, and there were three fatalities. Six pulmonary embolisms occurred after discharge from the acute care facility. Spinal cord injury accounted for 31% of all pulmonary embolisms in the total trauma population of 2525 patients. After inferior venal caval filters were inserted in 15 patients, no case of deep venous thrombosis or pulmonary embolism occurred.*

Woratyla SP, Morgan AS, Mackay L, Bernstein B, Barba C. Factors associated with early-onset pneumonia in the severely brain-injured patient. *Conn Med* 1995;59:643–647. *Among 125 patients with closed head injury, pneumonia was diagnosed in 60%, and early pneumonia developed in 48%. Early pneumonia was more frequent in patients with a lower score on the Glasgow Coma Scale (5) and in those with swallowing disorders and evidence of aspiration. Patients with early pneumonia had prolonged intubation times, intensive care unit stays, and hospital stays.*

CHAPTER

61 Skeletal Diseases

Udaya B.S. Prakash

U.B.S. Prakash: Pulmonary and Critical Care Medicine, Mayo Medical School and Mayo Medical Center, Rochester, Minnesota 55905.

INTRODUCTION

The skeletal thorax is as much a part of the respiratory system as are the lungs, and hence it plays a major role in normal pulmonary function. Instability of the chest wall can lead to respiratory failure, as exemplified by ventilatory failure in patients with flail chest. Congenital and acquired defects and diseases of the thoracic cage may interfere with the normal respiratory mechanics. Occasionally, diseases of the extrathoracic skeleton may be associated with lung problems. An excellent example of this is the pulmonary parenchymal process that occurs in patients with ankylosing spondylitis. In this chapter, some common and uncommon skeletal diseases in which the respiratory system is involved are discussed. Certain disease entities, such as Marfan's syndrome, that are not primary skeletal diseases are nonetheless covered here, because skeletal abnormalities are clinically evident in such patients. The major spinal deformities are scoliosis, kyphosis, pectus excavatum, pectus carinatum, and straight-back syndrome. Discussions of respiratory complications in ankylosing spondylitis and several other skeletal disorders are also included.

KYPHOSCOLIOSIS

Scoliosis is deformity of the spine characterized by marked lateral curvature, kyphosis is the abnormally accentuated posterior curvature of the spine, and kyphoscoliosis is the combination of the two, which results in a lateral bending and rotation of the vertebral column. Pulmonary problems occur in both scoliosis and kyphoscoliosis (Fig. 1).

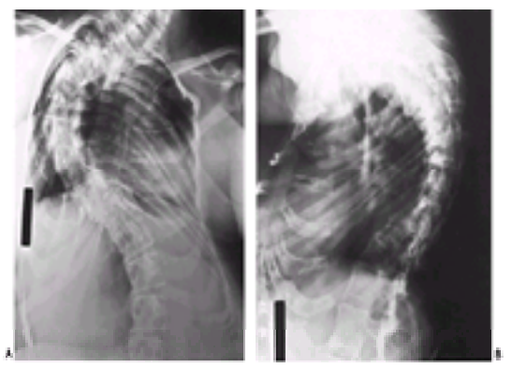

FIG. 1. Severe thoracic kyphoscoliosis. **A:** Posteroanterior view. **B:** Left lateral view.

Scoliosis is by far the most common spinal deformity. An incidence of 4/1000 population was found by a roentgenographic survey. Scoliosis is classified etiologically into five varieties: idiopathic, congenital, neuropathic (poliomyelitis, cerebral palsy, and syringomyelia), myopathic (muscular dystrophy, amyotonia, and Friedreich's ataxia), and traumatic. Scoliosis also is seen in mesenchymal disorders and in association with neurofibromatosis. In practice, 80% of cases of scoliosis are idiopathic. Among infants, the male-to-female ratio is 6:4, but among cases that begin in adolescence—the largest group—the ratio is 1:9, and overall it is 2:8. Infantile scoliosis is reported usually to involve a curvature toward the left, whereas scoliosis in adolescent girls is usually toward the right. A familial basis for idiopathic scoliosis exists. Among first-, second-, and third-degree relatives of children with idiopathic scoliosis, abnormal spinal curvature occurs 20 times as often as in a comparable group of the general population. In congenital scoliosis of early onset, there is failure of alveolar multiplication, whereas in idiopathic scoliosis, the alveoli do not enlarge normally.

Idiopathic scoliosis in adolescent girls usually involves 7 to 10 vertebrae. The curvature or angulation of a scoliotic spine is best measured by the Cobb method (Fig. 2). Pulmonary symptoms are not seen until the curvature exceeds 70°. Adolescent idiopathic thoracic curves of 60° to 80° have been observed to increase by an average of 30° during a period of 25 years after completion of growth. The Cobb angle has been traditionally employed in the clinical assessment and correlation of spinal deformity and pulmonary function tests. However, a study of 70 adolescents (mean age, 13.8 years) with idiopathic right thoracic scoliosis found that the mean values for the Cobb angle, vertebral rotational flexibility, kyphosis, and rib-vertebral angle asymmetry (in radiographs of standing as well as supine bending positions) differed significantly between patients with >80% of predicted vital capacity and those whose vital capacity was £60% of predicted values. Roentgenologic features indicative of better pulmonary function included rotational flexibility exceeding 55%, rib-vertebral angle asymmetry (standing) of <25°, and kyphosis of 15°. The two parameters of deformity, vertebral rotational flexibility and rib-vertebral angle asymmetry, provided a better prediction of respiratory function than the commonly used Cobb angle.

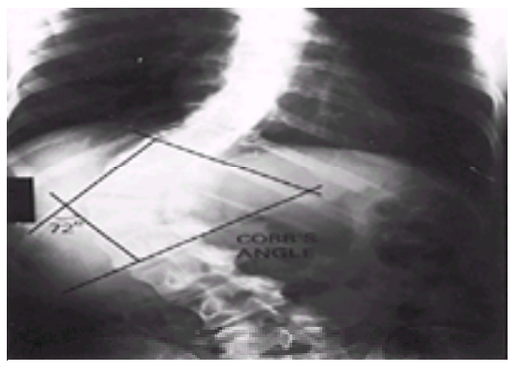

FIG. 2. The Cobb angle is determined by lines drawn perpendicularly to the tangents from the end plates of the most tilted superior and inferior vertebrae.

The scoliotic angle is an important predictor of respiratory failure. In a long-term study of 24 patients with unfused scoliosis, pulmonary function tests were performed 20 years apart, and respiratory failure occurred only in patients who had a vital capacity of 45% of the predicted value during the initial testing and an angle 110°; the initial vital capacity was the strongest predictor of the development of respiratory failure, followed by scoliotic angle. In a study of 29 patients with adolescent idiopathic thoracic scoliosis of 60°, maximal inspiratory pressure was found to be reduced, but maximal expiratory pressure was normal. The low maximal inspiratory pressure was attributed to the mechanical disadvantage resulting from the chest deformity.

Abnormalities of Pulmonary Function

The most common abnormality of pulmonary function is a reduction in static lung volumes, including vital capacity and total lung capacity. An inverse relationship exists between the angle of scoliotic curvature and the values (as a percentage of predicted values) for vital capacity, total lung capacity, functional residual capacity, residual volume, and static compliance of the total respiratory system. The ventilatory function may be impaired even in mild forms of scoliosis. The force developed by the respiratory muscles is a more important determinant of ventilatory defect than is the degree of spinal curvature. The decreased lung compliance is most pronounced in scoliotic patients with muscle weakness. In kyphoscoliosis, prediction of lung volume from body height results in significant underestimation, but arm span serves satisfactorily for this purpose. A method has evolved by which the theoretical height of these patients is predicted from the angle of scoliosis, length of spine, and actual height.

Even though restrictive lung dysfunction is typical in patients with severe scoliosis, obstructive airway disease and positive bronchodilator response are present. Extensive pulmonary function testing in 44 children (36 girls, 8 boys) between the ages of 10 and 18 years with idiopathic scoliosis before surgical correction showed significant restrictive defect in 41% of subjects, whereas air flow obstruction was noted in 7% of subjects. However, the ratio of total gas volume (by plethysmography) to functional residual capacity (by helium dilution) demonstrated moderate or severe gas trapping in 20 subjects (46%). Bronchodilator administration resulted in significant improvement in airway mechanics. Other studies of pulmonary function studies in children with idiopathic scoliosis have shown diminished vital capacity, 1-second forced expiratory volume, gas transfer, and maximal static expiratory airways pressure, but no significant diminution in total lung capacity or maximal inspiratory pressure.

The characteristic deformity seen in scoliosis causes one hemithorax to become smaller than the other. This inherent mechanical inefficiency of ventilation is the major factor in causing respiratory embarrassment. Patients with moderate to severe kyphoscoliosis have significant oxygen desaturation during exercise and should thus routinely be tested by oximetry during exercise for assessment of ambulatory oxygen therapy. Although hypoxemia often is present and has been attributed to alveolar hypoventilation resulting from small tidal volumes, arterial CO_2 tension ($PaCO_2$) usually is normal. In advanced cases, however, increased $PaCO_2$ is common and signifies the onset of serious respiratory insufficiency. Increased ratios of physiologic dead space to tidal volume (V_D/V_T) and elevated alveolar-arterial oxygen tension gradients [$P(A\text{-}a)O_2$] have been demonstrated. Studies employing xenon 133 have shown that the gas exchange abnormality in idiopathic scoliosis is primarily a consequence of ventilation-perfusion maldistribution resulting from deformity of the ribs. The proportion of ventilation, oxygen consumption, and volume on the side of convexity is less than on the side of concavity. However, a study with radionuclide methods did not find consistent differences in perfusion between the convex and concave sides of the curvature. Although adolescents with mild, asymptomatic scoliosis (thoracic curvature of 35°) demonstrate little or no impairment of lung volumes at rest, abnormal ventilatory patterns develop during exercise, hypoxia, or hypercapnia.

Clinical Features

Symptoms and signs of respiratory failure usually do not appear until the fourth or fifth decade. Cardiorespiratory failure is likely to occur when the vital capacity is 40% of the predicted normal value. Patients in whom cor pulmonale develops exhibit severely diminished total lung capacity. A retrospective survey of approximately 800 scoliotic subjects attending a chest clinic during a 25-year period revealed that cardiorespiratory failure attributable to scoliosis was the cause of death in 11 patients; in 10 of these the scoliotic curve had first been observed at 5 years of age, whereas the onset was during early adolescence (11 years) in only one.

The term *Quasimodo syndrome* is employed to describe severe kyphoscoliosis with abnormal sleep patterns. Sleep apnea and hypopnea occur more frequently in patients with kyphoscoliosis. Derangements in breathing pattern and arterial oxygen saturation apparently are unrelated to the degree of thoracic deformity, pulmonary function, $PaCO_2$, or chemical drives to breathe. Hypoventilation occurs in patients with kyphoscoliosis during sleep, particularly rapid-eye-movement (REM) sleep. Hypoventilation secondary to reduced chest wall movements is the main mechanism responsible for hypoxemia and hypercapnia during sleep. Pure obstructive sleep apnea caused by spinal deformity alone is uncommon.

An interesting observation has been the significant association between scoliosis and pulmonary infection with *Mycobacterium avium* complex. In an evaluation of 67 patients with pulmonary disease caused by *M. avium* complex, 52% of patients were discovered to have scoliosis. This skeletal abnormality was significantly more common among all patients with *M. avium* complex infection than among patients with *M. tuberculosis* infection or the general population. This increased risk for infection among scoliotic subjects is most likely related to structural bronchopulmonary abnormalities rather than to immunologic or other well-known risk factors.

Atelectasis of a lobe as a result of scoliosis-related bronchial stenosis has been described. Clinically significant bronchiectasis is a late complication in patients with severe kyphoscoliosis. Subclinical lung damage by this mechanism may predispose to secondary infections observed in some patients.

Treatment of Kyphoscoliosis

Significant improvements in pulmonary function test results is unlikely in the majority of patients who undergo corrective surgery. The aim of all therapies in this group of patients is to halt progression of the spinal deformity and thereby prevent further progression of pulmonary dysfunction. In a study of 14 adults who underwent anterior spinal surgery for correction of scoliosis, a follow-up evaluation 32 months later revealed a fall in mean forced vital capacity of 0.21 L despite improvement in the Cobb angle of 31%. The inference from this study is that in adults with reasonable lung function, the fall in forced vital capacity is small and clinically insignificant. Another study noted that whereas pulmonary function test values normalize in adolescent patients by 2 years after thoracoplasty, long-term pulmonary function in adults remains diminished. In advanced cases with hypercapnic respiratory failure, the treatment is mainly aimed at assisted ventilation to improve oxygenation and treat hypercapnia. It has been recommended that children with congenital scoliosis caused by multiple anomalies undergo surgery at an early age, before deformity becomes too severe.

Milwaukee brace or spinal fusion and reduction of the deformity by the posterior placement of Harrington's distraction strut bars have been the standard approaches to therapy of kyphoscoliosis. Many studies have shown no appreciable difference in lung function between patients with the Milwaukee brace and those with surgical correction. In severe respiratory failure resulting from kyphoscoliosis, cuirass respirators have been used with varying success. In a meta-analysis of five studies comprising a total of 173 patients, the Harrington's rod therapy resulted in an increase in mean vital capacity ranging from 2%–11% of predicted vital capacity.

Nighttime ventilatory support using continuous positive airway pressure is helpful in many patients with respiratory failure caused by secondary scoliosis. A comparison study of 13 clinically stable patients with kyphoscoliosis treated by nocturnal positive pressure ventilation via a nasal mask and 13 patients with kyphoscoliosis and acute respiratory insufficiency treated by nocturnal ventilation via tracheostomy concluded that both treatments are effective in the long-term management of respiratory failure in these patients. It appears that if nocturnal positive pressure ventilation via a nasal mask is initiated earlier in patients with chronic respiratory failure, the need to use an invasive technique, such as tracheostomy, is delayed.

Acute respiratory failure in adults with severe thoracic spinal deformity is associated with a higher mortality, but successful management of acute respiratory failure is

possible in the majority of patients. Pulmonary function deteriorates at a slower rate after acute respiratory failure in these patients, who tend to be middle-aged, than in patients in whom acute respiratory failure develops as a result of chronic obstructive respiratory disease.

Postoperative Respiratory Complications

Postoperative respiratory complications after spinal fusion are common in patients with nonidiopathic scoliosis who are 20 years of age or older, undergo anterior spinal fusion, are mentally retarded, and have relative arterial hypoxemia or obstructive pulmonary dysfunction. In a report of 32 pediatric patients (18 boys and 14 girls; mean age, 13 years) with severe restrictive lung disease (mean vital capacity, 31% of predicted normal), 54 reconstructive spinal surgical procedures were followed by pulmonary complications in six patients (19%). They included pneumonia, reintubation, pneumothorax, respiratory arrest, or the need for tracheostomy, with three patients requiring tracheostomy. Patients in whom thoracotomy or a thoracoabdominal approach was used had a significantly higher number of pulmonary complications. Lung function measurements in anesthetized young patients undergoing spinal correction have shown immediate and short-term deterioration of respiratory mechanics. However, in one study that assessed the effects of spinal fusion on pulmonary function test values in a homogeneous population of 42 women with idiopathic scoliosis by measuring lung function before and a minimum of 3 years (mean, 7.7 years) after surgery, the only significant preoperative abnormality found was vital capacity reduced to 81% of predicted. A scoliotic angle exceeding 50° was associated with a significantly lower vital capacity. Postoperative evaluations showed that vital capacity increased significantly, by 12%.

PECTUS DEFORMITIES

Pectus Excavatum

The congenital deformity pectus excavatum (also called *funnel chest*) is characterized by a depressed sternum (usually above the xiphisternal junction) and symmetric or asymmetric prominence of the ribs on either side. The origin of pectus excavatum is unknown, but it is believed to be caused by excessive diaphragmatic traction on the lower sternum or a more lateral displacement of the heart into the left hemithorax. A report of 10 cases of pectus excavatum noted pulmonary sequestration and other pulmonary abnormalities in nine patients and suggested a connection between pulmonary sequestration and the development of this deformity. However, when the common occurrence of pectus excavatum in clinical practice is considered, this incidence seems unusually high. Pectus excavatum usually occurs sporadically, although a dominant pattern of inheritance has been described. It may be associated with Marfan's syndrome and other connective tissue diseases. The majority of patients are asymptomatic, but some experience exertional dyspnea, precordial pain, palpitation, and a sensation of dizziness. Pulmonary function is usually normal, but with very severe deformity the vital capacity, total lung capacity, and maximal breathing capacity may be decreased.

Chest roentgenograms may reveal displacement of the heart to the left. The right parasternal soft tissues of the anterior chest wall give rise to the appearance of right middle lobe disease on posteroanterior roentgenograms (Fig. 3A). Sternal depression is best appreciated on lateral views (Fig. 3B). Paradoxical increase in cardiac size on inspiration has been described.

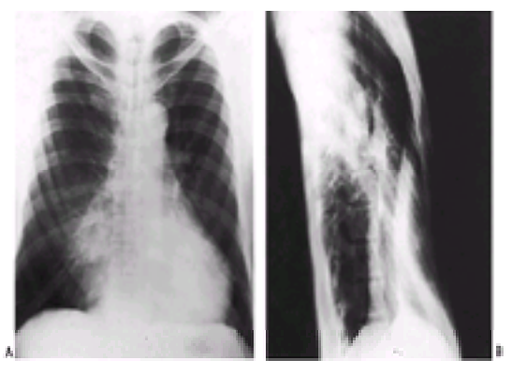

FIG. 3. Pectus excavatum. **A:** Right border of the heart is obliterated, and an infiltrate is apparent in the right middle lobe. The ribs on the right appear crowded. **B:** Right lateral view shows sternal depression.

In the study mentioned earlier, 27% of 67 patients with *M. avium* complex infection were found to have pectus excavatum deformity. By comparison, only 5% with *M. tuberculosis* infection had this skeletal abnormality. The prevalence of pectus excavatum among women with *M. avium* complex infection was significantly different from that among either the general population or patients infected with *M. tuberculosis,* whereas the prevalence of *M. avium* infection in male patients with pectus excavatum was significantly different from that in the general population but not from that in patients infected with *M. tuberculosis.* Possible mechanisms for this putative association include bronchopulmonary structural abnormalities secondary to pectus excavatum, impaired mucociliary function, impaired pulmonary lymphatic drainage, and altered alveolar macrophage function. It is unlikely that the skeletal abnormalities occurred as a result of mycobacterial infection, because there were no indications of chronic or past tuberculous infections.

An earlier study reported an apparent increase in infections of the lower respiratory tract among a series of U.S. Air Force recruits with pectus excavatum. Two cases of congenital bronchial atresia with pectus excavatum are reported; the authors indicate that costosternal retraction during the efforts to overcome the airway obstruction may have played a part in causing pectus excavatum.

In patients with significant pectus excavatum, pulmonary function tests usually show restrictive phenomena. The restrictive lung dysfunction does not appear to be related to age, severity of the deformity at physical examination, or pulmonary symptoms. In a study of 152 patients who underwent surgery for pectus excavatum at a mean age of 15 years, lung function was reevaluated after 8 years, and it was noted that the restrictive pulmonary dysfunction worsened despite a reduction in the symptoms of most patients and despite a significant increase in anteroposterior diameter of the chest.

Pectus Carinatum

Pectus carinatum is a congenital or acquired deformity of the chest cage characterized by protrusion of the sternum. It is a relatively rare chest deformity with an occurrence rate of 1 to 2/1000 population. Type I pectus carinatum, or “pigeon breast,” is caused by an overgrowth of rib cartilages, resulting in forward buckling of the sternum. Pectus carinatum type II, or “pouter pigeon breast” (Currarino-Silverman syndrome), is characterized by premature fusion of the manubriosternal joint and sternal segments, resulting in high carinate chest deformity. Both types of pectus carinatum deformities are frequently associated with congenital heart disease. The common cardiac anomalies in type I deformity are congenital atrial or ventricular septal defects. Conversely, nearly 50% of patients with those forms of heart disease have pectus carinatum. Some have reported that chronic and prolonged asthmatic attacks produce this deformity. Most patients with pectus carinatum are asymptomatic, but it has been suggested that they are subject to recurrent respiratory infections.

Pectus Deformatum

Pectus deformatum is the term used to describe an axially rotated sternum with an *S*-shaped frontal or sagittal plane. Among 80 patients with various abnormalities of the thoracic cage, pectus deformatum was noted in 13 (16%), and the incidence was identical to that of pectus carinatum. Pulmonary function abnormalities are usually mild, somewhat similar to those in pectus excavatum and pectus carinatum.

Surgical Correction of Pectus Deformities

Pectus deformities are surgically corrected for cosmetic reasons, to alleviate cardiopulmonary dysfunctions, and to prevent progressive postural deformities. In a study of 88 patients who underwent surgical correction of any of the pectus deformities just discussed, the operation appeared to have a favorable effect on chest roentgenologic indices but resulted in undercorrection in pectus excavatum and overcorrection in pectus carinatum. Furthermore, the study revealed that patients with preoperative lung function values that were 75% of predicted values experienced a functional improvement after corrective surgery. Interestingly, the pulmonary dysfunction worsened if lung function values were 75% of predicted. Another pulmonary function study of 138 patients before and after surgical correction of pectus excavatum reported that although the corrective procedures produced an excellent cosmetic result, there was no beneficial effect on pulmonary function. Among 227 children with pectus excavatum and 25 with pectus carinatum (195 boys and 57 girls) who underwent repair of pectus deformities, preoperative exercise limitation was reported by 51% and frequent respiratory infections or asthma were reported by 32%. Surgical repair through a transverse incision, with subperiosteal resection of the lower four or five costal cartilages from sternum to costochondral junction bilaterally, resulted in improvements in exercise tolerance, endurance, respiratory symptoms,

and cosmetic appearance in 98% of patients. The authors of this study recommend operation at an early age with routine use of substernal support.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis, also known by other names, including *rheumatoid spondylitis* and *Marie-Strumpell disease,* is a chronic disorder characterized by progressive inflammation of the spine and adjacent soft tissues. The sacroiliac, hip, and shoulder joints are commonly affected. The disease affects men (male-to-female ratio 10:1) 16 to 40 years of age but begins most often in the third decade. The cause is unknown. Ankylosing spondylitis may be inherited by a single autosomal dominant factor, with a 70% penetrance in men and a 10% penetrance in women. A high association exists between ankylosing spondylitis and the histocompatibility antigen HLA-B27. Extraskeletal manifestations are numerous and include incompetence of the aortic valve, varying degrees of heart block, acute anterior uveitis, fever, anemia, fatigue, and weight loss.

The most widespread involvement of the respiratory system occurs when ankylosing spondylitis causes chest wall pain, diminished chest wall movement, and a dorsal stoop. Although pulmonary involvement has been reported in 2%–70% of these patients in the clinical setting, only a small percentage (5%) demonstrate clinically discernible pulmonary problems. In a review of 2080 patients with ankylosing spondylitis, pleuropulmonary manifestations were noted in only 28 (1.3%). The most common chest roentgenologic finding was fibrobullous apical lesions in 26 patients. Other pleuropulmonary features included aspergilloma in five and pleural effusion with nonspecific pleuritis in three patients. A peculiar type of fibrotic process in the upper lobes characterized by nodular and linear lesions has been observed in 14%–30% of patients. The process initially appears as linear strands in the upper lobes, beginning medially and radiating laterally. When the spine resembles bamboo, these linear strands give rise to a “telephone pole” appearance. Occasionally, the linear strands are replaced by small nodules that show cavitation or appear cystic (Fig. 4). Computed tomography may reveal bullous changes, mycetomas, parenchymal fibrosis, and pleural thickening. The cystic spaces and cavities occasionally become infected by *Aspergillus* species, *M. avium* complex, *M. kansasii,* or *M. scrofulaceum.*

FIG. 4. Ankylosing spondylitis demonstrates “bamboo spine,” bilateral apical fibrous cavitary process, and right diaphragmatic calcification.

Diffuse interstitial pneumonitis and fibrosis are uncommon. Bronchoalveolar lavage and bronchial biopsies in patients with ankylosing spondylitis have failed to indicate subclinical alveolitis. Bilateral pleural effusion has been described in a patient with quiescent ankylosing spondylitis. A case of tracheobronchomegaly is reported in association with ankylosing spondylitis.

Upper airway involvement in the form of cricoarytenoid ankylosis occurs in some patients. Respiratory failure resulting from cricoarytenoid ankylosis has necessitated therapeutic tracheostomy in four patients. Calcification and ossification of cartilaginous structures may occur in the large airways. Obstruction by ossified arytenoid cartilage has been treated by endoscopic arytenoidectomy. Carcinoma of the upper lobes of lungs is another unusual long-term complication. Pathologic analysis of lung tissue in ankylosing spondylitis has demonstrated nonspecific fibrosis with lymphocytic infiltrates, dilated bronchi, and thin-walled bullae and cavities. Diaphragmatic calcification is seen in a small number of patients.

Ankylosing spondylitis alters lung function by modifying the mechanical properties of the thoracic cage. The ankylosis of the costovertebral joints rarely produces symptoms, even though pulmonary function test values are abnormal in these patients. Pulmonary function tests reveal diminished total lung capacity, vital capacity, and diffusing capacity for carbon monoxide. Increases in residual volume and functional residual capacity are the other findings, although in some studies the functional residual capacity was decreased. Lung function studies in 16 patients with ankylosing spondylitis recorded a mean total lung capacity of 83% of predicted and normal total respiratory resistance. Ventilation studies using xenon 133 have shown decreases in ventilation and gas volumes in the upper lobes; however, one study concluded that the upper zones of the lungs are not underventilated in patients with ankylosing spondylitis except in the presence of radiographically visible fibrosis. In a study of 32 patients with ankylosing spondylitis, pulmonary function test findings were compared with those of a control population. The patients had no lung symptoms, and their chest roentgenographic findings were normal. The main findings were reduced lung volumes, a raised closing volume-to-vital capacity ratio, and decreased airways conductance. The lung volume reduction correlated with disease duration, thoracic mobility, and degree of acute-phase reaction. The stiff spondylitic thorax probably was the main contribution to the impairment of lung function in these patients, but the findings in this study also suggested involvement of the small airways. Despite abnormal pulmonary function test findings, the majority of patients with ankylosing spondylitis are able to perform normal physical activities. Although diaphragmatic calcification occurs in some patients with ankylosing spondylitis, diaphragmatic function is unimpaired and compensates well for the minor restrictive changes found in tests of respiratory function.

In a report of the coexistence of seronegative spondyloarthropathy and sarcoidosis in 12 patients, the authors observed that the pelvic and spinal manifestations of sarcoidosis can mimic those of spondyloarthropathy. The coexistence of sarcoidosis and spondyloarthropathy is probably caused by chance, as there are no shared predisposing genetic factors and the number of reported cases is small.

Treatment is by mobilizing physiotherapy coupled with a home exercise program to encourage mobility and improve cardiovascular fitness. The role of medication is to ease symptoms and hence enable exercise. No treatments exist that can prevent the development of fibrobullous disease or halt its progression, although this may happen spontaneously. Treatment of established aspergillosis, especially when aspergillomas have formed, is unsatisfactory and carries substantial risks for morbidity and death.

CERVICAL HYPEROSTOSIS

Cervical hyperostosis of the spine is anatomically manifested by bony outgrowths arising from the anterior aspects of the vertebral bodies and extending over the disk spaces. Also known as *diffuse idiopathic skeletal hyperostosis* (*DISH*), the condition was observed in 12% of 215 routine autopsies. The abnormality is most common in men; the average age is 66 years. The pharyngeal masses formed by the bony outgrowths can be extensive and may occasionally be visualized or palpated at the time of physical examination. These hyperostotic spurs are known to cause dysphagia, foreign-body sensation, aspiration, respiratory distress, and dysphonia. Dysphagia occurs in 17%–28% of patients with this disorder.

Bilateral vocal cord paralysis with airways obstruction has been described in patients with DISH. The pathogenesis is infection superimposed on ulceration of the cricoid produced by laryngeal movement over a large, sharp osteophyte. Severe, acute airway obstruction caused by a cervical osteophyte pressing on the posterior trachea is described in a 68-year-old man; tracheostomy followed by resection of the osteophyte was therapeutically successful. Dysphagia and aspiration are the results of mechanical compression. Nonsteroidal anti-inflammatory drugs and antireflux precautions should be suggested for patients who have dysphagia. Surgical removal of the hyperostotic process is required in severe cases.

Cervical spondylosis can be associated with pressure symptoms in the neck area. Dyspnea and paresis of the left hemidiaphragm relieved by laminectomy are described.

OSTEOPOROSIS

Compression fractures of multiple thoracic vertebral bodies as a result of osteoporosis produce an anatomic anomaly akin to kyphosis. With severe compression fracture, a gentle (nonacute angle) thoracic gibbus or hyperkyphosis develops in some patients. Furthermore, a markedly shortened thoracic vertebral column leads to reduced lung volumes. A study of the effect of thoracic kyphosis on respiratory mechanics in 15 women with kyphosis resulting from spinal osteoporosis showed the vital capacity, inspiratory capacity, total lung capacity, and lateral expansion of the thorax to be lower in the osteoporotic group. These mechanical factors and the pain secondary to compression fracture have the potential to cause respiratory dysfunction. The pulmonary effects of significant osteoporosis are similar to those observed

in scoliosis. Seventy-four women referred for evaluation of osteoporosis were subjected to pulmonary function testing, and those with thoracic wedge compression fractures secondary to osteoporosis had a significantly lower predicted forced vital capacity than did those without fractures. The degree of hyperkyphosis as measured by the Cobb angle had an appreciable effect on this parameter. The study estimated that a fall of approximately 9% in the predicted forced vital capacity might be expected for each thoracic vertebral fracture.

STERNOTOMY

Median sternotomy is a common surgical procedure employed in the vast majority of cardiac surgeries, particularly coronary artery bypasses and valve replacement procedures. A restrictive ventilatory defect follows median sternotomy. Vital capacity, 1-second forced expiratory volume, and functional residual capacity may decline to as little as 40% of preoperative values 1 to 3 days after coronary artery bypass grafting. These changes are more pronounced after the use of internal mammary artery bypass than after saphenous vein grafting. This is reported to be related to disruption of the internal mammary artery-derived vascular supply of the phrenic nerves. The diminished lung function begins to reverse by the end of the first postoperative week, and recovery is almost total at 3 weeks. The causes of lung dysfunction include pain, atelectasis, pulmonary edema, pulmonary embolism, hemothorax, diaphragmatic paralysis (“frost-bitten” phrenic nerve), pleurotomy, and chest wall instability. A study of rib cage mechanics in 16 men before and 1 week and 3 months after median sternotomy for coronary artery grafting revealed that reduced and uncoordinated rib cage expansion contributed to the restrictive ventilatory defect. Pre-existing cardiopulmonary disease influences the reduction in lung volumes. Obviously, resection of pulmonary parenchyma will result in permanent loss of lung function contributed by the resected segment or lobe.

MARFAN'S SYNDROME

A heritable generalized disorder of connective tissue, Marfan's syndrome is manifested clinically by abnormalities of the skeletal system (excessive length of long bones), eyes (ectopia lentis), and cardiovascular system (aneurysm of the thoracic aorta, septal and valvular cardiac anomalies). Pulmonary abnormalities are observed in approximately 10% of patients with Marfan's syndrome and include generalized honeycombing of the lungs, spontaneous pneumothorax, and bronchiectasis (Fig. 5). Of these, spontaneous pneumothorax is the most common and is seen in nearly 5% of adolescents and adults. Spontaneous pneumothorax and bullae are causally related to Marfan's syndrome. Necropsy studies of four infants with this syndrome and pulmonary emphysema showed that the elastic fibers in alveolar ducts and sacs were irregularly thickened, wavy, fragmented, and clumped. Diffuse honeycombing of the lungs and spontaneous pneumothorax were reported as the presenting features of Marfan's syndrome in a boy. In two cases, bilateral bullous disease with spontaneous pneumothorax was reported. Fibrosis of the upper lobes also is reported in Marfan's syndrome. A report described three members of a family—a father and two sons, all afflicted with Marfan's syndrome—who had multiple bilateral episodes of pneumothorax that required repeated drainage procedures.

FIG. 5. Marfan's syndrome with hyperinflation, bullous changes, dilated tortuous aorta, and “tall” lungs.

Structural abnormalities of the right middle lobe have been described. Ciliary dyskinesia also has been observed in a patient with Marfan's syndrome. Additionally, deformities of the thoracic cage resulting from abnormalities of the vertebral column, ribs, and sternum are common in this syndrome and may occur in any combination and degree of severity. Both scoliosis and pectus excavatum occur and may cause pulmonary dysfunction. Tracheal weakness, presumably resulting from structural deficiency of the cartilages, has been reported in a patient.

A review of published reports disclosed nearly 50 patients with bullous lesions, lung cysts, or emphysema, 22 of whom were younger than 20 years and two thirds of whom were male. In the same review of an additional 100 patients with Marfan's syndrome, 11 had spontaneous pneumothorax, with recurrence in 10 and bilateral appearance in six, pneumonia or recurrent respiratory infections in eight, and bronchiectasis in two. Chest roentgenograms revealed emphysematous bullae in five, fibrosis of the upper lobes in four, and aspergilloma in two. Another review of 249 patients older than 12 years reported the frequency of pneumothorax to be 4.4%, with recurrent or bilateral pneumothorax in 3%. This review suggested that definitive surgical therapy should be considered at the first occurrence of pneumothorax because of the high rate of recurrence after treatment with a chest tube.

Pulmonary dysfunction occurs in the absence of thoracic cage abnormality. An important aspect of interpreting the pulmonary function test results is the recognition that the values are based on age, sex, and standing height. The unusually long length of the legs in patients with Marfan's syndrome contributes disproportionately to these calculations. Studies of pulmonary function in patients with Marfan's syndrome have revealed diminished total lung capacity and vital capacity and mildly lowered flow rates at low lung volumes, with decreased diffusing capacity and elastic lung recoil, but only minimal abnormalities of pulmonary function have been noted in some cases. A study involving 79 patients with Marfan's syndrome concluded that persons with this syndrome who have, at most, mild thoracic deformity do not have significant abnormalities of static pulmonary function, and thus the connective tissue defects in the lungs seem to have minimal clinical impact beyond the risk for pneumothorax. However, tests of dynamic lung function were not performed in this group of subjects. In a report of 11 children with Marfan's syndrome, airway reactivity as measured by methacholine challenge was noted in all children, even though only one patient had a diagnosis of asthma. An unusual case of Marfan's syndrome with hypercoagulability complicated by multiple pulmonary emboli has been described.

The prevalence of obstructive sleep apnea is higher in patients with Marfan's syndrome. Sleep apnea in these patients is not related to obesity. Indeed, patients with Marfan's syndrome usually are tall and thin rather than obese. Excessive collapsibility of the upper airway resulting from connective tissue defect has been postulated as one of the reasons. A more likely mechanism is related to the characteristically constricted maxilla and the high-arched palate. Measurement of nasal airway resistance by posterior manometry in patients with Marfan's syndrome has shown high resistance. The indices of maxillary constriction as determined by measurement of nasal airway resistance have been shown to correlate with the severity of sleep apnea.

ACHONDROPLASIA

Achondroplasia is the most common skeletal dysplasia resulting in short-limbed dwarfism. The disorder results from abnormal endochondral bone formation. Pulmonary complications are common in achondroplastic infants and children younger than 2 years. Factors that influence respiratory manifestations include associated deformities of the chest wall and involvement of respiratory centers at the level of the brainstem and upper cervical cord. The thoracic skeletal abnormalities include reduced chest cage measurements, pectus excavatum, accentuated thoracic kyphosis, or thoracic lordosis. Detailed physiologic abnormalities in 12 healthy subjects with achondroplasia showed that the reduction in vital capacity was out of proportion to what would be expected if these subjects had limbs of normal size; the other pulmonary function parameters were normal. In a study of 58 female and 44 male achondroplastic subjects between 7 and 60 years of age, the values for vital capacity were 68% and 72% of predicted normal values for normally proportioned men and women, respectively.

Upper airway involvement, nasal obstruction, hypoxemia, and obstructive sleep apnea are more common in younger achondroplastic subjects. The most important breathing disorder during sleep in children with achondroplasia is upper airway obstruction. The short cranial base and midfacial hypoplasia increase the risk for upper airway obstruction during sleep. Sleep apnea and death caused by acute or chronic compression of the lower brainstem or cervical spinal cord have been noted in infants with achondroplasia. One study found no relationship between apnea type and foramen magnum stenosis. Obstructive sleep apnea is reported to occur more often in older subjects with achondroplasia. Resolution of sleep apnea by tracheostomy in achondroplastic dwarfs has resulted in normalization of growth hormone release and normal growth. Apneustic breathing is a rare pattern of neurogenic breathing characteristic of some patients with achondroplasia. In a report of five patients with achondroplasia, all of whom demonstrated apneustic breathing, the authors speculate that compression of the lower medullary respiratory centers and afferent pathways in the spinal cord were responsible for the abnormal breathing pattern.

RIGID SPINE SYNDROME

In rigid spine syndrome, a rigid spine is associated with a myopathy predominantly affecting proximal limb muscles. Histologic analysis of skeletal muscles, including the diaphragm, may show the presence of autophagic vacuoles in muscle fibers. Although this syndrome is more common in children, respiratory failure secondary to respiratory muscle weakness has been described in adults. The cause of respiratory failure is extreme flattening of the chest and fixation of the thorax as a result of contracture of costovertebral joints. In almost all reported cases of rigid spine syndrome, the patients have died of respiratory failure. Respiratory muscle involvement is a significant feature of rigid spine syndrome, resulting in hypercapnic ventilatory failure in some patients. Investigation of thoracic abnormalities and respiratory muscle function in nine patients with rigid spine syndrome showed a severe restrictive chest wall defect and limited mobility of the spine. Most importantly, significant respiratory muscle weakness was present in all patients. Respiratory muscle strength and endurance were 60% of control values. Even though six of the patients were emaciated and one patient was underweight, no relationship was seen between body mass index and respiratory muscle strength. Patients with hypoventilation demonstrated more pronounced respiratory muscle dysfunction.

Nocturnal ventilatory assistance has been employed to assist patients with severe hypoventilation and respiratory failure.

CRANIOFACIAL DEFORMITIES

Several types of craniofacial deformities have been described. These structural aberrations frequently are associated with upper airway problems. Severe sleep apnea, sometimes necessitating tracheostomy, is a recognized complication of various craniofacial structural abnormalities. Different grades of respiratory distress resulting from obstructive sleep apnea have been described in adults with craniofacial dysostosis, achondroplasia, metatropic dwarfism, Hallermann-Streiff syndrome, and Treacher Collins syndrome. Sleep apnea is a well-recognized aspect of micrognathia and Pierre Robin syndrome (bird-face syndrome). Tracheostomy is recommended in pediatric cases of craniofacial abnormalities with sleep apnea before reconstructive surgery is undertaken.

Pierre Robin syndrome is characterized by mandibular hypoplasia (micrognathia) and glossoptosis, often associated with a cleft palate. Upper respiratory obstruction is commonly present in this disorder. The tongue is posteriorly displaced (glossoptosis) as a consequence of micrognathia and anterior insertion of the tongue to the mandible. Severe airways obstruction may persist for months but may improve with time.

Because of micrognathia, patients with Treacher Collins syndrome are at greater risk for development of obstructive sleep apnea. Surgical correction of the micrognathia may relieve sleep apnea.

GORHAM'S DISEASE

Gorham's disease or Gorham-Stout disease (disappearing or vanishing bone disease) is characterized by massive osteolysis. It generally appears in the second and third decades of life with an equal sex distribution. A report in 1994 recorded that 146 cases of Gorham's syndrome were documented in the literature. Although any skeletal bone can be affected, the commonly involved bones are the innominate bones, thorax, and spine. Clinically, patients present with dull aching and weakness in an affected extremity. Pain is usually caused by pathologic fractures, which are a prominent feature of this disease. Histologically, lymphangiomatous tissue is observed in the affected skeletal structures. The predominant feature is the lymphatic dysplasia in skeletal structures as well as the thorax.

