The diagnosis of chronic thromboembolism must be confirmed with radionuclide ventilation–perfusion lung scans and pulmonary angiography. Ventilation–perfusion lung scans demonstrate at least segmental or larger mismatched defects. This is in contrast to primary pulmonary hypertension, in which ventilation–perfusion scans are normal or demonstrate only patchy, subsegmental defects. Angiographic findings include pouch defects, webbing, banding, and intimal irregularities. These are different from what is most often observed with acute thromboembolic obstruction of the pulmonary circulation, and it is therefore helpful to alert the angiographer of the clinical suspicion of CTEPH. Performance of angiography in the setting of increased pulmonary artery pressure is reasonably safe if only small amounts of nonionic

contrast material and/or selective angiographic injections are used to minimize dye load. This is particularly important in patients with right ventricular failure, which is a recognized risk factor for sudden death during angiography.

Treatment

The clinical importance of recognizing CTEPH is that pulmonary thromboendarterectomy can produce dramatic improvement in hemodynamics and functional status in selected patients. Patients in New York Heart Association functional Class III or IV status can move to Class I or II following operative intervention. However, pulmonary thromboendarterectomy is a technically demanding procedure performed in only a small number of centers. Patients must be carefully selected for optimum results. Overall mortality from this procedure is as high as 10%, even in referral centers. Reperfusion pulmonary edema in areas of clot removal and pulmonary vascular steal (blood flow diversion to areas of lung opened after thromboendarterectomy) may cause postoperative hypoxemia.

All patients must be maintained on lifelong anticoagulant therapy, and some require vena cava interruption as well.

Other Causes of Embolic Obstruction of the Pulmonary Circulation

Schistosomiasis, sickle cell disease, and fat, tumor, and amniotic fluid embolism are other examples of embolic syndromes affecting the pulmonary vascular bed that may cause pulmonary hypertension.

Schistosomiasis is a common cause of pulmonary hypertension in endemic areas and among immigrant populations. Pulmonary hypertension results from a combination of physical obstruction to the pulmonary vascular bed and vasculitis caused by the immunologic response to the foreign protein of the parasite.

Sickle-cell disease and other *mixed hemoglobinopathies* (S-C disease, S-b-thalessemia) commonly involve the pulmonary circulation either acutely or on a chronic basis. The chronic pulmonary vascular manifestations of this disease are most commonly observed in individuals who are long-term survivors. These patients most frequently seek medical attention as a result of the development of the “acute chest syndrome” consisting of fever, pleuritic chest pain, dyspnea, leukocytosis, hypoxemia, and pulmonary infiltrates. Pulmonary vascular occlusions caused by *in situ* thromboses in the pulmonary microcirculation are a frequent component of this syndrome. Accurate differentiation of infection from pulmonary vascular occlusion and/or infarction may be difficult. Mild pulmonary hypertension in this setting may be related to volume overload as a secondary consequence of chronic anemia and changes in blood viscosity. Survivors of the acute chest syndrome may develop chronic pulmonary disease consisting of pulmonary fibrosis, pulmonary hypertension, and cor pulmonale because of the cumulative effects of pulmonary vascular occlusion. This obstructive vasculopathy is thought to be the end result of several key events, notably emboli of necrotic bone marrow, *in situ* thromboses, and endothelial cell damage. In addition to hydration and prompt treatment of infection, the key principle for management of the pulmonary vascular complications of sickle cell disease is maintenance of an adequate oxygen tension. Anticoagulants have no documented role in the management of the *in situ* pulmonary vascular occlusion in these disorders and may be dangerous because of increased risk of spontaneous bleeding in these patients. Exchange transfusions are often used to treat refractory life-threatening hypoxemia. Individuals with sickle trait rarely develop manifestations of pulmonary vascular complications, although anecdotal reports of an increased risk of sudden death during strenous exercise highlight the need for further work in this area.

Fat embolism is a syndrome of pulmonary microemboli of bone marrow occurring most commonly in the setting of trauma and fracture of the pelvic or long bones of the thigh. The pulmonary microvascular disease has been described as a “toxic vasculitis” secondary to the effects of circulating free fatty acids. Although pulmonary hypertension has been reported in these patients, typically gas-exchange (ARDS) and central nervous system abnormalities dominate the clinical picture and the management of this disorder. The same is true for amniotic fluid embolism seen after placental membrane rupture, spontaneous delivery, or cesarean section. Septic pulmonary emboli may complicate bacterial and nonbacterial sepsis but rarely produce clinically significant pulmonary hypertension requiring specific therapy.

Pulmonary granulomatosis associated with intravenous drug use is a syndrome that appears to be increasing in frequency and worldwide distribution. This syndrome is specifically seen in individuals who inject aqueous suspensions of medications intended for oral use. These suspensions contain insoluble materials such as talc that may lodge in the pulmonary microvessels. The lungs of these patients demonstrate the presence of a diffuse vascular and perivascular granulomatous reaction. There is variable occlusion of pulmonary vessels by thrombosis or fibrosis, and plexogenic arteriopathy may be observed in severe cases. Over time, there may be transvascular migration of the foreign body emboli with the formation of interstitial granulomas, interstitial fibrosis, and pulmonary hypertension. The initiating factor is thought to be endothelial injury induced by the foreign body microemboli, such as talc. Other substances, including cotton fibers, cornstarch, and cellulose may also play a role. Clinically, these patients present with progressive dyspnea, diffuse reticular-nodular infiltrates on chest x-ray, and either obstructive or restrictive changes in PFTs with a low diffusing capacity. Only a small percentage of patients with this syndrome go on to develop clinically significant pulmonary hypertension.

PULMONARY VENOOCCLUSIVE DISEASE

Pulmonary venoocclusive disease (PVOD) is an unusual disorder of unknown etiology that is characterized by clinical and pathologic evidence of occlusion of postcapillary veins and venules; it may account for about 10% of cases of pulmonary hypertension of unknown etiology. This idiopathic disorder occurs in children and young adults, but its rarity has hampered the study of its epidemiology and demographics.

Pathology

Pulmonary venoocclusive disease is characterized by organized and recanalized thrombi in pulmonary veins and venules with eccentric fibrosis of the intima and medial hypertrophy and arterialization of veins (Fig. 3 and Color Plate 2). Alveolar capillaries are congested with blood. There are findings consistent with long-standing hydrostatic pulmonary edema, such as lymphatic dilation and interstitial edema. Because precapillary arterioles may also demonstrate intimal fibrosis and fibrinoid necrosis of media, it is possible that this disease is actually a more generalized obstructive angiopathy.

Pathophysiology

Obstruction of the pulmonary venous system in venoocclusive disease increases pulmonary artery pressure and resistance in the absence of an elevation of left ventricular end-diastolic pressure. Passive increases in venous pressure, thrombotic obstruction of microvessels, and remodeling of pulmonary arteries all contribute to pulmonary hypertension in PVOD.

Clinical Presentation and Diagnosis

Patients usually present with dyspnea. The major clinical challenge is establishing the diagnosis of PVOD and distinguishing it from other, more common conditions. Pulmonary venoocclusive disease may simulate congestive heart failure with interstitial and alveolar edema and pulmonary vascular congestion on chest x-ray. The absence of distended upper lobe veins or left ventricular enlargement are important clues to the presence of PVOD as a cause of pulmonary edema. Other causes of pulmonary venous obstruction, such as fibrosing mediastinitis and congenital venous atresia or stenosis, should be excluded. In addition, it may be difficult to distinguish PVOD from primary pulmonary hypertension. In many patients with PVOD, pulmonary capillary wedge pressure is normal with elevated P_{pa}, suggesting that the site of obstruction is in venules rather than large veins. Finally, the presence of basilar rales and interstitial infiltrates on chest x-ray in some patients with PVOD may lead to an incorrect diagnosis of interstitial fibrosis. Because of these difficulties in distinguishing among these conditions, open lung biopsy is necessary to unequivocally diagnose PVOD.

Treatment

There is no documented effective treatment for PVOD. Uncontrolled case reports suggest that anticoagulants, aspirin, steroids, azathioprine, calcium channel blockers, or prostacylin may have some benefit. Vasodilators are probably not indicated in these patients. Pulmonary vasodilation in the presence of venous obstruction may cause an increased pulmonary blood volume and pulmonary microvascular pressures and the development of pulmonary edema.

In addition to the idiopathic form of pulmonary venoocclusive disease, there are sporadic reports of other clinical associations. An acquired variant of this disorder is drug-induced pulmonary vascular disease (e.g., caused by bleomycin, BCNU, or mitomycin) with typical findings of pulmonary venoocclusive disease on pathologic exam. Other reported clinical associations include bone marrow transplantation, malignancy, and an unexplained genetic predisposition for this disorder, suggested by the finding of documented cases of pulmonary venoocclusive disease in siblings.

PULMONARY HYPERTENSION ASSOCIATED WITH HIV INFECTION

Pulmonary hypertension was first reported as a complication of human immunodeficiency virus infection in 1987. Since then, over 50 patients have been reported with

this complication of HIV infection from all causes. The estimated incidence of pulmonary hypertension in patients with HIV infection (0.5%) is higher than the estimated incidence of primary pulmonary hypertension (0.02%) in the general population, suggesting that the viral infection itself is somehow causally linked to the development of pulmonary hypertension. A direct or indirect effect of the virus on either pulmonary arterial smooth muscle cells or endothelial cells has been postulated. However, no clear evidence of arterial wall infection with HIV virus has been found in a small number of carefully examined cases.

In a recent review of published reports, only 33% of patients with HIV-associated pulmonary hypertension had AIDS. Most patients are normoxic, and CD4 lymphocyte cell counts may be normal. Thus, the pulmonary hypertension is not caused by concomitant respiratory infections. Patients with HIV-associated pulmonary hypertension demonstrate pathologic changes similar to primary pulmonary hypertension, including plexigenic arteriopathy.

Comparison of the clinical characteristics of patients with HIV-associated pulmonary hypertension with those of patients with primary pulmonary hypertension has demonstrated very few distinguishing characteristics. Although the magnitude of the pulmonary hypertension may be less severe at the time of presentation in HIV-associated pulmonary hypertension, the presence of Raynaud's phenomenon and the percentage of patients who respond to vasodilator therapy appear to be similar in both groups. Overall survival is poor in both groups of patients. Because of these similarities, HIV testing should be considered in cases of PPH for which no other associated cause is evident.