Pleuropulmonary manifestations include pleural effusion and development of lymphangiomatous tissue in the mediastinum. Massive pleural effusions, sometimes chylous, with high mortality have been described. Of the 146 cases of Gorham's syndrome documented in the literature, chylothorax was diagnosed in 26 (17%) of patients. Pneumothorax may be associated with chylothorax and may be seen in conjunction with chylous pleural effusion. Pulmonary lymphangiectasia, described in patients with some of these skeletal abnormalities, may be responsible for the chylous pleural effusion. Reports of successful treatment of chylothorax by high-dose radiotherapy and bleomycin have been published.

ADULT STILL'S DISEASE

Adult Still's disease is characterized by high fever, arthritis, evanescent rash, serositis, lymphadenopathy, splenomegaly, leukocytosis, and absence of rheumatoid factor and antinuclear antibodies. Pleuropulmonary complications, such as pleuritis and pneumonitis, occur frequently. The incidence of pleuropulmonary complications is reported to be approximately 30%, but estimates of up to 60% are recorded. The most common symptom is pleurisy with or without effusion. Persistent or severe pulmonary parenchymal infiltrates are uncommon. Diffuse interstitial lung disease has been described in a patient with adult-onset Still's disease. Fatal adult respiratory distress syndrome complicated by opportunistic pulmonary infections has been described in a 65-year-old woman.

OSTEOGENIC SARCOMA AND OTHER SKELETAL NEOPLASMS

Pulmonary metastatic disease is a relatively common complication of osteogenic sarcoma and other soft-tissue sarcomas, including Ewing's sarcoma of bone, rhabdomyosarcoma, and synovial sarcoma. The pulmonary lesions almost always present as lung nodules, either solitary nodules or multiple bilateral nodules. Pulmonary metastases may appear with the primary tumor or follow it by several months to years after therapy of the primary tumor. The median doubling time for pulmonary metastatic nodules secondary to bone or soft-tissue sarcomas is estimated to be 35 days (estimated 95% range, 3.9 to 352 days). Follow-up chest roentgenography should be considered in the majority of these patients. Periodic computed tomography of the chest is more accurate in detecting smaller nodules than the plain chest roentgenogram. One of the unusual features of metastatic osteogenic sarcoma is calcification of the metastatic lung lesion.

Spontaneous regression of pulmonary metastatic osteosarcoma is extremely rare, even after curative therapy of the primary tumor. Therefore, pulmonary metastatectomy with or without adjuvant therapy is the accepted therapy. Up to 50% of patients with osteogenic sarcoma in whom pulmonary metastases develop can be satisfactorily treated with continued effective chemotherapy and pulmonary metastatectomies, as long as good local control is achieved in the primary tumor. The presence of bilateral, extensive, or recurrent disease is not a contraindication to thoracotomy, because aggressive resection of multiple nodules and improved chemotherapy appear to prolong survival of these patients in comparison with survival rates of historical control subjects. In patients presenting with simultaneous primary tumor and pulmonary metastatic disease, the cure rate is potentially as high as it is in those patients who present with primary tumor alone. Because the majority of patients are young and otherwise healthy, thoracotomy with resection of lung nodules—sometimes repeated and bilateral—is associated with low morbidity and mortality. Patients who undergo resection of pulmonary metastatic osteogenic sarcoma generally have a better prognosis than those with other soft-tissue tumors.

In a report of 152 patients (median age, 19 years; range, 5 to 33 years) who underwent 258 thoracic explorations for resection of metastatic Ewing's sarcoma (28), rhabdomyosarcoma (6), soft-tissue sarcoma other than rhabdomyosarcoma (42), and osteosarcoma (76), the thoracic procedures consisted of 218 wedge resections, 19 anatomic resections, 14 wedge and anatomic resections, 4 wedge and chest wall resections, and 3 wedge resections/other procedures. Complete resection was achieved in 121 patients (80%). The median survival from initial thoracotomy was 2.2 years. Unfavorable prognostic factors included three or more positive nodules, histology other than osteosarcoma, and incomplete resection. Predictors of shorter survival included the following: two or more metastatic lung nodules, left-sided thoracic location of metastatic lesion(s), age 14 years or older at diagnosis, or histology that depicted rhabdomyosarcoma. In a study of 36 patients with pulmonary metastatic osteogenic sarcoma, the 5-year survival rate following pulmonary metastatectomy was 23%.

In a study of 12 patients with Ewing's sarcoma of bone who relapsed with pulmonary metastases alone and were treated with surgical resection of the metastatic lesions but no additional radiotherapy or chemotherapy, five were continuously free of disease at follow-ups ranging between 3 and 14 years (mean, 9 years). The remaining seven patients died with uncontrolled disease 12 to 39 months (mean, 22 months) after thoracotomy. These results seem to indicate that an aggressive surgical approach should be considered for a selected group of patients with Ewing's sarcoma who relapse with only lung metastases.

Extraskeletal osteosarcomas are rare malignancies that account for about 1% of all soft-tissue sarcomas. One study of 40 patients (mean age, 51 years; male-to-female ratio, 1.9:1) with extraskeletal osteosarcoma found pulmonary metastases in 81%. The primary tumors originated in the lower limbs in 68% of cases and presented in 90% of patients as an enlarging soft-tissue mass; nine patients had a history of trauma. Morphologically, all were high-grade osteosarcomas. Distant metastases occurred, usually within 3 years, in 65%, but lung involvement was noted in 81%. The overall 5-year survival rate was 37%.

Benign giant-cell tumor of bone demonstrates the unusual ability to metastasize to the lungs. It is estimated that 9% of such tumors may metastasize to the lungs. Approximately 50 such cases have been reported. In a report of six patients with pulmonary metastasis of giant-cell tumor, one patient exhibited spontaneous regression and another died of pulmonary complications.

MISCELLANEOUS TOPICS

The increased risk for deep vein thrombophlebitis and pulmonary embolism in patients who undergo orthopedic procedures, particularly arthroplasty of the hip, knee, and other joints, is discussed elsewhere, as is the topic of fat embolism following fractures of bone and orthopedic procedures. Orthopedic procedures such as

intramedullary femoral nailing and arthroplasty in which chemical adhesive cement (methyl methacrylate) is used have been followed by pulmonary complications.

Femoral nailing after reaming has been shown to be associated with higher risk for development of adult respiratory distress syndrome in comparison with unreamed femoral nailing. The risk for respiratory complications is even higher in those with “borderline pulmonary status.”

Measurement of growth rate of lung metastases in 21 patients with bone or soft-tissue sarcoma. *Br J Cancer* 1993;68:414–417. *The volume doubling time (T2) of 52 lung metastases from soft-tissue sarcomas in 21 patients was calculated from measurements done on plain chest radiographs. Follow-up times ranged from 14 to 819 days. The median doubling time was 34.9 days (estimated 95% range, 3.9 to 352 days).*

Boyer J, Amin N, Taddonio R, Dozor AJ. Evidence of airway obstruction in children with idiopathic scoliosis. *Chest* 1996;109:1532–1535. *In a review of pulmonary function test findings in 44 children (36 girls, 8 boys) between the ages of 10 and 18 years with idiopathic scoliosis before surgical correction, 18 subjects (41%) had significant restriction, whereas three subjects (7%) met the criteria for air flow obstruction. However, moderate or severe gas trapping was exhibited by 20 subjects (46%). The authors conclude that although restrictive defects are commonly present in children with idiopathic scoliosis, significant gas trapping also frequently occurs.*

Chuang JH, Wan YL. Evaluation of pectus excavatum with repeated CT scans. *Pediatr Radiol* 1995;25:654–656. *Repeated CT scans taken an average of 1.25 year apart in eight children with pectus excavatum showed that the initial pectus indices ranged from 3.6 to 6.8 (mean, 5.4), and the follow-up indices ranged from 3.5 to 6.7 (mean, 5.3). No progress of pectus excavatum was found during the study period. The routine five axial chest CT sections also helped to specify a pectus index based on the central section taken through the deepest part of the deformity, and provided useful information for further conservative or surgical management.*

Cistulli PA, Richards GN, Palmisano RG, Unger G, Berthon-Jones M, Sullivan CE. Influence of maxillary constriction on nasal resistance and sleep apnea severity in patients with Marfan's syndrome. *Chest* 1996;110:1184–1188. *Nasal airway resistance measurements and evaluations of maxillary arch morphology in 13 consecutive patients with Marfan's syndrome and 13 control subjects showed that the mean nasal resistance in patients was more than twice that in the control group. The patients also had marked constriction of the maxillary arch. The authors conclude that the significant correlation between indices of maxillary constriction and severity of sleep apnea suggest that maxillary constriction may play an important role in the pathophysiology of obstructive sleep apnea in Marfan's syndrome.*

Cistulli PA, Sullivan CE. Sleep apnea in Marfan's syndrome. Increased upper airway collapsibility during sleep. *Chest* 1995;108:631–635. *Measurements of upper airway closing pressures during sleep in 12 patients with Marfan's syndrome (10 of whom had obstructive sleep apnea) and six control subjects revealed increased upper airway collapsibility in all 12 patients. The authors conclude that the increased collapsibility is related to the characteristic connective tissue defect of Marfan's syndrome.*

Culham EG, Jimenez HA, King CE. Thoracic kyphosis, rib mobility, and lung volumes in normal women and women with osteoporosis. *Spine* 1994;19:1250–1255. *Lung volumes and rib mobility were measured in 15 women with kyphosis resulting from spinal osteoporosis and in 15 healthy women. Vital capacity, inspiratory capacity, total lung capacity, and lateral expansion of the thorax were lower in the osteoporotic group. There was a significant negative correlation between kyphosis angle and inspiratory capacity, vital capacity, and lateral expansion of the thorax in osteoporotic women with thoracic kyphosis.*

Day GA, Upadhyay SS, Ho EK, Leong JC, Ip M. Pulmonary functions in congenital scoliosis. *Spine* 1994;19:1027–1031. *Clinical and roentgenologic evaluations of the spinal deformity and pulmonary function in 36 patients with congenital scoliosis treated by surgery showed that the mean total lung capacity was 89% of predicted value, and mean vital capacity and forced vital capacity were 74% of predicted value. The mean residual volume was significantly increased (154% of predicted value). The mean total lung capacity in the nonsurgically and surgically treated patients was 99.8% of predicted value and 82% of predicted value, respectively.*

Derveaux L, Clarysse I, Ivanoff I, Demedts M. Preoperative and postoperative abnormalities in chest x-ray indices and in lung function in pectus deformities. *Chest* 1989;95:850–856. *In this study of 88 patients with pectus deformities (pectus excavatum, pectus carinatum, pectus deformatum, and pectus excavatum with scoliosis) 1 to 20 years after corrective surgery, preoperative lung function was decreased in pectus excavatum only. In all groups, lung function worsened after surgery. A stepwise discriminant analysis performed on the large group with pectus excavatum indicated that postoperative lung function was decreased if the preoperative value of 1-second forced expiratory volume or vital capacity was approximately >75% of predicted and vice versa.*

Ellis ER, Grunstein RR, Chan S, Bye PT, Sullivan CE. Noninvasive ventilatory support during sleep improves respiratory failure in kyphoscoliosis. *Chest* 1988;94:811–815. *Seven patients with severe thoracic kyphoscoliosis were treated by either intermittent positive pressure ventilation or continuous positive airways pressure, both administered through a nose mask. Detailed follow-up studies after 3 months of treatment showed normal sleep patterns and improvement in daytime blood gases, lung volumes, and respiratory muscle strength.*

Ferdoutsis M, Bouros D, Meletis G, Patsourakis G, Siafakas NM. Diffuse interstitial lung disease as an early manifestation of ankylosing spondylitis. *Respiration* 1995;62:286–289. *A rare case of a 35-year-old asymptomatic woman with ankylosing spondylitis complicated by interstitial pulmonary disease of the upper lung. The patient's mother and sister also were found to have ankylosing spondylitis, but without lung involvement. History and physical and laboratory examinations as well as open lung biopsy excluded other causes of an interstitial pulmonary disease.*

Finlay G, Concannon D, McDonnell TJ. Treatment of respiratory failure due to kyphoscoliosis with nasal intermittent positive pressure ventilation (NIPPV). *Ir J Med Sci* 1995;164:28–30. *Description of experience with four patients with respiratory failure caused by kyphoscoliosis who were treated with nasal intermittent positive pressure ventilation. Two of the patients presented with acute respiratory acidosis. All patients survived to be discharged from hospital on home ventilation. Significant improvements were noted in PO_2, PCO_2, and pulmonary function. The authors conclude that nasal intermittent positive pressure ventilation is useful in the management of both acute and chronic ventilatory failure caused by kyphoscoliosis.*

Fisher LR, Cawley MI, Holgate ST. Relation between chest expansion, pulmonary function, and exercise tolerance in patients with ankylosing spondylitis. *Ann Rheum Dis* 1990;49:921–925. *Detailed studies in 33 patients with ankylosing spondylitis showed that chest expansion does not have a significant effect on exercise tolerance and that there is a significant association between vital capacity and exercise tolerance as measured by a subject's maximal oxygen capacity ($D\dot{V}O_{2max}$). The results suggest that patients who exercise regularly can maintain a satisfactory work capacity despite very restricted spinal and chest wall mobility.*

Fonkalsrud EW, Salman T, Guo W, Gregg JP. Repair of pectus deformities with sternal support. *J Thorac Cardiovasc Surg* 1994;107:37–42. *Among 227 children with pectus excavatum and 25 with pectus carinatum (195 boys and 57 girls) who underwent repair of pectus deformities, preoperative exercise limitation was reported by 51%, and 32% had frequent respiratory infections or asthma. Repair was performed through a transverse incision, with subperiosteal resection of the lower four or five costal cartilages from sternum to costochondral junction bilaterally. More than 98% of patients showed improvement in exercise tolerance, endurance, respiratory symptoms, and cosmetic appearance.*

Goertzen M, Baltzer A, Schulitz KP. Long-term results after operation for funnel chest. *Arch Orthop Trauma Surg* 1993;112:289–291. *A review of 36 patients who underwent surgical correction of funnel chest deformity with an average follow-up of 7.6 years revealed the following: the mean age at operation was 14 years, preoperative cardiorespiratory disorders were reported by 76% of patients, and 71% showed electrocardiographic and pulmonary alterations. Postoperatively, cardiorespiratory disorders were significantly reduced, but the electrocardiographic changes were not. The long-term results were good or fair in 90% of the patients.*

Green HD, Mollica AJ, Karuza AS. Gorham's disease: a literature review and case reports. *J Foot Ankle Surg* 1995;34:435–441. *A review of the literature on Gorham's disease (disappearing bone disease, massive osteolysis, idiopathic osteolysis, essential osteolysis, progressive atrophy of bone, spontaneous absorption of bone, phantom bone, hemangiomatosis/lymphangiomatosis of bone, progressive osteolysis), with two case reports of suspected Gorham's disease of the bones of the foot.*

Haller JA Jr, Colombani PM, Humphries CT, Azizkhan RG, Loughlin GM. Chest wall constriction after too extensive and too early operations for pectus excavatum. *Ann Thorac Surg* 1996;61:1618–1624. *A review of 12 children and teenagers in whom severe cardiorespiratory symptoms developed because of failure of chest wall growth after very extensive pectus excavatum operations (removal of five or more ribs) at very early ages (4 years). The authors conclude that the extensive procedures removed or prevented growth center activity, resulting in restriction of chest wall growth with marked limitation of ventilatory function. They recommend delay in operative repair in small children until at least 6 to 8 years of age.*

Haslock I. Ankylosing spondylitis. *Baillieres Clin Rheumatol* 1993;7:99–115. *A detailed review of pulmonary and other aspects of ankylosing spondylitis. The author states involvement of the respiratory system is most widespread when ankylosing spondylitis gives rise to chest wall pain, diminished chest wall movement, and a dorsal stoop. As healing of the inflammatory process takes place, calcification occurs, leading to rigidity of these structures with consequent loss of chest expansion, which is exacerbated by the increasingly kyphotic spinal posture and inefficiency of intercostal muscles.*

Heij HA, Vos A, de Kraker J, Voute PA. Prognostic factors in surgery for pulmonary metastases in children. *Surgery* 1994;115:687–693. *A retrospective analysis of 139 thoracotomies performed in 91 patients between 1 and 19 years of age with metastatic osteogenic sarcoma (40 patients), nephroblastoma (24 patients), Ewing's sarcoma (12 patients), and various other tumors (15 patients). Twenty-three patients (25%) were alive at the time of publication. Negative prognostic factors were incomplete excision, primary tumor not controlled, or metastases developing during treatment.*

Iseman MD, Buschman DL, Ackerson LM. Pectus excavatum and scoliosis. Thoracic anomalies associated with pulmonary disease caused by *Mycobacterium avium* complex. *Am Rev Respir Dis* 1991;144:914–916. *Study of a consecutive series of 67 patients with pulmonary disease caused by* Mycobacterium avium complex *and 55 patients with* M. tuberculosis *infection showing that among those with* M. avium *infection, pectus excavatum was present in 27% and scoliosis in 52%; overall, 47 of the 67 (70%) had one or both of these anomalies. By comparison, of those with* M. tuberculosis *infection, only 5% had pectus excavatum, only 13% had scoliosis, and none had both.*

Jones DJ, Paul EA, Bell JH, Wedzicha JA. Ambulatory oxygen therapy in stable kyphoscoliosis. *Eur Respir J* 1995;8:819–823. *A study of 13 patients with stable kyphoscoliosis (mean PaO_2, 8.96 kPa; mean $PaCO_2$, 6.52 kPa) who were treated with oxygen at 2 L/min observed that supplemental oxygen produced significant improvements in desaturation, breathlessness scores, and recovery time compared with baseline. There was no relationship between baseline desaturation and changes in walking distance. Although exercise desaturation, breathlessness, and recovery times were significantly improved with ambulatory oxygen at 2 L/min, walking distance was unaffected.*

Kay RM, Eckardt JJ, Seeger LL, Mirra JM, Hak DJ. Pulmonary metastasis of benign giant-cell tumor of bone. Six histologically confirmed cases, including one of spontaneous regression. *Clin Orthop* 1994;302:219–230. *Description of six patients with pulmonary metastases of benign giant-cell tumor of the bone. The authors state that the nature of these pulmonary metastases remains unpredictable. Of the six cases, one exhibited spontaneous regression and another died as a result of respiratory failure.*

Kearon C, Viviani GR, Kirkley A, Killian KJ. Factors determining pulmonary function in adolescent idiopathic thoracic scoliosis. *Am Rev Respir Dis* 1993;148:288–294. *In a cross-sectional study of 66*

adolescents with idiopathic thoracic scoliosis who had not previously had spinal surgery, the angle of scoliosis was one of four features of spinal deformity associated with a reduced vital capacity; a greater number of vertebrae involved, cephalad location of the curve, and loss of the normal thoracic kyphosis made an equal and additive contribution to pulmonary impairment.

Kesten S, Garfinkel SK, Wright T, Rebuck AS. Impaired exercise capacity in adults with moderate scoliosis. *Chest* 1991;99:663–666. *Measurements of lung function and exercise tolerance in 15 adults with moderate kyphoscoliosis showed a slight reduction in forced vital capacity. However, exercise tolerance was significantly lower than previously reported in healthy adults ($D\dot{V}O_{2max}$ = 31.60 ± 9.12 vs. 37.07 ± 4.91 mL/kg per minute). Hypoxic and hypercapnic ventilatory responses were within predicted normal limits. The authors conclude that impairment of exercise performance in adults with moderate scoliosis likely arises from deconditioning and lack of regular aerobic exercise.*

Kharasch VS, Lipsitz S, Santis W, Hallowell JA, Goorin A. Long-term pulmonary toxicity of multiagent chemotherapy including bleomycin and cyclophosphamide in osteosarcoma survivors. *Med Pediatr Oncol* 1996;27:85–91. *Serial pulmonary function tests performed up to 12 years after the diagnosis of osteosarcoma in 35 children treated with bleomycin, cyclophosphamide, methotrexate, doxorubicin, cisplatin, and actinomycin D for 9 to 12 months initially showed a significant decline in all mean values for total lung capacity, 1-second forced expiratory volume, and diffusing capacity of the lung for carbon monoxide (D_LCO), but the transient decline in pulmonary function test values within 8 to 12 months after chemotherapy appeared to be associated with no significant long-term abnormalities of pulmonary function.*

Kinnear WJ, Johnston ID. Does Harrington instrumentation improve pulmonary function in adolescents with idiopathic scoliosis? A meta-analysis. *Spine* 1993;18:1556–1559. *Among 38 reports available, five with a total of 173 patients qualified for meta-analytic study of the effect of Harrington instrumentation in adolescents with idiopathic scoliosis. The results showed an increase in mean vital capacity ranging from 2%–11% of predicted vital capacity. The authors conclude that Harrington instrumentation leads to a small but statistically significant improvement in vital capacity.*

Lancaster L, McIlhenny J, Rodgers B, Alford B. Radiographic findings after pectus excavatum repair. *Pediatr Radiol* 1995;25:452–454. *Postoperative chest roentgenography after surgical repair of pectus excavatum in 65 children showed atelectasis in 64 children, pleural effusions in 38, congestion or edematous pattern in 30, pneumothorax in 12, and pneumomediastinum in four patients. Despite these abnormalities, the children uniformly did well clinically.*

Lee JS, Fetsch JF, Wasdhal DA, Lee BP, Pritchard DJ, Nascimento AG. A review of 40 patients with extraskeletal osteosarcoma. *Cancer* 1995;76:2253–2259. *In this study of 40 patients (mean age, 51 years; male-to-female ratio, 1.9:1) with extraskeletal osteosarcoma originating in the lower limbs (in 68% of patients), 90% of tumors presented as an enlarging soft-tissue mass; nine patients had a history of trauma. Histologically, all were high-grade osteosarcomas. Multiple local recurrences (in 45%) occurred within 3 years. Among the distant metastases (in 65%), lung involvement was noted in 81%.*

Lenke LG, Bridwell KH, Blanke K, Baldus C. Analysis of pulmonary function and chest cage dimension changes after thoracoplasty in idiopathic scoliosis. *Spine* 1995;20:1343–1350. *A prospective study of 19 adolescents and seven adults with idiopathic scoliosis who underwent pulmonary function testing before thoracoplasty surgery and at selected times up to 2 years after surgery recorded that at 3 months postoperatively, pulmonary function test values declined by 16% and 27% in the adolescents and adults, respectively. At 2 years, lung function test values returned to normal in the adolescents, but a residual 23% decline 2 years after surgery was noted in adults.*

Mador MJ, Tobin MJ. Apneustic breathing. A characteristic feature of brain stem compression in achondroplasia? *Chest* 1990;97:877–883. *The authors describe apneustic breathing in five patients with achondroplasia. All five patients displayed clinical, structural, and electrophysiologic features of cervicomedullary compression. The degree of apneustic breathing was reduced following decompressive surgery. The authors suggest that cervical and medullary compression is capable of producing apneustic breathing in the absence of vagal or pneumotaxic center lesions.*

Miller FR, Wanamaker JR, Hicks DM, Tucker HM. Cricoarytenoid arthritis and ankylosing spondylitis. *Arch Otolaryngol Head Neck Surg* 1994;120:214–216. *A description of the seventh case of cricoarytenoid arthritis secondary to ankylosing spondylitis and the first patient with bilateral vocal fold fixation as the initial presenting symptom of ankylosing spondylitis. Six previously reported cases of cricoarytenoid joint involvement in ankylosing spondylitis are discussed.*

Morshuis W, Folgering H, Barentsz J, van Lier H, Lacquet L. Pulmonary function before surgery for pectus excavatum and at long-term follow-up. *Chest* 1994;105:1646–1652. *Pulmonary function testing before and after a mean follow-up period of 8 years in 152 patients who were operated on for pectus excavatum. The mean age at surgery was 15.3 to 5.5 years. Restrictive lung dysfunction noted preoperatively was not related to age, severity of deformity at physical examination, or pulmonary symptoms. Only the patients with obstructive disease had significantly more pulmonary symptoms. At follow-up, the restriction of pulmonary function was increased despite improvement in the symptoms of most patients and despite a significant increase in the anteroposterior diameter of the chest.*

Pape HC, Regel G, Dwenger A, Krumm K, Schweitzer G, Krettek C, Sturm JA, Tscherne H. Influences of different methods of intramedullary femoral nailing on lung function in patients with multiple trauma. *J Trauma* 1993;35:709–716. *In a study comparing the pulmonary effects of femoral nailing after reaming (17 patients) with the effects of femoral nailing without reaming (14 patients), reaming was associated with higher risk for adult respiratory distress syndrome. The authors indicate that in "borderline patients," unreamed femoral nailing might offer an alternative by allowing primary intramedullary stabilization without the risk of adverse effects to the lung.*

Prevot J. Treatment of sternocostal wall malformations of the child. A series of 210 surgical corrections since 1975. *Eur J Pediatr Surg* 1994;4:131–136. *A classification of six groups of anatomic forms is presented based on 210 children who underwent corrective surgery for funnel chest (190 patients) or pigeon chest (20 patients): vertical cup-shaped (the most common), horizontal cup-shaped, vallecular, mixed, complex with sternal torsion, and polymalformations.*

Quigley PM, Haller JA Jr, Jelus KL, Loughlin GM, Marcus CL. Cardiorespiratory function before and after corrective surgery in pectus excavatum. *J Pediatr* 1996;128:638–643. *Pulmonary function testing and incremental exercise testing in 36 adolescents (age 16 ± 3 years) with pectus excavatum and 10 healthy control subjects (15 patients and six control subjects were re-examined postoperatively) showed that the patients had a significantly lower forced vital capacity than control subjects (81% vs. 98% of predicted value). Postoperatively, no change in forced vital capacity was noted among the patients. The authors conclude that some subjects with pectus excavatum have mild restrictive lung disease that is not affected by surgical repair, and after surgery they show a slight increase in exercise tolerance, suggesting improved cardiac function during exercise.*

Ras GJ, van Staden M, Schultz C, Stubgen JP, Lotz BP, van der Merwe C. Respiratory manifestations of rigid spine syndrome. *Am J Respir Crit Care Med* 1994;150:540–546. *Investigation of thoracic abnormalities and respiratory muscle function in nine patients with rigid spine syndrome showed a severe restrictive chest wall defect and limited mobility of the spine associated with clinically significant respiratory muscle weakness in all patients. Respiratory muscle strength and endurance were 60% of control values.*

Rawlins BA, Winter RB, Lonstein JE, Denis F, Kubic PT, Wheeler WB, Ozolins AL. Reconstructive spine surgery in pediatric patients with major loss in vital capacity. *J Pediatr Orthop* 1996;16:284–292. *Major reconstructive spinal surgery in 32 pediatric patients (18 boys and 14 girls; mean age, 13 years) with severe restrictive lung disease (vital capacity 40%) was followed by pulmonary complications (pneumonia, reintubation, pneumothorax, respiratory arrest, or need for tracheostomy) in six patients (19%), with three patients requiring tracheostomy. Patients in whom thoracotomy or a thoracoabdominal approach was used had a significantly higher number of pulmonary complications. The surgical and perioperative mortality rate was zero.*

Rosen G, Holmes EC, Forscher CA, Lowenbraun S, Eckardt JJ, Eilber FR. The role of thoracic surgery in the management of metastatic osteogenic sarcoma. *Chest Surg Clin N Am* 1994;4:75–83. *A detailed review of the role of thoracic surgery in the management of metastatic osteogenic sarcoma. The authors indicate that 50% of patients with osteogenic sarcoma in whom pulmonary metastases develop can be salvaged with continued effective chemotherapy and thoracotomies, as long as good local control is achieved in the primary tumor.*

Stokes DC, Wohl ME, Wise RA, Pyeritz RE, Fairclough DL. The lungs and airways in achondroplasia. Do little people have little lungs? *Chest* 1990;98:145–152. *Detailed testing of respiratory function in 12 healthy subjects with achondroplasia showed mildly reduced anteroposterior thoracic diameter in men. Vital capacity for all subjects was 10.8%–18.6% of predicted for achondroplastic subjects, but was reduced when compared with predicted values for people of average stature based on either sitting height or thoracic height. The authors conclude that although the lungs may be small, they are functionally normal, as are the airways.*

Temeck BK, Wexler LH, Steinberg SM, McClure LL, Horowitz M, Pass HI. Metastatectomy for sarcomatous pediatric histologies: results and prognostic factors. *Ann Thorac Surg* 1995;59:1385–1389. *Among 152 patients (median age, 19 years; range, 5 to 33 years) who underwent 258 thoracic explorations for resections of metastatic osteosarcoma (76), soft-tissue sarcoma other than rhabdomyosarcoma (42), Ewing's sarcoma (28), and rhabdomyosarcoma (6), an initial complete resection was accomplished in 121 (80%). With a median potential follow-up of 10.6 years, median survival from initial thoracotomy is 2.2 years.*

Tie ML, Poland GA, Rosenow EC III. Chylothorax in Gorham's syndrome. A common complication of a rare disease. *Chest* 1994;105:208–213. *This report notes that 146 cases of Gorham's syndrome are documented in the literature. Chylothorax occurred in 25 of these patients (17%). The authors describe two patients with chylothorax who were treated by thoracic duct ligation and compare their results with those of others to support early surgical intervention via a low, right-sided thoracotomy.*

Turner JF, Enzenauer RJ. Bronchiolitis obliterans and organizing pneumonia associated with ankylosing spondylitis. *Arthritis Rheum* 1994;37:1557–1559. *Description of bronchiolitis obliterans and organizing pneumonia (BOOP) in a patient with ankylosing spondylitis.*

Upadhyay SS, Mullaji AB, Luk KD, Leong JC. Evaluation of deformities and pulmonary function in adolescent idiopathic right thoracic scoliosis. *Eur Spine J* 1995;4:274–279. *Pulmonary function tests and measurements of spinal deformities in 70 adolescents (mean age, 13.8 years) with idiopathic right thoracic scoliosis (mean Cobb angle and vertebral rotation of 50° and 22°, respectively) showed that the vertebral rotational flexibility and rib-vertebral angle give a better prediction of pulmonary function than the widely used Cobb angle.*

Vanderschueren D, Decramer M, Van den Daele P, Dequeker J. Pulmonary function and maximal transrespiratory pressures in ankylosing spondylitis. *Ann Rheum Dis* 1989;48:632–635. *Clinical measurements and pulmonary function test values, including maximal transrespiratory pressures in 30 patients with ankylosing spondylitis, showed the following results: vital capacity, 79% of predicted; 1-second forced expiratory volume, 82%; FEV_1/VC ratio, 78%; total lung capacity, 85%; and transfer factor of the lung for carbon monoxide (T_LCO), 88%.*

Van Hoeyweghen RJ, De Clerck LS, Van Offel JF, Stevens WJ. Interstitial lung disease and adult-onset Still's disease. *Clin Rheumatol* 1993;12:418–421. *Description of a patient with adult-onset Still's disease complicated by biopsy-proven pulmonary fibrosis. Clinical signs of the interstitial lung disorder developed 3 years after the diagnosis of Still's disease was made. Radiologic and histologic progression was observed. Other causes of interstitial lung disorders were excluded.*

Ward WG, Mikaelian K, Dorey F, Mirra JM, Sassoon A, Holmes EC, Eilber FR, Eckardt JJ. Pulmonary metastases of stage IIB extremity osteosarcoma and subsequent pulmonary metastases. *J Clin Oncol* 1994;12:1849–1858. *In a review of 111 consecutive patients with high-grade nonmetastatic extremity osteosarcoma treated with preoperative chemotherapy and surgical resection and 36 patients treated with pulmonary metastatectomy, an overall 5-year survival rate of 53% was noted. The 5-year survival rate following resection of pulmonary metastasis was 23%.*

Wendling D, Dalphin JC, Toson B, Depierre A, Guidet M. Bronchoalveolar lavage in ankylosing spondylitis. *Ann Rheum Dis* 1990;49:325–326. *Bronchoalveolar lavage and bronchial biopsies in 15 patients with ankylosing spondylitis and 17 control subjects revealed no difference in total cell count, number of lymphocytes, $CD4^+/CD8^+$ ratio, orb_2-microglobulin concentrations in bronchoalveolar lavage fluid. Bronchoalveolar lavage IgA concentrations were not increased, but bronchial IgA deposits were more common in ankylosing spondylitis.*

Wong CA, Cole AA, Watson L, Webb JK, Johnston ID, Kinnear WJ. Pulmonary function before and after anterior spinal surgery in adult idiopathic scoliosis. *Thorax* 1996;51:534–536. *Results of pulmonary function studies before and after (mean follow-up, 32 months) spinal surgery in 14 patients (12 women; mean age, 27 years), all of whom underwent thoracotomy and anterior arthrodesis*

and five of whom also underwent posterior arthrodesis, were as follows: Cobb angle of the thoracic curve improved by 31% (from 59° to 39°), mean forced vital capacity decreased by 0.21 L, and decreases in mean 1-second forced expiratory volume and total lung capacity were also noted.

Zaccaria S, Ioli F, Lusuardi M, Ruga V, Spada EL, Donner CF. Long-term nocturnal mechanical ventilation in patients with kyphoscoliosis. *Monaldi Arch Chest Dis* 1995;50:433–437. *In a study of 13 clinically stable patients with kyphoscoliosis treated with nocturnal positive pressure ventilation via a nasal mask and 13 patients with kyphoscoliosis and acute respiratory insufficiency treated with nocturnal ventilation via tracheostomy, the authors conclude that both treatments are effective in the long-term management of respiratory failure in patients with kyphoscoliosis. The authors indicate that if nocturnal positive pressure ventilation via a nasal mask is initiated earlier in chronic respiratory failure, the need to use an invasive technique is delayed.*

Zucconi M, Weber G, Castronovo V, Ferini-Strambi L, Russo F, Chiumello G, Smirne S. Sleep and upper airway obstruction in children with achondroplasia. *J Pediatr* 1996;129:743–749. *Nocturnal polysomnography and brain computed tomography or magnetic resonance imaging in 16 children (mean age, 4.7 years) with achondroplasia and 25 children with adenotonsillar hypertrophy revealed no significant difference between groups with respect to sleep architecture. The most important breathing disorder during sleep in children with achondroplasia was upper airway obstruction.*

CHAPTER

62 Dermatologic Diseases

Udaya B.S. Prakash

U.B.S. Prakash: Pulmonary and Critical Care Medicine, Mayo Medical School and Mayo Medical Center, Rochester, Minnesota 55905.

INTRODUCTION

Dermatologic manifestations of diseases that originate in other organs are commonly encountered in clinical practice. Frequently, the dermatologic sign is the initial signal of an internal illness. The best example of this is the presentation of paraneoplastic manifestations in the form of clubbing, dermatomyositis, acanthosis nigricans, bullous pemphigoid, and other external clinical features that point toward the possibility of an underlying malignancy. Among the malignant disorders, respiratory neoplasms are well known to cause paraneoplastic syndromes listed above. Many vasculitic syndromes and collagenoses also produce significant cutaneous lesions. These disorders are discussed in Chapter 53 and Chapter 54. Nonmalignant disorders such as pulmonary infections and pulmonary sarcoidosis may demonstrate unusual dermal response in the form of erythema nodosum or erythema multiforme. This chapter addresses several of these entities and the respiratory manifestations of primary dermatologic diseases. However, many of these disorders cannot be classified as primary dermatoses, though their clinical presentations with cutaneous lesions warrant their inclusion here. Because of the lack of connection among most of the diseases included here, which makes an appropriate classification difficult, the diseases are discussed in alphabetic order.

ACANTHOSIS NIGRICANS AND OTHER PARANEOPLASTIC DERMATOSES

Acanthosis nigricans is an uncommon cutaneous disorder characterized by hyperpigmentation and epidermal hypertrophy (Fig. 1). The paraneoplastic category of acanthosis nigricans is associated, in 90% of cases, with gastric adenocarcinoma and other intraabdominal malignancies. Skin changes and an underlying neoplasm appear together in 60% of cases, whereas the cutaneous changes appear before clinical evidence of carcinoma in 20% of patients. Acanthosis nigricans may be the presenting clinical feature of lung cancer, adenocarcinoma of the lung being the most common type of pulmonary malignancy associated with this skin disorder. Acanthosis nigricans has also been observed in a patient with bronchoalveolar cell carcinoma. The prognosis in patients with acanthosis and associated cancer is dismal. Progressive skin changes signify a higher mortality.

FIG. 1. Acanthosis nigricans involving left axilla in a patient with adenocarcinoma of the lung. Marked hyperpigmentation and epidermal hypertrophy are the pathologic features.

Tripe palms, sometimes called Bazex's syndrome, are characterized clinically by rugose, thickened, velvety palms with pronounced dermatoglyphic ridges and sulci. Tenderness around the fingernails also has been observed in this entity. Histologic examination reveals an undulant epidermis with hyperkeratosis, acanthosis, and papillomatosis. Over two-thirds of the patients with tripe palms exhibit associated acanthosis nigricans. More than 90% of patients with tripe palms have an associated cancer, most commonly involving the lung or the stomach. Among the 75 patients with tripe palms, the most common underlying neoplasm was lung cancer (in 53%), whereas patients with both tripe palms and acanthosis nigricans had gastric cancer (in 35% of cases) or lung cancer (11% of cases). Importantly, in over 40% of patients, tripe palms were the presenting feature of a previously undiagnosed malignancy. Therefore, any patient with tripe palms must have a complete cancer workup, especially for lung and stomach cancer.

Bowen's disease is a chronic dermatosis characterized by the development of *in-situ* epidermoid carcinoma of the skin. This disease has been linked to arsenic exposure in some cases; arsenic is a known carcinogen. The arsenic content of American tobacco was quite high until the early 1960s. This may explain some of the cases of lung cancer associated with Bowen's disease described in the past.

Paraneoplastic pemphigus is a syndrome in which patients have a severe mucocutaneous eruption with clinical features similar to those of both erythema multiforme major (Stevens–Johnson syndrome) and pemphigus vulgaris, in association with non-Hodgkin's lymphomas and other malignant neoplasms. A patient has been described in whom non-Hodgkin's lymphoma in apparent complete remission following autologous bone marrow transplantation developed bullous pemphigoid-like reaction and respiratory disease. Deposits of IgG were observed within the epithelium of the bronchial mucosa.

Tylosis or hyperkeratosis palmaris et plantaris, *epidermolysis bullosa, porphyria cutanea tarda,* and *acquired hypertrichosis lanuginosa* are among the other paraneoplastic cutaneous dermatoses associated with bronchogenic carcinoma. Many of these dermatoses precede the onset of the malignancy.

ACUTE FEBRILE NEUTROPHILIC DERMATOSIS

Acute febrile neutrophilic dermatitis (Sweet's syndrome) is an uncommon, recurrent, often dramatic cutaneous disease manifested by fever, painful erythematous plaque-forming inflammatory papules on the face, neck, and limbs and arthralgias and leukocytosis. Most cases are associated with a viral upper respiratory infection. Approximately 20% of patients have associated malignancies, particularly hematologic neoplasms.

Pulmonary involvement has been described in several cases. Chest roentgenograms have revealed patchy pulmonary parenchymal infiltrates. Histologic features in lung biopsies have included diffuse interstitial edema, neutrophilic interstitial and alveolar exudates, bronchiolitis obliterans with organizing pneumonitis, recent hemorrhages, and hyperplasia of type I and II cells. Pulmonary pathologic findings in one patient consisted of marked intraalveolar neutrophilic infiltrates similar to skin biopsy findings, chronic interstitial pneumonitis, and minimal fibrosis; resolution was reported after corticosteroid therapy. A report on a 54-year-old woman with myelodysplasia described severe dyspnea and pulmonary infiltrates associated with recurrent episodes of Sweet's syndrome. Lung and skin biopsies revealed a sterile infiltration of the interstitial tissues by mature neutrophils. Although corticosteroid therapy resulted in rapid clinical improvement, recurrent episodes became increasingly resistant to therapy, and she ultimately died from respiratory failure. Rare cases of primary lung cancer have been described in association with Sweet's syndrome.