There has not been sufficient therapeutic experience in patients with HIV-associated pulmonary hypertension to make any definitive recommendations. Obviously, hypoxemia and concomitant lung infections should be treated aggressively.

PULMONARY HYPERTENSION ASSOCIATED WITH CARDIAC DISEASE

In general, pulmonary hypertension associated with heart disease is caused by increased pulmonary venous pressure or by increased pulmonary blood flow, both of which passively increase pulmonary artery pressure (see Chapter 67). Increased vascular reactivity to vasoconstrictors may result from long-standing increased flow or pressure. Eventually, the pressure or flow abnormalities cause pulmonary vascular remodeling, which perpetuates increased vascular resistance by further narrowing the pulmonary arterial cross-sectional area. In addition, pulmonary thromboemboli may complicate low-flow states or the sedentary life style that may be associated with cardiac disease. Thus, several factors may contribute to pulmonary hypertension associated with heart diseases.

Left Ventricular Failure

Left ventricular failure is the most common form of pulmonary venous hypertension in both adults and children. Causes of left ventricular failure include coronary artery disease and cardiomyopathies.

Left ventricular failure passively increases pulmonary artery pressure because of altered pressure–flow relationships in the pulmonary circulation, which occur in stages. The first stage begins with an increase in left ventricular end-diastolic pressure, which increases pulmonary blood volume until the pulmonary vascular bed is fully recruited. At this point, any additional increase in left ventricular end-diastolic pressure will increase pulmonary artery pressure. If pulmonary artery pressure rises to the point at which the critical microvascular pressure (~25 mmHg) is exceeded, fluid accumulates in the pulmonary interstitial compartment. As this process continues, alveolar edema formation begins with loss of lung volume and a further increase in pulmonary vascular resistance related to compression of small pulmonary vessels by the accumulating alveolar edema fluid. Localized hypoxic vasoconstriction may also contribute to the increase in pulmonary artery pressure at this stage. These acute changes are readily reversible with resolution of the left ventricular dysfunction, assuming there has been no overt damage to the pulmonary vascular bed.

Mitral stenosis secondary to rheumatic heart disease is also associated with pulmonary hypertension caused by sustained increases in pulmonary venous pressure. Pulmonary hypertension results from passively increased pulmonary artery pressure and from remodeling of pulmonary arteries and veins. Pathologic changes include medial hypertrophy and fibrosis of pulmonary arteries and veins. The pulmonary hypertension associated with this acquired cardiac condition is usually reversed after valve replacement.

Congenital Cardiac Disease

Pulmonary hypertension is a common manifestation of congenital heart disease. The unifying pathogenetic feature in these congenital abnormalities (ventricular septal defect, atrial septal defect, patent ductus arteriosus) is that there is a chronic increase in blood flow through the pulmonary vascular bed as a result of left-to-right shunting (“high-flow states”). Over time, if the primary defect is not corrected, pulmonary vascular resistance progressively increases following structural changes in the pulmonary arteries. The elevation of pulmonary vascular resistance ultimately may reverse the direction of shunt blood flow, with subsequent development of cyanosis and severe exercise intolerance (Eisenmenger's syndrome).

The morphologic changes in pulmonary vessels are initiated by the primary pathologic increase in pulmonary blood flow through the shunt. The progression of pathologic changes correlates with the increase in pulmonary vascular resistance (see Table 2). Reversible changes include the development of medial hypertrophy and intimal hyperplasia (grades I and II). As pulmonary vascular resistance increases, the vascular lumen is occluded by progressive intimal hyperplasia and, ultimately, by formation of plexiform lesions (grades III and IV). Plexiform lesions and fibrinoid necrosis represent advanced, irreversible changes (grades IV and V). Recent work has emphasized an important relationship between the development of the changes in the pulmonary vascular bed and altered lung growth. Thus, the early pathologic effects of chronic high-flow states on the pulmonary vasculature are now recognized as changes in the normal pattern of pulmonary vascular growth and development. Medial smooth muscle hypertrophy or extension of vascular smooth muscle into peripheral pulmonary arteries, diminished size and number of peripheral pulmonary arteries, and an increase in intercellular connective tissue proteins in the vessel walls are all aspects of an altered pattern of pulmonary vascular growth. It appears that both microvascular endothelial cells and smooth muscle cells produce factors that modulate cell growth in response to pulsatile flow and that may be altered by shear stress from increased blood flow.

A detailed discussion of the treatment of congenital cardiac disease is beyond the scope of this chapter. The basic treatment is surgical repair of the lesion before severe pulmonary hypertension occurs. The rapidity with which pulmonary hypertension develops in these syndromes is dependent on the anatomic site of the left-to-right shunt. Pulmonary hypertension develops only after many years in patients with atrial septal defects, whereas ventricular septal defects are associated with the development of pulmonary hypertension in early childhood. In addition, variability in the rapidity of the development of pulmonary hypertension with a specific cardiac defect among different patients suggests a genetic predisposition for the risk of development of pulmonary vascular disease. Other factors in addition to blood flow, such as increased pressure and shear stress, probably interact and contribute to the development of pulmonary vascular disease and pulmonary hypertension in this patient population. Detection of congenital cardiac abnormalities before the development of severe pulmonary vascular disease is a key component of care. Patients who have already developed severe pulmonary vascular disease may not be helped by surgery at a late disease stage. In fact, they may experience further clinical deterioration following surgery related to the presence of advanced pulmonary vascular disease.

Diagnosis

Pulmonary hypertension caused by cardiac disease usually presents with symptoms and signs referrable to the underlying disease. Dyspnea on exertion, syncope, and arrhythmias may all be seen. Echocardiography is an effective means of screening for the presence of heart disease, with examination of mitral valvular and left ventricular function. Transesophageal echocardiography may be useful in diagnosis of septal defects. A Doppler flow study, in conjunction with infusion of saline or bubbles, may reveal transseptal shunts. As noted above, sampling of blood for oxygen saturation at the time of right heart catheterization is necessary to exclude left-to-right intracardiac shunts. Increased pulmonary vascular wedge pressures and decreased cardiac output are diagnostic of pulmonary hypertension associated with left ventricular failure.

PULMONARY HYPERTENSION ASSOCIATED WITH LUNG DISEASE

Lung diseases are the most common causes of pulmonary hypertension. Patients with pulmonary hypertension associated with lung disease typically present with symptoms and signs related to the underlying lung disease. This form of secondary pulmonary hypertension is not generally observed until the lung disease is severe, as assessed by pulmonary function testing. The prognosis is generally determined by the underlying lung disease, although the presence of pulmonary hypertension is an unfavorable prognostic sign.

Chronic Obstructive Pulmonary Disease

Several mechanisms contribute to the development of pulmonary hypertension in patients with chronic obstructive pulmonary disease. The most important initiating factor, discussed earlier in this chapter, is alveolar hypoxia leading to acute hypoxic vasoconstriction and a resultant elevation in pulmonary artery pressure and resistance. Global alveolar hypoxia causes generalized vasoconstriction, which may help to recruit additional parts of the underutilized pulmonary vascular space for participation in gas exchange. Sustained alveolar hypoxia causes vascular smooth muscle hypertrophy and remodeling of the pulmonary circulation (Fig. 3 and Color

Plate 1B). If the elevated pulmonary artery pressure is sustained, then sustained increased right ventricular work is required to maintain cardiac output at the same normal level over time.

Several other mechanisms contribute to the development of pulmonary hypertension in COPD. Destruction of the pulmonary vascular bed decreases pulmonary cross-sectional area as a direct result of the disease process and thereby contributes to the elevation in pulmonary artery pressure. Increased lung volume has complex effects on pulmonary vessels. Pressure in the extraalveolar vessels (vessels not exposed to alveolar pressure) may actually fall with the increase in lung volume related to the “tethering effect” of being pulled open by the hyperinflated lung. However, the net effect of increased lung volume is increased pulmonary artery pressure and vascular resistance as a result of compression of alveolar vessels by the raised intraalveolar pressure. Potentiation of hypoxic vasoconstriction by additional vasoconstrictor stimuli, such as acidosis associated with hypercapnia, increased blood viscosity that may accompany polycythemia, and increased platelet aggregation within the pulmonary vasculature, may also contribute to pulmonary hypertension.

Pulmonary hypertension in patients with COPD is multifactorial in origin, with sustained alveolar hypoxia being the most important initial stimulus triggering the acute and chronic events culminating in an elevated pulmonary artery pressure. In general, pulmonary hypertension in patients with COPD correlates with the severity of the underlying lung disease. There is no significant correlation between pulmonary hypertension and resting P_aO_2 or P_aCO_2. Pulmonary artery pressure also increases during exercise, indicating a limited ability of the structurally compromised pulmonary vascular bed to accommodate the normal increase in pulmonary blood flow during exercise. The contribution of this exacerbation of pulmonary hypertension during exercise to morbidity and mortality in patients with COPD is not well defined.

Another factor that may exacerbate the development of pulmonary hypertension in COPD is worsened hypoxemia during sleep. Nocturnal oxygen desaturation is very common in this patient population; the most severe episodes occur during REM sleep. Although the cause of the hypoxemia during sleep is probably multifactorial, the most important contributing factor is centrally mediated hypoventilation during REM sleep. Nocturnal hypoventilation is thought to reflect the diminished contribution of the rib cage to ventilation secondary to hypotonia of the intercostal muscles. In addition to hypoventilation during REM sleep, these patients also commonly demonstrate a significant reduction in normal central regulation of ventilation, with decreased ventilatory response to hypoxia and hypercapnia. There may also be a familial component to the postulated altered sensitivity of this brainstem control of ventilation, which can be exacerbated by drugs or alcohol. Other possible contributing factors to sleep-related hypoxemia are decreased lung volume (FRC) and worsening of ventilation–perfusion imbalance.

The net result is that diminished alveolar ventilation during sleep may cause profound oxygen desaturation for prolonged times on a recurring basis (“episodic hypoxia”) in association with a significantly increased pulmonary artery pressure. In the available studies that have actually measured the changes in pulmonary hemodynamics during sleep, episodes of oxygen desaturation were accompanied by increases in pulmonary artery pressure ranging from 10 to 20 mmHg. The increases in pulmonary artery pressure were reversed when oxygen saturation returned to baseline, linking oxygen desaturation to the altered pulmonary hemodynamics. Thus, sustained pulmonary hypertension in COPD may be caused by these recurring episodes of oxygen desaturation, which further increase pulmonary artery pressure. Studies in animal models lend support to the notion that intermittent, cyclic decreases in oxygen saturation may increase pulmonary artery pressure more than continuously decreased saturation. Nevertheless, the overall contribution of the alterations in pulmonary hemodynamics during sleep to the magnitude of pulmonary hypertension and the overall clinical course of patients with COPD remain undefined.

The clinical manifestations of pulmonary hypertension in COPD are synonomous with the signs and symptoms of cor pulmonale discussed in detail in Chapter 67. It is important to remember that the clinical signs of cor pulmonale, including evidence of right ventricular enlargement and pulmonary hypertension, may be obscured by the presence of severe lung disease, specifically hyperinflation. Auscultation of a right-sided S_3 or a loud P_2 may be difficult to appreciate in the patients with overdistended lungs. Similarly, right ventricular enlargement on chest x-ray may be obscured by hyperinflation. Hyperinflation may displace a normal liver, which may be mistaken for hepatic enlargement compatible with passive congestion on physical exam.

Determining whether the etiology of increased dyspnea in an individual patient is secondary to left heart failure or an exacerbation of airways disease is always a challenge. Finally, chest pain secondary to right ventricular ischemia and syncope are two additional symptoms associated with pulmonary hypertension that may also occur in patients with cardiac disease.

Restrictive Lung Disease

In this category we consider diseases of the lung parenchyma, such as idiopathic pulmonary fibrosis, asbestosis and other pneumoconioses, and a group of heterogeneous disorders that share the common feature of loss of lung volume that is not the direct result of a primary disease process affecting the lung parenchyma. This latter category includes thoracic cage deformities, diaphragm weakness, neuromuscular disorders, and diseases of the spinal cord.

The mechanisms leading to the development of pulmonary hypertension in chronic interstitial lung disease are similar to those discussed above for obstructive disease. Hypoxic vasoconstriction, compression and/or obliteration of lung vessels by fibrosis with loss of lung volume, and destruction of vascular surface area all contribute to pulmonary hypertension. The relationship between lung volume and pulmonary vascular resistance in parenchymal restrictive lung disease is well defined. Typically, vital capacity <50% of predicted is associated with the presence of pulmonary hypertension at rest, whereas vital capacity between 50% and 80% of predicted is associated with the development of pulmonary hypertension only during exercise. In restrictive parenchymal disease, the major anatomic site of this increase in pulmonary arterial pressure and vascular resistance is the extraalveolar vessels, which are no longer tethered open as lung volume falls.

There are two important mechanisms for the development of pulmonary hypertension in thoracic cage deformities, diaphragmatic disorders, neuromuscular disease, and spinal cord injury. In all of these disorders, loss of lung volume imposes a mechanical or anatomic limitation on the patient's respiratory system. Critical loss of lung volume can cause alveolar hypoventilation, with consequent decreases in alveolar oxygen tension and hypercapnia providing the stimuli for pulmonary vasoconstriction and pulmonary hypertension. In addition, superimposed conditions, such as atelectasis or infection, alter ventilation–perfusion relationships and help to maintain hypoxic vasoconstriction. In many thoracic cage disorders (kyphoscoliosis, thoracoplasty, or restrictive pleural disease), there is compression of lung vessels related to loss of lung volume, which also increases pulmonary artery pressure and resistance, as described under obstructive disease. Long-standing hypoxia causes remodeling of the pulmonary circulation, as described above, which also contributes to loss of pulmonary vascular cross-sectional area.

Treatment

Treatment of patients with secondary pulmonary hypertension should be focused on correction of the underlying respiratory system abnormality.

Supplemental oxygen can correct arterial hypoxemia and reduce pulmonary arterial pressure and vascular resistance associated with both obstructive and restrictive lung diseases. The rationale for this therapy emerged from the findings of several studies demonstrating that the overall prognosis and survival of patients with chronic obstructive pulmonary disease are correlated with the presence and severity of pulmonary hypertension. Patients with a pulmonary vascular resistance greater than 550 dyne-sec-cm^{-5} have an overall prognosis that is the equivalent of inoperable lung cancer.

The finding that the acute administration of supplemental oxygen to patients with advanced COPD reduced pulmonary artery pressure opened a new chapter in the use of oxygen as a therapeutic agent on a chronic basis. The acute administration of oxygen to patients with COPD produces significant, moderate reductions in pulmonary artery pressure and resistance. Pulmonary artery pressure does not return to normal immediately in many patients, probably because of morphologic changes in the walls of blood vessels and obliteration of the pulmonary vasculature secondary to the disease process. The efficacy of prolonged oxygen therapy for chronic bronchitis and emphysema has been unequivocally established in clinical trials by the Nocturnal Oxygen Therapy Trial Group and the British Medical Research Council Working Party. Reductions in pulmonary artery pressure and vascular resistance and long-term mortality were observed in both studies, although the reductions in pulmonary vascular resistance were modest.

These latter findings suggest that the survival benefit cannot be attributed solely to changes in pulmonary hemodynamics. The basis for this survival benefit remains undefined, but oxygen therapy is the only approach to date that has been shown to prolong life in patients with COPD. Supplemental oxygen administration does not change lung function. Maximal vasodilatory effects are observed with continuous oxygen administration (>16 hrs/day), especially during sleep. Prolonged administration of oxygen for weeks further decreases mean pulmonary artery pressure, suggesting that supplemental oxygen therapy not only reverses hypoxic vasoconstriction but may partially reverse some of the morphologic changes in the pulmonary vessels. The indications for home oxygen therapy are discussed in Chapter 43.

The long-term efficacy of supplemental oxygen administration in restrictive lung disease has never been validated in prospective clinical trials. There are far fewer patients with advanced restrictive disease who develop pulmonary hypertension and cor pulmonale, perhaps because of advanced underlying lung disease culminating in death. Many of the mechanisms of pulmonary hypertension are undoubtedly similar. Therefore, in the absence of evidence that this approach is contraindicated or ineffective, it is reasonable to administer supplemental oxygen to appropriately hypoxemic patients with restrictive lung disease.

Obviously, patients with chest wall disorders causing restriction and hypoventilation require treatment of hypoventilation, including (potentially) mechanical ventilation.

There is continuing controversy regarding the benefits of vasodilator treatment of pulmonary hypertension secondary to pulmonary disease. On the one hand, pulmonary hypertension often worsens during an exacerbation of chronic obstructive pulmonary disease in relation to superimposed acute hypoxemia and hypercarbia and may contribute to the deterioration of right heart function and symptoms of right heart failure. This rationale for pharmacologic treatment of pulmonary hypertension in COPD patients is weakened by the lack of selective pulmonary vasodilators and the potential for worsening of the matching of ventilation and perfusion, resulting in further decreased arterial oxygen tension. In addition, systemic hypotension and tachycardia may be significant side effects. Thus, vasodilator therapy is not recommended for pulmonary hypertension secondary to COPD or restrictive lung disease.

PULMONARY HYPERTENSION ASSOCIATED WITH SLEEP-RELATED BREATHING DISORDERS AND PRIMARY DISORDERS OF HYPOVENTILATION

Many patients with severe obstructive sleep apnea demonstrate periodic elevations in pulmonary artery pressure that are preceded by oxygen desaturations. These reversible oscillations of pulmonary artery pressure are initiated by decreased oxygen tension and thus represent examples of acute hypoxic vasoconstriction. Despite these periodic oscillations of pulmonary artery pressure, sustained pulmonary hypertension does not develop in the majority of patients with obstructive sleep apnea alone. Development of sustained daytime pulmonary hypertension also does not correlate with the severity of the sleep-related breathing disorder alone (i.e., the number or frequency of apneic events). Several studies have demonstrated that sustained pulmonary hypertension requires the presence of daytime hypoxemia and hypercapnia. Thus, the patients with obstructive sleep apnea who are at greatest risk for the development of resting, daytime pulmonary hypertension are those with underlying obstructive or restrictive lung disease, associated abnormalities of ventilatory control, or obesity.

The most important etiologic factors that contribute to the initiation and maintenance of pulmonary hypertension in these patients are hypoxic vasoconstriction and the added vasoconstrictor stimulus of respiratory acidosis from hypercapnia. Another potential contributor to pulmonary hypertension is increased venous return caused by generation of significant negative intrathoracic pressure during breathing with an obstructed airway. The development of pulmonary hypertension in primary alveolar hypoventilation or the obesity hypoventilation syndrome is also dependent on the development of alveolar hypoxia and acidosis, as noted above for obstructive sleep apnea. Correction of the primary process leading to oxygen desaturation and/or hypoventilation will reverse pulmonary hypertension in these disorders.

SUMMARY

The pathophysiology of pulmonary hypertension includes both functional and structural changes in the pulmonary circulation. Functional alterations that increase pulmonary vascular resistance include increases in blood flow, pulmonary venous pressure, and blood viscosity and increased reactivity of vascular smooth muscle to vasoconstrictor and decreased reactivity to vasodilator stimuli. Factors that decrease aggregate pulmonary arterial cross-sectional diameter also increase pulmonary vascular resistance; these include vascular obstruction, vasoconstriction, vessel obliteration, and vascular remodeling. Pulmonary hypertension is the end result of one or more of these pathophysiological changes that occur in response to primary or secondary pulmonary vascular diseases. Thus, the diagnostic approach to the patient with suspected pulmonary hypertension is to evaluate for underlying heart or lung diseases that might cause pulmonary hypertension. The diagnosis of “primary” pulmonary hypertension can be made only in the absence of secondary causes. Therapy is directed at the underlying heart or lung disease in patients with secondary pulmonary hypertension. Oxygen is the treatment of choice for hypoxemic patients. Patients with primary pulmonary hypertension may benefit from treatment with anticoagulants, lung transplant, or, in selected cases, vasodilator therapy.