ANHIDROTIC ECTODERMAL DYSPLASIA

Anhidrotic ectodermal dysplasia is a hereditary, usually X-linked disorder characterized by insufficient sweating, sparse hair, and scanty teeth. Predisposition to severe bronchitis has been observed. The common upper respiratory infections occur often in these patients and have been ascribed to scanty mucus and deficient cilia. Absence of mucous glands in the tracheobronchial tree and increased incidence of asthma are the other respiratory features described in this disorder.

ATAXIA-TELANGIECTASIA

Also known as Louis–Bar syndrome, ataxia-telangiectasia is characterized by a progressive cerebellar ataxia, oculocutaneous telangiectasia, and recurrent sinopulmonary infections. This disorder is associated with deficiency of IgA and IgE and the development of lymphoreticular malignancies. In addition, granulocytopenia, noted in many of these patients, is a factor in frequent infections. Repeated sinopulmonary infections are noted in three-fourths of patients with ataxia-telangiectasia, usually starting at approximately 4 to 6 years of age. Infection in nonrespiratory organs is uncommon. Severe neurologic impairment, bronchiectasis, and pulmonary fibrosis are usually progressive, leading to death by the time of adolescence. Roentgenologically, abnormalities are similar to those in cystic fibrosis, and both diseases also manifest chronic paranasal sinusitis. Upper airway dysfunction, identified by abnormal maximum inspiratory and expiratory flow–volume loops, has been described in patients with olivopontocerebellar atrophy.

BLUE RUBBER BLEB NEVUS SYNDROME

More than 40 cases of the blue rubber bleb nevus syndrome (Bean's syndrome), which is characterized by the presence of rubbery blue hemangiomas of the skin and gastrointestinal tract associated with gastrointestinal hemorrhage, have been reported in the literature. The rubbery angiomas of skin are variable in size, compressible, and refill on release of pressure. Hemangiomas may occur in other organs, including the pleura. Those of the gastrointestinal tract cause profuse hemorrhage, whereas hemothorax has resulted from pleural hemangiomas. Hemothorax and hemopericardium are described in a patient with this syndrome. Histologic examination of pleural specimens has shown features similar to those in the skin.

CHEST WALL LESIONS

Confusion arises when chest roentgenograms reveal unusual abnormalities caused by lesions located in the chest wall. Initially diagnosed as pulmonary parenchymal lesions, many of these undergo extensive diagnostic testing. Good physical examination with a posteroanterior stereo chest roentgenogram and a lateral view will exclude an intrathoracic lesion. Unusual density, significant calcification, and association with skin lesions in areas other than the thoracic cage assist in excluding an intrathoracic lesion (Fig. 2 and Fig. 3).

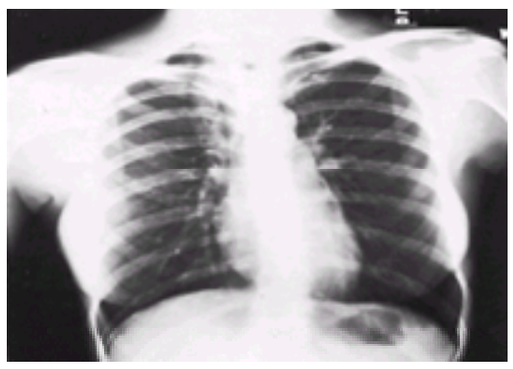

FIG. 2. Thick braid of hair masquerading as a superior mediastinal mass in the right paratracheal region.

FIG. 3. Calcified skin lesions appearing as intrapulmonary lesions on a single posteroanterior view.

CHRONIC MUCOCUTANEOUS CANDIDIASIS

Mucocutaneous candidiasis is an uncommon disorder associated with certain immunologic defects. Deficiency of the IgG_2/IgG_4 subclass and absence of antibodies against pneumococcal and *Hemophilus* polysaccharide occurs in patients with this disorder. Detailed studies of a pediatric patient with mucocutaneous candidiasis and recurrent pulmonary infections revealed a severe defect in cell-mediated immunity, but humoral immune responses were normal. The disease may be complicated by candidiasis involving the larynx, trachea, bronchi, and esophagus. Symptoms consist of hoarseness, hemoptysis, and dysphagia. Bacterial pneumonia, bronchopneumonic infiltrates, and bronchiectasis are some of the pulmonary manifestations described.

COGAN'S SYNDROME

Cogan's syndrome is a disease of unknown origin characterized by audiovestibular symptoms, nonsyphilitic interstitial keratitis, and systemic manifestations that include fever, anemia, elevated sedimentation rate, leukocytosis, and thrombocytosis. Complications include deafness, blindness, vasculitis, aortic insufficiency, and

death. Variable cardiovascular involvement leading to aortic insufficiency or orificial stenosis of coronary or aortic arch vessels is a common complication.

Respiratory involvement is present in approximately 20% of patients and includes mild, sometimes transient, chest roentgenologic abnormalities and pleuropericarditis. An upper respiratory tract infection precedes onset of the syndrome in approximately 40% of patients. A review of 78 patients noted transient pulmonary infiltrates and pleuritis in 9% and 5%, respectively. Recurrent lung infiltrates have been described.

CUTIS LAXA

Cutis laxa (generalized elastolysis) is a rare systemic disorder of connective tissue in which the elastic fibers become fragmented, disorganized, and fewer in number. A congenital (X-linked recessive) as well as an acquired variety have been described. The acquired cases manifest in midlife, and their origin, genetic or otherwise, is unknown. The dermatologic abnormalities in cutis laxa seem to result mainly from a developmental defect of the elastic network in the papillary dermis. Both the congenital and acquired varieties exhibit identical clinical, physiological, and pathologic abnormalities. Cutaneous pathologic findings are characterized by the disappearance of elastic fibers of the skin (Fig. 4). The skin changes lead to an appearance of early senility. Because the disease affects connective tissues all over the body, the clinical manifestations can be varied. Cutis laxa (loose skin), emphysema, aortic aneurysms, diverticula of bowel, and hernias are some of the complications. This disorder is distinct from Marfan's syndrome, Ehlers–Danlos syndrome, and pseudoxanthoma elasticum.

FIG. 4. Cutis laxa (generalized elastolysis) shows loss of skin elasticity over lower trunk and external genitalia. This patient also had severe emphysema.

The respiratory system ranks second only to the skin as the most commonly affected organ. The most frequent and serious pulmonary problem associated with cutis laxa is panlobular emphysema. Markedly elevated activity of an elastase-like serum enzyme, observed in some patients with cutis laxa, may predispose to the development of emphysema. Severe and rapidly progressive emphysema leads to early cor pulmonale, which is the most common cause of death among patients with the congenital variety. Emphysema also occurs in nearly 5% of patients with acquired cutis laxa. Other respiratory complications include pneumothorax, pulmonary fibrosis, pulmonary artery stenosis, eventration of the diaphragm, recurrent pulmonary infections, bronchiectasis, tracheobronchomegaly, and aneurysms of the thoracic aorta.

EHLERS–DANLOS SYNDROME

Ehlers–Danlos syndrome is a group of inherited disorders in which connective tissue diseases result from disorganization of collagen fibers. Deficiency of type III collagen may be responsible for the respiratory complications. Ultrastructural and biochemical analysis of the lung tissue have revealed a marked decrease in type III collagen and the production of less type III procollagen relative to type I procollagen by fibroblasts cultured from the abnormal lung. Electron microscopic examination of the lung tissue has shown dilated endoplasmic reticulum of the fibroblasts with normal collagen. Of the nine subtypes of Ehlers–Danlos syndrome, which generally are too difficult to distinguish from one another, only types I and IV are reported to be associated with a substantial risk of arterial rupture. Specifically, type IV, which is also known as the vascular or ecchymotic type, is associated with many serious complications. The disorder is clinically characterized by abnormal skin flaccidity, hyperextensibility of the joints, bleeding tendencies, atrophic scars, easy skin bruising, and pseudotumors.

Pulmonary involvement in Ehlers–Danlos syndrome results from weakness of the collagen in the lung tissue. Respiratory complications recorded include pneumothorax and bullous lung disease. Severe panacinar emphysema of lungs has been observed, and transient pulmonary cysts have been reported with this syndrome. Bronchiectasis resulting from weakened bronchial walls also has been reported. A dilated trachea, similar to that in Mounier–Kuhn syndrome, was noted in a patient with this disorder. Weakness of the pulmonary arterial wall may result in rupture and hemoptysis. Massive recurrent hemoptysis over a 6-year period followed by fatal lung hemorrhage has been described in a 27-year-old man. Pulmonary artery regurgitation and pulmonary valvular stenosis are described as well. An 18-year-old patient with Ehlers–Danlos syndrome, type IV, who developed recurrent large, thick-walled lung cavitary lesions, probably a manifestation of focal lung rupture, has been described. A patient with Ehlers–Danlos syndrome who presented acutely with clinical and roentgenologic features suggestive of aortic dissection was found to have mediastinal hematoma with no evidence of aortic dissection and was treated conservatively with no complications.

EOSINOPHILIC FASCIITIS

The syndrome of eosinophilic fasciitis consists of symmetric thickening of the deep fascia between muscle and subcutis of the arms, legs, and torso. Skin biopsy reveals a normal epidermis and an inflammatory infiltrate in the deep fascia. More than 200 cases of this unusual syndrome have been reported. Visceral involvement is generally mild or absent. Clinically, the affected skin is thickened and indurated.

When the skin around the thoracic cage becomes involved, the work of breathing is increased by the constricting effect of the thickened noncompliant skin (“hidebound chest”). Physical examination may reveal marked induration of the thoracic integument with a severely limited chest wall excursion. This extrapulmonary thoracic restriction has led to progressive respiratory limitation, documented by pulmonary function tests. Pulmonary parenchymal disease is not a feature, even though the diffusing capacity of carbon monoxide ($D_L CO$) in some patients with this disorder has been found to be reduced to a very low level.

EPIDERMOLYSIS BULLOSA DYSTROPHICA

Epidermolysis bullosa represents a group of rare hereditary bullous disorders marked by blister formation following relatively minor trauma. Three types of the disease occur depending on the site of disruption within the skin: simplex (above the basement membrane), dystrophic (below the basement membrane), and junctional (at the lamina lucida). Epidermolysis bullosa dystrophica generally presents in newborns and is characterized by noninflammatory bullous lesions that may affect the tracheobronchial mucosa and cause respiratory distress. Postmortem analysis of the airways in a 29-month-old boy who died from laryngeal obstruction secondary to this disorder showed intense mucosal inflammation and swelling of the seromucinous glands in the supraglottic airway. Localized subglottic edema and the formation of an inflammatory membrane in the trachea has led to chronic subglottic stridor. Even minimal trauma is reported to result in stricture formation. In one series of five children, three required tracheostomies acutely, and one died of airway obstruction. The laryngeal cysts are distinct from the cutaneous bullae or bullous pemphigoid.

ERYTHEMA MULTIFORME

Erythema multiforme is a systemic disorder characterized by generalized eruptions of red or violaceous macules similar to urticaria, papules, vesicles, or bullae, involvement of various internal organs, and fever. The most characteristic skin lesion is known as a target or bull's eye. A more severe form is generally described as Stevens–Johnson syndrome, in which mucocutaneous ulcerations are seen.

Although the association of erythema multiforme with respiratory infection caused by *Mycoplasma pneumoniae* is well known, the most common association of this disorder is with bacterial pneumonias caused by streptococci, *Pseudomonas* species, pneumococci, *Legionella* species, and *Hemophilus influenzae.* Erythema multiforme is also seen in association with histoplasmosis and blastomycosis. Noninfectious causes of erythema multiforme include penicillin, antipyretics, barbiturates, and sulfonamides. A literature review of 70 cases of *Mycoplasma* pneumoniae infections associated with the Stevens–Johnson syndrome recorded that none of the cases exhibited erythema multiforme. Most patients had prodromal symptoms of an upper respiratory tract infection before the onset of the eruption and an underlying pneumonia. These findings led the authors to conclude that *M. pneumoniae* is the most common infectious agent associated with the Stevens–Johnson syndrome and that the infection is not associated with erythema multiforme. Another report noted that four of seven cases of erythema multiforme were caused by *M. pneumoniae*

infection.

Respiratory complications include bronchopneumonic infiltrates, massive pneumonic consolidations, miliary lesions, hilar lymphadenopathy, and, uncommonly, pleural effusions. Clinically, the pulmonary manifestations are indicated by laryngotracheobronchitis, cough, hemoptysis, dyspnea, and cyanosis. In a 46-year-old woman with active systemic lupus erythematosus, severe Stevens–Johnson syndrome developed 8 hr after intravenous urography with the nonionic contrast medium iopamidol. The illness included erythema multiforme, intrahepatic cholestasis, pulmonary infiltrates, and acute renal failure, which led to her death. Rapidly progressive and fatal bronchiolitis obliterans was observed in a middle-aged woman. Stevens–Johnson syndrome with supraglottic laryngeal obstruction has been described.

The diagnosis and management of erythema multiforme and Stevens–Johnson syndrome are complex and controversial. Systemic corticosteroids have been used successfully in many instances.

ERYTHEMA NODOSUM

Erythema nodosum is a self-limited cutaneous disorder characterized by inflammatory nodules in the dermis and subcutaneous tissues, commonly along the extensor aspects of the legs. This form of panniculitis is clinically characterized by pain in the anterior tibial area, followed by development of tender pink nodules on the shins. The lesions normally resolve spontaneously over a period of several weeks. The appearance is so characteristic that biopsy is seldom required. Erythema nodosum is most likely a hypersensitivity reaction to a broad variety of disorders, especially drug reactions and infection by viruses, bacteria, and fungi. The cause of erythema nodosum remains unknown in approximately half the patients.

Sarcoidosis is one of the common diseases associated with erythema nodosum. Erythema nodosum has been observed in 13% of two large series of patients with sarcoidosis. Erythema nodosum can be the presenting manifestation of sarcoidosis. The presence of erythema nodosum in patients with sarcoidosis is associated with a good prognosis, and an acute onset of sarcoidosis with erythema nodosum signifies a good prognosis and spontaneous resolution. In a retrospective study of 818 patients with sarcoidosis, 16% of patients presenting with erythema nodosum followed a chronic course. Bronchoalveolar lavage in patients who had an acute inflammatory onset of sarcoidosis and erythema nodosum has demonstrated high CD4/CD8 lymphocyte ratios and a higher proportion of T lymphocytes than in patients presenting with respiratory complications after erythema nodosum resolved. Erythema nodosum in conjunction with non-Hodgkin's lymphoma that presents as a solitary pulmonary nodule has also been described.

Histoplasmosis and coccidioidomycosis are common causes of erythema nodosum in the United States. Pulmonary blastomycosis associated also with erythema nodosum has been described. Among 305 children with postprimary tuberculosis, erythema nodosum was observed in 37 (12%) children. As in sarcoidosis, erythema nodosum in association with these infections denotes a good prognosis because such a combination confirms the development of antibodies or hypersensitivity to the pathogenic antigens. Erythema nodosum was observed in 28% of 88 cases of tularemia in northern Finland, and pulmonary tularemia was present in 27% of the patients. Erythema nodosum was seen more often in patients with pulmonary tularemia than in other forms of the disease.

FAMILIAL MEDITERRANEAN FEVER

Familial Mediterranean fever, also known as periodic disease, is an autosomal recessive inherited disorder characterized by recurrent episodes of fever accompanied by inflammation of the peritoneum, pleura, synovial membranes (recurrent polyserositis), and skin. The disorder predominantly affects persons of Mediterranean origin (Sephardic Jews, Armenians, and Arabs) and is rare in other groups. The most serious complication of the disease is amyloidosis, which is the cause of death in a substantial proportion of adult patients. Abdominal pain, which occurs in more than 95% of patients, is an important aspect of the disease. Acute arthritis occurs in 17% to 75% of patients.

Pulmonary manifestations commonly occur in the form of pleuritic chest pain in 35% to 85% of patients. Recurrent pleuritic chest pains are common and may be associated with small pleural effusions. Right-sided effusions are reported to be more common. Pulmonary hypertension and pulmonary amyloidosis have been described in familial Mediterranean fever.

Asthma is reported to occur less commonly in patients with familial Mediterranean fever. A study of 148 parents of patients with familial Mediterranean fever and of 148 ethnically matched control persons demonstrated an apparently reduced prevalence of asthma in the heterozygotes compared with the control subjects (three versus six). The authors of this study concluded that their data were in agreement with previous studies that demonstrated decreased asthma prevalence in patients with familial Mediterranean fever.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu disease) is an autosomal dominantly inherited disorder characterized by telangiectasia of the skin and mucous membranes and intermittent bleeding from arteriovenous malformations and fistulas. The prevalence of simultaneous hereditary hemorrhagic telangiectasia and pulmonary arteriovenous malformation during a 10-year period in one Scandinavian county of more than 429,207 inhabitants was 2.6 per 100,000. The male–female ratio was 1:2. Telangiectasias of the skin and oral, nasal, and conjunctival mucosa manifest in the second and third decades of life. They appear bright red, punctate or linear, and blanch under pressure. Gastrointestinal bleeding occurs in approximately 15% of patients.

Hereditary hemorrhagic telangiectasia is the most common cause of pulmonary arteriovenous fistula. In a study of seven families that participated in screening for pulmonary arteriovenous malformations and hereditary hemorrhagic telangiectasia, 36 (80%) of the 45 screened family members were found to have hereditary hemorrhagic telangiectasia, and 13 (36%) of the 36 family members with hereditary hemorrhagic telangiectasia were proven to have pulmonary arteriovenous malformations by pulmonary angiography. A report on 53 patients with pulmonary arteriovenous malformations observed that 42 (79%) patients had associated hereditary hemorrhagic telangiectasia.

The rate of occurrence of pulmonary arteriovenous fistulas is determined by the mutations in endoglin. In a genetic study, members of families with the mutation in endoglin (the locus has been designated ORW1) exhibited a 29% prevalence of pulmonary arteriovenous malformations compared to a prevalence rate of 3% in families in which ORW1 was excluded. A genetically determined location for a second ORW locus with linkage to chromosome 12 has been identified in patients with significantly reduced incidence of pulmonary involvement.

Pulmonary arteriovenous malformation is a rare cause of cyanosis in the newborn. Among the nine previously reported neonatal cases, typical signs at presentation included cyanosis, murmur, and congestive cardiac failure. Chest roentgenographs commonly exhibited cardiomegaly, oligemia, and focal pulmonary density. The majority of pulmonary fistulas are detected in the third and fourth decades of life. The pulmonary fistulas usually occur in the lower lobes of lungs and are multiple in nearly 35% of patients. Typically, chest roentgenograms show the pulmonary arteriovenous fistulas as oval or round homogeneous nodular lesions that measure from a few millimeters to several centimeters in diameter. These fistulas tend to evolve and continue to enlarge over long periods, sometimes as long as 24 years. A standard chest roentgenogram may show a nodular shadow but can easily obscure small afferent and efferent vessels attached to the fistula (Fig. 5). The risk of relying solely on the standard chest roentgenogram becomes apparent when a transthoracic needle aspiration is performed, with resultant serious hemorrhage. Simple tomography generally discloses an artery entering the fistula and a vein leaving it (Fig. 6). Pulmonary angiography confirms the diagnosis in virtually all cases and is required before embolotherapy or surgical resection of a fistula is undertaken (Fig. 7). Cases of spontaneous pneumothorax and hemothorax secondary to intrapleural rupture of an arteriovenous fistula have been observed. Endobronchial mucosal or submucosal telangiectases are distinctly uncommon. They may come to light when bronchoscopy is performed to investigate hemoptysis. Telangiectasia of the nasal mucosa occurs more frequently than does endobronchial fistula and leads to recurrent bouts of epistaxis.

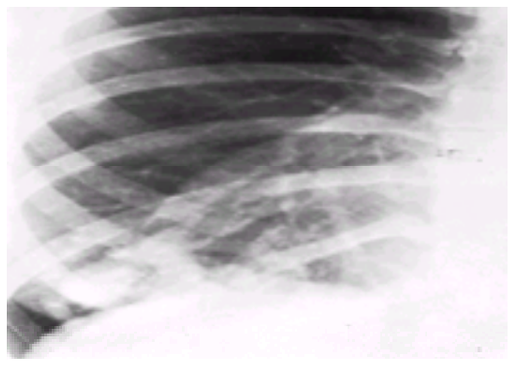

FIG. 5. Pulmonary arteriovenous malformation in right lower lobe of a patient with hereditary hemorrhagic telangiectasia reveals afferent and efferent vessels attached

to the fistula.

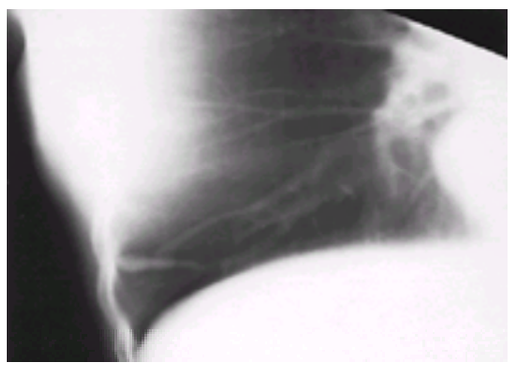

FIG. 6. Localized tomography sometimes is necessary to identify pulmonary arteriovenous malformation, especially when the fistula is small.

FIG. 7. Pulmonary angiogram in hereditary hemorrhagic telangiectasia shows a large arteriovenous malformation in the left lower lobe.

Dyspnea and hemoptysis are the two common symptoms. The severity of dyspnea depends on the degree of right-to-left shunting. Although dyspnea is present in nearly 60% of patients, hemoptysis (occurring in 10% to 20%) is the most common presenting symptom. This can be brisk but usually is not life-threatening. In a study of 143 patients with pulmonary arteriovenous malformations associated with hereditary hemorrhagic telangiectasia, 11 (8%) patients (seven women and four men) had a history of either massive hemoptysis or hemothorax; one patient died as a result of the pulmonary hemorrhage. Among the seven women, three had pulmonary hemorrhage during pregnancy. The increased risk of bleeding from the arteriovenous malformations during pregnancy has been reported in several cases.

Clinical examination may reveal cyanosis, clubbing of fingers, and a bruit or a continuous vascular noise or hum over the site of the fistula. Pulmonary artery catheterization generally reveals diminished arterial oxygen tension and saturation but normal pulmonary artery pressure. Echocardiography is a less invasive method for detecting extracardiac right-to-left shunts. After venous injection of indocyanine green dye or agitated saline, the characteristic contrast flow pattern consists of a markedly delayed appearance of echoes in the left ventricle. However, this type of assessment does not calculate the degree of shunt. Physiological shunt calculation is accomplished by administering 100% oxygen and obtaining blood samples for measurements of gas tensions.

Paradoxic embolism is a common and serious complication of pulmonary arteriovenous fistulas; the occurrence of this complication has been noted at presentation in more than one-third of patients. A report on 53 patients with pulmonary arteriovenous malformations observed that 19 (36%) patients had neurologic problems compatible with paradoxic embolization. Among 67 patients with pulmonary arteriovenous malformations associated with hereditary hemorrhagic telangiectasia, strokes and transient ischemic attacks were recorded in 37%. Another report observed that four of five patients with asymptomatic small or moderately sized pulmonary arteriovenous malformations presented with stroke caused by paradoxic embolism. A review of the English literature in 1990 disclosed 52 cases of neurologic complications, but not all were caused by paradoxic emboli originating in pulmonary arteriovenous fistulas. Indeed, among a series of more than 200 reported patients with hereditary hemorrhagic telangiectasia and associated neurologic sequelae, 61% developed neurologic lesions secondary to pulmonary arteriovenous fistula, whereas 36% of the patients with neurologic manifestations exhibited vascular malformations of the brain and spinal cord.

Various neurologic manifestations are reported in up to 30% of patients. Brain abscess, estimated to occur in approximately 1% of patients, can be the presenting feature of hereditary hemorrhagic telangiectasia. Mental obtundation, headache, visual disturbances, hemiplegia, and seizures are the most common presenting features of paradoxic embolism to the neurologic system. Leukocytosis and fever are not prominent features, and blood cultures are generally sterile. However, in patients with brain abscesses, anaerobic and microaerophilic streptococci are the most common pathogens isolated. In a series of 31 patients with hereditary hemorrhagic telangiectasia and neurologic involvement, 13 patients died, and patients without abscess drainage or with delayed diagnosis had a higher mortality.

Unusual complications described in patients with hereditary hemorrhagic telangiectasia include high-output congestive cardiac failure, portosystemic encephalopathy (from hepatic arteriovenous malformations), and disseminated intravascular coagulation. In a report on 47 patients with documented hereditary hemorrhagic telangiectasia, disseminated intravascular coagulation was observed in 51%.

The treatment of choice is pulmonary artery embolo-therapy (therapeutic embolization) using coils and other intravascular devices. The aim of such treatments is to reduce right-to-left shunts. As new fistulas evolve in the same patient, or recanalization occurs in the embolized fistulas over a period of time, repeated embolizations may be necessary (Fig. 8 and Fig. 9). A publication on embolo-therapy in 67 patients with pulmonary arteriovenous malformations associated with hereditary hemorrhagic telangiectasia reported that the physiological improvements remained stable for 5 years after embolotherapy, complications were minimal, and surgery was not required in any patient. In another report on 11 patients with pulmonary arteriovenous malformations, lung function tests before embolotherapy disclosed normal vital capacity and FEV_1/FVC ratios, reduced D_LCO (mean 71% of predicted; range 36% to 123%), a resting supine arterial oxygen saturation of 86% (range 67% to 95%), mean shunt fraction of 33% (range 15 to 47%), and well-preserved exercise capacity. Six months after therapy, the mean shunt fraction decreased from 33% to 19%, and resting arterial oxygen saturation increased from 86% to 92%. A consistent improvement in D_LCO was also seen. There were no long-term complications following embolotherapy. In another report, 32 patients with 92 pulmonary arteriovenous malformations (with feeding arteries >3 mm) were treated by coil embolization and followed up for a mean period of 25 months, and the mean shunt fraction decreased from 16.6% to 7.4%; treatment was incomplete in two patients, one of whom was subsequently treated surgically. Others also have documented the immediate improvement in respiratory symptoms, exercise capacity, and gas exchange at rest and during exercise as a result of the embolization-induced reduction in right to left shunt. Even though hypoxia induced by right-to-left shunt does not respond to oxygen therapy, many patients subjectively feel better with supplemental oxygen.

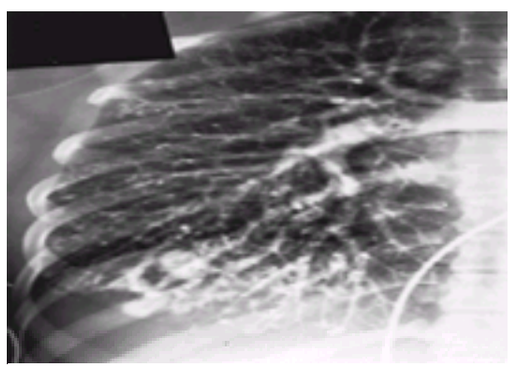

FIG. 8. Multiple arteriovenous malformations the right lower lobe. This patient had multiple bilateral arteriovenous malformations.

FIG. 9. Chest roentgenogram of the patient shown in Fig. 8 after multiple steel-coil embolizations. This patient has required several embolizations for recurrent arteriovenous malformations.

Complications of coli embolization therapy have been noted in 10% of procedures. They have included potentially serious problems such as systemic coil embolization, cerebrovascular accident, and myocardial puncture.

Large arteriovenous fistulas (diameter of efferent vessel exceeding 10 mm) may require surgical resection. The life expectancy of patients with hereditary hemorrhagic telangiectasia is not reduced provided treatable complications are diagnosed and treated promptly.

HYPERHIDROSIS

Hyperhidrosis, or abnormally excessive production of sweat, can signify an underlying malignancy. Unilateral hyperhidrosis of the chest cage has been described in patients with lung cancer. In most reported cases, hyperhidrosis has been limited to the same side as the tumor. It is speculated that direct irritation of nerves may excite the autonomic efferent fibers. The presence of hyperhidrosis indicates a poor prognosis. Resection of a cervical rib may abolish the hyperhidrosis.

Anhidrosis or abnormally diminished production of sweat can be encountered as part of the paraneoplastic syndrome. An example of this is the anhidrosis seen in Horner's syndrome, in which the other features include ipsilateral miosis and ptosis. These changes as well as anhidrosis occur on the same side as the pulmonary neoplasm.

MALIGNANT ATROPHIC PAPULOSIS

Malignant atrophic papulosis (Degos' disease) is a rare multisystemic disorder characterized by typical skin and gastrointestinal symptoms. Many patients demonstrate a rapidly fatal course. The presenting clinical feature is the appearance of crops of asymptomatic oval skin lesions ranging from 2 to 8 mm in diameter. A review of 60 reported cases of Degos' disease found that 17 included intrathoracic abnormalities, most of which were found incidentally at postmortem. The most common intrathoracic findings were pleuritis and pericarditis. Bilateral hemorrhagic pleural effusions, pleural plaques, pulmonary infarcts, and pulmonary abscesses also were noted.

MASTOCYTOSIS

Systemic mastocytosis, or mast cell disease, is an uncommon disorder characterized by urticaria pigmentosa, hepatosplenomegaly, osteosclerotic bone lesions, and diarrhea, nausea, vomiting, and flushing. Respiratory manifestations include interstitial lung disease and extensive peribronchial and alveolar infiltration with mast cells. There are several reports of systemic mastocytosis associated with mediastinal germ cell tumors.

NEUROFIBROMATOSIS

Neurofibromatosis (von Recklinghausen's disease) is a common disease of variably expressive autosomal dominant inheritance characterized by café-au-lait spots, freckling, and neurofibromas of skin and internal organs. Its incidence is one per 3000; approximately half the cases occur sporadically. Cutaneous lesions are the result of the maldevelopment of neural crest cells. The number of dermal neurofibromas varies from individual to individual. Large plexiform neurofibromas develop along peripheral nerves and involve deeper tissues. Extracutaneous (visceral) involvement may not be apparent during life unless such lesions produce symptoms.

Respiratory involvement occurs in 10% to 15% of patients with neurofibromatosis. Although neurofibromatosis is a congenital disorder, the lung involvement does not become evident until adulthood. Up to 20% of patients older than 35 years develop diffuse interstitial fibrosis. Diminished perfusion and ventilation to apices of the lungs has been documented by radionuclide studies in a patient with cutaneous neurofibromatosis. Bullous lung disease may occur alone or in combination with diffuse pulmonary fibrosis. Pulmonary fibrosis usually is seen in the basal areas of the lungs, whereas the bullous lesions occur predominantly in the apical areas (Fig. 10). Cystic lung disease resembling honeycomb lung also has been described.

FIG. 10. Neurofibromatosis with pulmonary manifestations showing bullous changes in the upper lung zone and honeycomb changes in the lower lungs.

The pulmonary parenchymal disease is attributed to a mesenchymal defect resulting in primary deposition of collagen. The histologic features mimic those of idiopathic pulmonary fibrosis. Ultrastructural studies have shown fragmentation of collagen fibers in the lung. The clinical manifestations are mild, usually consisting only of exertional dyspnea, but a restrictive pattern of pulmonary function and diminished diffusing capacity often are observed.

Intrathoracic neurofibromas and meningoceles may be associated with a dermal form of neurofibromatosis, but these usually remain undetected because they rarely are symptomatic (Fig. 11). An earlier review of the literature reported 27 cases of intrathoracic meningoceles with neurofibromatosis. Since then, more than a dozen such associations have been reported. When these lesions are situated in the posterior mediastinum, as they commonly are, they may represent so-called dumbbell tumors with intraspinal extension. Magnetic resonance imaging of the involved spinal area is helpful in assessing the anatomic extent of such tumors.

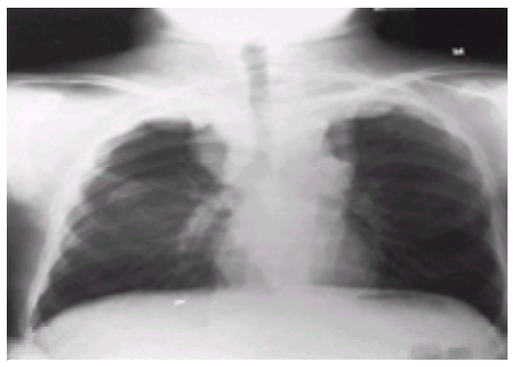

FIG. 11. Neurofibromatosis with intrathoracic neurofibromas.

Neurofibromatosis can involve the mediastinum. A 44-year-old woman with a dumbbell-shaped mediastinal mass developed a large pleural effusion, respiratory failure, and fatal hemoptysis. Autopsy revealed systemic neurofibromatosis involving the mediastinum and pleura. Mediastinal and pleural hemorrhage probably occurred as a result of an eroded thoracic artery. Primary pulmonary parenchymal neurofibromas are rare. Benign neurogenous tumors arising in the trachea are also uncommon. A report described a patient with neurofibromatosis who presented with dyspnea caused by endotracheal neurofibroma. Hoarseness may result from recurrent laryngeal nerve involvement.

Primary or secondary malignancy in the lung has been overlooked in two patients with generalized neurofibromatosis because of roentgenographic confusion caused by overlying cutaneous lesions (see above regarding chest wall lesions). Neurofibromatosis is associated with an increased incidence of malignancy, ranging from malignant tumors of the central nervous system to Wilms' tumor, rhabdomyosarcoma, leukemia, and pheochromocytoma. In 5% of patients, the neurofibromas in neurofibromatosis undergo transformation to malignant degeneration and commonly metastasize to the lungs. Scar cancer of the lung has been reported as a complication of the chronic pulmonary process in neurofibromatosis.

NONSUPPURATIVE PANNICULITIS

Sometimes referred to as *Weber–Christian disease,* nonsuppurative panniculitis is characterized by cutaneous nodular fat necrosis of the panniculus adiposum. Tender, erythematous subcutaneous nodules appear over the extremities and trunk.

A review in 1976 reported pulmonary involvement in only five cases. Pulmonary manifestations include pulmonary fat emboli and infarcts, lipogranulomatous pneumonitis with nodules measuring 0.8 to 3 cm in diameter, and fluffy roentgenographic densities bilaterally. Recurrent pneumonia and pleural effusion also occur. Interestingly, a_1-antitrypsin deficiency has been found in some patients with acute panniculitis. There is no report of emphysematous lung disease occurring as a result of this.

OCULOCUTANEOUS ALBINISM

Sometimes called *pulmonary ceroidosis* or the *Hermansky–Pudlak syndrome,* oculocutaneous albinism is an autosomal recessive disorder characterized by oculocutaneous tyrosinase-positive albinism, platelet pool disease with moderate bleeding tendency, and ceroid-like inclusions in the reticuloendothelial system. A review of the literature in 1989 recorded more than 200 cases of the Hermansky–Pudlak syndrome, the most striking feature of which is the presence of clinically recognizable oculocutaneous albinism. However, the most frequent clinical complication is hemorrhage, and epistaxis is the most common hemorrhagic manifestation.

Respiratory involvement is a recognized complication in oculocutaneous albinism. The primary disease affects men and women equally, but the incidence of lung disease is twice as high in women as in men. The pulmonary disease is similar to idiopathic pulmonary fibrosis and usually begins in the third or fourth decade of life. Bronchoalveolar lavage in asymptomatic patients has shown that the concentration of platelet-derived growth factor-related peptides is six times greater in patients with Hermansky–Pudlak syndrome than in normal subjects. These peptides are important in the initiation of alveolar remodeling in the fibrotic lung disorders and are perhaps involved in the pathogenesis of lung disease in this syndrome.

Clinically, constant nonproductive cough and progressive dyspnea are the chief symptoms. Dyspnea can develop suddenly over several weeks or gradually over years, and the respiratory disease can progress to end-stage fibrosis and death. The pulmonary pathology in oculocutaneous albinism is compatible with oxidant injury as it parallels pathologic alterations seen with pulmonary oxygen toxicity. Bronchoalveolar lavage may show alveolar macrophages containing typical ceroid-like material. Brown-pigmented histiocytes have been demonstrated in the alveolar spaces. Increased levels of immunoglobulins, numbers of IgG- and IgA-secreting cells, and normal percentages of helper and suppressor T cells are observed. The pulmonary fibrosis is an irreversible and progressive process. No specific therapy is available for the lung disease.

Pulmonary ceroidosis occurs in many of the approximately 30 disorders in which systemic or localized deposition of ceroid occurs. Sea-blue histiocytosis syndrome is an example of ceroidosis, and lung involvement is present in 11% of these patients. Idiopathic pulmonary ceroidosis may represent pulmonary alveolar deposition of ceroid-like material in the absence of clinical or biochemical data characteristic of any specific ceroid storage disease. Interestingly, deposition of ceroid-like pigment in the pulmonary alveolar macrophages has been reported in eight patients with carcinoma of the stomach.

PEMPHIGOID

The association of bullous pemphigoid with lung cancer was discussed earlier. Cicatricial pemphigoid, however, is a nonparaneoplastic chronic vesiculobullous disease of the mucosal epithelium that primarily involves the oral cavity and the eyes. This chronic mucosal blistering disorder exhibits a predilection for subsequent scar formation. Airway obstruction and laryngeal stenosis, several of which required tracheostomy, have been described in patients with cicatricial pemphigoid. An unusual case of a 20-year-old woman who died of respiratory failure and was noted to have cicatricial pemphigoid of the bronchi is reported. A case of a 22-year-old man with cicatricial pemphigoid in whom severe stenosis of the left mainstem bronchus developed 2 years after onset of the disease is described; therapy by sleeve resection and end-to-end anastomosis was successful. Pulmonary hemorrhage associated with bullous pemphigoid of the lung has been described. Stenosis of the nasopharynx or larynx has resulted in obstructive sleep apnea.

PSEUDOXANTHOMA ELASTICUM

Pseudoxanthoma elasticum is a rare disorder characterized by fragmentation and calcification of elastic fibers in skin, blood vessels, and retina. Both autosomal dominant and recessive forms have been described. The basic defect is unknown. One patient with pseudoxanthoma elasticum has been reported in whom the lung biopsy showed widespread deposition of calcium in the walls of some arteries, arterioles, and venules, with swollen, short, irregularly clumped elastic fibers and irregularity of the elastic laminae.

PYODERMA GANGRENOSUM

Pyoderma gangrenosum is a painful, chronic, destructive, and ulcerating skin disease of unknown origin. The occurrence of this disorder in intestinal diseases is well known. In a report on 86 patients with this disease, inflammatory bowel disease was present in 36%. Asthma or chronic obstructive pulmonary disease was noted in 5%. Pulmonary abscess has been described in a patient with pyoderma gangrenosum, but the relationship between pyoderma gangrenosum and pulmonary disease remains unclear. Pyoderma gangrenosum of the skin and trachea has been described in a 9-month-old boy.

TUBEROUS SCLEROSIS

Tuberous sclerosis (Bourneville's disease) is an autosomal dominant disease of mesodermal development characterized clinically by epilepsy and mental retardation and pathologically by congenital tumors and malformations of the brain, skin, and viscera. The classic clinical triad in tuberous sclerosis consists of adenoma sebaceum, mental retardation, and seizures. Skin lesions, in addition to adenoma sebaceum or dermal angiofibroma, include ash leaf spots (a hypopigmented skin lesion, the earliest to appear in tuberous sclerosis), shagreen patches (hamartomas of connective tissue seen in 50% of patients and located over the lumbosacral area), and periungual fibromas (benign pink fibrous neoplasms adjacent to the nails and seen in 15% to 20% of patients). Poliosis, or hypopigmentation of the scalp

hair or eyelashes, also is seen. Extracutaneous manifestations include seizure disorder, electroencephalographic abnormalities, or both in 80% to 90%, mental retardation of wide-ranging severity, a hamartomatous lesion of the central nervous system, retinal phakomas, angiomyolipomas of the kidney, renal and bone cysts, and cardiac rhabdomyomas.