CHAPTER

66 Thromboembolic Syndromes

Graham F. Pineo · Russell D. Hull

G.F. Pineo and R.D. Hull: Department of Medicine, University of Calgary, Calgary, Alberta T2E 0A1, Canada.

INTRODUCTION

Pulmonary embolism results in death in approximately 150,000 patients per year in the United States and contributes to death in another 150,000 patients. After acute myocardial infarction and stroke, pulmonary embolism is the third most common cause of cardiovascular death. It is the most common preventable cause of death in hospitalized patients. Venous thromboembolism (pulmonary embolism and/or venous thrombosis) frequently develops in hospitalized patients with one or more comorbid disorders, but this condition may also develop in otherwise healthy individuals who have undergone orthopedic surgery or trauma or who are pregnant. Although effective prophylaxis is available for most of these situations, venous thromboembolism can occur unexpectedly in ambulant patients, particularly if they have been exposed to risk factors in the preceding months. When venous thromboembolism occurs, it is important that appropriate objective testing be performed so that an accurate diagnosis can be established and treatment can be instituted immediately. A massive pulmonary embolus may be the first indication that venous thromboembolism has occurred. This can, unfortunately, be fatal within a short time in up to a third of patients.

This chapter highlights practical approaches to the diagnosis and treatment of venous thromboembolism. It covers the use of anticoagulants, thrombolysis, embolectomy, and vena cava filters.

PATHOGENESIS OF VENOUS THROMBOEMBOLISM

Factors that predispose an individual to the development of venous thromboembolism are shown in Table 1. Deep venous thrombosis usually arises in the deep veins of the calf muscles or, less commonly, in the proximal deep veins of the leg. When deep venous thrombosis remains confined to the calf veins, it is associated with a low risk of clinically important pulmonary embolism. However, without treatment, approximately 20% of calf-vein thrombi extend into the proximal venous system, where they may pose a serious and potentially life-threatening disorder. Untreated proximal venous thrombosis is associated with a 10% risk of fatal pulmonary embolism and at least a 50% risk of pulmonary embolism or recurrent venous thrombosis. In addition, the postphlebitic syndrome is associated with extensive proximal venous thrombosis and carries its own long-term morbidity. Pulmonary emboli in most cases (90%) originate from thrombi in the deep venous system of the legs. Less common sources of pulmonary embolism include the deep pelvic veins or renal veins, the inferior vena cava, the right heart, and occasionally the axillary veins. The clinical significance of pulmonary embolism depends on the size of the embolus and the cardiorespiratory reserve of the patient.

Clinical risk factors
Surgical and nonsurgical trauma
Previous venous thromboembolism
Immobilization
Malignant disease
Heart disease
Leg paralysis
Age (>40)
Obesity
Estrogens
Parturition
Inherited or acquired abnormalities
Activated protein C resistance
Protein C deficiency
Protein S deficiency
Antithrombin III deficiency
Anticardiolipin syndrome
Heparin-induced thrombocytopenia

TABLE 1. *Factors predisposing to the development of venous thromboembolism*

Venous thromboembolism is generally considered to be a single disorder. Therefore, the diagnostic approach may initially focus on the legs or the lungs, and testing starts with the least invasive methods and proceeds to more invasive methods. The treatment of venous thrombosis or pulmonary embolism is basically the same.

CLINICAL FEATURES

The clinical features of venous thrombosis include leg pain, tenderness and swelling, a palpable cord, discoloration, venous distention and prominence of the superficial veins, and cyanosis. None of the symptoms or signs is unique, and each may be caused by nonthrombotic disorders. This makes the clinical diagnosis of venous thrombosis highly nonspecific. Some patients with relatively minor symptoms and signs may have extensive deep venous thrombi. Other patients may have florid leg pain and swelling suggestive of extensive deep venous thrombosis, but objective testing may produce negative results. Thus, objective testing is mandatory to confirm or exclude a diagnosis of venous thrombosis.

Pulmonary embolism may present clinically in various ways, depending on the size, location, and number of emboli and on the patient's underlying cardiorespiratory reserve. In general, the clinical manifestations of acute pulmonary embolism can be divided into several syndromes that overlap considerably. There may be (1) transient dyspnea and tachypnea in the absence of other associated clinical manifestations; (2) the syndrome of pulmonary infarction or congestive atelectasis (also known as ischemic pneumonitis or incomplete infarction), including pleuritic chest pain, cough, hemoptysis, pleural effusion, and pulmonary infiltrates on the chest x-ray; (3) an assortment of less common and highly nonspecific clinical features such as confusion and coma, pyrexia, wheezing, resistant cardiac failure, and unexplained arrhythmia; or (4) acute massive pulmonary embolism.

In patients with acute massive pulmonary embolism, there is usually a dramatic presentation: a sudden onset of severe shortness of breath, hypoxemia, and right ventricular failure. Symptoms include central chest pain (often identical to angina), severe dyspnea, and, frequently, syncope, confusion, or coma. Examination reveals

a patient in severe distress with tachypnea, cyanosis, and hypotension. The marked increase in pulmonary vascular resistance leads to acute right ventricular failure with the presence of large A waves in the jugular veins and a right ventricular diastolic gallop. When pulmonary hypertension is present, there is marked right ventricular dilation with a shift of the intraventricular septum, decreasing cardiac output, and a further decreasing coronary perfusion. This frequently results in cardiorespiratory arrest. If patients with a massive pulmonary embolus survive, they are acutely threatened by any further pulmonary thromboembolism.

It is now widely accepted that the clinical diagnosis of pulmonary embolism is highly nonspecific. Multiple studies indicate that this diagnosis is not confirmed by objective testing in more than half of all patients with clinically suspected pulmonary embolism.

Patients given a clinical diagnosis of either deep vein thrombosis or pulmonary embolism have been assessed for clinical probabilities of the diagnosis before objective testing. Although such pretest probabilities have been useful in the hands of experienced clinical investigators, they still require further assessment by prospective studies before their use can be generalized. At the present time, algorithms involving objective tests must be used to establish the diagnosis for a large proportion of patients with suspected venous thromboembolism.

LABORATORY FEATURES

A number of laboratory abnormalities have been associated with venous thromboembolism. These include increased levels of fibrinopeptide A and fibrinogen degradation products, thrombin–antithrombin complexes, prothrombin fragment 1.2, and D-dimer. Patients with venous thromboembolism frequently have other comorbid conditions including cancer, recent surgery or trauma, infection, and inflammation. Also, many of the laboratory changes associated with venous thromboembolism are highly nonspecific.

The D-dimer assay has been evaluated in several studies of patients who had clinically suspected deep vein thrombosis that was later confirmed by objective testing. D-dimers can be measured by ELISA or by latex agglutination assays. When the appropriate cutoff is used, the negative predictive value of these tests is very high in patients with suspected venous thromboembolism. Several of these assays have a rapid turnaround time, and some of them are quantitative, so that they can now be studied in a prospective fashion in patients with suspected venous thromboembolism.

OBJECTIVE TESTS FOR THE DIAGNOSIS OF VENOUS THROMBOEMBOLISM

Ancillary Tests

Various ancillary tests such as the chest x-ray, arterial blood gas measurement, and the electrocardiogram, as well as laboratory tests for fibrinopeptide A, D-dimer, and serum lactate dehydrogenase, have a role in the diagnosis of venous thromboembolism, but they all lack sensitivity and specificity. The main role of these tests is to rule out other conditions that may mimic pulmonary embolism. Such conditions are acute myocardial infarction, pneumonia, or pneumothorax. In the case of venous thrombosis, objective tests include B-mode ultrasound, duplex ultrasonography, color flow ultrasonography, impedance plethysmography (IPG), and ascending venography. For the diagnosis of pulmonary embolism the objective tests include ventilation/perfusion lung scanning and pulmonary angiography.

Ultrasonography

Venous imaging using real-time B-mode ultrasound, with or without Doppler assessment, is a promising technique for evaluating patients with clinically suspected deep venous thrombosis. As shown in prospective studies, the single criterion of vein compressibility is highly sensitive and specific for proximal venous thrombosis (sensitivity and specificity both greater than 95%). Other criteria, such as echogenicity or change in venous diameter during a Valsalva maneuver, are less useful: the visualization of an echogenic band is highly sensitive but nonspecific (specificity 50%), and the percentage of change in venous diameter during a Valsalva maneuver is both insensitive and nonspecific.

Real-time B-mode venous ultrasound is insensitive for isolated calf-vein thrombosis, and, as with IPG, serial testing is required to detect patients who develop proximal extension. B-mode venous ultrasound may fail to detect isolated iliac vein thrombi. This is a practical clinical limitation in patient groups in whom isolated iliac-vein thrombosis is not uncommon, such as the pregnant patient with clinically suspected venous thrombosis. Color flow imaging and other technological advances have improved the ability of B-mode venous imaging to detect isolated iliac-vein thrombi and calf-vein thrombi.

Doppler ultrasound is highly sensitive and specific for diagnosing proximal venous thrombosis in symptomatic patients. Doppler ultrasound is more sensitive than IPG in symptomatic calf-vein thrombosis and in proximal venous thrombosis in patients with increased central venous pressure or with arterial insufficiency. Doppler ultrasound can be used in a patient whose leg is in a plaster cast or externally fixed, who is in traction, or who has had a leg amputated. Ultrasonography lacks both sensitivity and specificity for the detection of asymptomatic venous thrombosis in postoperative patients. Ascending venography remains the only reliable test for the detection of venous thrombosis in the high-risk patient or for clinical trials.

Impedance Plethysmography

Impedance plethysmography (IPG) is sensitive and specific for proximal venous thrombosis in symptomatic patients, but it is insensitive for calf-vein thrombosis. In patients with clinically suspected venous thrombosis, positive IPG results can be used to make therapeutic decisions as long as no clinical conditions known to produce false-positive results are present. A normal result essentially excludes the diagnosis of proximal venous thrombosis but does not exclude calf-vein thrombosis. This potential limitation can be overcome by performing serial IPG, which is based on the concept (now confirmed by clinical observation) that calf-vein thrombi are clinically important only when extension into the proximal veins occurs; at this point, detection with IPG becomes possible.