Some consider tuberous sclerosis and pulmonary lymphangioleiomyomatosis to be the same clinical entity because of the many striking similarities in clinical, roentgenologic, and pathologic features. However, the presence of hormonal (estrogen, progesterone) receptors in lymphangioleiomyomatosis may distinguish it from tuberous sclerosis, although not all patients with lymphangioleiomyomatosis exhibit these receptors. Chylous effusion is more common in lymphangioleiomyomatosis, whereas angiomyolipomas are much more common in tuberous sclerosis. The difficulty of separating these two entities as distinct diseases is further enhanced by the observation that several patients reported in the literature with the diagnosis of tuberous sclerosis have responded favorably to hormonal therapy that is used to treat pulmonary lymphangioleiomyomatosis. Furthermore, the clinical features are not overt in many patients; indeed, a study of nine patients with pulmonary tuberous sclerosis noted that there was an average delay of 8 years before the correct diagnosis was made. Details on pulmonary lymphangioleiomyomatosis are included in Chapter 63.

Morphologic analysis of the lungs affected by tuberous sclerosis reveals multiple cysts measuring a few millimeters in diameter. The walls of the cysts are formed of hypertrophied smooth muscle cells. The compression of the bronchioles caused by the hypertrophied smooth muscles leads to obstruction, air trapping, bulla formation, and pneumothorax. The compression of the pulmonary venules results in venous congestion and hemoptysis, whereas the compression of the pulmonary arterioles may lead to pulmonary hypertension. The same mechanism, when it involves the lymphatic channels, causes chylothorax. Ultrastructural morphologic analysis of the lung in tuberous sclerosis has shown findings identical to those in lymphangioleiomyomatosis. Cystic disease of the lung with focal adenomatoid proliferation is among the least common pathologic features of tuberous sclerosis.

Pulmonary function tests demonstrate obstructive pulmonary dysfunction despite the nodular interstitial appearance of lungs on the chest roentgenograms. Obstruction to airflow is caused by the compression of the smaller airways by the smooth muscles that undergo hyperplasia. This mechanism also contributes to the increased lung volumes and thoracic hyperinflation. Air-space lesions, however, are reported to be more important than muscular proliferation in bringing about these physiological abnormalities.

Respiratory disease is seen in fewer than 2% of patients with tuberous sclerosis. Often, there is a delay in the diagnosis of pulmonary disease, and many patients are treated for asthma or emphysema. A review of the literature in 1971 noted that there were only 31 cases of pulmonary tuberous sclerosis. Pulmonary tuberous sclerosis usually involves other organs. Indeed, in the largest series of nine patients with pulmonary tuberous sclerosis reported in 1995, seizure was the most common presenting feature. The pulmonary disease tends to develop in adult life, occurs much more commonly among women of childbearing age (between 18 and 34 years) who do not have mental retardation and epileptic seizures. Lung disease has been observed in a mother and daughter from a family with tuberous sclerosis for four generations. Only two male patients with pulmonary tuberous sclerosis are described; neither had pathologic documentation of lung disease. The disease may be rapidly fatal after the onset of respiratory symptoms. Exertional dyspnea is the most common respiratory symptom and may progress to the point of disability. Hemoptysis occurs in up to 25% of patients. The diffuse pulmonary interstitial process may progress to honeycombing and cyst formation, spontaneous pneumothorax, and cor pulmonale (Fig. 12). An earlier review of the literature revealed 19 cases of spontaneous pneumothorax secondary to tuberous sclerosis, with eight patients dying of this complication. Chylous pleural effusion secondary to lymphatic obstruction from mediastinal lymphadenopathy can occur. Significant pulmonary hypertension also has been reported.

FIG. 12. Tuberous sclerosis with extensive reticulonodular infiltrates with some sparing of lower lung zones.

Chest roentgenograms in tuberous sclerosis may show diffuse interstitial infiltrates in later stages of the disease. In the early stages, reticular or reticulonodular changes are found. Bullous changes and hyperinflation of lungs are also common. Spontaneous pneumothorax is common. Pleural effusion may be secondary to pneumothorax or to chylous effusion. In up to 25% of patients, normal chest roentgenograms may contribute to missed diagnoses. In such cases, a high-resolution computed tomographic (CT) scan of the lung is helpful. High-resolution CT scans of lungs in tuberous sclerosis have shown thin-walled cysts less than 20 mm in diameter scattered randomly in all parts of the lungs, with normal-appearing lung tissue between cysts. The CT findings are identical in tuberous sclerosis and pulmonary lymphangioleiomyomatosis (Fig. 13). The CT findings correlate better with D_LCO than do chest roentgenograms.

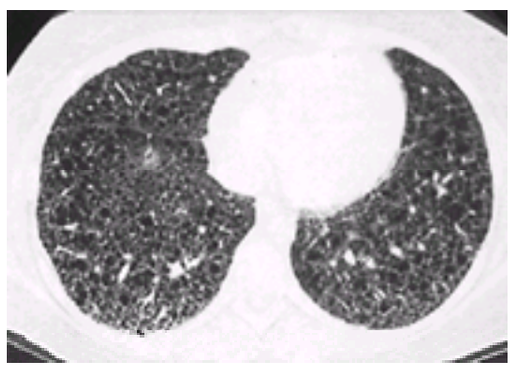

FIG. 13. Tuberous sclerosis of lung evaluated by high-resolution computed tomography, showing typically diffuse fine honeycombing.

Therapy has included to hormonal manipulations including progesterone, tamoxifen, and oophorectomy. Lung transplantation is an option in patients with progressive respiratory failure. Hypoxemic patients benefit from supplemental oxygen therapy. Complications such as pneumothorax and chylothorax require chest tube drainage and/or pleurodesis. Overall survival among nine patients (average age 33 years) with pulmonary tuberous sclerosis followed for an average of 17 years was 78%; two patients died of respiratory failure at 46 and 53 years of age. Presence or absence of lung involvement in tuberous sclerosis does not seem to affect the mortality rate. Pneumothorax, however, has been associated with higher mortality. In a review of 34 patients reported in the literature up to 1971, the average time between the onset of respiratory symptoms and death was approximately 5 years; the cause of death was pulmonary involvement in 86% of patients, 59% of whom died from cor pulmonale and 41% from pneumothorax. Only 25% of affected children live beyond their 20th year.

YELLOW NAIL SYNDROME

The term yellow nail syndrome was first employed in 1964 to describe yellow discoloration of the fingernails in association with lymphedema in 13 patients (Fig. 14). Further experience with more than 150 patients portrayed in the literature has demonstrated the association of yellow nails with pleural effusion and bronchiectasis. Lymphedema of the breasts has been described in many patients with the yellow nail syndrome. The origin of yellow nail syndrome is unknown, although a few cases seemed to follow episodes of pneumonia. The mechanism of nail discoloration is undefined, and the nail changes are not present in all patients. Histopathologic changes in the nail matrix and bed demonstrate dense, fibrous tissue replacing subungual stroma with numerous ectatic, endothelium-lined vessels that mimic pleural alterations in this syndrome. Based on these findings, it is hypothesized that primary stromal sclerosis may lead to lymphatic obstruction and lymphedema.

FIG. 14. Yellow nail syndrome with characteristic yellow discoloration of nails.

Among 97 patients with yellow nail syndrome, most developed the disease in early middle age; the male-to-female ratio was 1:1.6. Yellow nail syndrome has been described in an 8-year-old. Whereas more than half the patients develop nail changes, the majority do not notice the nail discoloration because its onset is subtle. Nails of both hands and feet are affected, becoming thickened, excessively curved along both axes, very slow growing, and of yellowish-gray hue; cuticle and lunula are usually absent, and onycholysis generally is evident. Nail discoloration may precede or follow pleural effusion and lymphedema. Lymphangiography of the lower extremities has shown hypoplasia or aplasia of the lymphatics, similar to that occurring in primary lymphedema.

The recurrent pleural effusions are most likely the result of lymphatic hypoplasia. Measurements of the rate of pleural fluid turnover have indicated that accumulation of pleural fluid in yellow nail syndrome results from defective lymphatic drainage rather than excess production. Histologic examination of the pleura shows thickening with fibrosis, chronic inflammatory infiltration, and dilation of lymphatic capillaries in the visceral pleura. The pathologic process affects not only the lymphatic system but also the pleural capillaries. Ectasia of lymphatic capillaries has been documented by electron microscopy. Pleural effusion may precede the onset of nail changes by several years. The fluid may be an exudate or a transudate. In some patients, the pleural fluid glucose level may be reduced. Pleural effusions range from small, unilateral, and asymptomatic to large, bilateral, recurrent, and debilitating. The pulmonary symptoms depend on the size of the pleural effusion and the severity of associated bronchiectasis. Empyema thoracis has been reported as a complication of the yellow nail syndrome.

Bronchiectasis of lower lobes is now included in the definition of yellow nail syndrome. Bronchiectasis limited to upper lung zones has been noted in a patient, but the mechanism responsible for its development is unknown. Many patients develop sinus infections. Among 17 patients with yellow nail syndrome, 14 (83%) suffered severe rhinosinusitis that predated nail changes in four, coincided with yellow nails in six, and occurred later in the remaining patients. In general, patients responded poorly to conventional medical and surgical treatment, with the exception of endoscopic sinus surgery.

Even though several cases have been described in association with carcinomas of breast, lung, and larynx, there is no clear indication that yellow nail syndrome is a paraneoplastic process. Nevertheless, the nail changes have resolved with successful treatment of the malignancy. There has been one report of a case of yellow nail syndrome following penicillamine therapy that resolved after discontinuation of the drug. A report of eight patients with proved diagnoses of the acquired immunodeficiency syndrome (AIDS) and *Pneumocystis carinii* pneumonia described yellow discoloration of the distal portions of the nails in four patients, with some showing ridging, loss or decrease in size of lunulae, and opaqueness. Yellow nail syndrome has been described in association with rheumatoid arthritis in three patients as well as in two mentally retarded siblings.

Nonpulmonary complications of yellow nail syndrome include keratosis obturans involving the external ear and excess cerumen, chylous ascites, hypoalbuminemia, chyluria, intestinal lymphangiectasia, pericardial effusion, giant-cell interstitial infiltrates, lymphedema of the eyelids, nephrotic syndrome, and Raynaud's phenomenon.

Large, recurrent, or debilitating pleural effusions require repeated thoracentesis, pleuroperitoneal shunting, medical or surgical pleurodesis, or pleurectomy. Chylous effusions are more difficult to cure, although successful therapy has been achieved with dietary restriction of fat and supplements of medium-chain triglycerides. Treatment of pulmonary disease (bronchiectasis and sinus infections) also may resolve the nail changes. There are reports of resolution of the nail changes following topical vitamin E solution. There also are reports of spontaneous resolution of nail discoloration without change in the patient's respiratory status.

INTRODUCTION

The respiratory system is affected by the normal anatomic and physiologic alterations that take place throughout pregnancy, parturition, and early postpartum. A healthy pregnant woman experiences minimal or tolerably mild respiratory symptoms. A pre-existing pulmonary problem, however, can be exacerbated by pregnancy. On the other hand, the normal course of the pregnancy can be adversely affected by pre-existing respiratory disorders to the point of threatening the pregnancy itself. In pregnancy, the clinical course of primary pulmonary diseases such as asthma, sarcoidosis, and certain infectious processes may vary from that in the nonpregnant patient. Likewise, the treatment of pulmonary disease in the pregnant patient may differ because some of the drugs normally used may interfere with pregnancy or cross the placental barrier and adversely affect the fetus. The pulmonary system can also be involved by pathologic processes exclusive to pregnancy, such as amniotic fluid embolism and trophoblastic pulmonary emboli that can occur after removal of a benign hydatidiform mole. The various pulmonary complications described in pregnancy and the postpartum are listed in Table 1. In this chapter, the physiologic changes noted in normal pregnancy, lung involvement by obstetric and gynecologic pathology, as well as the pulmonary manifestations in the disorders of the reproductive organs are included.

Pulmonary complications	Obstetric causes
Dyspnea of pregnancy	Mechanical Hormonal (biochemical) Hemodynamic changes Pulmonary disease (see below)
Pneumothorax and pneumomediastinum	Valsalva maneuver (second stage of labor)
Pulmonary edema	Aspiration pneumonia Eclampsia Tocolytic therapy Pulmonary embolism Amniotic fluid embolism Disseminated intravascular coagulation Trophoblastic embolism Transfusion reactions Sepsis (septic abortion)
Pleural effusion	Postpartum Eclampsia Pulmonary edema (see above) Pulmonary embolism Amniotic fluid embolism
Pulmonary embolism	Metastatic choriocarcinoma Thromboembolism Amniotic fluid embolism Septic embolism (septic abortion)
Pulmonary hypertension	Unknown Recurrent pulmonary embolism Trophoblastic emboli

Note: Sarcoidosis, mumps, asthma, coccidioidomycosis, tuberculosis, and cystic fibrosis, though not complications due to pregnancy, may be present in conjunction with, and thereby affect, pregnancy, and vice versa.

TABLE 1. *Pulmonary complications in pregnancy*

PREGNANCY

Dyspnea

Dyspnea due to mechanical, biochemical, and hemodynamic factors during pregnancy is common. By the twelfth week of pregnancy, more than 20% of women experience dyspnea at rest, whereas nearly two-thirds are dyspneic on exertion. The incidence of dyspnea increases from 15% in the first trimester to 50% by the 19th week and 75% by the 31st week of gestation. Upward displacement of the diaphragm by the enlarging uterus results in slightly diminished lung volumes in the second half of pregnancy. Diaphragmatic fatigue following prolonged contractions, particularly before and during labor, may contribute to dyspnea. Late pregnancy is commonly associated with a decrease in expiratory reserve volume, a mild decrease in functional residual capacity, and a slightly reduced total lung capacity. Airway closure is too insignificant to cause clinical problems. Diffusing capacity during early pregnancy is unchanged or slightly increased over nonpregnant values in the same patient and then diminishes to a plateau during the latter half of pregnancy.

Resting ventilation and, to a lesser extent, oxygen consumption are increased at rest and during exercise in pregnancy as well as during labor. Hyperventilation is a common feature of pregnancy, but the overall pH remains relatively intact because of increased renal excretion of bicarbonate. Severe hyperventilation, however, during labor has resulted in tetany. Arterial oxygen tension (PaO_2) is elevated because of the hyperventilation. However, an abnormally high alveolar-arterial oxygen tension difference near term, possibly because of small airways closure, partially offsets the high PaO_2 . Changes in concentrations of progesterone are also important in producing the ventilatory changes in pregnancy.

Smoking in Pregnancy

Studies in children have demonstrated a clear association between passive exposure to maternal smoking and frequency of acute respiratory illness and chronic pulmonary conditions such as wheezing or asthma. Infants of mothers who smoke during pregnancy have reduced respiratory function and are more likely to develop wheezing. In a study in which healthy infants born to women who smoked during pregnancy were compared to infants born to women who did not smoke during pregnancy, maternal smoking was associated with significant reductions in forced expiratory flow in their young offspring. Maternal smoking during pregnancy may impair *in utero* airway development or alter lung elastic properties and these effects may be important factors predisposing infants to the occurrence of wheezing illness

later in childhood. In another study, respiratory-function data from 461 infants showed that *in utero* smoke exposure, a family history of asthma, and maternal hypertension during pregnancy were associated with reduced respiratory function after birth. This led the authors to speculate that these factors adversely affect lung development *in utero.* A study of the relationship between maternal smoking during pregnancy and lung function in 493 white and 383 black schoolchildren 9 to 11 yr of age in three areas of Philadelphia observed that maternal smoking during pregnancy was associated with significant deficits in FEF_{25-75} and FEV_1/FVC and the observed deficits were larger for black children than for white children, and they were larger for boys than for girls. Suburban white schoolchildren whose mothers smoked during pregnancy had significantly reduced lung function.

Barotrauma

Spontaneous pneumothorax and pneumomediastinum may appear during pregnancy, but these are more likely to occur during the second stage of labor. Repeated Valsalva maneuvers are the most frequent cause of these problems. Pneumomediastinum is a rare complication of pregnancy, and symptoms usually are not noted until after delivery.

Pulmonary Edema

Obstetric causes of pulmonary edema include aspiration pneumonia, sepsis, transfusion reactions, allergic reactions, disseminated intravascular coagulation, amniotic fluid embolism, toxemia of pregnancy, tocolytic therapy, and eclampsia, the latter being the most common cause of pulmonary edema in pregnancy. In a report on 32 obstetric patients who required admission to a critical care unit, preeclampsia was the most common reason (22%). Eclampsia remains the leading cause of maternal mortality in developing countries. A study of 126 patients with eclampsia showed acute respiratory insufficiency in 24% and a mortality of 6%. Morphologic changes in the lungs include intravascular coagulation, fibrin deposition, and intraalveolar hemorrhage. Focal areas of bronchopneumonia also may occur. Hemodynamic studies have shown reductions in colloid osmotic pressure, pulmonary capillary leak, and left ventricular failure. Left ventricular dysfunction is common enough that echocardiography has been recommended to evaluate all pregnant women who develop pulmonary edema. Decreased venous tone and venous resistance have been suggested as the reasons for iatrogenic pulmonary edema. Surgical procedures, pyelonephritis, and other infections during pregnancy pose an increased risk for the development of pulmonary edema and acute respiratory distress syndrome.

Tocolytic therapy, employed to arrest uterine contractions, is associated with the development of pulmonary edema in up to 4.5% of pregnant women who are thus treated. Women with twin gestations are more likely to develop this complication, and the syndrome can occur within 12 hours postpartum. The mechanisms responsible for tocolytic therapy-induced pulmonary edema likely include a combination of volume overload, decreased colloid oncotic pressure, and increased hydrostatic pressure.

A review of tocolytic therapy-induced pulmonary edema from 1966 to 1988 revealed 58 cases. Terbutaline, a b adrenergic agonist was the most commonly used tocolytic agent, in 41% of patients, following by isoxsuprine in 33%, ritodrine in 17%, and salbutamol in 10%. The mean duration of tocolytic therapy was 54 hours. Symptoms included dyspnea (76%), chest pain (24%), and cough (17%), and these occurred before delivery in 70% of cases. The mean PaO_2 was 50 mmHg. Chest roentgenograms showed bilateral alveolar infiltrates and a normal-sized heart. The response to diuresis was rapid, with full recovery over a period of 24 hours, but there were 2 deaths.

Pleural Effusion

Pleural effusions occur with toxemia of pregnancy, preeclampsia, pulmonary edema, pulmonary embolism, choriocarcinoma, and amniotic fluid embolism. Small pleural effusions are common in the postpartum period in normal pregnancy. In a retrospective study of 112 pregnant women who underwent normal delivery, pleural effusion was noted in 46%, where as a prospective study of 30 normal pregnancies revealed pleural effusion in 67%. These effusions were noted within 24 hours of delivery, and all were asymptomatic and small. The factors that promote pleural effusion include increased blood volume and decreased colloid osmotic pressure normally seen in pregnancy and the impaired lymphatic drainage secondary to elevated systemic venous pressure from Valsalva maneuvers during the second stage of labor. Pleural effusion as an uncommon complication of ureteral obstruction by the gravid uterus has been described in a patient. Several cases of transudative pleural effusion in connection with severe preeclampsia are reported.

Pulmonary Embolism

Pulmonary embolism is a rare complication of pregnancy, but it is second only to abortion as a cause of maternal death. It occurs with higher frequency during the postpartum period, especially after a difficult labor and an abnormal postpartum hemorrhage. An earlier review of several series observed the incidence of deep vein thrombosis to be 0.29 per 100 deliveries. Among the 32,337 pregnancies reviewed at the Mayo Clinic, superficial phlebitis was seen in 12 per 1000 patients and deep phlebitis was seen in 2 per 1000 pregnancies. The prepartum and postpartum incidences of thrombophlebitis were 1 in 1902 patients and 1 in 622 patients, respectively. More than 75% of phlebitic episodes occurred during the first month after delivery, especially within the first 3 days postpartum. Calf veins were involved in 50%. Pulmonary embolism was noted to have an incidence of 0.4 per 1000 persons (13 of 32,337 pregnancies), and 10 of these occurred during the first postpartum month. The incidence of pulmonary embolism is increased also during the first trimester.

The factor V Leiden mutation which leads to activated protein C resistance is an important risk factor for thrombophlebitis and pulmonary embolism during pregnancy (especially the first trimester), after pregnancy, or during oral contraceptive use. A study of 50 women who had deep venous thrombosis and/or pulmonary embolism identified 10 women with activated protein C resistance caused by factor V Leiden mutation. First-trimester deep venous thrombosis and/or pulmonary embolism developed in 6 of the 10 women with the mutation compared with 3 of 40 women without the mutation. Another coagulopathy that plays a significant role in pregnancy-associated thrombophlebitis and pulmonary embolism is the presence of antiphospholipid antibody syndrome. Also known as lupus anticoagulant syndrome or anticardiolipin antibody syndrome, the antiphospholipid antibody syndrome is characterized by the presence of antiphospholipid antibodies in serum. Obstetric complications attributed to this syndrome include recurrent (three or more) miscarriages, fetal death in utero, intrauterine growth restriction, preterm delivery, early or severe eclampsia, and abruptio placentae. Thrombophlebitis and pulmonary embolism are common.

Coumarin drugs, unlike heparin, cross the placenta and may cause fetal hemorrhage and congenital malformations, with a perinatal mortality of 18%. Treatment of antepartum thrombophlebitis or pulmonary embolism should start with intravenous heparin, followed by coumarin after the first trimester. Coumarin should be replaced by intravenous heparin at the thirty-seventh week of gestation. All anticoagulants are withheld from the time of labor to 6 hours after delivery. Then heparin and coumarin should be resumed as in conventional patients. The availability of low-molecular heparin for prophylactic use in patients with high- or known-risk for development of thromboembolic diseases has been shown to be effective. The use of prophylactic low molecular weight heparin therapy during part of their pregnancy in 24 women carrying 27 pregnancies with known risk of veno-pulmonary thromboembolic diseases showed that none of the treated women developed clinical signs of thromboembolic diseases during pregnancy or 6 weeks postpartum. All the babies were born healthy and none of the women had any side effects due to the treatment.

Pulmonary Hypertension

The incidence of primary pulmonary hypertension in pregnancy is higher than that in nonpregnant nubile women. A review of 602 cases of primary pulmonary hypertension from 51 medical centers recorded that 4.5% of the cases were associated with pregnancy. Another analysis of 73 women with primary pulmonary hypertension showed that 8% of the cases were related to pregnancy. A rigorous screening of these patients (all of whom were referred for heart-lung transplantation) to detect an underlying etiology for the pulmonary hypertension failed to disclose evidence of thromboembolic disease. Recurrent noncardiogenic pulmonary edema has been described in patients with pregnancy-induced hypertension. The reason for the increased incidence of primary pulmonary hypertension in pregnancy remains unknown.

Amniotic Fluid Embolism

Amniotic fluid embolism is an uncommon complication of parturition. In the United States, the incidence is in the range of 1 in 20,000 to 30,000 deliveries. Amniotic fluid embolism carries an exceedingly high mortality, with a fatal outcome in 86% of cases. Nearly 10% of maternal deaths in the 1960s were attributed to this complication. As the frequency of other causes of mortality in pregnancy has diminished, the percentage of deaths due to amniotic fluid embolism has risen, and it is reported to be second only to pulmonary thromboembolism.

The average age at occurrence of amniotic fluid embolism is 32 years, and the risk factors include multiparity, very strong (tetanic) uterine contractions during labor, a large fetus, a dead fetus, and large quantities of particulate matter, including meconium. In one study of 40 cases of amniotic fluid embolism, the occurrence of abruptio placentae and placenta previa was noted in 45%. Rupture of the cervix (in 54% to 60% of cases), amniocentesis, and legal abortions also have caused amniotic fluid embolism.

Originally, the pathogenesis was attributed to an anaphylactoid reaction, but there has been no proof of this. The pathogenesis probably comprises a combination of three factors including pulmonary microvascular obstruction with subsequent systemic hypotension, pulmonary hypertension with acute cor pulmonale, and

ventilation-perfusion inequality. Detailed studies have shown that left ventricular failure is the only consistent abnormality.

Clinically the patient develops, during labor or immediately postpartum, chills, shivering, cough, cyanosis, convulsions, and profound shock. The survivors almost always develop disseminated intravascular coagulopathy, resulting in excessive uterine hemorrhage. The diagnosis is made on a clinical basis presumptively and definitively at postmortem. The diagnosis also can be made by identifying mucin and squamous cells in a blood smear taken from a central venous line such as a pulmonary artery catheter.

Pathologic examination of the lungs show overwhelming obstruction of the pulmonary arteries are by amniotic fluid contents—namely, mucin, fetal squamous cells, vernix fat globules, meconium, and lanugo hairs (Fig. 1). Mucin is almost always present, and the cellular elements are seen 80% of the time, with special stains and immunoperoxidase. Treatment is supportive, as the use of corticosteroids and anticoagulants has not changed the course of the disease.

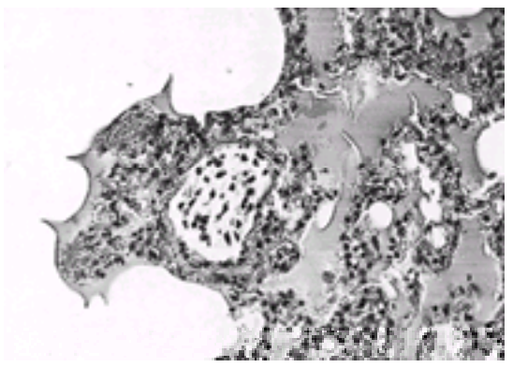

FIG. 1. Amniotic fluid embolism. Pulmonary arteriole occluded by fetal cells, vernix, and mucin.

Asthma

Asthma is encountered in pregnancy with an estimated frequency of 0.4% to 1.3% and is reported to complicate gestation in approximately 1% of pregnant women. Publications have reported both an improvement and worsening of asthma during pregnancy in approximately 5% to 46% of women. A study of 31 asthmatic women reported that mild to moderately severe asthmatics exhibit an improvement in asthma in the last trimester, but in more than one-third there may be a postpartum deterioration. In contrast, a prospective study of 198 pregnancies among 181 asthmatics reported that asthma caused no emergencies during labor and there was no difference between asthmatic and control subjects with regard to length of gestation, birth weight, incidence of perinatal deaths, low Apgar scores, neonatal respiratory difficulties, hyperbilirubinemia, or malformations. However, the study observed that severe asthma or systemic corticosteroid treatment (or both) during pregnancy increased the incidence of preeclampsia in the mother and hypoglycemia in the infant. Another significant finding was that among the asthmatic women, 28% of births were by cesarean section, compared with 17% in the control group.

Two cross sectional community studies indicated that asthmatic mothers were more likely to have a preterm delivery than nonasthmatic mothers and that asthmatic mothers did not have an increased risk of delivering small, growth retarded babies. Maternal asthma, paternal asthma, and premature birth, in that order, increased the risk of later childhood respiratory morbidity. Another study analyzed the hormonal factors and clinical and physiologic parameters during the preconception period (in 20 asthmatic women) and after conception and delivery (in 16 of 20 women), and noted that both airway responsiveness and asthma severity showed statistically and clinically significant improvements during pregnancy and returned toward preconception levels postpartum. A significant association between pregnancy-induced hypertension and asthma during pregnancy has been observed. It also appears that there is a significant upward trend in the incidence of asthma during pregnancy in women without, with moderate, and with severe pregnancy-induced hypertension. The reasons for this relationship is not obvious.

The improvement in asthma during pregnancy may be induced by progesterone- and other hormone-induced reduction in the contractility of airway smooth muscle, increased free serum cortisol, and the steroid's prolonged duration of action. The latter explanations are supported by the observation that other inflammatory conditions, such as rheumatoid arthritis also improve during pregnancy. The effect of mechanical factors responsible for dyspnea in nonasthmatic pregnant, discussed above, is also important in the deterioration of asthma during pregnancy.

Management of asthma during pregnancy is similar to that in the nonpregnant patient. In a prospective study of 181 asthmatic women with 198 pregnancies, 40% of the patients were managed during pregnancy with the same antiasthmatic medications as before pregnancy, 18% required less medication, and 42% needed more. Theophylline therapy at term did not influence labor or delivery. During the second and third trimesters until term, moderate doses of theophylline are safe. However, the safety of theophylline treatment during the first trimester with regard to teratogenicity remains to be determined. b-agonists are also safe, but an increased risk of fetal malformation has been mentioned with the use of epinephrine. Catecholamines inhibit uterine contractions. Corticosteroids may cause fetal adrenal insufficiency, but this risk is believed to be negligible. Hypoglycemia in the infant is a complication of maternal corticosteroid therapy, and therefore plasma glucose must be carefully monitored in the newborn. Status asthmaticus unresponsive to medical therapy during pregnancy may necessitate termination of the pregnancy. Respiratory distress can complicate pregnancy in women with severe obstructive pulmonary disease. Endotracheal intubation and mechanical ventilation in the postpartum period may be required. Bronchiectasis, if mild, does not seem to pose special problems for the pregnant patient. The National Institute of Health (NIH) has indicated that undertreatment of pregnant asthmatics, partially because of unfounded fears of adverse pharmacologic effects on the developing fetus, remains the major problem in the management of asthma during pregnancy in the United States.

Tuberculosis

The annual incidence of tuberculosis among pregnant women has varied depending on the period during which the data were collected. A report in 1972 recorded an incidence of tuberculosis among pregnant women in New Orleans of 4.8%. The rate of tuberculosis among American women of childbearing age (15 to 45 years) declined from 3.8 per 100,000 in 1977 to 2.35 per 100,000 in 1987, then increased to 2.5 per 100,000 in 1989 among Hispanic white women.

Pregnancy neither predisposes to the development or progression of tuberculosis nor alters the clinical presentation of the disease. A study of 1565 pregnancies during which tuberculosis was active showed no evidence of a negative consequence of pregnancy on tuberculosis during gestation, although most of the relapses developed in the postpartum period. A corollary to this is that tuberculosis neither affects nor complicates the course of pregnancy or the type of delivery. However, mother-to-fetus or -newborn transmission of tuberculosis is an important clinical consideration in the management of the pregnant tuberculous patient. The modes of spread of *tubercle bacilli* from mother to fetus or newborn include hematogenous or lymphogenous spread, transmission through placenta, and tuberculous endometritis during pregnancy. A detailed review of the topic concluded that despite the potential for transmission *in utero,* the newborn is at greater risk of acquiring tuberculosis postpartum than congenitally, particularly if born to a mother whose sputum contains *tubercle bacilli* and whose condition remains undiagnosed and untreated.

Radiation hazard from repeated chest roentgenography should be minimized in pregnant women. In those suspected of having tuberculosis, a chest roentgenogram should be obtained after the 12th week of gestation with proper shielding of the abdomen, and it should be performed only when a positive result of a tuberculin skin test requires exclusion of active pulmonary tuberculosis. However, it may be necessary sooner if the patient has symptoms that are highly suggestive of pulmonary tuberculosis. Tuberculin skin testing is not contraindicated in pregnancy as it does not affect pregnancy or the fetus. The tuberculin response in pregnancy is no different from that in nonpregnant woman. Induced sputum and gastric washings on a repeated basis are valuable.

Active pulmonary tuberculosis diagnosed during pregnancy should be treated promptly, the initial drug combination being isoniazid (300 mg/day) and rifampin (600 mg/day) for at least 9 months. Ethambutol may be used if the clinical situation warrants addition of the third or alternate drug. Because of their potential to cause fetal toxicity, pyrazinamide, streptomycin, and other aminoglycosides should be avoided. Active disease detected at the time of delivery should be treated. During the postpartum period, antituberculous drugs are continued until the prescribed treatment period is completed. Antituberculous therapy is not a contraindication to breast-feeding. Other precautions—namely, the isolation precautions, study of contacts, and preventive therapy for the infant and close contacts—is similar to the approach in nonpregnant tuberculous patients. Tuberculosis is not an indication for routine therapeutic interruption of pregnancy.

Sleep Apnea

Even though several cases of obstructive sleep apnea in pregnancy are reported, the prevalence of sleep apnea in pregnancy is unknown. The effects of pregnancy on the severity of pre-existent sleep apnea also are unknown. More important is the effect of obstructive sleep apnea-induced hypoxemia on fetal maturation. Chronic

hypoxemia induced in an animal model has caused fetal polycythemia, but the heart rate and respiratory movements were not greatly affected. Intrauterine growth retardation in maternal obstructive sleep apnea has been reported and may be present even if external cardiotocography shows normal fetal heart rate reactivity to fetal movements despite apneic episodes and periods of desaturation in the pregnant woman. Early recognition and treatment of obstructive sleep apnea in pregnancy might prevent problems with fetal development. Nasal continuous positive airway pressure (CPAP) treatment and other nonhormonal therapies pose no threat to the development of the fetus, but careful monitoring of fetal status and maternal cardiopulmonary condition is imperative.

Molar Pregnancy

Thoracic complications can occur after removal of a benign hydatidiform mole. The incidence of trophoblastic pulmonary emboli varies between 2% and 11%. Clinically, a wide spectrum of pulmonary findings occur, including the development of pulmonary hypertension and pulmonary edema. Among 128 women who underwent evacuation of hydatidiform mole, 9.4% developed acute, severe respiratory distress, and trophoblastic embolism was identified in 7 patients. The incidence of respiratory complications increased from 0 at less than 16 weeks' gestation to 27% when the uterus had developed beyond 16 weeks. In a review of 60 patients with benign trophoblastic disease, 5 developed pulmonary complications, with 2 progressing into acute respiratory distress syndrome from pulmonary edema. Possible etiologies for the respiratory manifestations include trophoblastic emboli, hypervolemia, and intravascular coagulation. Chest roentgenograms may reveal rounded lesions.

Choriocarcinoma

Choriocarcinoma is most often preceded by molar pregnancy. It is a fetal neoplasm that invades maternal tissue and it occurs in 1 in 20,000 pregnancies. Pulmonary metastases occur frequently in patients with gestational choriocarcinoma. The interval between pregnancy and pulmonary metastases varies from 1 to 60 months. Pulmonary metastases have been reported in 68% of patients with choriocarcinoma. The pulmonary lesions may be multiple, discrete, calcified, and associated with pleural effusion. Hemoptysis is seen in patients with chest roentgenographic abnormalities. In a series of 179 patients, 36 presented with pulmonary symptoms, and all but 1 had abnormal chest roentgenograms. Among 131 patients with gestational trophoblastic tumor, 57% had pulmonary metastases detected on plain chest roentgenography. Pulmonary involvement was commonly extensive, with 43% having more than 10 pulmonary metastases and 60% having a pulmonary lesion more than 5 cm in diameter. Eleven percent developed early respiratory failure requiring mechanical ventilation within one month of presentation. Other pulmonary features included greater than 50% lung opacification in 25 patients, mediastinal involvement in 25 patients, and pleural effusion 36 patients.

Most patients with pulmonary metastasis from choriocarcinoma achieve remission with chemotherapy alone. The major aspect of management of patients with high-risk, metastatic gestational trophoblastic tumors includes polychemotherapy. Therapeutic regimen employing etoposide, high-dose methotrexate, actinomycin D, cyclophosphamide and vincristine, is reported to result in complete response rates of 80% to 94% and survival rates of 82% to 100%. The factors that determine poor response to treatment are metastases to sites other than the lung and vagina, more than eight metastases, previous failed chemotherapy and a World Health Organization (WHO) score over 8. Tumor emboli and hemothorax also can occur. Gestational choriocarcinoma has presented as an endobronchial lesion. The indications for surgical resection of lung metastasis are limited, but in appropriately selected patients, resection of a lesion resistant to chemotherapy can be curative.

Miscellaneous Obstetric Disorders

Sarcoidosis

Sarcoidosis does not seem to have any adverse effects on the course of pregnancy. Pregnancy, on the other hand, is reported to lead to improvement of sarcoidosis in some patients. In patients whose chest roentgenograms demonstrate disease resolution before pregnancy, a normal chest roentgenogram is likely to persist through the prenatal period and gestation. Patients with active sarcoidosis usually experience partial or complete resolution of chest roentgenographic abnormalities during pregnancy, although many in this group will experience exacerbation of sarcoid within 3 to 6 months after delivery. Those with a fibrotic process secondary to sarcoidosis are likely to show no changes in their chest roentgenograms. One possible explanation for the frequent ameliorating effect of pregnancy on sarcoidosis is the increased serum levels of corticosteroids.

Rhinitis

Rhinitis occurs frequently during pregnancy, and although many causes, including altered vagal function, hormonal imbalance, and others, have been proposed, the rhinitis of pregnancy may not be a distinct entity.

Varicella

Varicella pneumonia seems to occur more commonly in pregnant women. A review of the literature in 1980 noted that approximately 10% of all reported cases of varicella pneumonia were in pregnant women, and the maternal mortality rate was approximately 45%. A study in 1996 of 28 pregnant women with varicella infection observed the incidence of pneumonia to be 3.6% and reported that pregnant women are not at increased risk of developing varicella pneumonia. Furthermore, all pregnant patients recovered uneventfully and no congenital anomalies or perinatal complications were noted in the infants of the 26 mothers who were followed up.

Coccidioidomycosis

Coccidioidomycosis shows a propensity to disseminate during pregnancy. One report on 50 pregnant women observed a 50% rate dissemination. The risk of dissemination was higher in those who contracted the infection during pregnancy, particularly in the second and third trimesters. Amphotericin B, the drug of choice in disseminated coccidioidomycosis, has no detrimental effects on pregnancy and poses minimal risk to the fetus.

Cystic Fibrosis

Cystic fibrosis poses special problems in pregnancy. As women with cystic fibrosis are living longer, pregnancy is becoming increasingly common in this group of women. Premature labor and delivery remain a significant risk for pregnant women with cystic fibrosis, contributing to a high rate of perinatal death. Maternal illness and death result from deteriorating pulmonary function. In a study of 11 pregnancies among 8 women with cystic fibrosis, the maternal condition deteriorated during and after pregnancy and did not return to the pregravid state. Prepregnancy FEV^1 appears to be the most useful predictor of important outcome measures in pregnancies in women with cystic fibrosis. A retrospective study of 22 pregnancies in 20 patients with cystic fibrosis noted that 18 pregnancies were completed producing healthy, noncystic fibrosis infants (12 female). Even though there was a 13% decrease in FEV^1 and 11% decrease in FVC during pregnancy, these values returned to normal after labor.

Systemic Lupus Erythematosus

Systemic lupus erythematosus may be exacerbated during pregnancy. Several cases of lupus pneumonitis developing during the postpartum period have been described.

Wegener's Granulomatosis

Wegener's granulomatosis is reported to relapse during pregnancy. A review noted that there were 15 pregnancies recorded in 10 women with Wegener's granulomatosis. Among these, the diagnosis of Wegener's granulomatosis was documented during pregnancy in 4 cases and during postpartum period in 3 cases. Eight pregnancies occurred in women with known Wegener's granulomatosis and the disease relapsed during 5 pregnancies. Two cases ended with maternal death.

Pulmonary Arteriovenous Malformations

Pulmonary arteriovenous malformations associated with hereditary hemorrhagic telangiectasia (Osler-Rendu-Weber syndrome) pose several additional pulmonary problems. Pregnant women with this syndrome face the risk of increased hypoxemia due to elevation of the intrapulmonary shunt fraction. In a report of a case, the pregnancy was terminated at 35 weeks' gestation because of life-threatening hypoxemia; the increased shunting was the result of the physiologic increase in blood volume during pregnancy. There are several reports of the arteriovenous fistulas enlarging during pregnancy and rupturing into the lungs or pleura and causing serious complications such as massive hemothorax and increasing hypoxia.

Diaphragmatic Rupture

Diaphragmatic rupture leading to respiratory failure is another rare but potentially lethal complication of pregnancy.

GYNECOLOGIC DISORDERS

Several gynecologic diseases produce pulmonary complications. Some of these represent a peculiar association of pulmonary and gynecologic disorders rather than complications. Table 2 lists the pulmonary complications of the gynecologic diseases.

Pulmonary complication	Gynecologic etiology
Pneumothorax, pneumomediastinum (catamenial)	Pleural endometriosis
	Air entry via genital tract into pleural space
Hemoptysis	Endobronchial endometriosis
Pulmonary nodules or atelectasis	Endobronchial endometriosis
	Benign metastasizing leiomyoma
	Pulmonary lymphangioleiomyomatosis
Pleural effusion	Ovarian neoplasm (Meigs-Salmon syndrome)
	Pulmonary lymphangioleiomyomatosis
	Uterine fibroids
	Pleural endometriosis
Premenstrual exacerbation of asthma	Hormonal imbalance (?)

TABLE 2. *Pulmonary complications in gynecologic diseases*

Thoracic Endometriosis

A literature review in 1996 of 110 cases of thoracic endometriosis observed the following clinical features: pneumothorax in 73%, hemothorax in 14%, hemoptysis in 7%, and lung nodules in 6%. The right hemithorax was involved in more than 90 percent of all manifestations except for nodules. Hemothorax was more often associated with presence of pleural and pelvic endometriosis compared with other manifestations.

Catamenial Pneumothorax

Catamenial pneumothorax is a syndrome of spontaneous recurrent pneumothorax occurring within 48 to 73 hours of the onset of menses. Pleural disease is associated more frequently with pelvic endometriosis. Until pneumothorax recurs, it is impossible to determine clinical coincidence from the specific syndrome of catamenial pneumothorax. Catamenial pneumothorax is the most common thoracic complication of endometriosis. A review in 1990 noted that there were approximately 100 cases in the literature. Among 196 cases of spontaneous pneumothoraces in women younger than 50 years, 5.6% were catamenial. Usually seen in women between the ages of 30 and 35 years, catamenial pneumothorax is almost always (90% to 95%) right-sided and small. The majority of patients present with chest pain or mild dyspnea, though the syndrome can be asymptomatic.

Pneumothorax is believed by some to be caused by pleural endometriosis (Fig. 2). However, clinical and pathologic evidence of pelvic endometriosis is demonstrated in only 22% to 37% of cases. Pleural or diaphragmatic endometrial implants have been visualized at thoracotomy in 23% to 35% of patients. Air originating in the genital tract is believed to make its way through defects in the diaphragm. Examination at the time of thoracotomy for treatment of catamenial pneumothorax has revealed defects in the diaphragm, and closure of these defects has resulted in the absence of recurrent pneumothorax. However, such diaphragmatic defects or fenestrations have been found in only 19% to 33% of the cases explored. The diaphragmatic defects have been observed with thoracoscopy using a bronchoscope.

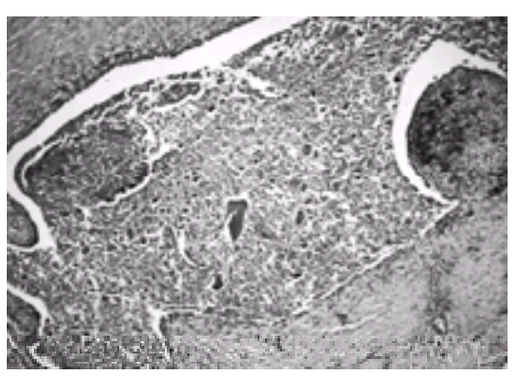

FIG. 2. Pleural endometriosis causing pneumothorax.

Pulmonary Endometriosis

Pulmonary endometriosis is rare. The endometrial tissue in the lung is presumed to originate from hematogenous spread or celomic metaplasia. Pleural endometriosis is believed to spread from pelvic or peritoneal deposits. Another possibility is the hematogenous metastasis of viable endometrial tissue after uterine surgery or cesarean section. This argument is supported by the finding that pulmonary endometriosis is almost always detected in the lower lung, which receives a higher blood supply. Pathologic analysis of pleuropulmonary tissue in patients with thoracic endometriosis generally shows changes typical of endometriosis.

Pulmonary parenchymal endometriosis appears later (mean age, 39 years) and is associated with pelvic endometriosis in only 10% of cases, catamenial hemoptysis in 82%, and catamenial pain and dyspnea in 18%. A literature review in 1996 of 110 cases of thoracic endometriosis observed the lung nodules in 6%. Endobronchial endometriosis has been reported to cause catamenial hemoptysis and airways obstruction with segmental atelectasis. Other symptoms include chest pain, dyspnea, or pleural effusion. Asymptomatic pulmonary density is another manifestation. Chest roentgenograms have revealed solitary pulmonary nodules in parenchymal endometriosis.

Ovulation-suppressing agents such as danazol sometimes are helpful in preventing recurrent pneumothorax. A case of catamenial pneumomediastinum that responded to danazol has been described. Spontaneous pneumothorax has also been described in a patient with carcinoma of the cervix.

Premenstrual Asthma

Premenstrual worsening of asthma (premenstrualasthma) has been reported in several publications. Severe asthmatics are reported to be more prone to premenstrual deterioration of asthma. In a study involving 126 consecutive women aged 14 to 46 years who attended an outpatient asthma clinic, a detailed questionnaire and twice-daily peak expiratory flow (PEF) measurements revealed premenstrual deterioration of asthma in 40%. The falls in peak flow were modest and of a degree that would not be expected to result in increased dyspnea. No correlations were found between premenstrual exacerbation of asthma and symptoms of premenstrual tension, consumption of aspirin, use of the contraceptive pill, cycle length, or behavior of asthma during pregnancy. Even mild asthmatics who were previously unaware of premenstrual asthma have been shown to observe a premenstrual deterioration of asthmatic symptoms and PEF rate without showing any significant changes in spirometry or airway reactivity.

The mechanism of premenstrual exacerbation of asthma is unclear. Progesterone level reaches a peak approximately 7 days before menstruation and rapidly falls almost to zero at the onset of the period. It is known that progesterone is a smooth-muscle relaxant in the gastrointestinal tract, genitourinary system, and vascular tree, and the fall in progesterone concentration in the late luteal phase might be associated with the withdrawal of a relaxant effect on bronchial smooth muscle. There are earlier reports on treatment of ovarian asthma by irradiation of the ovaries and progesterone preparations. Progesterone is a well-known respiratory stimulant and is

known to cause hyperventilation, which may heighten the sensation of breathlessness. However, the peak serum concentrations of progesterone are reached several days before symptomatic deterioration of asthma, and therefore, progesterone-induced hyperventilation is an unlikely explanation for premenstrual exacerbation of asthma. Analysis of clinical data from 182 nonpregnant, adult females with asthma aged 13 years to menopause showed a 4-fold variation in asthma presentations during the perimenstrual interval, indicating that the monthly variations in serum estradiol levels may influence the severity of asthma in adult females.

Estrogen Replacement Therapy

Estrogen replacement therapy may play a role in the pathophysiology of asthma. Long-term use and/or high doses of postmenopausal hormone therapy may increase subsequent risk of asthma. A prospective study of a cohort of pre- and postmenopausal women 34 to 68 years of age during 582,135 person-years of follow-up documented 726 new cases of asthma. Postmenopausal women who were never users of replacement hormones had a significantly lower age-adjusted risk of asthma than premenopausal women. Those who had 10 or more years' of replacement hormones had twice the age-adjusted risk of asthma compared with women who never used postmenopausal hormones.

Ozone (O_3) exposure during the follicular phase of the menstrual cycle is reported to elicit enhanced airway response and lead to airway inflammation. One study noted while the socioeconomic status appeared to affect FEV_1 responsiveness to ozone, with the middle socioeconomic group being the most responsive to ozone, the phase of menstrual cycle did not have an impact on individual responsiveness to ozone.

Effect of Menses on Respiration

Menses also affect normal respiration in nonasthmatic women. The respiratory-stimulating effect of progesterone was mentioned above. The level of progesterone varies during the menstrual cycle in adult women. In a study of 30 healthy female adults, respiratory muscle function, measured by maximal static inspiratory and expiratory pressures, was assessed during the midfollicular and midluteal phases of the menstrual cycle; the results showed that inspiratory muscle endurance was 26% higher in the midluteal phase than in the midfollicular phase, whereas the respiratory muscle strength and pulmonary function were unchanged. Other studies have shown that resting ventilation, ventilatory response to hypoxia or hypercapnia, and resistance to genioglossal activity are elevated during the luteal phase. These findings imply that the high inspiratory muscle endurance in the midluteal phase may be related, at least in part, to high plasma progesterone levels. A study of variations in carbon monoxide diffusing capacity (D_LCO) during the menstrual cycle in 14 healthy women (8 were using oral contraceptives) with a mean age of 29 years observed the D_LCO to vary significantly during the menstrual cycle, with the highest values occurring prior to menses and the lowest values occurring on the third day of menses, with a mean difference between them of 9%.

Metastasizing Benign Leiomyoma

Metastasizing benign leiomyoma is an oddity in pulmonary diseases and an oxymoron. Uterine fibroleiomyomas (also called well-differentiated leiomyosarcoma) are known to be associated with multiple pulmonary fibroleiomyomas. Although slow-growing, these are believed to be pulmonary metastases—hence the term metastasizing benign leiomyoma. A review of 23 reported cases revealed the following: The age span among patients studied was 30 to 74 years (mean, 47 years), three-fourths had uterine leiomyomas, and all but 2 were white. Most cases were discovered during routine chest roentgenographic examination. The lesions were nodular, bilateral in 15, recurrent in 3, and increased in size in 7 patients. Roentgenographically, these nodular densities may range from 0.5 to 4.5 cm in diameter (Fig. 3 and Fig. 4) and, occasionally, pleural effusion is also seen. Nodules may grow in premenopausal women and remain stationary in postmenopausal women.

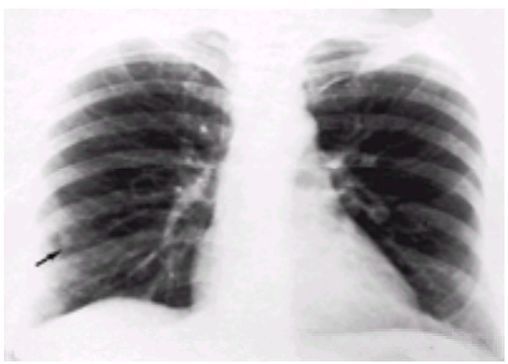

FIG. 3. Benign metastasizing leiomyoma in the lungs. Arrows point to small nodules in the lungs.

FIG. 4. Benign metastasizing leiomyoma in right upper lobe (RUL); cavitation as a result of secondary infection is demonstrated.

REPRODUCTIVE ORGANS

Diseases of the reproductive organs are occasionally associated with pulmonary problems. The main entities included in this discussion are Meigs-Salmon syndrome, Klinefelter's syndrome, Turner's syndrome, and Young's syndrome. Lymphangioleiomyomatosis is also included here although it is not a primary gonadal disease, it responds to ovarian hormones. Pleuropulmonary metastases are common in patients with malignancies of the reproductive organs.

Meigs-Salmon Syndrome

Meigs-Salmon syndrome, also known as Meigs-Salmon-Cass syndrome, is characterized by the coexistence of ovarian fibroma or other solid ovarian tumors, ascites, and pleural effusion. Pleural effusion occurs in 3% of patients with ovarian neoplasms that measure more than 6 cm in diameter. A variant of this syndrome is described in which the clinical features were highly suggestive of Meigs-Salmon syndrome but the ovary showed degenerative changes without tumor. The pleural effusions in this syndrome are more common on the right, are transudative chemically, and may become voluminous. The transportation of fluid from the peritoneum to the pleural space is via the diaphragmatic lymphatics. Massive edema of the ovary without neoplastic changes has been reported to cause hydrothorax and ascites. Very large ovarian tumors are capable of producing respiratory failure by upward push on the diaphragm. The effusions and ascites usually disappear with removal of the ovarian tumor.

Uterine Fibroids

Uterine fibroids have been responsible for the occurrence of pleural effusion in several cases. These patients were between the ages of 30 and 45 years and presented with abdominal distension and mass. There were no menstrual abnormalities. The pleural effusions were right-sided in 75% and hemorrhagic in 1 patient. Both transudates and exudates have been described. The pathogenesis of the pleural effusion in these patients and in Meigs-Salmon syndrome is unknown, although there

exists the possibility of active exudation of fluid by the tumors or inflamed peritoneum and lymphatic or venous obstruction.

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis is a rare disorder that affects women of childbearing age and is characterized by progressive dyspnea, spontaneous pneumothorax, chylothorax, and hemoptysis caused by diffuse cystic changes in the pulmonary parenchyma and marked proliferation of peribronchial smooth muscle in a lymphatic distribution. Lymphangioleiomyomatosis is an uncommon pulmonary condition of unknown origin and pathogenesis. Although the oral contraceptive pill has been implicated in the pathogenesis of pulmonary lymphangioleiomyomatosis, a case control study of 23 patients with the disease did not support this hypothesis. However, many consider this a primarily an ovarian disorder with predominantly respiratory manifestations. The rationale for this assumption is that first, the disease generally presents in women during their childbearing years. Second, there is exacerbation of the disease during menses and pregnancy. Third, estrogen and progesterone receptors are present in lung tissue. And, fourth, clinical improvement has been documented following treatment with progesterone or oophorectomy. There have been reports of only 6 women older than 55 years developing symptomatic pulmonary lymphangioleiomyomatosis. Patients who develop pulmonary lymphangioleiomyomatosis are less likely to have been pregnant or to have had children.

Lymphangioleiomyomatosis is sometimes discussed with tuberous sclerosis because of the similarities noted in the pulmonary pathologic specimens. Further, lymphangioleiomyomatosis and tuberous sclerosis have been reported to co-exist in some patients. Nevertheless, the usual presence of clinical features such as mental retardation, development of angiomyolipomas, adenoma sebaceum, subungual fibromas, and other various skin lesions in patients with tuberous sclerosis distinguish these two entities. The absence of angiomyolipomas is not always the case in lymphangioleiomyomatosis. Indeed, in a report on 17 patients with pulmonary lymphangioleiomyomatosis, 47% were found to have renal angiomyolipomas.

The majority of the clinical features are the result of abnormal proliferation of smooth muscles in the lung parenchyma. The hypertrophied bundles of smooth muscle encircle and obstruct airways, pulmonary arterioles and venules, and the lymphatic channels. These changes result in obstructive airway disease, hemoptysis, and accumulation of chylous pleural effusion. Clinical features include progressive dyspnea resembling that of ordinary chronic obstructive lung disease, recurrent pneumothorax (in more than 60%), unilateral or bilateral chylous pleural effusions (in 25%), and hemoptysis (in 50%) in nubile women. The around the distal airways causes venular congestion and disruption, resulting in hemoptysis and alveolar hemosiderosis. Abdominal and thoracic lymphatics as well as lymph nodes may become involved. Chylous ascites and a doughy abdomen are sometimes the presenting features.

Histologically, two types of pulmonary lesions have been observed; a predominantly cystic type and a predominantly muscular type. Patients with predominantly cystic pattern of disease are reported to have a poorer prognosis compared with those who have muscular type of disease.

Chest roentgenograms show diffuse reticulonodular infiltrates in 50% to 80% of patients (Fig. 5). Normal chest roentgenography that is noted in some patients may lead to the wrong diagnosis of asthma or obstructive lung disease. Lung hyperinflation is observed in up to 25%. Cystic spaces measuring 0.5 to 1.5 cm in diameter and bullous changes are seen in 12% to 40% of patients. Pneumothorax (50% to 80%) and pleural effusion (30% to 40%) may be present. The smooth-muscle proliferation around the distal airways leads to alveolar destruction and development of cystic changes and pneumothorax. Likewise, the smooth-muscle proliferation around the pulmonary lymphatics produces lymphatic obstruction and development of chylothorax. Despite the presence of the above-noted typical clinical and roentgenologic features, the diagnosis was delayed by an average of 44 months (range, 1 to 219 months) in a series of 32 patients with lymphangioleiomyomatosis. Bronchoscopic lung biopsy may be adequate, or an open-lung biopsy may be required for the diagnosis. However, typical clinical features combined with characteristic findings depicted by high-resolution computed tomography may establish the diagnosis (Fig. 6). Histopathologic features of lung parenchyma include accumulation of smooth-muscle bundles in the alveolar walls, especially around bronchioles and venules (Fig. 7). Ultrastructural and immunofluorescent examination of these smooth-muscle bundles has shown higher glycogen content of muscle cells and smooth-muscle antigens. There are no serologic (antibody) tests to identify these antigens.

FIG. 5. Lymphangioleiomyomatosis of lungs. Diffuse nodular infiltrates, relative sparing of lower lung zones, and hyperinflation of lungs can be seen.

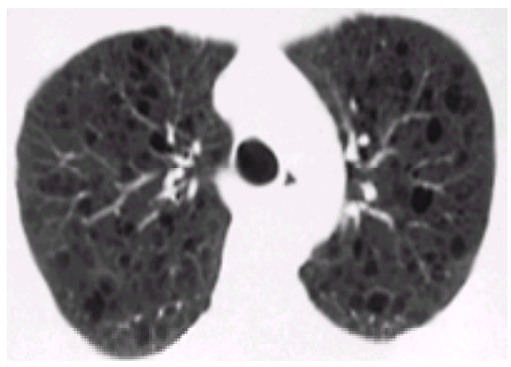

FIG. 6. Lymphangioleiomyomatosis of lungs imaged with high-resolution computed tomography showing typical cystic spaces.

FIG. 7. Lymphangioleiomyomatosis in the lung tissue showing hypertrophy of bronchial smooth-muscle bundles.

Compression of the airways by the hypertrophied smooth muscles is responsible for the severe obstructive pulmonary dysfunction. Studies of pulmonary mechanics in 8 women with lymphangioleiomyomatosis showed increased total lung capacity (114% of predicted) and residual volume (207% of predicted), reduced ratios of 1-second forced expiratory volume to forced vital capacity (62% of predicted), moderately reduced retractive force at total lung capacity (67% of predicted), increased static compliance (128% of predicted), and markedly elevated pulmonary flow resistance (266% of predicted). Maximal flow-static recoil curves demonstrated changes

secondary to predominantly airway narrowing rather than loss of lung elastic forces. Lymphangioleiomyomatosis is one of the rare diseases in which even though the chest roentgenogram suggests a restrictive type of process (nodular or interstitial), the pulmonary function tests reveal characteristics of obstructive pulmonary disease.

Treatment should be initiated as soon as the diagnosis is established because of the progressive nature of the disease. Patients should be advised against pregnancy and the use of estrogen preparations. Treatment options for lymphangioleiomyomatosis continue to evolve. A meta-analysis of 30 cases reported in the literature noted that although eight treatment regimens were used, progesterone or oophorectomy or both were the most effective treatments, resulting in improvement or stabilization of the disease in the majority of cases. Another report on 8 women with lymphangioleiomyomatosis treated by various antiestrogen therapies concluded that without a control group, it was difficult to ascertain whether the treatments were responsible for the apparent improvement of the disease. Medroxyprogesterone is given in doses equivalent to at least 10 mg/day on either a daily or monthly basis. Rapidly progressive cases should be considered for both progesterone therapy and oophorectomy. Tamoxifen therapy and tetracycline pleurodesis have been used success fully to control recurrent chylothorax. However, tamoxifen therapy is reported not only to lack evidence of proved effectiveness but also to be closely associated with the recurrence of pneumothoraces and exacerbation of the disease. Persistent chylothorax may require surgical pleurodesis or placement of a pleuroperitoneal shunt. Single or double lung transplantation has become a therapeutic option for refractory cases. Progressive respiratory distress and death within 10 years has been noted in refractory cases.

Klinefelter's Syndrome

Klinefelter's syndrome is the most common example of male hypogonadism in phenotypic men, characterized by the presence of two or more X chromosomes, the most common karyotype being XXY. It is morphologically manifested by varying degrees of seminiferous tubular failure and decreased Leydig cell function. Clinical features include small and firm testes, infertility, decreased testosterone level, gynecomastia and, frequently, eunuchoid features and mild mental retardation. Respiratory disease is known to be more prevalent in these patients than in the population at large. Pulmonary manifestations described have included asthmatic bronchitis, recurrent pulmonary infections, bronchiectasis, pectus excavatum, kyphoscoliosis, pulmonary cysts, respiratory infections, and emphysema. Restrictive lung dysfunction is attributed to chest wall abnormalities, even though pulmonary restriction has been demonstrated in the absence of parenchymal or musculoskeletal abnormalities. A detailed physiologic study of 13 patients with Klinefelter's syndrome reported that none exhibited chest wall restriction, but 4 patients demonstrated significantly reduced lung compliance. The authors concluded that the likely cause of pulmonary restriction, noted in 8 patients (62%), was a decrease in the compliance of the lung matrix, probably related to the absence of testosterone.

Turner's Syndrome

Turner's syndrome is a disorder of sex differentiation. Its clinical features include an XO sex chromosome constitution, dwarfism, sexual infantilism, webbing of the neck, and cubitus valgus. Thoracic manifestations consist of square and shield-like chest, pleural effusions, coarctation of the aorta, and rib notching.

Young's Syndrome

Young's syndrome, or obstructive azoospermia, denotes primary infertility in men who have normal spermatozoa in the epididymides but none in the ejaculate. This entity differs from the well-known links between infertility and lung diseases noted in ciliary dysmotility syndromes and cystic fibrosis. Unlike the immotile cilia syndrome, Young's syndrome has no demonstrable ultrastructural ciliary disorders and, unlike cystic fibrosis, normal sweat and pancreatic functions are present. Indeed, electron microscopy of nasal cilia in 12 patients with Young's syndrome has confirmed normal ciliary ultrastructure. Young's syndrome is estimated to have a prevalence rate comparable to that of Klinefelter's syndrome and higher than that of either cystic fibrosis or the immotile cilia syndrome.

The underlying abnormality in Young's syndrome is unknown, although it is presumed to be a mucous defect. Mucociliary clearance, as determined by nasal ciliary beat frequency, is shown to be abnormal in Young's syndrome. It is not clear whether this is the cause or effect of sinusitis. The relative disorientation of distal ciliary axoneme in patients with Young's syndrome may be due to a structural defect but is more likely a consequence of abnormal mucus. However, use of mucoregulatory agents in these patients has not been helpful.

Mercury intoxication has been proposed as an etiologic factor in the development of Young s syndrome. Calomel (mercurous chloride) was removed from teething powders and worm medication in the United Kingdom in 1955. An interesting study of 274 men with obstructive azoospermia undergoing epididymovasostomy observed that the incidence of Young's syndrome fell significantly from 114 of 227 men born up to 1955 to eight of 47 men born since then. This decline in incidence of Young's syndrome in those born after 1955 was similar to that observed with pink disease (mercury intoxication).

More than half the patients in the original series had severe chest disease in childhood. In a study of 34 infertile men with obstructive azoospermia and normal controls, the following abnormalities were noted in those with Young's syndrome: grossly abnormal sinus roentgenograms (59%), sinusitis (56%), repeated otitis media (32%), chronic bronchitis (35%), abnormal chest roentgenograms (53%), and bronchiectasis (29%) (Fig. 8). Airflow obstruction was observed in 15 patients. Although this controlled study confirmed that a significant excess of sinopulmonary disease exists in this group, the reason for the relationship between obstructive azoospermia and lung disease remains undefined.

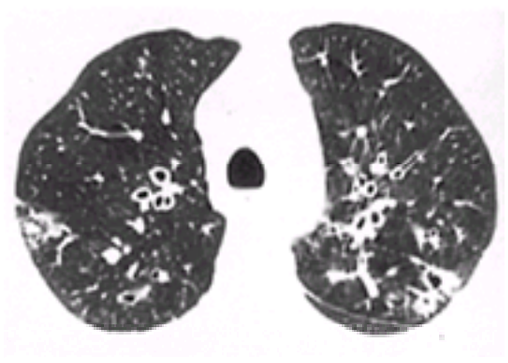

FIG. 8. Young's syndrome with bronchiectasis documented by high-resolution computed tomography showing bilateral bronchiectasis.

Sexual Activity and the Lung

The coital act is physically strenuous even in healthy humans. The presence of chronic respiratory disease affects this function in many patients in the form of functional impotence or lack of libido. Although a considerable number of patients with respiratory diseases are concerned about their inability to have normal sexual intercourse, very few mention this aspect of their health to their physicians. Part of the reason is the patients' embarrassment in bringing up this medically irrelevant topic, and part is due to physicians' failure to inquire about it. Several medications, particularly b-blocking agents, cause impotence. However, none of the drugs used in chronic obstructive pulmonary disease or other common lung diseases is known to affect sexual function. Medroxyprogesterone used in some patients with central sleep apnea may result in impotence after long-term therapy. In hypoxemic patients, supplemental oxygen therapy during sexual intercourse may be helpful.

Coital Hemoptysis

Coital hemoptysis has been described in a patient with coronary artery disease. Despite recurrent episodes of hemoptysis that necessitated several visits to his physician, the patient did not provide the history of sexual activity in relation to hemoptysis. Increased cardiovascular demands and left ventricular dysfunction brought on by sexual activity were concluded to be physiologic reasons for the hemoptysis. Postcoital catamenial pneumothorax not associated with endometriosis has also been reported.

Postcoital Asthma

Postcoital asthma and rhinitis (honeymoon rhinitis) brought on by sexual activity have been described in several patients. A study of 3 men and 1 woman with post-coital asthma or rhinitis observed clinically significant attacks of asthma or rhinorrhea during and immediately after sexual intercourse; indeed, 1 man required several visits to the emergency department and hospitalization on one occasion. All had a previous history of asthma, and anxiety was noted to be a predominant feature in the patients and their sexual partners. Sexual excitement, rather than exercise, may have caused asthma in one of the patients who developed asthmatic

symptoms before sexual intercourse. Allergy to human seminal plasma in female subjects has also been reported to cause postcoital asthma.

Reflux Dyspareunia

Reflux dyspareunia denotes heartburn occurring during sexual intercourse. In a prospective study of 100 women with known gastroesophageal reflux, 77% suffered from reflux symptoms (severe in 6, moderate in 22, and mild in 49) during sexual intercourse. The supine position and increased intraabdominal pressure may account for the reflux symptoms during sexual intercourse. Although the number of women with hiatal hernia was not mentioned, the presence of gastroesophageal reflux during coitus is as important as other factors in causing reflux dyspareunia. No mention has been made in the literature on reflux dyspareunia-related aspiration.

Risk factors for early respiratory failure. *J Reprod Med.* 1994;39:175–8. *Among 131 patients with gestational trophoblastic tumor, 75 (57.3%) patients had pulmonary metastases detected on plain chest roentgenography. Pulmonary involvement was commonly extensive, with 32 (42.7%) patients having 10 pulmonary metastases and 45 (60%) patients having a pulmonary lesion 5 cm in diameter. Eight (10.7%) patients developed early respiratory failure requiring mechanical ventilation within one month of presentation.*

Baren JM, Henneman PL, Lewis RJ. Primary varicella in adults: pneumonia, pregnancy, and hospital admission. *Ann Emerg Med.* 1996;28:165–9. *Retrospective study of primary varicella infection in 130 adult patients (69 women) among whom 28 were pregnant. The incidence of pneumonia in pregnant patients was 3.6%. All 7 hospitalized pregnant patients and the 19 (of 21) discharged pregnant patients recovered uneventfully. No congenital anomalies or perinatal complications were noted in the infants of the 26 mothers with documented follow-up. Authors concluded that pregnant women are not at increased risk of developing varicella pneumonia.*

Bernstein SM, Newell JD Jr, Adamczyk D, Mortenson RL, King TE Jr, Lynch DA. How common are renal angiomyolipomas in patients with pulmonary lymphangiomyomatosis? *Am J Respir Crit Care Med* 1995;152:2138–43. *Among 17 patients with pulmonary lymphangiomyomatosis, eight (47%) patients had renal angiomyolipomas. The authors indicate that early detection of renal angiomyolipoma by abdominal CT may be important, because lesions with dimensions larger than 4 cm may present an increased risk for complications related to tumor growth or hemorrhage.*

Bouros D, Papadakis K, Siafakas N, Fuller AF Jr. Natural history of patients with pulmonary metastases from uterine cancer. *Cancer* 1996;78:441–447. *Among 1665 patients with uterine cancer, 100 patients (6%) who had pulmonary metastases showed the following clinical features: median age of 65.5 years, 59 adenocarcinomas, 21 sarcomas, and 14 adenosquamous carcinomas. Lung metastases were found at the time of diagnosis of the primary tumor in 22 patients. Of all patients with lung metastases, 75% did not survive 1 year; however 6% survived more than 5 years after diagnosis of metastatic disease.*

Carter EJ, Mates S. Tuberculosis during pregnancy. The Rhode Island experience, 1987 to 1991. *Chest.* 1994;106:1466–1470. *During a 4-year period, seven of 22 women aged 21 to 32 years with culture-proven tuberculosis were pregnant at time of diagnosis; pregnant patients with pulmonary conditions were more likely to be found through routine screening, to be asymptomatic, and more likely to present with unilateral non-cavitary, smear-negative disease.*

Chen HI, Tang YR. Effects of the menstrual cycle on respiratory muscle function. *Am Rev Respir Disease* 1989;140:1359–1362. *Respiratory muscle and pulmonary functions were measured and compared in the midfollicular phase and in the midluteal phase of the menstrual cycle in 30 healthy adult women. The results showed that the inspiratory muscle endurance was greater in the midluteal phase than in the follicular phase (815-43 versus 649-62 cmH_2O/min, respectively), whereas the respiratory muscle strength and pulmonary function were unchanged. Authors concluded that inspiratory muscle endurance is affected by the menstrual cycle, i.e., higher in the midluteal phase and lower in the midfollicular phase.*

Clark SL. Asthma in pregnancy. National Asthma Education Program Working Group on Asthma and Pregnancy. National Institutes of Health, National Heart, Lung and Blood Institute. *Obstet Gynecol* 1993;82:1036–1040. *This manuscript is a summary of a comprehensive report dealing with asthma and pregnancy issued by the working group on Asthma and Pregnancy, National Institutes of Health (NIH), National Heart, Lung, and Blood Institute. The report was developed by a panel of obstetricians, pharmacologists, internists, allergists, and pulmonologists, who met over an 18-month period under the auspices of the NIH.*

Corrin B, Liebow AA, Friedman PJ. Pulmonary lymphangiomyomatosis. A review. *Am J Pathol* 1975;79:348–382. *Among 57 patients with pulmonary lymphangiomyomatosis, all patients were women in the reproductive age group with the major complaint of breathlessness. Death from pulmonary insufficiency resulted within 10 years. Pneumothorax, chylous effusions and hemoptysis were frequent complications A very detailed discussion of all aspects is included.*

Crausman RS, Jennings CA, Mortenson RL, Ackerson LM, Irvin CG, King TE Jr. Lymphangioleiomyomatosis: the pathophysiology of diminished exercise capacity. *Am J Respir Crit Care Med* 1996;153:1368–1376. *Spirometry, lung volumes, lung mechanics, and exercise physiology in 16 patients with lymphangioleiomyomatosis showed normal TLC and Vtg, but RV was elevated in 88% of the subjects. A moderate to severe obstructive pattern was present in 69% of patients, and the DLCO was reduced, often markedly, in 81% of the patients. Strong correlations between overall exercise performance and indices of airflow and vascular involvement were present.*

Cunningham J, Dockery DW, Gold DR, Speizer FE. Racial differences in the association between maternal smoking during pregnancy and lung function in children. *Am J Respir Crit Care Med* 1995;152:565–569. *A study of the relationship between maternal smoking during pregnancy and lung function in 493 white and 383 black schoolchildren 9 to 11 yr of age in three areas of Philadelphia observed that maternal smoking during pregnancy was associated with significant deficits in FEF_{25-75} and FEV_1/FVC and the observed deficits were larger for black children than for white children, and they were larger for boys than for girls.*

Dawkins KD, Burke CM, Billingham ME, Jamieson SW. Primary pulmonary hypertension and pregnancy. *Chest* 1986;89:383–388. *During a 12-month period, 73 female patients with primary pulmonary hypertension were evaluated as potential recipients of a heart-lung transplant; and in six (8%), primary pulmonary hypertension appeared to be related to pregnancy. Histologic confirmation of the diagnosis was available in four patients, and other causes of pulmonary hypertension were excluded as far as possible in the remaining two patients.*

Desai DK, Moodley J, Naidoo DP, Bhorat I. Cardiac abnormalities in pulmonary oedema associated with hypertensive crises in pregnancy. *Br J Obstetr Gynaecol* 1996;103:523–528. *A prospective observational study of 16 patients with hypertensive crises in pregnancy complicated by pulmonary edema recorded echocardiographic evidence of impaired left ventricular systolic function in 4 of 16 (25%) patients and left ventricular diastolic filling abnormalities in the remaining 12 patients who had preserved systolic function. In 7 patients, the use of dexamethasone to enhance fetal lung maturity appeared to contribute to the development of pulmonary edema.*

de Veciana M, Towers CV, Major CA, Lien JM, Toohey JS. Pulmonary injury associated with appendicitis in pregnancy: who is at risk? *Am J. Obstet Gynecol* 1994;171:1008–1013. *This case-control study of 49 patients with appendicitis during pregnancy noted 7 cases of pulmonary edema or infiltrates in 7 and adult respiratory distress syndrome in 2 patients. By multivariate analysis, the following factors were estimated to predict 99% of the pulmonary complications: a fluid overload 4 L, respiratory rate 24 breaths/min, maximum temperature 100.4°F, and tocolytic usage.*

Edenborough FP, Stableforth DE, Webb AK, Mackenzie WE, Smith DL. Outcome of pregnancy in women with cystic fibrosis. *Thorax 1995;50:170–174. A retrospective study of 22 pregnancies in 20 patients with cystic fibrosis noted that 18 pregnancies were completed producing healthy, non-cystic fibrosis infants (12 female). Mothers lost 13% of FEV1 and 11% of FVC during pregnancy, most of which was regained. Microbiological status remained unchanged. Four mothers died up to 3.2 years following delivery. FEV1 (%) showed the best correlation with maternal weight gain, gestation, birth weight, and maternal survival.*

Eliasson AH, Phillips YY, Tenholder MF. Treatment of lymphangioleiomyomatosis. A meta-analysis. *Chest* 1989;96:1352–1355. *A comprehensive review of the literature revealed 30 cases of lymphangioleiomyomatosis treated with eight regimens of treatment. Evaluation with predetermined criteria (meta-analysis) showed that administration of progesterone or oophorectomy or both are the most effective treatments, resulting in improvement or stabilization of the disease in the majority of cases.*

Friedman KJ, Teichtahl H, De Kretser DM, Temple-Smith P, Southwick GJ, Silverman LM, Highsmith WE Jr, Boucher RC, Knowles MR. Screening Young syndrome patients for CFTR mutations. *Am J Respir Crit Care Med* 1995;152:1353–1357. *An evaluation of 13 patients with Young syndrome, including screening for more than 30 different mutations within the CFTR gene, revealed normal sweat chloride concentration in all patients. The incidence of CFTR mutations (1 in 26) did not differ significantly from the expected carrier frequency in this population. The authors concluded that it is unlikely that the typical Young syndrome patient has a clinical disease associated with CFTR mutation on both alleles.*

Grodstein F, Stampfer MJ, Goldhaber SZ, Manson JE, Colditz GA, Speizer FE, Willett WC, Hennekens CH. Prospective study of exogenous hormones and risk of pulmonary embolism in women. *Lancet* 1996;348:983–987. *In this prospective study through questionnaires sent every 2 years (1976-92) to 11,259 women, 123 cases of primary pulmonary emboli (no identified antecedent cancer, trauma, surgery, or immobilization) were recorded. In current users of oral contraceptives, the risk of primary PE was about twice that in non-users. However, past use showed no relation to PE.*

Handelsman DJ, Conway AJ, Boylan LM, Turtle JR. Young's syndrome. Obstructive azoospermia and chronic sinopulmonary infections. *N Engl J Med* 1984;310:3–9. *A study of 29 men with Young's syndrome, a combination of obstructive azoospermia and chronic sinopulmonary infections. Men with this syndrome have only mildly impaired respiratory function and normal spermatogenesis; the azoospermia is due to obstruction of the epididymis by inspissated secretions.*

Hankins GD, Harvey CJ, Clark SL, Uckan EM, Van Hook JW. The effects of maternal position and cardiac output on intrapulmonary shunt in normal third-trimester pregnancy. *Obstet Gynecol* 1996;88:327–330. *Ten normotensive nulliparas between 36 and 38 weeks' gestation underwent pulmonary hemodynamic measurements sequentially in the left lateral, right lateral, supine, knee-chest, sitting, and standing positions. Directly measured Qs/Qt averaged 15.3% in left lateral, 15.2% in right lateral, 13.9% in supine, 12.8% in knee-chest, 13.8% in sitting, and 13.0% in standing positions. Authors concluded that this is the first report of directly measured Qs/Qt in normal pregnant women in the third trimester and that Qs/Qt values reported in pregnancy are higher than those reported in nonpregnant individuals.*

Heffner JE, Sahn SA. Pleural disease in pregnancy. *Clin Chest Med* 1992;13:667–78. *A detailed review of pleural effusion, pneumothorax, and other pleural disorders in pregnancy. The incidence, clinical manifestations, and, where appropriate, therapeutic options of these disorders are discussed.*

Hendry WF, A'Hern RP, Cole PJ. Was Young's syndrome caused by exposure to mercury in childhood? *BMJ* 1993;307:1579–1580. *An interesting study of 274 men with obstructive azoospermia undergoing epididymovasostomy observed that the incidence of Young's syndrome fell significantly from 114 (50%) of 227 men born up to 1955 to eight (17%) of 47 men born since then. This decline in incidence of Young's syndrome in those born after 1955 was similar to that observed with pink disease (mercury intoxication).*

Hirsch DR, Mikkola KM, Marks PW, Fox EA, Dorfman DM, Ewenstein BM, Goldhaber SZ. Pulmonary embolism and deep venous thrombosis during pregnancy or oral contraceptive use: prevalence of factor V Leiden. *Am Heart J* 1996;131:1145–1148. *A study of 50 women who had deep venous thrombosis (DVT) and/or pulmonary embolism (PE) identified 10 women with activated protein C resistance caused by factor V Leiden mutation. First-trimester DVT and/or PE developed in 6 of the 10 women with the mutation compared with 3 of 40 women without the mutation. Authors conclude that the factor V Leiden mutation is an important risk factor for DVT and/or PE during pregnancy (especially the first trimester), after pregnancy, or during oral contraceptive use.*

Hornby PJ, Abrahams TP. Pulmonary pharmacology. *Clin Obstet Gynecol* 1996;39:17–35. *This article reviews the basic principles of pharmacodynamics and pharmacokinetics, with a special emphasis on the pharmacologic considerations that must be taken into account when treating the patient with respiratory disease who is also pregnant or nursing the neonate. A description of the four classes of therapeutic agents used for COPD is given with a discussion of the scientific evidence for their safety during pregnancy.*

Hughson WG, Friedman PJ, Feigin DS, Resnik R, Moser KM. Postpartum pleural effusion: a common radiologic finding. *Ann Intern Med* 1982;97:856–858. *A retrospective study of 112 patients and a prospective study of 30 patients and 30 controls to ascertain the incidence of postpartum pleural effusion noted pleural effusion on chest radiographs in 51 patients (46%) in the retrospective study, and 20 patients (67%) in the prospective study. There was no difference between patients with effusion and those without in age, race, parity, antepartum complications, method of delivery, fetal outcome, or postpartum complications.*

Jones WB, Romain K, Erlandson RA, Burt ME, Lewis JL Jr. Thoracotomy in the management of gestational choriocarcinoma. A clinicopathologic study. *Cancer* 1993;72:2175–2181. *Among 9 patients with choriocarcinoma metastatic to the lung who underwent 11 thoracotomies, 6 patients achieved complete remission for periods ranging from 3 months to 18 years, and three patients died of their disease.*

Joseph J, Sahn SA. Thoracic endometriosis syndrome: new observations from an analysis of 110 cases. *Am J Med* 1996;100:164–170. *An analysis of data on 110 patients with thoracic endometriosis syndrome described in the literature showed that the peak incidence for pelvic endometriosis was between 24 and 29 years and the peak incidence for thoracic endometriosis was between 30 and 34 years. Thoracic complications included pneumothorax in 73%, hemothorax in 14%, hemoptysis in 7%, and lung nodules in 6% of patients.*