The effectiveness and safety of IPG have been evaluated by prospective clinical trials in patients with clinically suspected venous thrombosis. From these studies the following recommendations can be made: (1) a positive result by IPG is highly predictive of acute proximal vein thrombosis (positive predictive value greater than 90%), and (2) it is safe to withhold anticoagulant therapy in symptomatic patients who remain negative by serial IPG for 10 to 14 days.

As does ultrasonography, IPG lacks sensitivity for the detection of asymptomatic venous thrombosis after surgery. False-positive results may occur in disorders that interfere with arterial inflow or venous outflow. Such disorders include severe congestive cardiac failure, constrictive pericarditis, severe arterial insufficiency, hypotension, and external compression of the veins. Most of these disorders are readily recognized on clinical grounds.

Venography

Venography is accepted as the standard objective method for the diagnosis of venous thrombosis. Venography is a difficult technique to perform well, and accurate interpretation requires considerable experience. A number of venographic abnormalities have been defined as criteria for the diagnosis of acute deep vein thrombosis. The most reliable of these is an intraluminal filling defect that is present on all films and can be seen in a number of projections. Other venographic abnormalities, such as nonfilling of a segment of the deep venous system or nonfilling of the entire deep venous system above the knee, may be caused by technical artifacts, particularly if the dye is injected too far proximally into the dorsal foot vein. Such artifacts may then be interpreted either to indicate a thrombus because the vein is not filled or as normal because a filling defect is not seen. The common femoral, external iliac, and common iliac veins may not be adequately filled by ascending venography. This can lead to an incorrect diagnosis because of inadequate venography. In the case of nonfilling of an entire segment of the deep venous system, the diagnosis of acute or recurrent venous thrombosis must depend on the use of other tests such as IPG or ultrasound.

There are a number of problems related to venography. Even in the best of circumstances, it may be impossible to cannulate a vein on the dorsum of the foot, and so ascending venography may be impossible on one or both legs. If there is inadequate filling of the common femoral or iliac systems, it may be necessary to perform a femoral venogram.

Venography is associated with a number of clinically troublesome side effects. Pain may occur in the foot while dye is being injected, or there may be delayed pain in the calf 1 or 2 days after injection. The procedure may be complicated by superficial phlebitis and even deep vein thrombosis in a small percentage of patients with normal venograms (1% to 2%). Other, less common complications of venography include hypersensitivity to the radiopaque dye and local skin or tissue necrosis as a result of extravasation of dye at the site of injection. Both nonionic and high-ionic contrast media may cause or aggravate renal insufficiency in patients at high risk for these complications (patients with established renal disease, hypertension, heart failure, diabetes, or multiple myeloma, for example). The risks of venography must be carefully weighed in such circumstances and reviewed with the patient before venography is performed.

Ventilation/Perfusion Lung Scanning

Perfusion lung scanning is the key diagnostic test for patients with suspected pulmonary embolism. A normal perfusion scan excludes significant pulmonary embolism.

An abnormal perfusion scan, however, is nonspecific and may occur in conditions that produce either increased radiographic density (such as pneumonia, atelectasis, and pleural effusion) or a regional reduction in ventilation (such as chronic obstructive lung disease, acute asthma, bronchial mucous plugging, and bronchitis, which are frequently associated with normal radiography).

Ventilation imaging improves the specificity of an abnormal perfusion scan by differentiating between embolic occlusion of the pulmonary vasculature and perfusion defects occurring secondary to a primary disorder of ventilation. Recent prospective clinical trials have shown that the basic premise, that perfusion defects that ventilate normally (ventilation/perfusion mismatch) result from pulmonary embolism but that matching ventilation/perfusion abnormalities are due to other conditions, has been shown to be incorrect.

Ventilation lung scanning is helpful only if the perfusion defect is segmental or larger and is associated with ventilation mismatch. Pulmonary angiography shows that such patients have a high probability (³86%) of pulmonary embolism. Other abnormal findings on lung scans, such as matching ventilation/perfusion defects (either segmental or subsegmental), subsegmental defects with ventilation mismatch, or perfusion defects that correspond to an area of increased density on the chest radiograph (nondiagnostic perfusion scan), are associated with a 20% to 40% frequency of pulmonary embolism. Therefore, further investigations, including pulmonary angiography and objective tests for venous thrombosis, must be carried out in patients with nondiagnostic ventilation/perfusion scan findings. Pulmonary angiography and/or venography should be used when other approaches are unavailable or inconclusive. The morbidity associated with these tests is substantially less than that arising from unnecessary anticoagulant therapy and inappropriate hospitalization.

At least 80% of patients with pulmonary embolism have thrombi that originate in the lower leg veins. Prospective studies in patients with nondiagnostic lung scan findings who have adequate cardiorespiratory reserve have indicated that serial noninvasive leg testing is a simple and safe alternative to pulmonary angiography. If the noninvasive leg test is positive initially or on serial screening, anticoagulant treatment can be instituted. On the other hand, if noninvasive leg testing remains negative for 10 to 14 days, anticoagulant therapy can be safely withheld. Pulmonary angiography is required in patients with decreased cardiopulmonary reserve and nondiagnostic lung scan findings.

Pulmonary Angiography

Pulmonary angiography is the accepted diagnostic reference standard for pulmonary embolism. The diagnosis is established if there is an intraluminal filling defect that is present on multiple films or if there is abrupt termination (cutoff) of a vessel greater than 2 to 5 mm in diameter that is visible on multiple films in different projections. Other abnormalities, such as oligemia, vessel pruning, and loss of filling of small vessels, are nonspecific and occur in a variety of conditions, including pneumonia, atelectasis, bronchiectasis, emphysema, and pulmonary carcinoma.

In recent years, the diagnostic resolution of pulmonary angiography has been markedly improved, and the risk to the patient decreased, by the use of selective catheterization with repeated injections of small volumes of dye. This is a safe technique in the absence of severe chronic pulmonary hypertension or severe cardiac or respiratory decompensation. Clinically significant complications including tachyarrhythmias, endocardial or myocardial injury, cardiac perforation, cardiac arrest, and hypersensitivity reactions to contrast medium occur in fewer than 3% to 4% of patients.

TREATMENT OF VENOUS THROMBOEMBOLISM

The objectives of treatment in patients with venous thromboembolism are (1) to prevent death from pulmonary embolism, (2) to prevent recurrent venous thromboembolism, and (3) to prevent the postphlebitic syndrome.

The accepted anticoagulant therapy for venous thromboembolism is a combination of continuous intravenous heparin and oral warfarin sodium. The use of heparin and warfarin simultaneously has become the standard clinical practice for all patients with venous thromboembolism who are medically stable. Exceptions include patients who require immediate medical or surgical intervention such as thrombolysis or insertion of a vena cava filter or patients at high risk for bleeding. The length of the initial intravenous heparin therapy has been reduced to 5 days, thus shortening the hospital stay and leading to significant cost saving.

Heparin Therapy

The anticoagulant activity of unfractionated heparin depends on a unique pentasaccharide that binds to antithrombin III (ATIII) and potentiates the inhibition of thrombin and activated factor X (X_a) by ATIII. Heparin also catalyzes the inactivation of thrombin by another plasma cofactor, heparin cofactor II, which acts independently of ATIII. Several other effects of heparin are (1) the release of tissue factor inhibitor, (2) the binding to numerous plasma and platelet proteins, endothelial cells, and leukocytes, and (3) increased vascular permeability. The anticoagulant response to a standard dose of heparin varies widely among patients. It is necessary, therefore, to monitor the anticoagulant response of heparin by measuring either the activated partial thromboplastin time (aPTT) or heparin levels, and to titrate the dose to the individual patient.

The laboratory test most commonly used to monitor heparin therapy is the aPTT. The traditional approach has been to adjust the heparin infusion dose to maintain the aPTT within a defined “therapeutic range.” Over the years, this therapeutic range has evolved as a result of clinical custom to the use of upper and lower limits (an aPTT ratio of 1.5 to 2.5 times control). The clinical practice of adjusting the heparin dose to maintain the aPTT response within this range is based on two concepts: (1) that maintaining the aPTT ratio above the lower limit of 1.5 will minimize recurrent venous thromboembolic events and (2) that maintaining the aPTT ratio below the upper limit of 2.5 will minimize the risk of bleeding complications.

It has been established, from experimental studies and clinical trials, that the efficacy of heparin therapy is dependent on achieving a critical therapeutic level of heparin within the first 24 hr of treatment. Patients receiving heparin, by either continuous intravenous infusion or intermittent subcutaneous injection, who do not achieve therapeutic aPTT values during initial therapy have an increased risk of recurrent venous thromboembolism over the subsequent 3 to 12 weeks. The critical therapeutic level of heparin, as measured by the aPTT, is the one that will produce 1.5 times the mean control value or the upper limit of the normal aPTT range. This corresponds to a heparin blood level of 0.2 to 0.4 mL by the protamine sulfate titration assay and 0.35 to 0.70 u/mL by the anti-factor-X_a assay. However, the aPTT and heparin blood levels determined with reagents from different manufacturers and even with different batches of the same reagent vary widely. It is therefore vital for each laboratory to establish the minimal therapeutic level of heparin, as measured by the aPTT, that will provide a heparin blood level of at least 0.2 units/ml using the protamine titration assay for each batch of thromboplastin reagent being used, particularly if the reagents are provided by different manufacturers.

Although there is a strong correlation between subtherapeutic aPTT values and recurrent thromboembolism, the relationship between supratherapeutic aPTT and bleeding (aPTT ratio 2.5 or more) is less definite. Indeed, bleeding during heparin therapy is more closely related to underlying clinical risk factors than to aPTT elevation above the therapeutic range. Recent studies confirm that age greater than 65 years and female gender increase the risk of bleeding on heparin.

Numerous audits of heparin therapy indicate that administration of intravenous heparin is fraught with difficulty and that the clinical practice of using an *ad hoc* or intuitive approach to heparin dose titration frequently results in inadequate therapy. For example, an audit of physician practices at three university-affiliated hospitals showed that 60% of patients failed to achieve an adequate aPTT response (ratio ³1.5) during the initial 24 hrs of therapy. Furthermore, 30% to 40% of patients remained subtherapeutic over the next 3 to 4 days.