Kelly YJ, Brabin BJ, Milligan P, Heaf DP, Reid J, Pearson MG. Maternal asthma, premature birth, and the risk of respiratory morbidity in schoolchildren in Merseyside. *Thorax* 1995;50:525–530. *Two cross sectional community studies of 1872 children (5-11 years) in 1991 and 3746 children in 1993 indicated that asthmatic mothers were more likely to have a preterm delivery than non-asthmatic mothers and that smoking was a separate risk factor for preterm delivery. Asthmatic mothers did not have an increased risk of delivering small, growth retarded babies. Maternal asthma, paternal asthma, and premature birth, in that order, increased the risk of later childhood respiratory morbidity.*

Kent NE, Farquharson DF. Cystic fibrosis in pregnancy. *Can Med Assoc J* 1993;149:809–813. *A total of 20 reports citing cases of pregnancy in women with cystic fibrosis were reviewed. Of 217 pregnancies in 162 women, spontaneous abortion occurred in 10 (4.6%), Pregnancy progressed beyond 20 weeks in 81.6% of cases; 24.3% of the deliveries were preterm. The maternal death rate did not exceed that among age-related women with CF who were not pregnant. Poor outcomes were associated with a weight gain of less than 4.5 kg and a forced vital capacity of less than 50% of the predicted value.*

Kitaichi M, Nishimura K, Itoh H, Izumi T. Pulmonary lymphangioleiomyomatosis: a report of 46 patients including a clinicopathologic study of prognostic factors. *Am J Respir Crit Care Med* 1995;151:527–533. *The clinical and pathologic features of 46 patients from Japan, Korea, and Taiwan with pulmonary lymphangioleiomyomatosis showed reduction of FEV1/FVC ratio. This and an increase in TLC correlated with a poor prognosis at 2, 3, and 5 yr after the first examination. Histologically, two types of pulmonary lesions were observed; a predominantly cystic type and a predominantly muscular type.*

Lapinsky SE, Kruczynski K, Slutsky AS. Critical care in the pregnant patient. *Am J Respir Crit Care Med* 1995;152:427–455. *This state of the art review with 482 references includes discussions on physiologic changes, fetal oxygenation, drug therapy, mechanical ventilation, eclampsia, amniotic fluid embolism, and pulmonary edema as they relate to critical illness and critical care in the pregnant patient.*

Lehrer S, Stone J, Lapinski R, Lockwood CJ, Schachter BS, Berkowitz R, Berkowitz GS. Association between pregnancy-induced hypertension and asthma during pregnancy. *Am J Obstet Gynecol* 1993; 168:1463–1466. *This study noted a significant association between pregnancy-induced hypertension and asthma during pregnancy. In addition, there was a significant upward trend in the incidence of asthma during pregnancy in women without, with moderate, and with severe pregnancy-induced hypertension. The authors conclude that both pregnancy-induced hypertension and asthma might be caused by a factor/s affecting smooth muscle reactivity.*

Mabie WC, Hackman BB, Sibai BM. Pulmonary edema associated with pregnancy: echocardiographic insights and implications for treatment. *Obstet Gynecol* 1993;81:227–234. *A prospective study of 45 pregnant or recently postpartum women admitted to an obstetric intensive care unit with pulmonary edema used echocardiography between 1 and 4 days after the onset of pulmonary edema and detected decreased systolic function in 19, normal systolic function but increased left ventricular mass and presumed diastolic dysfunction in 17, and normal hearts in 9 patients. The authors recommend echocardiography to evaluate all pregnant women with pulmonary edema.*

Masson RG. Amniotic fluid embolism. *Clin Chest Med* 1992;13:657–665. *This paper is devoted to the review of amniotic fluid embolism. The author indicates that amniotic fluid embolism is the most unpredictable and catastrophic complication of pregnancy, accounting for 10% to 20% of maternal deaths and the pulmonary edema commonly seen in this syndrome is probably due primarily to alveolar capillary leakage and may be potentiated by high maternal extracellular volume, low colloid osmotic pressure, and, in some patients, by depressed myocardial function.*

Neville E, Brewis R, Yeates WK, Burridge A. Respiratory tract disease and obstructive azoospermia. *Thorax* 1983;38:929–933. *A study of 34 infertile men with mechanical azoospermia noted that 19 patients (59%) had grossly abnormal sinus radiographs, 19 (56%) gave a history of sinusitis; of these, six (18%) had sinus operations, 11 patients (32%) had histories of repeated otitis media, 10 patients had bronchiectasis, and the chest radiograph was abnormal in 18 patients.*

Pauli BD, Reid RL, Munt PW, Wigle RD, Forkert L. Influence of the menstrual cycle on airway function in asthmatic and normal subjects. *Am Rev Respir Disease* 1989;140:358–362. *This study of 11 asthmatics and 29 normal control subjects indicated that asthmatics not previously aware of premenstrual activation of asthma will record a premenstrual worsening of asthma symptoms and peak expiratory flow rates. These changes were not related to a deterioration in spirometry and airway reactivity or to the absolute levels of circulating progesterone and estradiol.*

Pauzner R, Mayan H, Hershko E, Alcalay M, Farfel Z. Exacerbation of Wegener's granulomatosis during pregnancy: report of a case with tracheal stenosis and literature review. *J Rheumatol* 1994;21:1153–1156. *This review of 15 pregnancies recorded in 10 women with Wegener's granulomatosis reported that pregnancy may significantly contribute both to the relapse of Wegener's granulomatosis and to its appearance. The article also describes a woman with Wegener's granulomatosis who relapsed twice during 2 pregnancies and developed tracheal stenosis. A therapeutic abortion was performed during the second pregnancy.*

Pisani RJ, Rosenow EC III. Pulmonary edema associated with tocolytic therapy. *Ann Intern Med* 1989;110:714–718. *Fifty-eight case reports served as the database for this review article on tocolytic pulmonary edema. Authors note that women at risk were receiving or had recently received sympathomimetic agents to arrest uterine contractions, with or without steroids. The incidence of the syndrome is higher in women with twin gestations.*

Rasmussen C, Wadt J, Jacobsen B. Thromboembolic prophylaxis with low molecular weight heparin during pregnancy. *Int J Gynaecol Obstet* 1994;47:121–125. *Prophylactic low molecular weight heparin therapy during part of their pregnancy in 24 women carrying 27 pregnancies with known risk of veno-pulmonary thromboembolic diseases showed that none of the treated women had clinical signs of thromboembolic diseases during pregnancy or 6 weeks postpartum. All the babies were born healthy and none of the women had any side effects due to the treatment.*

Rizk NW, Kalassian KG, Gilligan T, Druzin MI, Daniel DL. Obstetric complications in pulmonary and critical care medicine. *Chest* 1996;110:791–809. *In this extensive review with 196 references, the authors discuss the physiologic changes and pulmonary disorders including tuberculosis, thromboembolism, pneumonia, peri- and postpartum hemorrhage, and other respiratory complications.*

Robinson CA, Rose NC. Tuberculosis: current implications and management in obstetrics. *Obstet Gynecol Survey* 1996;51:115–124. *This review article discusses the issues of diagnosis and treatment of asymptomatic infection and active tuberculosis in pregnant women, the need for universal screening of all prenatal patients and the benefit and potential perinatal toxicity of chemotherapy in both immunocompetent patients and those infected with human immunodeficiency virus.*

Sansores RH, Abboud RT, Kennell C, Haynes N. The effect of menstruation on the pulmonary carbon monoxide diffusing capacity. *Am J Respir Crit Care Med* 1995;152:381–384. *A study of variations in DLCO during the menstrual cycle in 14 healthy women (8 were using oral contraceptives) with a mean age of 29 years observed the DLCO to vary significantly during the menstrual cycle, with the highest values occurring prior to menses and the lowest values occurring on the third day of menses, with a mean difference between them of 9%.*

Schatz M, Zeiger RS, Hoffman CP, Harden K, Forsythe A, Chilingar L, Saunders B, Porreco R, Sperling W, Kagnoff M, et al. Perinatal outcomes in the pregnancies of asthmatic women: a prospective controlled analysis. *Am J Respir Crit Care Med* 1995;151:1170–1174. *A study of 486 pregnant (28 wk) women with asthma and 486 pregnant nonasthmatic controls with normal pulmonary function found no significant differences in incidences of preeclampsia, perinatal mortality, preterm births, low-birth-weight infants, intrauterine growth retardation, or congenital malformations in the pregnancies of the asthmatic women as compared with the matched controls.*

Seal E Jr, McDonnell WF, House DE. Effects of age, socioeconomic status, and menstrual cycle on pulmonary response to ozone. *Arch Environ Health* 1996;51:132–137. *In this study, 372 healthy white and black young adults, between the ages of 18 and 35 y, were exposed only once to 0.0, 0.12, 0.18, 0.24, 0.30, or 0.40 ppm ozone for 2.3 h. Prior to and after exposure, pulmonary function tests were obtained. The results indicated that the decrements in FEV1 decreased as the subjects' ages decreased; socioeconomic status, as reflected by education of fathers, also appeared to affect FEV1 responsiveness to ozone, with the middle socioeconomic group being the most responsive. The phase of menstrual cycle did not have an impact on individual responsiveness to ozone.*

Skobeloff EM, Spivey WH, Silverman R, Eskin BA, Harchelroad F, Alessi TV. The effect of the menstrual cycle on asthma presentations in the emergency department. *Arch Intern Med* 1996;156:1837–1840. *Analysis of clinical data from 182 nonpregnant, adult females with asthma aged 13 years to menopause showed a 4-fold variation in asthma presentations during the perimenstrual interval, when serum estradiol levels decreased sharply after prolonged peak. Authors concluded that the monthly variations in serum estradiol levels may influence the severity of asthma in adult females.*

Stenius-Aarniala BS, Hedman J, Teramo KA. Acute asthma during pregnancy. *Thorax* 1996;51:411–414. *A study of 504 pregnant asthmatic subjects who were prospectively followed and treated showed that patients with inadequate inhaled anti-inflammatory treatment during pregnancy run a higher risk of suffering an acute attack of asthma than those adequately treated with an anti-inflammatory agent. Authors concluded that if the acute attack of asthma is relatively mild and promptly treated, it does not have a serious effect on the pregnancy, delivery, or the health of the newborn infant.*

Stenius-Aarniala BS, Riikonen S, Teramo K. Slow-release theophylline in pregnant asthmatics. *Chest* 1995;107:642–647. *A case-control study in which 212 pregnant asthmatics with theophylline treatment were compared with findings in 292 pregnant asthmatics without theophylline and 237 nonasthmatic pregnant control subjects. Authors concluded that during the second and third trimesters until term, moderate doses of theophylline are safe but the safety of theophylline treatment during the first trimester with regard to teratogenicity remains to be determined.*

Stick SM, Burton PR, Gurrin L, Sly PD, LeSouef PN. Effects of maternal smoking during pregnancy and a family history of asthma on respiratory function in newborn infants. *Lancet* 1996;348:1060–1064. *Respiratory-function data from 461 infants showed that* in-utero *smoke exposure, a family history of asthma, and maternal hypertension during pregnancy were associated with reduced respiratory function after birth. The authors speculate that these factors adversely affect lung development* in utero.

Troisi RJ, Speizer FE, Willett WC, Trichopoulos D, Rosner B. Menopause, postmenopausal estrogen preparations, and the risk of adult-onset asthma. A prospective cohort study. *Am J Respir Crit Care* Med 1995;152:1183–1188. *This prospective study of a cohort of pre- and postmenopausal women 34 to 68 yr of age during 582,135 person-years of follow-up documented 726 new cases of asthma.*

The authors concluded that estrogen plays a role in the pathophysiology of asthma and that long-term use and/or high doses of postmenopausal hormone therapy increase subsequent risk of asthma.

VanWinter JT, Nichols FC III, Pairolero PC, Ney JA, Ogburn PL Jr. Management of spontaneous pneumothorax during pregnancy: case report and review of the literature. *Mayo Clin Proc* 1996;71:249–252. *Report of a case of recurrent spontaneous pneumothorax during the third trimester of pregnancy that necessitated surgical intervention; at thoracotomy, a large bulla was excised from the lower lobe of the right lung; abrasive pleurodesis was subsequently done. Clinical aspects of 22 nonmalignancy-related spontaneous pneumothoraces during pregnancy are discussed.*

CHAPTER

64 The Normal Adult Pulmonary Circulation

Steven M. Scharf

S.M. Scharf: Pulmonary and Critical Care Division, Long Island Jewish Medical Center, New Hyde Park, New York 11042.

INTRODUCTION

The survey of the adult pulmonary circulation that follows in the next few chapters emphasizes the interplay between structure and function in determining the behavior of the normal and abnormal pulmonary vascular bed. We especially emphasize the clinical course of patients with pulmonary hypertension and cor pulmonale (right ventricular failure on the basis of lung disease). This chapter is devoted to a description of the anatomy, physiology, and biochemistry of the pulmonary vascular bed. We also consider aspects of the physiology of lung extravascular water homeostasis, the physiological–anatomic basis for pulmonary edema, and the function of pulmonary endothelia. In addition, we consider the normal function of the bronchial circulation. Finally, we consider the physiology of pulmonary hypoxic vasoconstriction.

PULMONARY VASCULAR ANATOMY

General Considerations

The principal function of the lungs is to transport the respiratory gases O_2 and CO_2 into and out of the bloodstream. In the mammalian lung, this is done by a remarkable system of air- and blood-containing vessels, folded together in an elastic structure in such a way that these vessels are in intimate contact, yet their contents do not physically mix. The normal adult human requires the transfer of 200 to 250 ml/min of O_2 into the body at rest. However, the transport of O_2 can increase to 3000 to 4000 mL/min at maximum exercise. In diseased lungs, O_2 transport capacity can be limited, which in turn limits the transport of O_2 into peripheral tissues, the ultimate target.

To accomplish its task, the pulmonary vasculature affords a capillary surface area (i.e., blood vessels exposed to air-containing compartments) measuring 50 to 80 m^2 and only some 300 nm thick. In normal lungs, which receive all the output from the right ventricle (approximately 5 L/min), there is 290 ± 50 mL/m^2 volume in the pulmonary circulation. Of this pulmonary blood volume, approximately 50 mL/m^2 is found in the gas-exchanging vessels, the capillaries. Any given red cell normally spends approximately 0.75 sec in air-exchanging vessels, which affords ample time for gas exchange across the wall of the vessel by the process of diffusion.

Several differences between systemic and pulmonary circulations should be emphasized. First, the major site of flow resistance in the pulmonary circulation is in alveolar capillaries, as opposed to precapillary vessels in the systemic circulation. Second, pulmonary microvascular pressures are extremely variable within the lung, depending on the anatomic location of the vessel (dependent versus independent regions), the site of the vessel within the parenchyma (intraalveolar versus extraalveolar), and the state of lung inflation. Third, the systemic vessels within the lung (bronchial circulation and pleural vessels) drain into the same venous bed as the pulmonary vessels by a network of anastomoses that constitute potential shunts from one bed to another.

Careful morphometric analysis of the pulmonary vascular tree reveals that there are more arteries than airways. After a few generations, pulmonary arteries lose their muscular media, and the most peripheral branches consist only of endothelium and internal elastic membrane. This flimsy structure is very susceptible to direct mechanical interactions, either compression or tethering open, by surrounding lung parenchyma. Extension of muscular coats from arterial generations that normally have them (diameter 100 to 500 µm) into peripheral arteries that normally do not is one of the prime histologic manifestations of pulmonary hypertension. The muscular coat in pulmonary arterioles is relatively smaller (3% to 4% of cross-sectional diameter) than that in systemic arterioles (40% to 50% of cross-sectional diameter). Sympathetic and parasympathetic innervation of pulmonary vessels is sparser than that of systemic vessels. The pulmonary circulation has no valves. Pulmonary veins are also relatively more thin-walled than systemic veins of the same diameter. These factors mean that the pulmonary circulation normally has an enormous capacity to accommodate increased blood flow by either distention or recruitment of pulmonary vessels (see section on Pulmonary Capillaries), with little increase in pressure.

Pulmonary Capillaries

The pulmonary capillary network is different from that in the systemic circulation. Systemic arterioles give rise to successive generations of capillaries as in a spreading brush, which reunite on the venous side. One can trace the connection between systemic arterioles and the capillaries to which they give rise. The situation is different in the pulmonary system. Pulmonary capillaries in the alveolar walls form a dense hexagonal network of cylindrical tubes into and out of which conducting vessels are connected. Other, more complicated models have been proposed to account for biological irregularity and to make mathematical analysis feasible. Some of these models postulate sheet-like flow in capillaries rather than tube flow. In this situation, classic laminar flow does not apply.

It is useful to distinguish among three types of vessels in the pulmonary microvasculature: intraalveolar, alveolar corner, and extraalveolar vessels. *Intraalveolar* microvessels are contained within and virtually fill the walls between separate adjacent alveoli. They are subject to changes in intraalveolar pressure, being compressed when alveolar pressure increases relative to pleural pressure (lung inflation) and vice versa. They are also subject to the effects of alveolar surface tension. Thus, capillary morphology depends on lung volume, vascular pressures, and alveolar surface forces.

Corner vessels are found at the junction of three alveoli. They are contained within folds of the endothelium, or pleats, beneath sharp curvatures of the alveolar surfactant film. In this way, corner vessels are contained within a space surrounded by smooth curved tissue surfaces, which protect them from perturbations of alveolar pressure. Hence, when intraalveolar pressure is increased, thus shutting off flow through alveolar walls, flow can continue from arterial to venous channels, even when there are swings in alveolar pressure.

Extraalveolar vessels are small vessels not exposed to alveolar pressure and are surrounded by a connective tissue sheath. They are exposed to interstitial pressure, which decreases as the lungs inflate (i.e., as intraalveolar pressure increases relative to pleural pressure). Hence, lung inflation tends to open extraalveolar vessels while closing intraalveolar vessels. The differing behavior of intraalveolar and extraalveolar vessels accounts for lung volume-dependent changes in pulmonary vascular volume and resistance.

Pulmonary capillaries have an average diameter of approximately 5 µm. Although the diameter of erythrocytes is larger (7 to 8 µm), these cells are extremely deformable because of their biconcave shape and lack of nucleus. This means they normally pass freely through the capillary. However, if deformability is severely reduced, as might occur, for example, with sickle cell disease, then erythrocytes will be sequestered in the precapillary and capillary vessels. Similarly, the neutrophil is approximately 700 times less deformable than the erythrocyte because of its viscous cytoplasm and the presence of a nucleus. This means that the tendency to be

trapped and sequestered is far greater for neutrophils than for erythrocytes.

PULMONARY VASCULAR PRESSURES

The pulmonary vascular bed is a low-pressure, low-resistance bed that accommodates all the cardiac output. Normally, pulmonary vascular pressures are measured relative to atmospheric pressure and are zero-referenced to a level 5 cm below the angle of Louis in the supine patient (approximate level of the right atrium). Normal limits for pressure values in the pulmonary circulation are given in Table 1. Pulmonary arterial pressure contours resemble those seen at the aortic root, with a dicrotic notch (Fig. 1). However, pulmonary arterial pressures recorded from bedside balloon-tipped catheter systems may not resemble those recorded under ideal conditions. Under ideal conditions, the frequency response of the catheter transducer system used to record pulmonary arterial pressure should be flat to approximately 80 Hz. The presence of bubbles in the line or, as is common in long indwelling catheters used in critical care units, fibrin clots at the catheter tip can severely dampen this response such that high-frequency components of the signal are damped and the signal can resemble a mean. Other causes of damped recording include tubing kinks, an excessive number of stopcocks, and cracked fittings. On the other hand, pulmonary artery catheters may demonstrate excessive high-frequency components, sometimes caused by vibration or knocking of the catheter, which may make interpretation difficult. Finally, pulmonary arterial pressure is subject to transmitted changes in intrathoracic pressure. With normal quiet breathing (i.e., under catheterization laboratory conditions), these are small. However, in the presence of abnormal ventilatory patterns (e.g., airway obstruction or positive-pressure ventilation), these may be considerable. In such cases, referencing pulmonary vascular pressures to atmosphere may be confusing at best and misleading at worst. Many investigators and clinicians overcome this problem by referencing intravascular pressure to esophageal pressure as an estimate of intrathoracic pressure.

Pulmonary arterial pressure	
Systolic	22–30 mmHg
Diastolic	6–12 mmHg
Mean	10–12 mmHg
Left ventricular end-diastolic pressure (left atrial mean)	6–12 mmHg
Right ventricular end-diastolic pressure (right atrial mean)	0–6 mmHg
Cardiac index	2.7–3.5 liters/min per m^2
Pulmonary vascular volume	290 ml/m^2
Capillary blood volume	80–120 ml
Pulmonary vascular resistance	150–200 $dynes/cm^2$

TABLE 1. *Approximate normal pulmonaryhemodynamic values for adults*

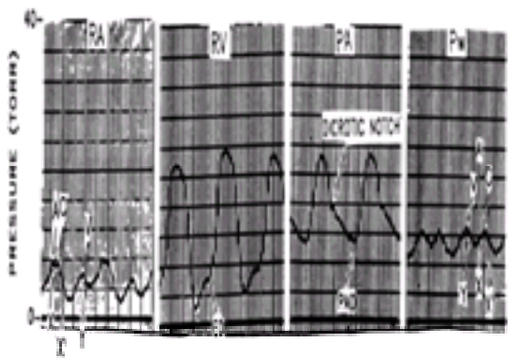

FIG. 1. Normal pulmonary and right heart pressures. These were measured using a standard saline-filled balloon-tipped catheter and are of particularly excellent quality for this type of system. Note mean right atrial (RA) pressure is equal to right ventricular (RV) end-diastolic (ED) pressure. Pulmonary arterial diastolic (PAD) pressure is equal to mean pulmonary wedge pressure (P_w), which, under most circumstances, is equal to left ventricular end-diastolic pressure. (Courtesy of Dr. Gary Friedman.)

Pulmonary venous pressure is equal to left atrial (LA) pressure. Both left and right atrial (RA) pressures exhibit three waveforms per beat, the *a, c,* and *v* waves (see Fig. 1). The *a* wave coincides with atrial contraction and peaks approximately 80 msec after the P wave on the surface electrocardiogram (ECG). The *v* wave is caused by atrial filling during ventricular systole, aided by descent of the atrioventricular (AV) valve ring. The origin of the *c* wave, a minor deflection, is not as well established but may be related to bulging of the AV valves into the atria at the onset of ventricular systole. The pressure descent following the *a* wave is called the *x* descent, that following the *c* wave is the *x'* descent, and the *y* descent follows the *v* wave. The right ventricular (RV) waveform is characterized by a gradual upsloping curve during diastole (ventricular filling) with a rapid steep upstroke at the onset of ventricular systole. The RV end-diastolic pressure is normally equal to mean RA pressure because there is no flow across the open tricuspid valve.

During diastole, there is normally no flow across the pulmonary bed. Hence, there is no pressure gradient from pulmonary artery to vein, and so pulmonary artery end-diastolic pressure is normally equal to pulmonary venous and left atrial pressure. Because mean LA pressure is normally equal to left ventricular (LV) end-diastolic pressure, pulmonary artery end-diastolic pressure becomes a measure of LV filling pressure. Of course, if pulmonary vascular resistance is elevated (see below), then flow continues throughout diastole, and pulmonary artery end-diastolic pressure is greater than pulmonary venous pressure. If a catheter is wedged into a small pulmonary vessel such that flow ceases through the vessel, then there is no longer a pressure drop from catheter tip to pulmonary vein, and the pressure recorded from the wedged catheter is equal to LA and LV end-diastolic pressure, provided the catheter is wedged in a so-called zone 3 portion of the lung (defined below). A similar recording can be made by using a balloon-tipped catheter in a small branch of the pulmonary artery to stop flow. The pressure recorded often is called the *capillary wedge pressure,* although it has very little to do with pulmonary capillary pressure when blood is flowing. Pulmonary *occlusion* pressure is a better term. Of course, if there are mitral valve problems, then pulmonary occlusion pressure is not equal to LV end-diastolic pressure.

PULMONARY CAPILLARY PRESSURES

Pulmonary capillaries are interposed between arterioles and veins. Capillary hydrostatic pressure provides the gradient for filtration of fluid into the interstitium and alveoli (pulmonary edema). Thus, one would ideally want to measure this in clinical situations where pulmonary edema is a consideration. For any given arterial-to-venous channel, capillary pressure depends on the longitudinal distribution of resistance along the channel as well as on flow. Capillary pressure (P_c) is related to blood flow through the channel ($\dot{Q}_c$), venous resistance (R_v), and pulmonary venous pressure (P_{pv}) by the laminar flow equation:

$$P_c = P_{pv} + \dot{Q}_c R_v$$

Because flow is related to inflow pressure (P_{pa}) and arterial resistance (R_a) for each channel, P_c can be shown to be related to P_{pa} and to the ratio of venous to arterial resistance (R_v/R_a):

$$P_c = [(R_v/R_a)P_{pa} + P_{pv}]/[1 + (R_v/R_a)]$$

This is easily derived from laminar flow relationships. Thus, pulmonary capillary pressure is, in part, a function of the ratio of venous to arterial resistance (R_v/R_a), downstream pressure (P_{pv}), and arterial pressure (P_{pa}).

A number of techniques have been devised to measure capillary pressure. The arterial occlusion technique has been proposed as clinically useful. This technique is based on the assumption that most pulmonary vascular compliance between a catheter tip in a branch of the pulmonary artery and venous outflow is located in

pulmonary capillaries. When arterial flow in the branch is stopped by wedging the catheter tip distally or inflating a balloon just proximal to the catheter tip, pressure immediately falls to the level in the pulmonary capillaries (no flow, no pressure gradient). Then, as the capillary reservoir empties, pressure falls exponentially to that of the pulmonary veins. Thus, two phases can be distinguished in the wedged catheter: first an initial fall to the level of pulmonary capillary pressure, and then a slower fall leading to equilibration with the pulmonary venous pressure and with the usually measured wedge pressure. Unfortunately, a number of theoretical and practical problems remain before this technique can be recommended as a routine clinical measure.

PULMONARY BLOOD FLOW

Although the pulmonary circulation receives all the cardiac output, the distribution of blood flow within the lung is far from uniform. Physiologists frequently speak about *upstream* and *downstream* loci in a vascular bed. These terms are relative and connote an orientation more toward the arterial (upstream) or more toward the venous (downstream) side of the circulation. In the upright human, there is a hydrostatic gradient down the lung as a result of gravitational effects on the column of blood (approximately 30 cm H_2O, the approximate height of the adult human lung). West and co-workers conceived of the distribution of blood flow within the lung according to the relation between pulmonary arterial (P_{pa}), alveolar (P_{alv}), and venous (P_{pv}) pressures. Pulmonary hydrostatic pressures increase from apex to base of the upright lung because of the gravitational acceleration and are equal to r*gh,* where r is fluid density (1.05 g/cm^3 for blood), *g* the gravitational acceleration constant (980 cm/sec^2 on the planet Earth at sea level), and *h* the vertical distance down the lung. Because r and *g* remain constant, vascular pressure increases approximately 1 cm H_2O for each centimeter down the lung.

With a mean P_{pa} of 20 cm H_2O, P_{pa} falls to zero 20 cm from the bottom of the lung. With a mean P_{pv} of 10 cm H_2O, P_{pv} falls to zero 10 cm from the bottom of the lung. With the lung at rest and the glottis open, alveolar pressure (P_{alv}) is constant throughout the lung (P_{alv} = 0). This distribution of pressures results in three zones of flow within the lung (Fig. 2). In zone 1 (more than 20 cm from the bottom of the lung), both P_{pa} and P_{pv} are less than zero (= P_{alv}). Pulmonary vessels are collapsed, and flow is zero. In zone 2 (in our example, 10 to 20 cm from the bottom of the lung), P_{pa} exceeds P_{alv}, which exceeds P_{pv}. Flow is thus determined by the gradient between P_{pa} and P_{alv}, *not* the gradient between P_{pa} and P_{pv}. In zone 3 (less than 20 cm from the lung base in our example), P_{pa} is less than P_{pv}, which is less than P_{alv}. Here, flow is determined by the gradient between P_{pa} and P_{pv}, as in standard ohmic resistances. According to this scheme, the distribution of blood flow is explained by a series of simple Starling resistors (collapsible tubes with a pressure surrounding the collapsible segment). In fact, the theory predicts that when P_{pa} is greater than P_{alv}, which, in turn, is greater than P_{pv} (zone 2), raising and lowering P_{pv} would have little effect on pulmonary blood flow because the effective back pressure to flow is P_{alv}, not P_{pv}. Only as P_{pv} is raised above P_{alv} does P_{pv} become the effective back pressure to flow.

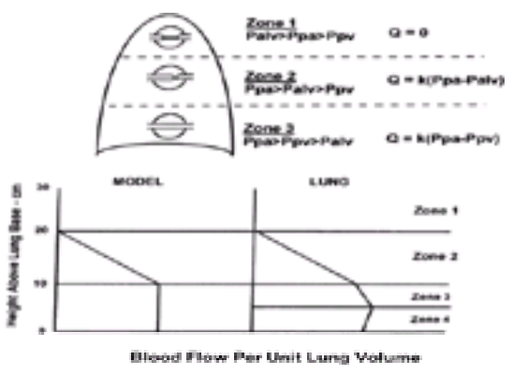

FIG. 2. Model of three lung zones based on relationships among pulmonary arterial (P_{pa}), alveolar (P_{alv}), and pulminary venous (P_{pv}) pressures. *Q* is flow; *k* is a proportionality constant with units of conductance. In the *lower panel* are shown representations of the theoretical (model) and actual (lung) changes in blood flow from apex to base in the upright human. Note that the appearance of zone 4 is not predicted on the basis of the simple model depicted in the *upper panel*. See text for discussion.

As with most models, the simple Starling resistor model does not explain all experimental results, as illustrated in Fig. 2. As expected, in zone 1 there is no blood flow. Flow in zone 2 increases down the lung because the gradient ($P_{pa} - P_{alv}$) increases one to one with decreasing height. Further increases in flow are not expected in zone 3 because both P_{pa} and P_{pv} increase one to one down the lung, and the gradient for flow ($P_{pa} - P_{pv}$) thus remains constant. However, actual flow does increase in zone 3, although at a slower rate than in zone 2. Further, a new zone, zone 4, is found—especially at low lung volumes—in which flow actually decreases toward the base. Flow may increase down the lung in zone 3 because pulmonary vascular resistance decreases with either distention of vessels or recruitment of closed vessels. The explanation for zone 4 may be that with increased capillary pressure, there is an increased hydrostatic gradient for transudation of fluid into the interstitium, possibly decreasing the diameter of microvessels in the interstitium. On the other hand, at low lung volume, the tendency for extraalveolar vessels to be held open is less, which would result in increased pulmonary vascular resistance toward the lung base because transpulmonary pressure decreases toward the lung base as well.

Finally, there are other factors, which are as yet poorly defined, that influence the distribution of blood flow within the lung that are independent of gravity. Recently, it has been demonstrated that for zone 3 conditions, gravity actually plays little role in determining the intralobar distribution of blood flow. One possibility is that the fractal geometry of the pulmonary vascular system explains the heterogeneity and small effect of gravity on flow in zone 3 conditions.

During normal spontaneous ventilation, most lung is in zone 3, with little of the lung in zone 1. In supine patients, there is practically no lung in zone 1 conditions. With hypovolemia, pulmonary vascular pressures fall, which leads to an increased proportion of the lung in zone 1, manifest as an increase in measured anatomic dead space. With positive-pressure mechanical ventilation, alveolar pressures can increase relative to vascular pressures, especially at high levels of positive end-expiratory pressure (PEEP). This leads to an increased proportion of the lung in zones 1 and 2 and increased numbers of lung units with high ventilation–perfusion ratios. Conversely, when pulmonary vascular pressures increase, as in congestive heart failure or pulmonary hypertension, the proportion of the lung in zone 3 increases, thus making blood flow more uniform within the lung. Of course, as blood flow increases in the apex, zone 1 diminishes. Because the apices receive relatively poor ventilation, units with decreasing ventilation–perfusion relationships could be created, thus contributing to hypoxemia in congestive heart failure. As previously indicated, there is normally a large reserve in the pulmonary vascular bed. A significant portion of the bed is underperfused (zone 1), thus allowing substantial reserve for recruitment of new vessels. In addition, there may be a significant reserve for distention of already perfused vessels. For these reasons, P_{pa} normally does not rise substantially with pneumonectomy provided the pulmonary vasculature is normal. With exercise, pulmonary blood flow (cardiac output) can increase considerably with only small increases in P_{pa}. This is because, with passive dilation of the pulmonary vascular bed, the resistance to blood flow through the pulmonary vascular bed decreases passively. We consider next the factors that actively regulate pulmonary vascular resistance.

PULMONARY VASCULAR RESISTANCE

The pulmonary bed often is modeled as a straightforward Poiseuille type of system where flow ($\dot{Q}$) is laminar and is determined by the gradient between mean P_{pa} and left atrial pressure (P_{la}) and a resistance term called *pulmonary vascular resistance* (PVR):

$$\dot{Q} = (1/\mathrm{PVR})(P_{pa} - P_{la})$$

If pulmonary blood flow were truly laminar and the pulmonary vascular bed were a simple ohmic resistance, then plotting the pressure drop across the bed as a function of flow would yield a straight line. Actual data demonstrate that $P_{pa} - P_{la}$ rises in a hyperbolic manner, with $\dot{Q}$ illustrating that PVR, calculated in the classic manner, *decreases* with increasing flow. As we have seen, the gradient ($P_{pa} - P_{la}$) is the driving pressure only for zone 3 lung. Thus, measurements of PVR by the usual equation or plot of $P_{pa} - P_{la}$ against $\dot{Q}$ fail to differentiate between changes in cross-sectional area from recruitment or from distention and critical closing pressure (usually approximately alveolar pressure).

As noted earlier, the presence of a gradient that develops between pulmonary arterial end-diastolic and pulmonary venous pressure (i.e., wedge pressure) is indicative of flow at end-diastole. The magnitude of this gradient increases with increased pulmonary vascular resistance, compliance, and blood flow.

A number of workers have performed studies plotting P_{pa} against $\dot{Q}$ When these plots are extrapolated to zero flow, the critical closing pressure of the vascular bed may be measured as the pressure at zero flow. The slope of the line is the true laminar flow resistance such that:

$$\dot{Q} = (1/\mathrm{PVR})(P_{pa} - P_c)$$

where P_c is the critical closing pressure of the bed when P_c exceeds P_{la} (zone 2). Although alveolar pressure can function as the critical closing pressure (when P_{alv} exceeds P_{la}), any pressure surrounding the pulmonary vessels can act similarly, whether caused by vasomotor tone or even increased interstitial pressure, as might occur in pulmonary edema. These plots sometimes lead to surprising conclusions. For example, Fig. 3 shows pulmonary pressure–flow curves obtained in dogs. With oleic-acid-induced pulmonary edema, a model of adult respiratory distress syndrome, there was an increase in the critical downstream pressure compared to a time-dependent control, which suggests that an increase in critical closing pressure of the pulmonary vascular bed is an important contributor to increased P_{pa} in this form of edema.

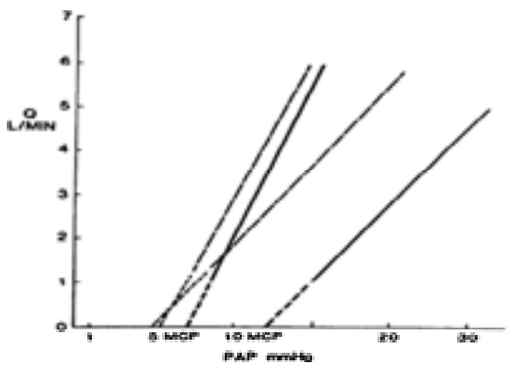

FIG. 3. Mean pressure–flow curves before and during oleic-acid-induced pulmonary edema. *Dashed lines* represent controls at time zero and at 5 hr. *Solid lines* represent before and 5 hr after oleic acid infusion. With time alone, there is a decrease in the slope (conductance) of the dashed lines but no change in the zero intercept, which represents the critical closing pressure of the pulmonary bed. With pulmonary edema, a similar decrease occurs in conductance *(solid lines).* However, note that the zero-intercept pressures also increase, suggesting an increase in the critical closing pressure of the vascular bed. $\dot{Q}$, volume of regular blood flow; PAP, pulmonary artery pressure; MCP, mean circulatory pressure. (Reprinted with permission from Prewitt RM, Ducas J. Hemodynamic management of acute respiratory failure. In: Scharf SM, Cassidy SS, eds. *Heart–Lung Interactions in Health and Disease.* New York: Marcel Dekker, 1989;906.)

Hydralazine and pulmonary emboli also lead to changes in critical closing pressure. Differentiating between effects on critical closing pressure and resistance of the pulmonary vascular bed has implications for the interaction between cardiac and pulmonary causes of pulmonary hypertension. For example, if pulmonary hypertension is produced by increased critical closing pressure, changes in P_{la} would have little effect on upstream pressure or flow. On the other hand, vasodilators such as hydralazine, which lower critical closing pressure, could make upstream pressures or flow *more* sensitive to fluctuations in P_{la}. Thus, it must be obvious that calculating the ratio $(P_{pa} - P_{la})/\dot{Q}$ may not give adequate information to infer the caliber of pulmonary resistance vessels or the state of vasomotor tone. This is because of the effects of passive dilation of the pulmonary bed (recruitment or distention), the intrapulmonary distribution of blood flow (percentage flow in any given lung zone), and the differential effects of resistance versus critical closing (or alveolar) pressure.

Pulmonary Vascular Impedance

The usual laminar flow approximations governing pulmonary resistance calculations assume that pulmonary vessels have rigid walls and that flow is nonpulsatile ($\dot{Q}$ = mean flow). We have already noted that the vessels are markedly distensible and that flow is pulsatile, being zero at end-diastole. Thus, calculations of PVR based on laminar flow profiles may be misleading, even taking into consideration the factors previously discussed.

It has been suggested that the calculation of input impedance (z) at the pulmonary arterial root is a better way of assessing the total hydraulic load placed on the right ventricle. Input impedance is the ratio of instantaneous pressure to instantaneous flow at a given frequency. Pressure and flow signals are analyzed, usually by Fourier transformation, and broken down into their respective harmonic series, each harmonic being a sine wave characterized by a frequency (a multiple of the heart rate, the dominant frequency), amplitude (called the *modulus*), and a phase angle. The pressure modulus is divided by the flow modulus to calculate impedance magnitude, and the phase angles are subtracted to yield the impedance phase. One advantage of using impedance analysis is that it takes into account two major determinants hindering RV ejection (i.e., two major determinants of RV afterload). These are the flow-resistive and capacitative behavior of the pulmonary bed. The development of electromagnetic catheter-tipped measurements of instantaneous flow velocity has enabled impedance measurements to be made in humans.

Effects of Lung Volume on Pulmonary Vascular Resistance and Blood Volume

The responses of intraalveolar and extraalveolar vessels to lung inflation are different. With increased transpulmonary pressure, intraalveolar vessels are compressed, whereas extraalveolar vessels are exposed to expanding forces. The net effect on pulmonary vasculature is biphasic, such that vascular capacitance is maximal at lung volumes close to functional residual capacity (FRC). As lung volume decreases below FRC, vascular capacity diminishes as a result of compression of extraalveolar vessels. As lung volume increases above FRC (as with ventilation with PEEP or in obstructive airways disease), vascular capacity diminishes from compression of intraalveolar vessels. As lung volume increases, the tendency for pulmonary edema to form around intraalveolar vessels diminishes because of increased interstitial pressure, whereas the tendency for edema formation increases around extraalveolar vessels because of decreased interstitial pressure. The balance of these tendencies may even lead to increased rate of edema formation as lung volume increases in noncardiogenic pulmonary edema. Biphasic compressive effects on the pulmonary circulation lead to biphasic effects of lung inflation on calculated PVR. As lung volume decreases below FRC, PVR rises, and as lung volume increases above FRC, PVR also rises. At high lung volumes, increased PVR caused by intraalveolar compression can lead to a substantial increase in RV afterload, especially in the presence of pulmonary edema.

PULMONARY VASOMOTION

The normal pulmonary vascular bed has very little resting vasomotor tone, PVR is low, and infusion of potent vasodilators rarely leads to decreases in baseline resistance. Whether the normally low PVR is the baseline natural state or reflects the continued chronic production of vasodilator substances is a matter of controversy. Nevertheless, it is clear that there are many influences capable of regulating pulmonary vasomotor tone. These include endogenously produced vasoconstrictors and vasodilators (Table 2), changes in autonomic tone mediated by central nervous system reflexes, a variety of pharmacologic agents, and changes in arterial blood gases, such as hypoxia, hypercapnia, and changes in pH. Changes in pulmonary vasomotor tone should be viewed on three levels: (1) global effects, or changes in overall PVR; (2) regional effects, or changes in the distribution of blood among various parallel channels (e.g., pulmonary hypoxic vasoconstriction); and (3) changes in longitudinal distribution of resistance, which could affect microcirculatory pressure gradients responsible for edema formation.

Vasoconstrictors	Vasodilators
α-Adrenergic agonists: norepinephrine, phenylephrine	Histamine (in preconstricted bed)
Angiotensin II	Prostacyclin (PGI_2)
Thromboxane A_2	β-Agonists: isoproterenol
Serotonin	Bradykinin
Histamine (in relaxed bed)	Prostaglandins E_1 and E_2
Prostaglandins $F_{2\alpha}$, E_2, and D_2	Platelet-activating factor (PAF, preconstricted bed)
Leukotrienes C_4 and D_4	Nitric oxide (endothelium-derived relaxing factor)
Interleukin-2	Adenosine
Tumor necrosis factor	
Endothelin-1	
Endothelium-derived constricting factor	

TABLE 2. *Some vasoactive mediators in the pulmonary circulation*

The state of initial vasomotor tone is important in determining the action of a given vasoactive agent. An example is histamine, which acts as a constrictor on dilated vessels and a dilator on constricted vessels.

Pulmonary Vasomotor Mediators

Vasoactive mediator substances (Table 2) are produced by many cell types within the lung, including interstitial mast cells and neutrophils, interstitial monocytes, alveolar macrophages, marginated neutrophils, and pulmonary endothelium. Many mediator substances are hypothesized to be released in response to acute lung injury and pulmonary embolism, which are responsible for changes in vasomotor tone (usually vasoconstriction) and vascular permeability. Among the most potent vasoactive substances are the eicosanoids, derived from arachidonic acid. Arachidonic acid is a 20-carbon polyunsaturated fatty acid released from tissue by the deacylation of cellular phospholipids. It may be metabolized by one of two pathways. The *cyclooxygenase* pathway leads to the production of the prostanoids—prostacyclin (PGI_2), thromboxane A_2, prostaglandin D_2 (PGD_2), PGE_2, and PGF_{2a}—and it is inhibited by a variety of pharmacologic agents including nonsteroidal antiinflammatory agents (e.g., aspirin and indomethacin). The *lipoxygenase* pathway leads to the production of the leukotrienes. Just as the prostenoids have been recognized as powerful vasoactive agents, the leukotrienes are also vasoactive agents. This allows for cross-talk between endothelium-derived factors such as PGE_2 and neutrophil-derived factors such as leukotriene D_4 in the regulation of vasomotor tone and permeability. A number of pharmacologic uses have been found for naturally occurring mediators. For example, prostacyclin, a powerful vasodilator, has been used in the treatment of primary pulmonary hypertension, and infusion of PGE_2 or PGE_1 can maintain patency of the ductus arteriosus of newborns.

Nitric Oxide

Since its discovery in 1980, the endothelium-derived relaxing factor, either the free radical NO or a related species, has been the subject of a great deal of basic and clinical research. This short-lived species (half-life 6 to 10 sec) is rapidly deactivated by hemoglobin bound to haptoglobin. This provides a mechanism to limit the action of NO downstream from the site of production and allows the actions of NO to be localized. Nitric oxide is derived from the terminal guanidino nitrogen atom of L-arginine, yielding NO and citrulline (see Fig. 4). The oxygen radical probably is provided by molecular oxygen. This reaction is catalyzed by a group of isoforms termed NO synthases (NOS). All NOSs can be inhibited to some degree by N^G-substituted L-arginine analogs. All contain four prosthetic groups: flavin-adenine dinucleotide, flavin-adenine mononucleotide, tetrahydrobiopterin (BH_4), and a heme complex, iron protoporphyrin IX. All NOS isoforms are dependent on calmodulin and NADPH. The brain isoform (bNOS) is found in the central and peripheral nervous system and functions as an intracellular messenger.

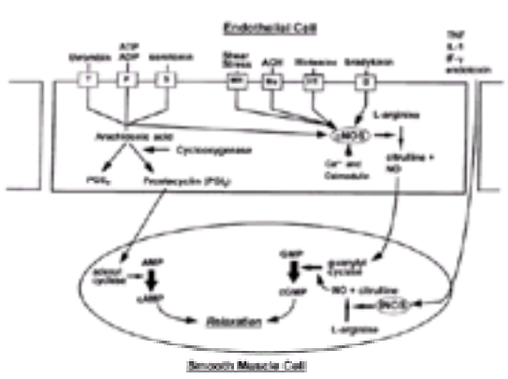

FIG. 4. Schematic depiction of endothelial cell–smooth muscle cell interactions leading to vasodilation. Endothelial cell receptors are shown as *square boxes* in the wall of the endothelium. T, thrombin receptor; P, purine receptor; S, serotonin receptor; MR, mechanoreceptor; Mu, muscarinic receptor; H1, histamine receptor; B, bradykinin receptor; TNF, tumor necrosis factor; IL-1, interleukin-1; IF-g, inteferon; cNOS, constitutive nitric oxide synthase.

Endothelial cell NOS (eNOS or cNOS), a constitutive isoform, is calcium and calmodulin dependent. The eNOS is a monomer with molecular mass of 133 kDa, bound to the cell membrane by a myristoylate bridge linked to the N-terminal glycine of the enzyme. The localization of the enzyme favors the formation of NO in high local concentration. As can be seen in Fig. 4, there are a number of receptor sites on endothelial cells that lead to activation of eNOS formation of NO. Endothelium-derived NO diffuses into the cytosol of vascular smooth muscle and leads to the activation of guanylyl cyclase. This in turn leads to the formation of cyclic guanosine monophosphate (cGMP). Increased cGMP triggers a reduction of calcium concentration by enhancing extrusion and sequestration of Ca^{2+}, which leads to smooth muscle relaxation. The eNOS-derived NO also has other actions such as regulation of adhesion and activation of circulating blood elements, cell killing, and increasing microvascular permeability.

Inducible NOS (iNOS) is an isoform not usually found in cells but is induced by inflammatory mediators such as bacterial endotoxin or the cytokines TNF-a, IL-1, or interferon-g. The role of NO derived from iNOS in systemic inflammatory response syndrome is a matter of extreme clinical interest. The iNOS is active as a dimer consisting of two 131-kDa units. In contrast to bNOS or eNOS, iNOS binds calmodulin so tightly that it does not require further addition of exogenous calmodulin to synthesize NO. Hence, iNOS is not regulated by intracellular Ca^{2+}. Nitric oxide formation catalyzed by iNOS located in vascular smooth muscle leads to relaxation, as does eNOS.

Because NO is a gas and highly soluble in water, inhaled NO acts readily on the pulmonary circulation. Because NO has such a short half-life, administering NO by inhalation leads to local effects on the pulmonary circulation with little in the way of systemic side effects. Thus, NO is being investigated as a local pulmonary vasodilator in a variety of clinical situations.

Other Functions of Pulmonary Endothelium

As suggested above, the vascular intima and its main constituent cell, the endothelium, can no longer be considered a simple layer of cells interposing a tissue barrier between the blood and vascular smooth muscle. Because the pulmonary circulation receives the entire cardiac output, it is an ideal location for performing a number of biological operations on the entire vascular system. Pulmonary endothelium contains a number of receptors for vasoactive substances or their precursors (see Fig. 4 and Fig. 5). For example, the potent vasoconstrictor angiotensin II is manufactured in the pulmonary endothelium from the precursor angiotensin I by a reaction catalyzed by angiotensin-converting enzyme.

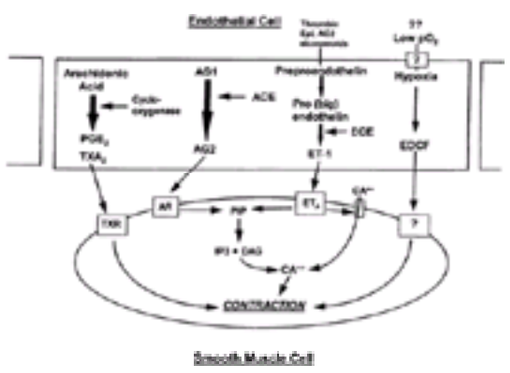

FIG. 5. Schematic depiction of endothelial cell–smooth muscle cell interactions leading to vasoconstriction. Epi, epinephrine; TXA_2, thromboxane A_2; AG1, angiotensin I; AG2, angiotensin II; ACE, angiotensin-converting enzyme; ECE, endothelin-converting enzyme; ET-1, endothelin-1; EDCF, endothelium-derived constricting factor; ET_A, endothelin-A receptor; TXR, thromboxane receptor; AR, angiotensin II receptor; PIP, phosphoinositol bisphosphate; IP3, inositol trisphosphate; DAG,

diacylglycerol.

The vasoconstrictor endothelin-1, a 21-amino-acid peptide, is the most potent vasoconstrictor currently known. It has a serum half-life of 2 min and hence has primarily local effects. Endothelin-1 is manufactured from pro- or big endothelin by endothelin-converting enzyme. Endothelin-A receptors are localized on vascular smooth muscle and mediate vasoconstriction. Endothelin-B receptors are located on vascular endothelium and are linked to vasodilation. When endothelin-1 binds to endothelin-A receptors, there is a biphasic rise in intracellular Ca^{2+}. The initial rise results from mobilization of intracellular Ca^{2+} stores by activation of phospholipase C, leading to generation of inositol trisphosphate and diacylglycerol (Fig. 5). The subsequent sustained rise in intracellular Ca^{2+} is from influx of extracellular Ca^{2+}. Endothelin release is stimulated by thrombin, epinephrine, calcium ionophore, angiotensin II, and some of the eicosanoids.

Endothelium-derived constricting factor is released from endothelial cells in response to hypoxia. The role of this substance in hypoxic vasoconstriction is being debated. Prostacyclin and PGE_2 are produced by pulmonary endothelium. Serotonin is extracted by pulmonary capillary endothelium. Angiotensin-converting enzyme also metabolizes the vasodilator bradykinin; thus, inhibition of angiotensin-converting enzyme would lead to increased systemic vascular resistance by inhibiting the formation of the vasoconstrictor angiotensin II and leading to the accumulation of the vasodilator bradykinin. The lung is a frequent site of injury in systemic inflammatory syndromes. Because of the interactions between pulmonary endothelial cells and a number of vasoactive mediators associated with inflammation, it is easy to understand why this should be so.

As discussed, the pulmonary endothelium interacts with vascular smooth muscle to produce contraction or relaxation by a variety of humoral mechanisms. Among the external forces acting on vascular endothelium are mechanical forces, probably acting via shear stress. Endothelial cells also secrete several growth factors that can regulate smooth muscle and fibroblast proliferation. These include growth-factor-like substances and a growth-inhibiting substance. The cross-talk between endothelium and surrounding lung tissue provides a series of mechanisms whereby chronic abnormalities in pulmonary vascular mechanics, i.e., chronically elevated pulmonary arterial pressures, can lead to remodeling of the pulmonary vasculature.

Autonomic Vascular Reflexes

The role of autonomic reflexes in controlling pulmonary vascular tone is less well understood than that for the systemic circulation. One should bear in mind that interspecies differences occur that may partially account for varying results in the literature. Relatively little is known about these responses in humans. In a number of species, both adrenergic and cholinergic nerve endings can be demonstrated in the pulmonary arterial bed, in the adventitia of large and small intrapulmonary arteries. Further, a- and b-adrenergic responses can be demonstrated after administration of exogenous selective a- or b-adrenergic agonists. Blocking of these responses by specific blockers can be demonstrated as well. Electric stimulation of pulmonary sympathetic nerves (i.e., by stimulating the stellate ganglion) causes pulmonary vasoconstriction, which has been variously manifest as an increase in pulmonary resistance or a decrease in pulmonary vascular compliance, primarily of large pulmonary arteries. Stimulation of the vagus nerve is more complex because it contains both sympathetic and parasympathetic fibers. According to some, sympathetic effects predominate with low baseline tone and cholinergic effects predominate with high baseline tone. Stimulation of muscarinic receptors by vagal stimulation or acetylcholine leads to vasodilation by release of NO.

A number of efferent brain–pulmonary vascular connections have been identified that may be responsible for the sympathetic component of the response to elevated cerebrospinal fluid pressure (Cushing's reflex). The ultimate change in PVR with autonomic stimulation depends on the interaction of sympathetically mediated pulmonary vasoconstriction, cholinergic vasodilation, resting tone, and concomitant changes in venous return and cardiac output, which lead to passive dilation of the bed. The role of neural control in maintaining oxygenation by matching ventilation and perfusion is not well known; nor are the mechanisms understood by which pathologic central nervous system stimulation may lead to abnormal water exchange, as in neurogenic pulmonary edema.

Finally, there are a number of afferent reflexes from pulmonary vasculature that lead to changes in ventilatory pattern. The existence of mixed venous CO_2-sensitive receptors that can regulate ventilation has been the subject of considerable controversy. These receptors have been postulated to contribute to the hyperpnea of exercise. The mixed venous CO_2 receptor may be identical to slowly adapting stretch receptors in the lung. However, a role for vagally carried bronchopulmonary C fibers has been postulated as well.

There is a large body of literature reporting that pulmonary vascular congestion can reflexively evoke systemic hypotension, bradycardia, and tachypnea. Unmyelinated C-fiber-innervated receptors in the interstitium of the lung may be stimulated by congestion of pulmonary microcirculation. Whether these *J-receptors* (for “juxtacapillary”) play a role, via vagally carried fibers, in mediating the tachypnea accompanying many pulmonary disorders such as pulmonary edema, pulmonary embolus, and fibrosis remains controversial, with evidence on each side of the argument. Whether these fibers are stimulated directly by vascular congestion or by release of a mediator substance is not known.

A number of chemical substances lead to the triad of bradycardia, hypotension, and apnea. This pulmonary chemoreflex can occur with the injection of certain naturally occurring mediators such as prostaglandins I_2 and E_2 and opiate peptides. Numerous other substances, including iced saline, when injected into the pulmonary artery through balloon-tipped catheters, are capable of causing this reflex.

Effects of Altered Gas Exchange on Pulmonary Circulation

It would be in the interest of preserving pulmonary ventilation–perfusion relationships if there were a mechanism allowing local vascular control by regional gas tensions such that areas of poor ventilation receive less blood flow. Hypoxic, hypercapnic, or acidotic lung regions would thereby undergo local vasoconstriction, shunting blood away from diseased areas. Both severe hypercapnia and acidosis are capable of causing vasoconstriction. Hypoxic pulmonary vasoconstriction has been most extensively studied. It should be noted that there are interspecies differences in the strength of, and possibly the mechanisms involved in, hypoxic vasoconstriction; these should lead to caution in comparing studies in different species. Failure of hypoxic vasoconstriction is probably a cause of hypoxemia seemingly out of proportion to the estimated size of a pulmonary lesion, as seen in pneumonia and atelectasis.

Graded decreases in alveolar P_{O_2} produce graded increases in pulmonary vascular resistance. The curve relating PVR to $P_{A_{O_2}}$ is roughly sigmoid in shape with a marked rise in the slope at $P_{A_{O_2}}$ » 60 torr. When hypoxia is confined to a local area of lung, then hypoxic vasoconstriction (HPV) is a mechanism for flow diversion from that area. For small segments, flow diversion is an effective means for shifting flow from hypoxic to normoxic lung regions. However, as the area of hypoxic lung gets larger, flow diversion becomes less effective. With whole-lung hypoxia, flow diversion does not occur. At this stage, elevated pulmonary arterial pressures may lead to redistribution of flow from bases to apices. This will lead to lower ventilation–perfusion ratios in the bases. This unfavorable effect on the distribution of ventilation–perfusion relations within the lung may even exacerbate systemic hypoxemia. Further, there is a point at which the gain in arterial P_{O_2} is offset by increased right ventricular afterload produced by HPV.

It is generally agreed that the site of pulmonary HPV is in the small muscular precapillary pulmonary arteries, which suggests that the site of O_2 sensing is not confined to alveolar capillaries alone. Interestingly, changing $P_{A_{O_2}}$ leads to a parallel shift in the pulmonary pressure–flow curve. This suggests a primary effect on critical downstream pressure rather than overall vessel diameter *per se* as discussed above.

A number of factors are known to modify the strength of HPV in different animal species. With very severe hypoxia (P_{O_2} < 25 torr), vasodilation may be seen. Other mediators that modify the vigor of HPV include estrogen, prostacyclin, pregnancy (although this response may be variable), glucocorticoids, and neural stimuli. More work is needed to define these factors in humans, especially as relates to clinical situations.

It would seem strange that after all the investigation of HPV, there is no universal agreement as to the mechanisms involved. There are two major schools of thought. One is that acute hypoxia elicits HPV via release of mediators from surrounding lung and/or endothelial cells. The other states that HPV is a direct effect of regional hypoxia (either in air or blood) on pulmonary vascular smooth muscle.

Regarding the mediator hypothesis, many previously postulated candidates are no longer thought to be viable alternatives as primary mediators, although they may certainly act as modifiers. These include catecholamines, potassium, histamine, serotonin, angiotensin II, certain arachidonic acid metabolites, and various neurotransmitters. Endothelin-1 and endothelium-derived constricting factor are being considered for roles as primary mediators of HPV. One interesting hypothesis concerns the role of NO in HPV. Because NO is released tonically into the pulmonary circulation, inhibition of NOS could result in vasoconstriction. In fact, NOS inhibition can enhance the pulmonary pressor response to hypoxic challenge. This in turn suggests that NO plays a role modulating the vigor of the pulmonary pressor response to hypoxia. However, NOS inhibition does not abolish HPV, indicating that there is another primary mechanism at work.

Direct effects of hypoxia on the pulmonary vasculature are considered in the context of a three-part model: a hypoxia sensor, a transducer, and an effector. The effector is clearly vascular smooth muscle. The sensor is most likely located anatomically in precapillary arterioles. Because the presence of an intact endothelium is necessary for HPV, it is possible that this cell, with its potential to produce vasoconstrictors and vasodilators, acts as the primary sensor. The identity of the sensor within cells is likewise unknown. Possibilities include the mitochondrial oxidative phosphorylation system and cytochrome P_{450}. The transducer is likewise not universally agreed on; however, any one of a number of endothelium-derived vasoconstrictors could be a candidate (Fig. 5). Finally, an intriguing observation is that small pulmonary arteries exhibit membrane depolarization and action potential generation on exposure to hypoxia, suggesting that hypoxia may act directly on the vessel wall of these vessels. This work is consistent with the notion that there is a role for potassium influx and change in potassium channel conductance in the genesis of HPV.

In addition, the effect of local hypoxia on regional blood flow is the end result of a number of factors besides regional gas tensions. These effects include local compression or malformation of vessels as well as the systemic effects of hypoxemia. Thus, systemic adrenergic stimulation could add to the local mechanisms involved in hypoxic vasoconstriction.

Chronic hypoxemia, as occurs in high-altitude dwellers, is associated with structural changes in the pulmonary vascular bed in addition to the vasospasm of acute hypoxia. We have already alluded to the cross-talk between pulmonary endothelium-derived growth factors and smooth muscle, which may be responsible for architectural remodeling, including hyperplasia and hypertrophy of pulmonary arterial and arteriolar walls (i.e., smooth muscle and medial layers). In chronic high-altitude dwellers who move to sea level, pulmonary arterial pressures remain elevated, and dilatory reserve remains limited for an extended period of time, because of structural changes in pulmonary vasculature.

Pulmonary Edema Formation and Prevention in the Lung

Exchange of nutrients and fluids occurs at the capillaries, arterioles, and small veins, vessels that may be lumped under the term *microvasculature.* Fluid exchange at the microvascular level occurs by filtration, diffusion, and micropinocytosis. Filtration and diffusion are passive processes in which substances flow down a potential energy gradient.

The Starling Equation

In 1896, Starling described the balance of forces that regulate the flow of fluid (filtration) across microvasculature into and out of the interstitium. The force driving fluid *out* of microvasculature is the hydrostatic pressure gradient across the vessel wall, and that driving fluid *into* the microvessels is the colloid oncotic (or osmotic) pressure gradient across that wall. The classic relationship may be written:

$$\dot{Q}_f = K_f[(P_m - P_{is}) - k(\pi_m - \pi_{is})]$$

where $\dot{Q}_f$ is fluid flow across the microvessel, P_m is microvasculature hydrostatic pressure, P_{is} is interstitial hydrostatic pressure, p_m is microvascular plasma oncotic pressure, and p_{is} is interstitial oncotic pressure. The constant k is the reflection coefficient, which represents the degree to which proteins can move across the vessel wall. If $k = 0$, then protein moves freely, and there can be no oncotic gradient driving fluid back into the microvasculature. If $k = 1$, then the vessel wall is impermeable to protein. Constant k is usually close to 1. K_f is the filtration coefficient, which is made of terms representing the filtration constant of the microvascular membrane, membrane surface area, filtrate viscosity, and the distance across the vessel wall; it thus represents the conductance for fluid flux across the membrane. It can be seen that with a large K_f, even a small balance of forces in favor of fluid movement results in a large volume flow of fluid.

Plasma and interstitial fluid each contain approximately 280 mmol of crystalloid, which is freely interchangeable between the two compartments. Thus, the osmotic forces governing transvessel fluid exchange are dominated by the protein concentration gradient, approximately 7 g/100 mL, giving a plasma osmotic (oncotic) pressure of 28 mmHg. Pulmonary interstitial protein content is not known for certain and is often assumed to be close to zero. Thus, the edemagenic potential of the lung depends on the balance of forces, which is not necessarily constant but is related to regional variations in vascular and interstitial compartments. In addition, the lung is richly endowed with a lymphatic system, which can drain the interstitium (Fig. 6).

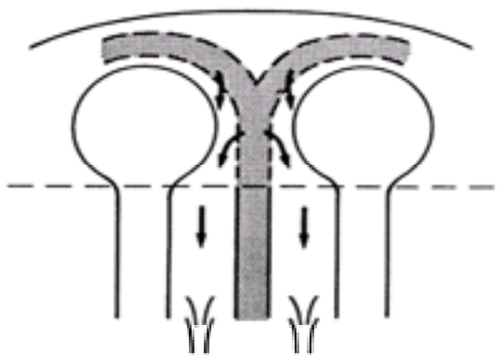

FIG. 6. Representation of the lung as three concentric compartments: airway, vascular, and interstitial. *Arrows* indicate the net filtration volume. Lymphatics drain the interstitium. (Reprinted with permission from Oppenheimer L, Goldberg HS. Pulmonary circulation and edema formation. In: Scharf SM, Cassidy SS, eds. *Heart–Lung Interactions in Health and Disease.* New York: Marcel Dekker, 1989;93–130.)

We have already considered most of the factors that govern microvascular filtration pressure. It should be noted that both extraalveolar and intraalveolar vessels contribute to edema formation, and the gradients across the walls of these vessels may be very different depending on the state of lung inflation. In general, microvascular filtration pressure increases from less to more dependent lung regions, and, for any given arterial pressure, microvascular filtration is greater as the ratio of arterial to venous resistance decreases. Thus, it is difficult to consider *the* capillary filtration pressure within the lung as if it were a unique entity, although various techniques have been used to estimate the overall mean filtration pressure for any given set of conditions.

It is important for preservation of normal gas exchange that the pulmonary interstitium, particularly in the intraalveolar compartment, remain dry—that is, without free fluid. Pulmonary interstitium, far from being a space, is composed of cellular elements, elastin, collagen, glycosamines, and proteoglycans and probably has a consistency similar to gelatin. Like microvascular pressure, interstitial pressure varies locally between extraalveolar and intraalveolar compartments, with lung inflation, along hydrostatic gradients and from hilum to parenchyma. In general, interstitial pressure is *less* than pleural pressure, is more negative in the extraalveolar than in the intraalveolar compartments, and is more negative in hilar than in peripheral lung regions. This leads to different transmicrovascular fluid pressure gradients within the lung such that the edemagenic potential varies within the lung, leading to a sequence of edema formation. Edema forms initially in the connective tissue of the alveolar septa. Following pressure gradients, it then accumulates around arterioles and bronchioles in the form of cuffs of fluid and travels to the interstitium around larger arteries, veins, and airways. This leads to the perivascular and peribronchial cuffing sign seen on chest roentgenograms. Ultimately, fluid may penetrate into the alveolar space to cause alveolar flooding.

Like other interstitial areas, the pulmonary interstitium has a biphasic pressure–volume curve. At low levels of hydration (low free fluid volume), large changes in fluid pressure produce small changes in volume. This stiff portion of the pressure–volume curve is found when interstitial pressure is negative and protects against edema formation because large pressure gradients, such as might be produced by lung inflation, are tolerated with little change in fluid volume. As water accumulates and the matrix opens up, the pressure–volume curve becomes more compliant, such that relatively small changes in pressure produce large volume changes. This allows the interstitium to soak up considerable amounts of fluid, thereby buffering against alveolar flooding.

Finally, pulmonary lymphatics, which drain into the systemic venous system, act as sump drains, removing excess interstitial fluid. Lymphatic flow increases with either increased microvascular pressure or increased microvascular permeability. With high microvascular pressures resulting in transudation of fluid, lymph is essentially an ultrafiltrate of plasma and has a low protein content. With increased vascular permeability, however, macromolecules usually leak through, and the protein content of lung lymph becomes high. Injection of substances that damage pulmonary microvessels often demonstrates two phased alterations of lung lymph. In stage 1, lymph protein content is low, although lung lymph flow is increased. This is consistent with elevation of pulmonary microvascular filtration pressure with little change in

vascular permeability. In phase 2, lung lymph flow is also increased, but protein content is high, consistent with permeability or leaky-capillary-type pulmonary edema.

Although the overall Starling balance for the lung is difficult to ascertain, estimates of microvascular fluid filtration pressure usually hover around 15 mmHg, albeit with considerable variation. Interstitial hydrostatic pressure is subatmospheric, approximately –8 mmHg. This gives a 23-mmHg (15 to –8 mmHg) gradient for outward fluid movement, which is more than counterbalanced by the inward-acting oncotic pressure gradient of 28 mmHg. Therefore, the overall balance of forces is approximately 5 mmHg in favor of movement of fluid out of the interstitium into the microvasculature. This does not leave much room for increases in microvascular filtration pressure, as might well occur with physiological maneuvers (i.e., exercise). Thus, the other mechanisms discussed that keep the interstitium fluid-free assume greater importance.

The Bronchial Circulation

The bronchial circulation is the systemic vascular supply to the airways, arising from the bronchial arteries, intercostal arteries, and aorta. The bronchial circulation constitutes the major nutritive blood supply to the bronchi down to the level of the respiratory bronchioles. Below this level, the pulmonary circulation performs this function. There is considerable anatomic variation in the origin of the bronchial arteries, which has practical importance in clinical situations where embolization of the bronchial circulation is used to treat massive hemoptysis. The bronchial circulation also sends branches to mediastinal and other extrapulmonary structures, including hilar lymph nodes and pleura (Fig. 7). The extrapulmonary bronchial circulation drains via the azygos and hemiazygos veins, whereas the intrapulmonary bronchial circulation drains via the pulmonary veins. There is evidence for anastomoses or potential anastomoses between bronchial and pulmonary circulations at every level of the vasculature, including arteries, capillaries, and veins. To supply airways to the level of the terminal bronchioles, the bronchial circulation forms two plexuses, one inside the airway in the submucosa and one outside the airway in the peribronchial tissue.

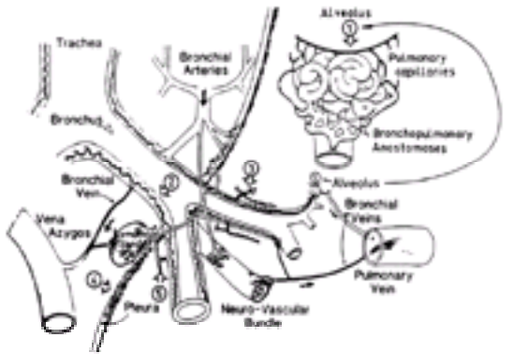

FIG. 7. Schematic depiction of the bronchial circulation. The *numbers* indicate possible sites of absorption of edema fluid. Note the many intra- and extrapulmonary sites supplied by the bronchial circulation. (Reprinted with permission from Deffeback ME, Butler J. The bronchial circulation and lung edema. In Scharf SM, Cassidy SS, eds. *Heart–Lung Interactions in Health and Disease.* New York: Marcel Dekker, 1989;131–154.)

The bronchial circulation normally constitutes only 1% to 2% of the cardiac output. However, this belies its potential importance. Because of its location and extensive networking, total bronchial blood volume is considerable; hence, bronchial blood velocity is slow. Thus, the bronchial circulation is well situated to participate in fluid and even gas exchange in the lung. When there is pulmonary vascular obstruction, bronchial blood flow via anastomoses to the pulmonary circulation helps maintain inflow from surrounding pulmonary networks and acts to prevent infarction. Of particular importance may be the role of the bronchial circulation in airway inflammation, when bronchial blood flow increases considerably.

Clearly, the bronchial circulation is important when considering the edema, bronchospasm, and inflammatory changes found in airways in a variety of disorders. In addition, the bronchial circulation acts to condition air in the bronchial tree that is not conditioned in the upper airways. The blood vessels of the airways may act to minimize heat loss during hyperventilation such as that induced by exercise. During exhalation, heat and water would be given back to the air, cooling the airway surface but minimizing heat loss to the outside. Similarly, the bronchial circulation plays an important role in regulating airway water, which can influence the rheology of mucus and thus affect the clearance of particulate matter from the lung as well as change the osmolality of the mucous lining layer. The latter is believed to affect airway smooth muscle tone, especially in asthmatic patients. Finally, in pathologic situations—most notably bronchiectasis, tumor, and lung abscess—local bronchial circulation increases considerably, in part because of opening of previously closed bronchial–pulmonary anastomoses. The hypertrophied bronchial circulation is responsible for hemoptysis in these situations, which may be life-threatening. Conditions associated with bronchial arterial hypertrophy and proliferation may be associated with right-to-left extracardiac shunting, hypoxemia, and increased cardiovascular load. Left-to-left shunts have been demonstrated, but only when the expansion of the bronchial circulation is large. Interestingly, these conditions are often associated with the clinical sign of digital clubbing.

CHAPTER

65 Pulmonary Hypertension: Pathophysiology and Clinical Disorders

Sharon Rounds · Michael V. Cutaia

S. Rounds and M.V. Cutaia: Pulmonary/Critical Care Section, Department of Medicine, Providence VA Medical Center and Brown University School of Medicine, Providence, Rhode Island 02908.

INTRODUCTION

As reviewed in the previous chapter (Chapter 64, The Normal Adult Pulmonary Circulation) the normal pulmonary circulation is a low-pressure, high-flow vascular bed that accommodates the entire cardiac output with each heartbeat. Increased cardiac output, a normal response to exercise, does not significantly increase pulmonary arterial pressure. The reasons for the high capacitance of the pulmonary circulation are recruitment of underperfused microvessels and distension of patent vessels in response to increases in blood flow. In addition, the tone of the smooth muscle in the media of pulmonary arterioles is lower, and the smooth muscle layer of pulmonary resistance vessels is thinner than that of most systemic vascular beds. The causes of the normally low tone of pulmonary arteriolar smooth muscle probably include both enhanced responsiveness to endogenous vasodilators and decreased responsiveness to vasoconstrictors.

Pulmonary hypertension occurs when pulmonary arterial pressure is inappropriately high for a given level of blood flow through the lungs. A useful clinical definition of pulmonary hypertension is a pulmonary artery pressure (P_{pa}) >25 mmHg at rest or >30 mmHg during exercise. Pulmonary hypertension may occur as a primary disorder of the pulmonary circulation, or it may be secondary to other heart or lung diseases. Examples of primary disorders of the pulmonary circulation include those in which pulmonary vessels are obstructed by thrombosis (i.e., recurrent pulmonary thromboembolism) or by vasoconstriction (i.e., idiopathic or primary pulmonary hypertension). Secondary pulmonary hypertension occurs as a complication of other disorders, such as pulmonary hypertension as a consequence of chronic hypoxia caused by chronic bronchitis. In this chapter we discuss the pathophysiology of pulmonary hypertension in the context of abnormalities of the normal mechanisms that maintain low pulmonary vascular pressure. We survey clinical disorders manifested by pulmonary hypertension, and we review the approach to diagnosis and treatment of pulmonary hypertensive disorders.

PATHOPHYSIOLOGY OF PULMONARY HYPERTENSION

In order to understand the pathogenesis of pulmonary hypertension, it is necessary to review the determinants of normal pulmonary vascular tone. As illustrated in Fig. 1, pulmonary vascular resistance is a function of inflow (pulmonary arterial) and outflow (left atrial or pulmonary venous) pressures and is inversely proportional to cardiac output. As noted above, the normal structure and function of pulmonary arterioles are those of a low-resistance circulation. Pulmonary arterial pressure increases with increases in cardiac output and with increases in left atrial pressure. Because of the remarkable capacity of the pulmonary circulation, acute changes in flow and venous pressures do not ordinarily cause significant pulmonary hypertension. However, if these conditions persist in a chronic state (weeks to months), then vasoconstriction, vascular remodeling, and subsequent narrowing of the vessels occur, as discussed below. Thus, conditions characterized by sustained increases in pulmonary blood flow, such as left-to-right intracardiac shunts, may result in secondary pulmonary hypertension. Similarly, conditions characterized by long-standing increases in left atrial and pulmonary venous pressures, such as mitral valvular stenosis, may also cause secondary pulmonary hypertension.

PULMONARY VASCULAR RESISTANCE

$$PVR\ (mmHg \cdot mm \cdot L^{-1}) = \frac{\bar{P}_{PA} - \bar{P}_{LA}}{\dot{Q}}$$

POISEUILLE'S LAW

$$R = \Delta P/\dot{Q} = \frac{8\mu \cdot l}{\pi \cdot r^4}$$

FIG. 1. Pulmonary vascular resistance (PVR) is calculated from the ratio of differences in pressure across the pulmonary vasculature to blood flow; P_{PA}, mean pulmonary arterial pressure (mmHg); P_{LA}, mean left atrial (or pulmonary venous) pressure (mmHg); *Q,* cardiac output (blood flow, L/min). The PVR may be expressed in units of dyne-seconds per cm^5 by multiplying this ratio by 80. Poiseuille's law indicates that the vascular resistance in a tube, the ratio of the pressure drop across the tube (D *P*) to blood flow (*Q*), is determined by blood viscosity (h), the length of the vessel (*l*), and the radius (*r*) of the vessel.

The factors that modulate pulmonary vascular resistance are delineated by Poiseuille's law, which describes resistance to flow through rigid tubes (Fig. 1). Pulmonary vascular resistance is directly proportional to the viscosity of blood and is inversely proportional to the radius to the fourth power of the aggregate cross-sectional area of the pulmonary vascular bed. Thus, conditions that increase blood viscosity, such as erythrocytosis, may exacerbate pulmonary hypertension. Most importantly, conditions that decrease the luminal area of the pulmonary circulation significantly increase pulmonary vascular resistance and arterial pressure.

Figure 2 illustrates conditions in which the aggregate cross-sectional area of the pulmonary circulation may be diminished. Loss of aggregate cross-sectional area occurs after surgical resection of lung tissue. Ordinarily, even pneumonectomy does not cause resting pulmonary hypertension because of the enormous reserve of the pulmonary circulation. Indeed, more than half of the pulmonary circulation must be removed before pulmonary hypertension is observed at rest. However, because cardiac output increases with exercise, pulmonary hypertension may occur after pneumonectomy. Similarly, if there is some other underlying disorder decreasing pulmonary arterial cross-sectional area, then further loss of area after lung resection may cause resting pulmonary hypertension. Another common cause of loss of pulmonary vascular luminal area is the destructive lung disease, emphysema. In emphysema, destruction of alveolar capillary septa results in loss of pulmonary capillaries and microvessels.

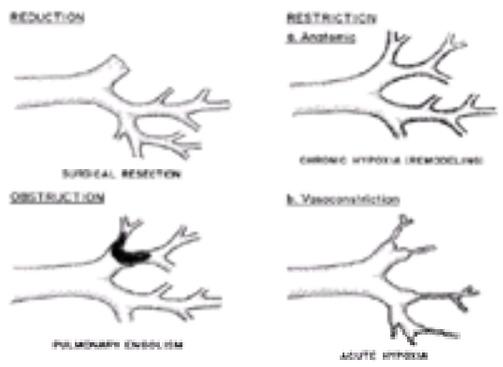

FIG. 2. Several commonly occurring mechanisms by which the aggregate cross-sectional area of the pulmonary vasculature may be reduced.

The luminal area of the pulmonary circulation may also be decreased by obstruction of vessels, such as occurs after pulmonary thromboembolism. Because of the huge cross-sectional area of the normal pulmonary circulation, acute pulmonary thromboembolism rarely causes sustained pulmonary hypertension unless there is massive embolization resulting in obstruction of more than half of pulmonary arteries. However, if there is an underlying disorder that has diminished the luminal area, then submassive thromboembolism may cause pulmonary hypertension. Also, recurrent thromboembolism with multiple small clots accumulating over a period of months to years causes sustained pulmonary hypertension. Other vascular obstructive causes of pulmonary hypertension include schistosomiasis, foreign body emboli as a result of intravenous drug abuse, and sickle cell disease.

Widespread narrowing of pulmonary vascular lumina is an important cause of loss of cross-sectional area. Narrowing may be caused by anatomic changes in the vascular wall structures, such as the vascular remodeling seen after chronic hypoxia or in primary pulmonary hypertension. Contraction of vascular smooth muscle causes vasoconstriction, another cause of decreased luminal area. Although a variety of mediators cause pulmonary arterial vasoconstriction, the most important cause of pulmonary vasoconstriction is acute alveolar hypoxia. Vasoconstriction and remodeling frequently occur simultaneously, as in conditions characterized by long-standing hypoxia, such as chronic mountain sickness or chronic bronchitis. Long-standing increases in intrathoracic pressure, as may occur with COPD, may also decrease vascular area by compression of pulmonary vessels.

Thus, increases in pulmonary blood flow, left atrial or pulmonary venous pressure, and blood viscosity and decreases in pulmonary arterial lumen area all increase pulmonary arterial pressure. These mechanisms of pulmonary arterial hypertension are summarized in Table 1 with clinical examples of characteristic disorders resulting in pulmonary hypertension. Some of these mechanisms, such as increased blood viscosity, exacerbate pulmonary hypertension but rarely, if ever, cause clinically significant disease by themselves. In many clinical disorders, more than one mechanism of pulmonary hypertension may be operant. For example, in primary pulmonary hypertension, vasoconstriction, structural remodeling, and *in situ* thromboses are all likely contributors to increased pulmonary vascular resistance. In chronic bronchitis, hypoxic vasoconstriction, structural remodeling, increased intrathoracic pressure, secondary erythrocytosis, and increased blood volume may all be present and contribute to pulmonary hypertension. In conditions of sustained increases in pulmonary blood flow, such as congenital left-to-right intracardiac shunts, sustained increases in flow eventually cause increased vasomotor tone and vascular remodeling that exacerbate and may perpetuate pulmonary hypertension. Thus, regardless of the original insult, the mechanism of sustained pulmonary hypertension is usually multifactorial. In subsequent sections of this chapter, we discuss in more detail the effects of acute and chronic hypoxia and clinical disorders of pulmonary hypertension, with correlation of pathologic and physiological changes and clinical manifestations.