The use of a prescriptive protocol for administering intravenous heparin therapy has been evaluated in two studies in patients with venous thromboembolism. In one clinical trial of the treatment of proximal venous thrombosis, patients were given either intravenous heparin alone, followed subsequently by warfarin sodium, or intravenous heparin and simultaneous warfarin sodium. This heparin nomogram is summarized in Table 2 and Table 3. Only 2% and 1% of the patients were subtherapeutic for more than 24 hrs in the heparin and warfarin group and the heparin group, respectively. Recurrent venous thromboembolism (objectively documented) occurred infrequently in both groups (7%), rates similar to those previously reported. These findings demonstrated that subtherapy was avoided in most patients and that the heparin protocol resulted in effective delivery of heparin therapy in both groups.

1. Initial intravenous heparin bolus: 5000 units
2. Continuous intravenous heparin infusion: commence at 42 ml/hr of 20,000 units (1000 units/hour) in 500 ml of two-thirds dextrose and one-third saline (a 24-hr heparin dose of 40,320 units), except in the following patients, in whom heparin infusion will be commenced at a rate of 31 ml/hr (1240 units/hr) (i.e., a 24-hr dose of 29,760 units):
   a. Patients who have undergone surgery within the previous 2 weeks.
   b. Patients with a previous history of peptic ulcer disease or gastrointestinal or genitourinary bleeding.
   c. Patients with recent stroke (i.e., thrombotic stroke within 2 weeks previously).
   d. Patients with a platelet count < 150 × 10^9 per liter.
   e. Patients with miscellaneous reasons for a high risk of bleeding (e.g., hepatic failure, renal failure, or vitamin K deficiency).
3. Heparin dose adjusted using the aPTT. The aPTT is performed in all patients as outlined below:
   a. 4 to 6 hr after commencing heparin: the heparin dose is then adjusted according to a nomogram (Table 3).
   b. 4 to 6 hr after implementing the first dosage adjustment.
   c. The aPTT is then performed as indicated by the nomogram for the first 24 hr of therapy.
   d. Thereafter, the aPTT will be performed once daily, unless the patient is subtherapeutic, in which case the aPTT will be repeated 4 to 6 hr after increasing the heparin dose.

TABLE 2. *Heparin protocol*[a]

aPTT	Infusion i.v. Rate change (ml/hr)	Infusion i.v. Dose change (U/24 hr)[b]	Additional action
≤45	+6	+5760	Repeated aPTT[c] in 4–6 hr
46–54	+3	+2880	Repeated aPTT in 4–6 hr
55–85	0	0	None[d]
86–110	-3	-2880	Stop heparin sodium treatment for 1 hr; repeated aPTT 4–6 hr after restarting heparin treatment
>110	-6	-5760	Stop heparin treatment for 1 hr; repeated aPTT 4–6 hr after restarting heparin treatment

[a] aPTT indicates activated partial thromboplastin time. Reproduced with permission from: Hull RD, Raskob GE, Rosenbloom D, et al. Optimal therapeutic level of heparin therapy in patients with venous thrombosis. *Arch Intern Med* 1992; 152:1589.
[b] Heparin sodium concentration, 20,000 U in 500 ml = 40 U/ml.
[c] With the use of Actin-FS thromboplastin reagent (Dade, Mississauga, Ontario).
[d] During the first 24 hr, repeated aPTT in 4 hr (-1 hr. Thereafter, the aPTT will be determined once daily unless subtherapeutic.

TABLE 3. *Intravenous heparin dose-titration nomogram for aPTT*[a]

In the other clinical trial, a weight-based heparin-dosing nomogram was compared with a standard care nomogram (Table 4). In the weight-adjusted group, 89% of patients achieved the therapeutic range within 24 hrs compared with 75% in the standard-care group. The risk of recurrent thromboembolism was more frequent in the standard-care group. This study included patients with unstable angina and arterial thromboembolism in addition to venous thromboembolism, indicating that the heparin protocol used for the treatment of venous thromboembolism in otherwise normal individuals was generalizable to other clinical conditions.

Initial dose	80 U/kg bolus, then 18 U/kg per hr
aPTT < 35 sec (<1.2 × control)	80 U/kg bolus, then 4 U/kg per hr
aPTT, 35–45 sec (1.2–1.5 × control)	40 U/kg bolus, then 2 U/kg per hr
aPTT, 46–70 sec (1.5–2.3 × control)	No change
aPTT, 71–90 sec (2.3–3.0 × control)	Decrease infusion rate by 2 U/kg per hr
aPTT > 90 sec (>3.0 × control)	Hold infusion 1 hr, then decrease infusion rate by 3 U/kg per hr

Complications of Heparin Therapy

The main side effects of heparin therapy include bleeding, thrombocytopenia, and osteoporosis, with rarer complications being hypersensitivity, hypoaldosteronism, and elevated liver enzymes. Approximately 5% of patients on continuous intravenous heparin experience major bleeding. Patients at particular risk are those who have had recent surgery or trauma or other predisposing comorbidities such as peptic ulcer, occult malignancy, liver disease, or hemostatic defects. Age greater than 65 years and female gender predispose to bleeding on heparin.

The management of heparin-related bleeding depends on the location and severity of bleeding, the risk of recurrent venous thromboembolism, and the level of the aPTT. Heparin should be discontinued temporarily or permanently. Patients with recent venous thromboembolism may be candidates for insertion of an inferior vena cava filter. If urgent reversal of the heparin effect is required, protamine sulfate can be administered.

Heparin-induced thrombocytopenia is a well-recognized complication of heparin therapy, usually occurring within 5 to 10 days after the start of heparin treatment. Approximately 1% to 2% of patients receiving unfractionated heparin will experience a fall in platelet count to less than the normal range or a 50% fall in the platelet count within the normal range. In the majority of cases, this mild to moderate thrombocytopenia appears to be a direct effect of heparin on platelets and is of no consequence. However, approximately 0.1% to 0.2% of patients receiving heparin develop an immune thrombocytopenia mediated by IgG antibody directed against a complex of PF4 and heparin. The development of thrombocytopenia may be accompanied by arterial or venous thrombosis. This may have serious consequences, such as death or limb amputation. The diagnosis of heparin-induced thrombocytopenia, with or without thrombosis, must be made on clinical grounds because the assays with the highest sensitivity and specificity are not readily available and have a slow turnaround time.

When the diagnosis of heparin-induced thrombocytopenia is made, heparin in all forms must be stopped immediately. In those patients who require ongoing anticoagulation, several alternatives exist: warfarin therapy, insertion of an inferior vena cava filter, the use of the defibrinogenating extract of snake venom, Arvin (Ancrod), the heparinoid Danaproid sodium (Organon), and, more recently, the specific antithrombins hirudin and Argatroban. Most of the reports in case series have included the use of Arvin or Danaproid, but clinical trials are currently under way to assess the efficacy and safety of the specific antithrombin agents.

Osteoporosis has been reported in patients receiving unfractionated heparin in doses of 20,000 units per day or more for more than 6 months. Demineralization can progress to the fracture of vertebral bodies or long bones, and the defect may not be entirely reversable.

Other complications of heparin therapy, such as hypersensitivity, elevated liver enzymes, and hyperkalemia secondary to hypoaldosteronism, are rare and of little clinical consequence.

Low-Molecular-Weight Heparin

Heparin currently in use clinically is polydispersed unmodified heparin and has a mean molecular mass ranging from 10 to 16 kDa. In recent years, low-molecular-weight derivatives of commercial heparin have been prepared that have a mean molecular mass of 4 to 5 kDa.

Low-molecular-weight heparins have a number of advantages over unfractionated heparin: they have greater bioavailability when given by subcutaneous injection; the duration of anticoagulant effect is greater, permitting once- or twice-daily administration; the anticoagulant response (anti-X_a activity) to low-molecular-weight heparin correlates highly with body weight, permitting administration without laboratory monitoring; and there is less bleeding with equivalent antithrombotic effect.

Several different low-molecular-weight heparins and one heparinoid are available for the prevention and treatment of venous thromboembolism in various countries. In North America, three low-molecular-weight heparins have been approved for clinical use, two in the United States and three in Canada. A large number of clinical trials of deep vein thrombosis prophylaxis have been carried out in general and in orthopedic surgery in both Europe and North America. Meta-analyses indicate that low-molecular-weight heparins are at least as effective as unfractionated heparin or warfarin in the prevention of postoperative deep vein thrombosis, and they have the added convenience of once-daily administration. However, the incidence of postoperative bleeding may be somewhat higher than with low-dose unfractionated heparin or warfarin. Low-molecular-weight heparin has become the prophylaxis of choice for patients undergoing high-risk surgery, such as total hip or total knee replacement.

Subcutaneous, unmonitored, low-molecular-weight hep- arin has been compared with continuous intravenous heparin in a number of clinical trials for the treatment of proximal venous thrombosis. In one clinical trial conducted in North America, there was a significant decrease in major bleeding and in mortality rate in patients treated with low-molecular-weight heparin compared with unfractionated heparin (Fig. 1). There was also a trend to decreased recurrent thromboembolism. Four other clinical trials, which also used long-term follow-up as an outcome measure, showed that low-molecular-weight heparin was at least as effective and safe as unfractionated heparin, although the differences were not significant. When all five studies were combined, low-molecular-weight heparin demonstrated a significant advantage with respect to recurrent venous thromboembolism, major bleeding, and mortality. Data from ongoing studies indicate that low-molecular-weight heparin is equally effective in the treatment of patients presenting with pulmonary embolism.