Mechanism	Clinical example
Increased blood flow	Atrial septal defect
Increased venous pressure	Mitral stenosis
Increased blood viscosity	Erythrocytosis
Decreased vascular area	
Surgical resection	
Obstruction	Thromboemboli
Obliteration	Emphysema
Extrinsic compression	Interstitial pulmonary fibrosis
Vasoconstriction	Acute hypoxia
	PPH
Vascular remodeling	Chronic hypoxia
Increased intrathoracic pressure	COPD

TABLE 1. *Mechanisms of pulmonary hypertension*

PATHOPHYSIOLOGY OF PULMONARY VASOMOTOR CONTROL

As noted above, the normal pulmonary circulation is a low-pressure, high-flow circuit maintained in a relative state of vasodilation as compared to the systemic circulation. Endogenous pulmonary vasodilators and vasoconstrictors are described in Chapter 64. Loss of normal balance among these substances can cause contraction of vascular smooth muscle and restriction of the pulmonary vascular bed, resulting in pulmonary hypertension. An example of such loss of balance in patients with primary and secondary pulmonary hypertension is the reported increase of the vasoconstrictor prostaglandin thromboxane A_2 relative to the vasodilator prostaglandin prostacyclin. Because the pulmonary endothelium is a site of synthesis and/or metabolism of many vasoactive mediators such as prostaglandins, it is possible that endothelial cell injury or dysfunction may cause or perpetuate pulmonary hypertension. In support of this idea, reduced expression of endothelial cell nitric oxide synthase has been reported in lungs of patients with pulmonary hypertension. This enzyme is responsible for synthesis of the potent vasodilator nitric oxide, also known as endothelial cell-derived relaxing factor. Similarly, enhanced expression of the potent vasoconstrictor endothelin-1 has been reported in pulmonary arterial endothelial cells in lungs of patients with pulmonary hypertension. However, it is not clear at this time whether changes in vasoactive mediator balance are primary

causes of or responses to abnormalities in pulmonary vascular tone.

Another potential cause of abnormal pulmonary vascular tone is enhanced responsiveness of vascular smooth muscle to vasoactive substances. Evidence in support of this idea comes from animal studies that show changes in pulmonary vascular reactivity after lung injuries. Depending on the cause of injury, vasoreactivity may be increased or decreased. In addition, patients with acute lung injuries, such as the adult respiratory distress syndrome, may have increased pulmonary vascular tone. Causes of pulmonary vascular smooth muscle dysfunction are not clear, but direct effects of cytokines and oxidants have been demonstrated *in vitro.*

The most important physiological stimulus for pulmonary vasoconstriction is the acute hypoxic pressor response. Diseases that cause alveolar hypoxia are characterized by vasoconstriction, which is at least partially ameliorated by administration of oxygen. As noted in the previous chapter, the site of acute hypoxic vasoconstriction is the precapillary arteriole. The mechanism of hypoxic vasoconstriction is not known. The magnitude of hypoxic vasoconstriction is enhanced by acidosis, which may be important in lung diseases characterized by hypoventilation and respiratory acidosis. There is significant variability among individuals in the magnitude of hypoxic vasoconstriction. This variation, which may be genetic in origin, may explain differences in the degree of pulmonary hypertension complicating lung diseases.

PATHOPHYSIOLOGY OF PULMONARY VASCULAR REMODELING

In 1958, Heath and Edwards described a histologic classification of vascular changes associated with pulmonary hypertension, encompassing a progression of changes from grade 1 to 6 (Table 2). These grades represent a continuum of abnormalities, with grade 1 being the most potentially reversible and grade 6 least likely to be reversible. Examples of these changes are illustrated in Fig. 3 and Plate 1 and Plate 2. In 1973, the World Health Organization proposed that causes of pulmonary hypertension could be characterized by distinct pathologic patterns—plexogenic pulmonary arteriopathy, thrombotic pulmonary arteriopathy, and pulmonary venoocclusive disease. It has subsequently been learned that there is considerable overlap among these pathologic patterns in given diseases. Indeed, it is not possible to diagnose a given cause of pulmonary hypertension with certainty from the pathologic pattern alone.

Grade	Pathology	Cause
I	Medial hypertrophy	Chronic hypoxia
II	Cellular intimal proliferation	Venous hypertension
III	Luminal occlusion caused by intimal hyperplasia ("onionskinning")	Primary PH
IV	Angiomatoid formation ("plexiform lesion")	Primary PH
V	Fibrinoid necrosis	Vasculitis

The pioneering work of Lynne Reid and her associates has yielded important insights into the pathogenesis of pulmonary hypertension based on pathologic studies of

human diseases and on studies of the pathogenesis of animal models of pulmonary hypertension. These investigators have shown that the process of pulmonary vascular remodeling results in restriction of the pulmonary vascular bed and consequent pulmonary hypertension, as noted above. Examples of causes of pulmonary vascular remodeling include chronic hypoxia; sustained increased blood flow, such as that caused by congenital right-to-left intracardiac shunts; and repeated endothelial cell injury. There are some differences among models and diseases in the degree of endothelial cell injury, inflammatory reactions, and patterns of muscle hypertrophy. However, the process of remodeling is strikingly similar regardless of the inciting stimulus, suggesting a stereotypic response to vascular injury. The best studied of the experimental models of remodeling is the response to chronic hypoxia.

Unlike large vessel atheromata in the systemic circulation, remodeling of the pulmonary vasculature occurs primarily in microvessels (<500 µm diameter). Restriction is caused both by reduction in vessel number and by wall thickening that encroaches on the vascular lumen. Each of the cell types of the vascular wall can participate in the process. Endothelial cell swelling, necrosis, or hypertrophy may narrow the vascular lumen (Color Plate 1A). In addition, endothelial cells may direct the synthesis of noncellular matrix with ensuing increases in intimal thickness (Color Plate 1C). Smooth muscle cell hypertrophy and hyperplasia are seen (Color Plate 1B). A very important role of vascular smooth muscle is the synthesis of matrix material, such as elastin, which contributes to hypertrophy of vascular media. In precapillary segments, hypertrophy and hyperplasia of pericytes and intermediate cells cause vascular narrowing. These cells may also undergo phenotype shifts toward smooth muscle cells with characteristic changes in contractile and synthetic properties. Adventitial fibroblasts undergo hyperplasia and markedly increase collagen production, resulting in dramatic increases in adventitial thickness (Color Plate 1B), which may impair responsiveness to vasodilators.

The mechanism of pulmonary vascular remodeling is a subject of intense research interest. It is thought that enhanced vasoconstriction may predispose to remodeling, perhaps stimulated by changes in shear forces. Growth factors, such as transforming growth factor-b (TGF-b), are involved in modulation of extracellular matrix production. Endothelial cell injury may be an important stimulus to the remodeling response. Hypoxia may play a direct role by stimulating production of other cytokines, such as vascular endothelial growth factor. Reduced production of inhibitors of vascular cell replication and synthetic functions may also be important. An example of such an inhibitory substance is endothelial cell-derived heparan sulfate. Inflammatory cells may contribute to remodeling by producing cytokines and growth factors, which, in turn, stimulate vascular smooth muscle cell replication. Emerging understanding of the genetic regulation of vascular cell replication and phenotype holds the promise of therapies that may delay or prevent vascular remodeling.

Perpetuation of structural changes, continued cell replication, and matrix accumulation suggest that control of normal reparative processes may be impaired in the process of vascular remodeling. The role of processes that cause involution of tissue, such as apoptosis (programmed cell death) or proteolysis of extracellular matrix, is not known at this time.

CLINICAL SYNDROMES OF PULMONARY HYPERTENSION

Clinical syndromes of pulmonary hypertension may be classified as those that primarily alter the pulmonary blood vessels and those that are secondary to underlying heart or lung diseases.

DISEASES OF THE PULMONARY BLOOD VESSELS

Diseases that primarily affect the pulmonary arteries include primary pulmonary hypertension, AIDS-related pulmonary hypertension, pulmonary vasculitides, and thromboembolic pulmonary hypertension. Pulmonary venoocclusive disease is probably a disease of both pre- and postcapillary vessels, distinguished by involvement of the pulmonary veins. We describe primary pulmonary hypertension in detail because it provides a useful background for consideration of the other pulmonary vascular diseases and pulmonary hypertension secondary to underlying heart or lung diseases.

PRIMARY PULMONARY HYPERTENSION

Definition

Primary pulmonary hypertension is a clinical syndrome of pulmonary hypertension that progresses rapidly to right ventricular failure and death. Primary pulmonary hypertension (PPH) is also known as unexplained or idiopathic pulmonary hypertension to distinguish this disorder from other syndromes of pulmonary hypertension that arise from underlying heart or lung diseases or are clearly complications of clotting or other systemic diseases, such as collagen vascular diseases. The diagnosis of PPH is based on the presence of clinical manifestations of pulmonary hypertension, demonstration of pulmonary hypertension by direct measurement of pulmonary artery pressure and vascular resistance, and exclusion of causes of secondary pulmonary hypertension. Although PPH is not a common disease, it is important to understand because the pathophysiology, signs, and symptoms are characteristic of pulmonary vascular disease *per se* and not of other underlying disorders. Primary pulmonary hypertension was first described by Dresdale in 1951; detailed pathologic descriptions were provided by Wagenvoort and Wagenvoort in 1970; and in 1973, the World Health Organization described three major pathologic types of disease. The Primary Pulmonary Hypertension Registry of the NHLBI collected important data on the natural history and prognosis of PPH in the 1980s. Since the advent of lung transplant for therapy of PPH and the application in the 1990s of molecular biological approaches to identification of potential mediators of the disease, additional information regarding pathology and pathogenesis has accumulated. However, knowledge of pathogenesis is still primitive. Indeed, it is likely that what is now called PPH is a clinical syndrome secondary to multiple diseases of distinct etiologies that can be recognized only at an end stage in the pathogenetic sequence because of lack of an easily applicable screening test for early diagnosis.

Demographics of Patients with PPH

The frequency of diagnosis of PPH among patients undergoing right heart catheterization has been reported to be about 1%; thus, PPH is probably not a common disease in the general population. The disease is generally considered to be a disease of younger people, with greatest incidence between the ages of 20 and 45 years. However, PPH has been reported among the elderly (age >65 years). It is particularly difficult to diagnose in older age groups because of the increased incidence of potentially confounding intercurrent heart or lung diseases. Thus, the diagnosis of PPH may be delayed in these individuals while other, more common disorders, such as coronary artery disease or COPD, are treated. In the PPH Patient Registry, the ratio of women to men was 1.7:1 regardless of age at diagnosis.

Pathology

The PPH Registry sponsored by the NHLBI investigated the pathology of 38 cases meeting clinical criteria for the diagnosis of PPH, with 33 patients exhibiting primary pulmonary arteriopathy and five exhibiting pulmonary venoocclusive disease in addition to arterial lesions. Among the histologic patterns observed in the 33 cases of pulmonary arteriopathy were plexiform lesions (Plate 1D), thrombotic lesions, medial hypertrophy with intimal fibrosis (Plate 1C), and isolated medial hypertrophy (Plate 1B). Thus, the vascular lumina were narrowed by both intimal and medial changes. These results and the work of preceding investigators suggest that *in situ* or embolic thromboses contribute to remodeling of the pulmonary circulation in PPH. In addition, the association of venoocclusive changes with pulmonary arteriopathy suggests that venoocclusive disease may be a syndrome resulting from multiple injuries to the entire pulmonary vascular tree rather than a single disease that primarily affects the pulmonary veins (see below).

Subsequent pathologic studies of lungs of patients undergoing lung transplantation for treatment of PPH have revealed increases in adventitial thickness, increased expression of mRNA of the connective tissue proteins collagen and elastin, and foci of inflammation associated with plexiform lesions. Thus, pathologic studies suggest that the pathogenesis of PPH involves sustained cell proliferation, extracellular matrix protein production, inflammation, and thrombosis.

Pathogenesis

Table 3 lists some of the disorders or conditions associated with PPH, which range from familial causes to exogenous toxins, such as the appetite supressant fenfluramine. It is evident that PPH is a heterogeneous group of disorders of differing pathogenetic sequences, culminating in the recognizable clinical syndrome. There are several factors that play a role in the pathogenesis of PPH. These factors include genetic predisposition, endothelial cell dysfunction, abnormalities in vasomotor control, thrombotic obliteration of vascular lumen, and vascular remodeling through cell proliferation and matrix production. This complex interaction is illustrated in Fig. 4. It is important to note that PPH likely results from both inherited and acquired conditions.

Familial
Menarche
Pregnancy
Autoimmune phenomena, e.g., Raynaud's phenomenon, positive antinuclear antibody
Hepatic cirrhosis
Appetite suppressants, e.g., aminorex, fenfluramine
Crack cocaine inhalation
Toxic oil (rapeseed oil) syndrome
HIV infection

TABLE 3. *Conditions associated with primarypulmonary hypertension*

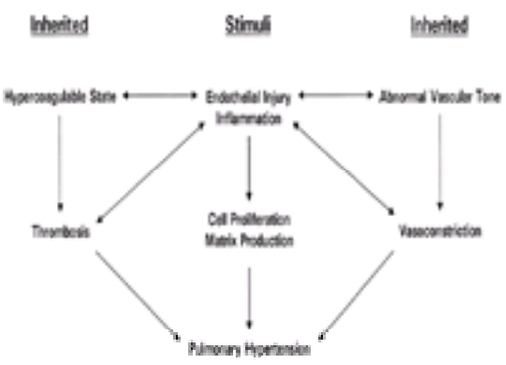

FIG. 4. Inherited and acquired factors that are likely to be important in the pathogenesis of PPH.

Not all individuals with associated disorders, such as hepatic cirrhosis, develop PPH. Thus, there may be inherited abnormalities of the pulmonary circulation that predispose to the development of PPH. In support of this contention, families have been described in which PPH occurs in an autosomal dominant pattern with a 2:1 female:male ratio but with differing degrees of disease expression. In addition, associations have been described among familial cases of PPH, autoantibodies, and major histocompatibility (MHC) loci, suggesting that some cases of familial PPH may be caused by inherited autoimmune causes. Thus, the search is ongoing for as yet unidentified gene(s) causing familial PPH.

As noted above, reports have been published of changes in endothelial cell expression of vasoactive mediators, such as nitric oxide, endothelin-1, and prostacyclin/thromboxane A_2, in patients with pulmonary hypertension, including patients with primary pulmonary hypertension. This has led to the hypothesis that PPH might originate as an endothelial cell injury. In support of this idea, animal models of PPH, such as that caused by monocrotoline, are characterized by endothelial cell dysfunction early in the course of injury. Furthermore, other animal models of repeated endothelial cell injury, such as that related to a-naphthylthiourea, ultimately cause sustained pulmonary hypertension. However, similar changes in endothelial cell-derived vasoactive mediators have been reported in patients with secondary pulmonary hypertension. Thus, it is also possible that reported changes in endothelial cell-derived vasoactive mediators are not causes of pulmonary hypertension *per se* but are markers of some other, underlying, more fundamental abnormality.

Changes in vasomotor tone and vascular reactivity are thought to occur in patients with PPH and to contribute to constriction of the pulmonary vascular bed. In support of this, there have been numerous reports of decreases in pulmonary vascular resistance in PPH in response to pharmacologic vasodilators, which provides the rationale for vasodilator therapy. However, not all patients with PPH respond to vasodilators. It is possible that these “nonresponsive” patients represent a more advanced stage of disease and/or that vascular remodeling has progressed to the point that their vessels are no longer capable of vasodilator responses.

As noted, above, pathologic studies of PPH have shown that thrombosis of pulmonary arteries is a frequent finding. Thus, it is likely that *in situ* thrombosis is an important contributor to pulmonary hypertension in this disease. In support of this, there have been reports of prothrombotic conditions in patients with PPH that may have been inherited or acquired. In addition, anticoagulant therapy may improve the prognosis of PPH.

Finally, vascular remodeling and subsequent restriction of the pulmonary vascular cross-sectional luminal area are a cause of pulmonary hypertension in PPH. The cause of remodeling is not known and likely differs among the various etiologies of PPH. Studies in animal models suggest that endothelial cell dysfunction may play a role. The presence of perivascular inflammatory cell foci in lungs of patients with PPH suggests that inflammation and inflammatory mediators, such as cytokines and oxidants, are also potential causes or perpetuators of the remodeling response.

Clinical Presentation of PPH

The PPH Patient Registry of the NHLBI has provided important information regarding the clinical presentation and natural history of PPH. Dyspnea was the most common presenting symptom, being noted in 60% of patients. Less commonly encountered symptoms were fatigue, chest pain, syncope, leg edema, and palpitations. At the time of diagnosis, the functional class of patients varied from NYHA Class II to severely disabled Class IV. The average time between onset of symptoms and diagnosis was 2 years.

The physical examination of patients with PPH is similar to that of patients with pulmonary hypertension of other causes. Signs of right heart strain and/or failure may be observed, including RV parasternal heaves, right-sided third and fourth heart sounds, tricuspid regurgitant murmurs, and pulmonary ejection and regurgitant murmurs.

The chest roentgenogram (Fig. 5) typically reveals enlargement of the main and hilar pulmonary arteries. A diameter of the right lower lobe pulmonary artery >17 mm is diagnostic of pulmonary hypertension. Pruning of the peripheral vasculature is common. The lung parenchyma is free of infiltrates in primary pulmonary hypertension, as contrasted with pulmonary hypertension secondary to interstitial lung disease. Right ventricular enlargement may be observed when the right ventricle occupies more than one-third of the retrosternal space on the lateral chest x-ray.

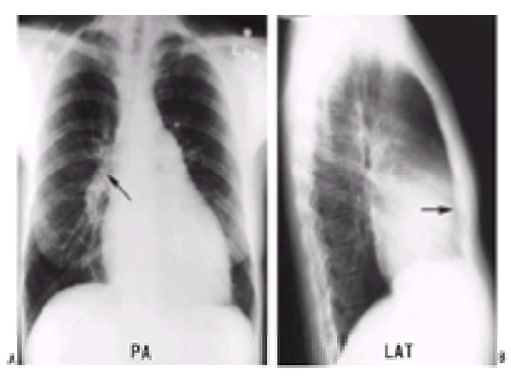

FIG. 5. Chest radiograph of a 47-year-old woman with idiopathic pulmonary hypertension (P_{pa} = 104/40 mm Hg). The hilar vessels *(arrow)* are enlarged on the posteroanterior (PA) view, and there is relative oligemia in the lung periphery. The heart is enlarged, and on the lateral (LAT) view there is filling of the retrosternal air space, indicating right ventricular enlargement.

In most patients, the electrocardiogram shows signs of right heart strain or enlargement, including right axis deviation, right ventricular hypertrophy, and right atrial enlargement. Although atrial fibrillation and other supraventricular tachyarrhythmias are common among patients with cor pulmonale secondary to lung disease, atrial fibrillation was not reported among patients admitted to the PPH Patient Registry.

An echocardiogram showed right ventricular enlargement in 75% of patients, although left ventricular dimensions were normal. Paradoxic septal motion and partial systolic closure of the pulmonic valve are other commonly observed echocardiographic abnormalities. However, some patients may not have signs of pulmonary hypertension on chest x-ray, ECG, or echocardiogram. Thus, these tests are relatively insensitive diagnostic tools. Echocardiography is also important in excluding other causes of pulmonary hypertension, such as mitral stenosis. Transesophageal echocardiography is useful in excluding atrial septal defect as a cause of flow-induced pulmonary hypertension. In addition, Doppler echocardiography may be used to estimate pulmonary artery pressure noninvasively when there is a regurgitant tricuspid jet.

Pulmonary function tests in patients with PPH may be normal but commonly reveal mild restrictive defects and decreases in the diffusing capacity for carbon monoxide. The changes in diffusing capacity may reflect obliteration of pulmonary microvessels by the remodeling process. The critical role of pulmonary function tests is to exclude significant obstructive or restrictive lung disease.

Arterial blood gases typically show mild to moderate arterial hypoxemia and respiratory alkalosis. The hypoxemia is caused by ventilation–perfusion mismatching and a small degree of right-to-left shunt, exacerbated by decreased cardiac output and mixed venous hypoxemia. Some patients may display more significant hypoxemia because of right-to-left shunting through a patent foramen ovale.

Positive tests of “autoimmunity,” such as antinuclear antibodies and rheumatoid factor, and the presence of Raynaud's phenomenon may be observed in patients with PPH. In the PPH Registry, 29% of patients had positive antinuclear antibody tests. These findings suggest an “autoimmune” pathogenesis for at least some cases of PPH.

Perfusion lung scans may be normal or may reveal diffuse patchy areas of decreased perfusion in patients with PPH. The presence of lobar or segmental abnormalities in lung scans suggests major vessel thromboembolism and should prompt further diagnostic investigation for that disorder, such as performance of pulmonary arteriograms.

Hemodynamic Features

Right heart catheterization is necessary for the definitive diagnosis of PPH. Patients in the PPH Patient Registry had severe pulmonary hypertension with increased mean pulmonary artery pressure (60 ± 18 mmHg, range 28 to 127 mmHg), mild to moderate increases in right atrial pressures (9 ± 6 mmHg, range 0 to 29 mmHg), and mildly reduced cardiac indices (2.27 ± 0.9 L/min per m^2, range 0.8 to 7.9 L/min per m^2). Pulmonary capillary wedge pressures were, by definition, normal.

Approach to Diagnosis

The diagnosis of PPH depends on exclusion of other disorders that may secondarily cause pulmonary hypertension. The general approach to diagnosis of the cause of pulmonary hypertension is outlined in Fig. 6.

FIG. 6. This schema illustrates the steps in diagnosis of PPH.

The clinical suspicion of PPH is raised by symptoms of dyspnea on exertion in the absence of other known underlying heart or lung diseases. Physical examination may suggest the presence of pulmonary hypertension by increased intensity of the pulmonic component of the second heart sound or by findings suggestive of right ventricular strain or failure. However, it should be noted that in early cases of PPH, these findings may not be present.

Chest x-ray is important in screening for infiltrative lung diseases and hyperinflation suggestive of COPD. High-resolution chest computed tomography may be useful in screening for occult interstitial lung diseases. Pulmonary function tests are important to exclude moderate or severe degrees of lung restriction or airways obstruction. Arterial blood gas analysis is useful to screen for hypoventilation and hypoxemia as causes of secondary pulmonary hypertension. Oxygen saturation during sleep may be necessary to exclude obstructive sleep apnea.

Echocardiography should be done to exclude mitral valvular disease and to assess RV and LV function. An ECG is useful to assess for signs of RV hypertrophy.

A ventilation–perfusion lung scan should be done to exclude major vessel thromboembolism. In some cases, pulmonary arteriography may be necessary to exclude chronic thromboembolism syndrome as a cause of pulmonary hypertension (see below). Although complications of arteriography are said to be increased in patients with pulmonary hypertension, if the procedure is performed with care by experienced operators, pulmonary hypertension *per se* is not a contraindication.

Right heart catheterization is necessary to confirm the diagnosis of primary pulmonary hypertension and to obtain important prognostic data—right atrial pressure and cardiac index. During catheterization, samples of blood from the superior vena cava, right atrium, right ventricle, and main pulmonary artery should be obtained for measurement of oxygen saturation to exclude left-to-right intracardiac shunting as a cause of pulmonary hypertension. A normal pulmonary capillary wedge pressure measurement excludes left ventricular failure as a cause of pulmonary hypertension.

In some patients, open lung biopsy may be necessary to exclude occult interstitial lung disease or pulmonary vasculitis or to confirm the presence of venoocclusive disease.

Finally, it is useful to obtain exercise studies in order to assess response to treatment in individuals with PPH. The 6-min walk is a simple and useful test, with measurement of the duration and distance of walking as well as changes in oxygen saturation with exercise.

Management of PPH

The pathology of PPH suggests possible areas for therapeutic intervention. The presence of *in situ* thromboses may certainly exacerbate and perpetuate increases in pulmonary vascular resistance. Indeed, a retrospective study suggested that mortality was improved in individuals treated with oral anticoagulation. In addition, mortality was improved in nonresponders to vasodilator therapy who were treated with oral warfarin. Thus, it seems reasonable to treat PPH with warfarin. Animal studies suggest that anticoagulant therapy with heparin-based agents may be more effective in that heparin may inhibit proliferation of medial vascular smooth muscle hypertrophy. However, variability in effectiveness of the antiproliferative properties of heparin preparations precludes routine use of these agents at this time.

Although moderate degrees of hypoxemia have been reported in patients with PPH, there are no firm data that oxygen therapy improves survival with PPH. However, hypoxia may exacerbate pulmonary hypertension via hypoxic vasoconstriction, and hypoxemia is associated with cardiac arrhythmias. Chronic hypoxemia can further exacerbate pulmonary hypertension via secondary erythrocytosis and vascular remodeling. Thus, hypoxemic patients with PPH should be given low-flow oxygen

therapy according to guidelines developed for patients with COPD (see Chapter 43).

Treatment of right heart failure is aimed at relieving symptoms. Diuretics may relieve peripheral edema and hepatic congestion. One should be careful to avoid development of metabolic alkalosis, which could depress ventilation and thereby exacerbate hypoxemia. In addition, because right ventricular function is highly dependent on preload, care must be taken to avoid excessive diuresis and decreased venous return to the right ventricle, with resultant decreased cardiac output and loss of responsiveness to vasodilators. Digitalis is not likely to be of benefit because of potential pulmonary vasoconstrictor effects.

The rationale for vasodilator therapy in PPH is the presence of potentially reversible vasoconstriction as an important cause of pulmonary hypertension. Even small reductions in right ventricular afterload might substantially improve RV output. Vasodilators decrease pulmonary arterial pressures and increase cardiac output in many patients with PPH. In the 1980s there was considerable interest in defining vasodilator responsiveness as a measure of severity and reversibility of PPH and interest in potential long-term beneficial effects of vasodilator therapy. Because all available vasodilators are effective in both the systemic and pulmonary circulations, a problem in vasodilator use has been the frequent complication of systemic hypotension. In addition, most vasodilators increase cardiac output with only mild decreases in pulmonary arterial pressures. Thus, definition of vasodilator effectiveness is problematic—both calculated pulmonary vascular resistance (see Fig. 1) and pulmonary arterial pressures have been used. We favor the conservative approach of defining a vasodilator response as a greater than 30% decrease in calculated pulmonary vascular resistance combined with a greater than 10% decrease in mean pulmonary arterial pressure. The PPH Patient Registry found that about one-third of patients undergoing vasodilator trials had both an increase in cardiac output and a decrease in mean pulmonary arterial pressure, whereas more than half had a decrease in total pulmonary resistance alone.

Some investigators have reported that acute vasodilator-induced decreases in pulmonary vascular resistance are associated with improved survival in PPH. However, long-term therapy with vasodilators was not associated with improved survival among patients in the PPH Registry.

More recent studies have suggested that long-term therapy with high doses of calcium blockers (nifedipine or diltiazem) or continuous infusions of epoprostenol (also called prostacyclin or prostaglandin I_2) may be associated with improved survival. In addition, 12 weeks of continous infusion of epoprostenol improved hemodynamics, symptoms of dyspnea, exercise capacity, and survival in patients with PPH, as compared to patients treated with “conventional therapy.” Thus, there may be a role for vasodilators in relieving symptoms and maintaining patients who are awaiting heart–lung transplantation. Vasodilator therapy should be instituted only after drug effectiveness and safety have been confirmed with right heart catheterization.

Continuous intravenous infusion of epoprostenol currently offers the most effective and best-studied mode of vasodilator therapy. However, infusional therapy is not without complications, mostly related to catheters, such as sepsis, thrombosis, and acute dyspnea associated with interruption of infusion. Other modes of vasodilator delivery may also prove effective, such as inhaled NO or aerosolized epoprostenol.

Heart–lung transplantation or single-lung transplantation offers the best hope for long-term therapy for PPH at this time. Unfortunately, limited donor organs make this therapy unavailable to many patients with PPH. It is reasonable to explore this option if clinical deterioration occurs or if hemodynamic parameters suggest a poor prognosis. However, optimism regarding transplantation must be tempered with recognition of complications of rejection and the potential for recurrence of primary pulmonary hypertension in the transplanted lung.

Survival and Prognosis

Median survival of patients in the PPH Registry was 2.8 years, with 34% of patients alive after 5 years. Thus, PPH is a disease with a poor prognosis.

Several factors were associated with poor survival. Mortality correlated best with measures of right ventricular hemodynamic function. Mean pulmonary arterial pressures over 85 mmHg, mean right atrial pressures over 20 mmHg, and cardiac indices less than 2 liters/min per m^2 were associated with poor survival. Thus, the presence of right ventricular failure indicated a poor prognosis. Accordingly, the risk of death was higher among patients with NYHA functional Class III or IV than among those with Class I or II function at the time of diagnosis. Indeed, survival was only 6 months for those with Class IV function.

Interestingly, the presence of Raynaud's phenomenon was associated with a worse prognosis for unclear reasons. In addition, decreased diffusing capacity also correlated with increased risk of mortality. Recent short-term studies suggest that drug therapy with intravenous infusions of epoprostenol may improve survival (3-month follow-up).

The most frequent causes of death in patients with PPH are progressive right ventricular failure and sudden death. Pneumonia is often fatal because alveolar hypoxia may cause pulmonary vasoconstriction and exacerbate pulmonary hypertension, with resulting inadequate cardiac output and cardiogenic shock. Some possible mechanisms for sudden death in PPH include bradyarrhythmias and tachyarrhythmias, acute pulmonary embolus, pulmonary hemorrhage, and sudden right ventricular ischemia.

PULMONARY HYPERTENSION ASSOCIATED WITH CONNECTIVE TISSUE DISEASE

Pulmonary hypertension may be associated with several connective tissue disorders, including scleroderma, mixed connective tissue disease, systemic lupus erythematosus, and rheumatoid arthritis. The incidence of pulmonary hypertension varies significantly among connective tissue disorders, but when it occurs, it may be devastating. In these disorders, pulmonary hypertension may occur in association with concomitant lung parenchymal disease, but it is also frequently observed in the absence of significant parenchymal lung disease.

As noted above, there is overlap between primary pulmonary hypertension and pulmonary hypertension associated with connective tissue disease. Female preponderance, similar symptoms on presentation (dyspnea and fatigue), and the frequent presence of restrictive changes in lung volumes, sometimes in the presence of a normal chest x-ray, are findings shared by both groups of patients. Raynaud's phenomenon and elevated rheumatoid factor and ANA titers are also frequently observed in both groups of patients. Despite these similarities, there are notable clinical differences between PPH and pulmonary hypertension associated with connective tissue disease. Patients with connective tissue disease and pulmonary hypertension tend to be older women and to have a much higher incidence of Raynaud's phenomenon. Pulmonary function tests may demonstrate the presence of more severe restrictive disease in patients with connective tissue disease who have concomitant pulmonary parenchymal disease.

Pathology

In addition to the clinical overlap noted above, the connective tissue disease disorders and primary pulmonary hypertension also show similar pathologies. Plexogenic arteriopathy is observed in both groups, suggesting a similar underlying pathogenesis. Intravascular thrombosis, possibly secondary to a hypercoagulable state, may contribute to pulmonary hypertension. An example of such a hypercoagulable state is the presence of circulating antiphospholipid antibodies. Vasculitis, with inflammatory cell infiltrate, has been reported in patients with pulmonary hypertension complicating SLE.

Pathogenesis

The pathology of pulmonary hypertension associated with connective tissue diseases suggests that restriction of the pulmonary circulation by remodeling and obstruction of the microvessels by thromboses are important in its development. Acute hypoxic vasoconstriction and compression of pulmonary vessels by abnormal lung parenchyma may also contribute to the magnitude of the pulmonary hypertension. Responsiveness to vasodilators and spontaneous fluctuation in levels of pulmonary hypertension in some patients suggest that vasoconstriction may also contribute to increased pulmonary vascular resistance.

There is little information available concerning the precise mechanisms of pulmonary hypertension at the cellular level. Elevated plasma levels of endothelin-1 in scleroderma suggest that this potent vasoconstrictor may contribute to pulmonary hypertension in that vasospastic disorder. Circulating anti-endothelial-cell antibodies have been reported in SLE complicated by pulmonary hypertension, suggesting an immunologic pathogenesis. Circulating factors that are toxic to endothelial cells have been reported in scleroderma.

Clinical Presentation

In general, the different connective tissue diseases have similar clinical presentations of pulmonary hypertension. Dyspnea is the most common symptom. Immunologic evaluation is not helpful in distinguishing which patients have pulmonary hypertension or will subsequently develop the condition. Right ventricular enlargement and prominent pulmonary arteries on chest x-ray and ECG findings of right axis deviation and right ventricular hypertrophy may suggest pulmonary hypertension. A severe decrease in diffusing capacity should raise the suspicion of pulmonary hypertension.

Features of Specific Disorders

Scleroderma is the connective tissue disorder in which pulmonary involvement is most frequent and pulmonary hypertension is most commonly observed. Although the exact incidence is not known, clinical studies have demonstrated that in patients with scleroderma undergoing right heart catheterization, the frequency of pulmonary hypertension is approximately 50%. The development of severe pulmonary hypertension culminating in cor pulmonale and death is highest in the CREST variant of scleroderma. The most common pulmonary parenchymal manifestation in this disease is interstitial fibrosis, but the magnitude of the pulmonary hypertension does not correlate well with the degree of fibrosis. In fact, again most notably in the CREST variant, patients may die of malignant pulmonary hypertension without significant pulmonary fibrosis. In accord with the high incidence of pulmonary hypertension by cardiac catheterization, pulmonary vascular pathology is frequently found on pathologic examination. Interestingly, there is a notable absence of plexogenic arteriopathy in the lungs of patients with scleroderma and pulmonary hypertension. This is in contrast with the findings in other connective tissue diseases, which are more similar to those of primary pulmonary hypertension. Endothelial cell injury, intimal and medial cell proliferation, and fibrosis of small arteries and arterioles are the major pathologic lesions. Vasculitis is unusual.

Several studies have confirmed that pulmonary vasoconstriction occurs when the hands of scleroderma patients are immersed in cold water. This has been described as Raynaud's phenomenon of the pulmonary vasculature and is additional evidence of a generalized disorder of vasospasm in these patients.

Mixed connective tissue disease is a syndrome consisting of features of systemic lupus erythematosus, scleroderma, Sjögren's syndrome, and polymyositis. Involvement of the respiratory system in this syndrome occurs in the majority of patients (82%). Pulmonary hypertension and cor pulmonale occur infrequently but are well described and may dominate the clinical course, leading to a fatal outcome. Although pulmonary function tests commonly suggest the presence of interstitial lung disease, pulmonary vasculopathy is typically more prominent than interstitial disease on pathologic examination of lung tissue. This vasculopathy is characterized by intimal thickening and medial hypertrophy of pulmonary arteries and arterioles and the presence of plexiform lesions.

Systemic lupus erythematosus (SLE) involves the respiratory system in 50% to 70% of patients, but the incidence of pulmonary hypertension is significantly lower, ranging from rare to »14%. Noninvasive measurement of pulmonary arterial pressures by repeated Doppler echocardiography studies in patients with SLE suggests that the prevalence of pulmonary hypertension may increase with time after diagnosis of SLE to as high as 43%. When pulmonary hypertension is present, it tends to be mild, with pulmonary artery systolic pressures generally less than 40 mmHg. The pathologic features include intimal and medial hypertrophy and plexiform lesions in more advanced cases. Vasculitis is unusual. The frequent association of antiphospholipid syndrome and SLE suggests that microvascular thrombosis may be an important cause of pulmonary hypertension in SLE.

Rheumatoid arthritis and polymyositis/dermatomyositis may also be complicated by pulmonary hypertension.

Diagnosis

Although decreased diffusing capacity is a sensitive pulmonary function test marker for the presence of pulmonary vascular disease, it is also a nonspecific marker because it may be abnormal in the presence of parenchymal lung disease without a pulmonary vascular component. Because it may be difficult to determine the presence and severity of pulmonary hypertension by clinical assessment and noninvasive laboratory testing alone, right heart catheterization is usually required for definitive diagnosis. However, because there is little evidence for beneficial effects of vasodilator therapy, it is difficult to justify invasive testing merely to document the presence of pulmonary hypertension. Doppler echocardiography is useful as a noninvasive means of estimating pulmonary arterial pressure in patients with regurgitant tricuspid jets.

Treatment

Pulmonary hypertension associated with connective tissue disorders does not typically respond to vasodilator therapy. However, a recent report documented a significant acute vasodilator response to the combination of oxygen and diltiazem administration in a patient with mixed connective tissue disease. Significant beneficial effects were achieved without major adverse side effects and were sustained over 1 year of follow-up. This approach with combined therapy warrants further investigation. Beneficial effects of therapy with corticosteroids and other forms of immunosupressive therapy in isolated case reports suggest some hopeful avenues for future clinical research. Patients with antiphospholipid antibodies and pulmonary hypertension should be treated with anticoagulation, and consideration should be given to plasmapheresis and immunosuppressive therapy as well.

In view of limited evidence of documented efficacy of most approaches to treatment of pulmonary hypertension associated with connective tissue disease, it is important to determine the response to supplemental oxygen administration in individual patients. The contribution of acute hypoxic vasoconstriction to pulmonary hypertension is sometimes difficult to determine from the clinical features alone. This was underscored by recent findings of a substantial reduction in pulmonary artery pressure and resistance following administration of oxygen in patients with scleroderma. These patients were found to have a significant vasodilatory response to oxygen administration compared to the patients with primary pulmonary hypertension, who demonstrated no response to oxygen administration.

PULMONARY HYPERTENSION ASSOCIATED WITH THROMBOEMBOLIC DISEASE

Acute pulmonary thromboembolism rarely causes significant pulmonary hypertension except in the case of massive embolism in which more than half of the pulmonary vascular bed is occluded. In patients with underlying pulmonary or cardiac disease, less vascular obstruction (30% occlusion) may be sufficient to cause pulmonary hypertension. The causes of acute pulmonary hypertension after thromboembolism include vascular obstruction, hypoxic vascoconstriction, and vasospasm caused by vasoactive mediators released from platelets. Most frequently, an embolized clot resolves within 3 weeks of the acute event, and acute thromboembolism rarely causes sustained pulmonary hypertension. The reader is referred to Chapter 66 for a more complete discussion of acute pulmonary thromboembolism.

However, in a minority (perhaps 2%) of patients with pulmonary thromboembolism, there may be repeated episodes of thromboemboli or failure of resolution of clot. These patients may progress to sustained pulmonary hypertension.

An interesting variant of thromboembolic pulmonary disease is chronic thromboembolic pulmonary hypertension (CTEPH). This disorder is characterized by incomplete resolution of proximal pulmonary arterial thrombotic obstruction, with residual recanalized clot and/or scarring. It is thought to result from undiagnosed (and therefore untreated) thromboemboli, with an estimated incidence of 0.5% of patients suffering an acute embolic event.

Pathology and Pathogenesis

Proximal pulmonary arteries are obstructed by fibrotic (“organized”) clot, which may extend to more peripheral vessels in a branching pattern. Pathologic studies of lung biopsies obtained at the time of thromboendarterectomy also revealed involvement of small pulmonary arteries, even in areas of lung unobstructed by proximal clot. The full range of pulmonary hypertensive lesions was demonstrated, including plexiform lesions. Thus, the development of sustained pulmonary hypertension in this disorder results from obstruction to flow in major arteries from proximal, incompletely resolved clot and also remodeling of small resistance arteries. How proximal obstruction causes vascular remodeling is not known.

The hemodynamic consequences of unresolved thromboembolic obstruction to the pulmonary vascular bed are increased pulmonary vascular resistance, leading to pulmonary hypertension and diminished right ventricular contractility. The specific consequences in an individual patient are dependent on the presence of preexisting cardiopulmonary disease.

Clinical Presentation

The clinical presentation of patients with chronic thromboembolic pulmonary hypertension is relatively nonspecific. Clinical suspicion may be raised by repeated episodes of acute thromboembolism, unexplained dyspnea, atrial fibrillation, syncope, or pulmonary hypertension. The presence of underlying cardiopulmonary disease is associated with a higher incidence of unresolved acute pulmonary emboli 1 year after an acute event.

Diagnosis