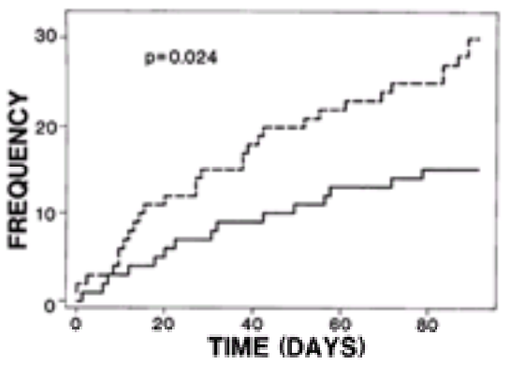

FIG. 1. Time-to-event analysis for patients who had recurrent venous thromboembolism or died (*solid line,* low-molecular-weight heparin; *dashed line,* unfractionated heparin). Fifteen of 213 patients receiving low-molecular-weight heparin (7%) had objectively documented recurrent venous thromboembolism or died, compared with 30 of 219 patients receiving intravenous heparin (13.7%) (p = 0.024). In each group the majority of these events occurred within the first 6 weeks. (From Hull RD, Raskob GE, Pineo GF, et al. Subcutaneous low-molecular-weight heparin compared with continuous intravenous heparin in the treatment of proximal-vein thrombosis. *N Engl J Med* 1992;326:975–988.)

Two recently completed randomized clinical trials show that low-molecular-weight heparin can be used safely to treat selected patients with venous thromboembolism as outpatients. Cost analyses indicate that low-molecular-weight heparin is cost effective in both the prevention and treatment of venous thromboembolism compared with standard treatment. When these agents become more available for treatment, they will undoubtedly replace intravenous unfractionated heparin in the initial management of patients with venous thromboembolism as well as in the management of other patients in whom intravenous heparin is currently used.

If patients experience bleeding while receiving low-molecular-weight heparin, protamine sulfate has been shown to reduce clinical bleeding, presumably by neutralizing high-molecular fractions of heparin, which are thought to be most responsible for it.

Oral Anticoagulant Therapy

The most common oral anticoagulant is a 4-hydroxycoumarin derivative, warfarin sodium. Warfarin exerts its anticoagulant effect by inhibiting the vitamin-K-dependent g-carboxylation of coagulation factors II, VII, IX, and X. This results in the synthesis of immunologically detectable but biologically inactive forms of these coagulation proteins. Warfarin also inhibits the vitamin-K-dependent g-carboxylation of proteins C and S. Protein C circulates as a proenzyme that is activated on endothelial cells by the thrombin–thrombomodulin complex to form activated protein C. Activated protein C inhibits activated factor VIII activity directly and, in the presence of protein S, also inhibits activated factor V. Therefore, vitamin K antagonists such as warfarin create a biochemical paradox by producing an anticoagulant effect through inhibition of procoagulants (factors II, VII, IX, and X) and a potentially thrombogenic effect by impairing the synthesis of naturally occurring inhibitors of coagulation (proteins C and S). Heparin and warfarin treatment should be overlapped by 4 to 5 days when warfarin treatment is initiated in patients with thrombotic disease.

The anticoagulant effect of the vitamin K antagonists is delayed until the normal clotting factors are cleared from the circulation, and the peak effect does not occur until 36 to 72 hr after drug administration. During the first few days of warfarin therapy, the prothrombin time reflects mainly the depression of factor VII, which has a half-life of 5 to 7 hrs. Equilibrium levels of factors II, IX, and X are not reached until about 1 week after the initiation of therapy. The use of small initial daily doses (10 mg, for example) is the preferred approach for initiating warfarin treatment. The dose–response relationship to warfarin therapy varies widely among individuals, and, therefore, the dose must be carefully monitored to prevent overdosing or underdosing. There is some evidence that elderly subjects are more sensitive to the effects of warfarin, and greater caution is required in establishing maintenance doses in order to prevent overanticoagulation.

A number of drugs interact with warfarin. Critical appraisal of the reports of such interactions indicates that the evidence substantiating many of the claims is limited. Nonetheless, patients must be warned against taking any new drugs without the knowledge of their physician.

Laboratory Monitoring and Therapeutic Range

The one-stage prothrombin time is the laboratory test most commonly used to measure the effects of warfarin. The prothrombin time (PT) is sensitive to reduced activity of factors II, VII, and X but insensitive to reduced activity of factor IX. Confusion about the appropriate therapeutic range has occurred because the different tissue thromboplastins used to measuring the PT vary considerably in their sensitivity to the vitamin-K-dependent clotting factors and in response to warfarin. Rabbit brain thromboplastin, which is widely used in North America, is less sensitive than standardized human brain thromboplastin, which has been widely used in the United Kingdom and other parts of Europe. A PT ratio of 1.5 to 2.0 using rabbit brain thromboplastin (the traditional therapeutic range in North America) is equivalent to a ratio of 4.0 to 6.0 using human brain thromboplastin. Conversely, a two- to threefold increase in the PT using standardized human brain thromboplastin is equivalent to a 1.25- to 1.5-fold increase in the PT using a rabbit brain thromboplastin such as Simplastin or Dade-C.

In order to promote standardization of the PT for monitoring oral anticoagulant therapy, the World Health Organization (WHO) has developed an international reference thromboplastin from human brain tissue and has recommended that the PT ratio be expressed as the *International Normalized Ratio* (INR). The INR is the PT ratio obtained by testing a given sample using the WHO reference thromboplastin. For practical clinical purposes, the INR for a given plasma sample is equivalent to the PT ratio obtained using a standardized human brain thromboplastin known as the Manchester Comparative Reagent (which has been widely used in the United Kingdom). The currently recommended therapeutic range for the treatment of venous thromboembolism is an INR of 2.0 to 3.0. The only possible exception is in the treatment of thrombosis complicating the anticardiolipin syndrome. In this case, retrospective reviews suggest that an INR of 2.5 to 3.5 may be more effective.

Warfarin is administered in an initial dose of 5 to 10 mg/day for the first 2 days, and the daily dose is then adjusted according to the INR. Heparin therapy is discontinued on the fourth or fifth day after initiation of warfarin therapy, provided the INR is prolonged into the therapeutic range (INR 2.0 to 3.0). The selection of the correct dosage of warfarin must be individualized because some individuals are either fast or slow metabolizers of the drug. Therefore, frequent INR determinations are required initially to establish therapeutic anticoagulation.

Once the anticoagulant effect and patient's warfarin dose requirements are stable, the INR should be monitored weekly throughout the course of warfarin therapy. However, if there are factors that may produce an unpredictable response to warfarin (concomitant drug therapy, for example), the INR should be monitored more frequently to minimize the risk of complications resulting from poor anticoagulant control.

Long-Term Treatment of Venous Thromboembolism and Pulmonary Embolism

Patients with venous thromboembolism (proximal venous thrombosis or pulmonary embolism) require oral anticoagulants for a period of 3 months to prevent recurrent disease. Attempts have been made to shorten the treatment period to 12 or 6 weeks, but outcomes in terms of recurrent disease are superior when oral anticoagulants

are used for 3 to 6 months. There may be an exception in patients who develop venous thromboembolism in association with an obvious and transient risk factor, such as trauma, orthopedic surgery, or bed rest. In these patients, the recurrence rate is lower than that in patients who have idiopathic venous thromboembolism, even when shorter courses of anticoagulants are used. Patients with continuing risk factors (such as malignancy, paralysis, or prolonged bed rest) may require long-term therapy until the risk has decreased. Patients with irreversible risk factors, such as deficiency of antithrombin III or activated protein C resistance, may require anticoagulant treatment indefinitely after an episode of venous thromboembolism. Patients with a first recurrence of venous thromboembolism have been treated empirically for 12 months, whereas those with a second recurrence usually receive lifelong anticoagulants. Clinical trials are currently under way to establish the most appropriate duration of anticoagulation in some of these clinical situations.

Adverse Effects of Oral Anticoagulants

The major side effect of oral anticoagulant therapy is bleeding. Bleeding during well-controlled oral anticoagulant therapy is usually caused by surgery or other forms of trauma or by local lesions such as peptic ulcer or carcinoma. Spontaneous bleeding may occur if an excessive dose of warfarin sodium is given and results in marked elevation of the INR. Such bleeding may be severe and even life-threatening. The risk of bleeding can be substantially reduced by adjusting the warfarin dose to achieve a less intense anticoagulant effect than has traditionally been used in North America (INR 2.0 to 3.0).

Nonhemorrhagic side effects of oral anticoagulants differ according to whether the coumarin derivatives (warfarin sodium, for example) or indanediones are administered. Nonhemorrhagic side effects of anticoagulants occur infrequently with the coumarin derivatives but more frequently with the indanedione derivatives; these include skin necrosis, dermatitis, and a syndrome of painful blue toes. Hypersensitivity reactions have been reported to occur in 1% to 3% of patients receiving indanedione derivatives and include rash, fever, hepatitis, leukopenia, renal failure, and diarrhea. These side effects may be fatal. In many patients, the indanedione derivatives also produce red discoloration of the urine, which may be confused with hematuria.

Coumarin-induced skin necrosis is a rare but serious complication and requires that oral anticoagulant therapy be stopped immediately. It usually occurs 3 to 10 days after therapy starts, is more common in women, and most often involves areas of abundant subcutaneous tissues such as the abdomen, buttocks, thighs, and breast. The mechanism of coumarin-induced skin necrosis, which is associated with microvascular thrombosis, is uncertain. It does, however, appear to be related, at least in some patients, to the depression of protein C, and patients with congenital deficiencies of protein C or S may be particularly prone to its development. To avoid the development of skin necrosis in patients with protein C or S deficiency who require anticoagulant therapy, intravenous heparin should be started, and then warfarin should be initiated without a loading dose. The heparin should be continued until the INR is therapeutic for at least 2 consecutive days.

Oral anticoagulants cross the placenta, and their use during pregnancy may cause fetal malformations. Two specific fetopathic syndromes are associated with oral anticoagulant administration during pregnancy. Treatment with oral anticoagulants during weeks 6 to 12 gestation may induce the syndrome of warfarin embryopathy in the fetus, that is, skeletal abnormalities ranging from stippled epiphyses to frank skeletal hypoplasia. Although most reported cases have occurred in infants of mothers receiving warfarin, it has also been reported to result from phenindanedione or acenocoumarin administration. Oral anticoagulant administration during the second or third trimester of pregnancy may result in central nervous system abnormalities in the fetus, including abnormalities of the ventricular system (Dandy–Walker malformation), dorsal midline dysplasia, and optic atrophy. Therefore, the use of oral anticoagulants is contraindicated at any time during pregnancy, and they should not be used in women planning a pregnancy. Adjusted-dose twice-daily subcutaneous unfractionated heparin is the anticoagulant of choice for venous thromboembolism occurring in pregnancy.

Antidote to Oral Anticoagulants

The antidote to the vitamin K antagonists is vitamin K_1. If the INR is increased excessively, treatment will depend on the level of the INR and whether or not the patient is bleeding. If the increase is mild (INR < 6.0), and the patient is not bleeding, no specific treatment is necessary other than reduction of the warfarin dose; the INR can then be expected to decrease during the next 24 hrs. If there is a more marked increase in the INR in patients who are not bleeding, treatment with small doses of vitamin K_1, given either orally or by subcutaneous injection (2.5 to 5.0 mg), should be considered. If there is a very marked increase in the INR (INR > 10.0), vitamin K_1 should be given, particularly to a patient who is either actively bleeding or at risk of bleeding.

Second-generation rodenticides, known as “super warfarins,” have an extremely long half-life. Accidental or intentional consumption of these agents requires repeated injections of vitamin K and fresh-frozen plasma for up to 1 to 2 years to overcome their effects completely.

The reported side effects of vitamin K include flushing, dizziness, tachycardia, hypotension, dyspnea, and sweating. Intravenous administration of vitamin K_1 should be carried out with caution to avoid inducing an anaphylactoid reaction. The risk of an anaphylactoid reaction can be reduced by giving vitamin K_1 slowly, no faster than 1 mg/min i.v. In most patients, i.v. administration of vitamin K_1 produces a demonstrable effect on the INR within 3 to 4 hrs and corrects the prolonged INR within 6 to 8 hr. Because the half-life of vitamin K_1 is less than that of warfarin sodium, a repeat course of vitamin K_1 may be necessary. If bleeding is very severe and life-threatening, vitamin K therapy can be supplemented by using concentrates of factors II, VII, IX, and X.

TREATMENT OF ACUTE MASSIVE PULMONARY EMBOLISM

The emergency management of massive pulmonary embolism includes the use of intravenous heparin, the use of oxygen, with or without mechanical ventilation and positive end-expiratory pressure (PEEP), volume resuscitation, and the use of inotropic agents and vasodilators. In addition to these supportive measures, specific treatment options for acute massive pulmonary embolism include (1) thrombolysis, (2) pulmonary thrombectomy, with or without cardiopulmonary bypass support, (3) transvenous catheter embolectomy or clot dissolution, and (4) insertion of an inferior vena caval filter.

Thrombolytic Therapy

Randomized clinical trials have demonstrated that the mortality rate from venous thromboembolism can be decreased by anticoagulant treatment. A mortality rate of less than 5% can be achieved with intravenous heparin and oral anticoagulants. This can be further reduced with the use of low-molecular-weight heparin. However, patients who present with acute massive pulmonary embolism and hypotension have a mortality rate of approximately 20% even when anticoagulants and other supportive measures are used. For such patients, the appropriate use of thrombolytic agents has a role. A high percentage of acute pulmonary emboli occur within 10 to 14 days of surgery and, therefore, are excluded from treatment protocols that use thrombolytic agents. These patients may be candidates for local infusion of low-dose thrombolytic agents.

In several randomized clinical trials, thrombolytic drugs have been compared with heparin for the treatment of pulmonary embolism. These trials compared urokinase (UK) with heparin, streptokinase (SK) with heparin, or tissue plasminogen activator (t-PA) with heparin. The dosage regimens used either a bolus or chronic infusion up to 72 hr. Outcome measures for accelerated thrombolysis included quantitative measures on repeat pulmonary angiograms, quantitative scores on repeat pulmonary perfusion scans, and measures of pulmonary vascular resistance. Although all studies demonstrated the superiority of thrombolysis (in particular with t-PA) in terms of resolution of both radiographic and hemodynamic abnormalities when measured within the first 24 hr, this advantage was short-lived. Repeat perfusion scans at 5 to 7 days revealed no significant difference between the patients treated with thrombolytic agents and those with heparin. Furthermore, the trials demonstrated neither a difference in mortality rate nor one in resolution of symptoms. Measurement of diffusion capacity and capillary volumes at 2 weeks and 1 year after treatment showed that those receiving thrombolytic therapy had higher diffusion capacity and lung capillary volumes than did patients receiving heparin. Follow-up of the same group of 23 patients an average of 7 years after thrombolytic treatment showed that patients who had been treated with thrombolytic therapy had lower pulmonary artery pressure and pulmonary vascular resistance than patients who had received heparin. The clinical relevance of these findings, however, must await further prospective studies.

Several randomized clinical trials have compared different thrombolytic agents using different treatment protocols: SK versus UK, UK with UK, t-PA with t-PA, and t-PA with UK. These studies again demonstrated resolution of angiographic, echocardiographic, and perfusion scan abnormalities as well as reduction of pulmonary pressure, but there was little or no difference between the regimens being compared. Again, the clinical relevance of the changes requires further study.

In weighing the risks and benefits of thrombolytic therapy, the main concern is bleeding. The incidence of major bleeding has decreased, particularly with the use of bolus or short-term infusions and with the use of newer thrombolytic agents. However, intracerebral hemorrhage continues to occur more frequently than with heparin.

At this time, the role of thrombolytic agents in the management of acute massive pulmonary embolism remains controversial. Although there is a more rapid dissolution of venous thromboemboli, the risk of serious bleeding is still a concern. Until there is a clearly demonstrated reduction in both morbidity and mortality from well-controlled prospective randomized clinical trials, the question of risk/benefit will remain. In the meantime, the use of thrombolytic agents has become simpler through the use of high-probability ventilation–perfusion scans or echocardiography to confirm the diagnosis, the use of short-term or bolus infusion of thrombolytic agents into peripheral veins rather than the pulmonary artery, the elimination of laboratory monitoring, and treatment on the medical ward rather than the intensive care unit. The fact that a high percentage of acute massive pulmonary emboli still occur after surgery, even though effective prophylactic regimens are available against

venous thromboembolism, indicates that greater efforts must be taken to ensure that these prophylactic measures are being applied in a more uniform fashion.

Thrombolytic therapy may benefit selected patients with acute massive venous thrombosis, such as those with phlegmasia cerulea dolens. In most patients with acute deep-vein thrombosis, however, the indication for thrombolytic therapy remains controversial, and most patients do well with unfractionated heparin or low-molecular-weight heparin. At present, randomized clinical trials have yielded no definitive evidence that thrombolytic therapy is associated with improved benefit by the prevention of postphlebitic syndrome.

Pulmonary Embolectomy in Massive Pulmonary Embolism

Pulmonary embolectomy is occasionally indicated in the management of massive pulmonary embolism. This is usually defined as the sudden occurrence of a massive embolus that produces severe cardiovascular decompensation with severe hypotension, oliguria, and hypoxia refractory to aggressive treatment. A somewhat more liberal set of indications are (1) an obstruction of more than 50% of the pulmonary vasculature, (2) arterial oxygen tension less than 60 mmHg, (3) systolic blood pressure less than 90 mmHg, and (4) urine output of less than 20 mL/hr. In some centers, patients who have contraindications to thrombolytic therapy or who have failed a trial of thrombolytic therapy are considered candidates for thrombectomy. On the other hand, others would argue that a patient who survives the first 2 hrs after an acute massive pulmonary embolus will probably survive with adequate medical management if no further pulmonary emboli occur. It will not be possible to perform a randomized trial comparing thrombolytic therapy with pulmonary embolectomy, and it is difficult to compare one case series of pulmonary thrombectomy with another because the case material often differs.

Early experience with the Trendelenburg procedure revealed unacceptably high mortality rates (>50%). Mortality rates between 16% and 57% have been reported with the use of cardiopulmonary bypass (CPB) support. In a review of 651 patients undergoing emergency pulmonary embolectomy, the survival rate was 59.3% with CPB support and 47.7% without CPB support. Patients with chronic pulmonary hypertension, other medical disorders, or with symptoms of more than 7 days' duration have higher mortality rates. Patients who have sustained a cardiac arrest before embolectomy also have a higher mortality rate. Greater care to avoid vasodilation at the initiation of anesthesia has decreased mortality rates. Pulmonary hemorrhagic infarction with reperfusion has been reported after pulmonary embolectomy. Other causes of death after embolectomy include cardiogenic shock, infection, and hypoxic brain damage. Pulmonary embolectomy is usually accompanied by insertion of a vena cava filter.

The role of pulmonary embolectomy remains unclear and will depend in part on the ready availability of a surgical team. Patients who are not candidates for thrombolysis (after recent surgery, for example) or who have not responded to maximal medical therapy may be candidates for pulmonary embolectomy. However, the recent report of successful thrombolysis with intrapulmonary UK in patients treated within 10 days of surgery casts further doubt on the need for this somewhat radical procedure.

Percutaneous Clot Extraction or Disruption in the Treatment of Acute Massive Pulmonary Embolus

In patients who have contraindications to anticoagulants or thrombolysis, pulmonary embolectomy via a catheter suction device inserted into the jugular or femoral vein under local anesthesia has been used in the treatment of acute massive pulmonary embolism. Mortality rates of 27% and 28% were observed. The most common cause of death was cardiac arrest from ventricular arrhythmia, right heart failure, and pulmonary hemorrhage. Some patients in whom clot extraction was not possible responded successfully to pulmonary embolectomy while on CPB. Inferior vena cava filters should be used in conjunction with catheter embolectomy.

Attempts have been made to fragment pulmonary emboli using conventional cardiac catheters or a catheter guide wire in conjunction with pulmonary thrombolytic therapy. Mechanical disruption of experimental pulmonary emboli in animals has been attempted using catheter-operated mechanical devices.

Catheter clot extraction is currently confined to a few centers with the required expertise. This procedure cannot be used in patients who suffer cardiac arrest. The exact future role of catheter clot extraction is unclear.

Inferior Vena Caval Interruption in the Treatment of Pulmonary Thromboembolism

The insertion of an inferior vena caval filter is indicated in:

The patient with acute venous thromboembolism and an absolute contraindication to anticoagulant therapy.

The rare patient with massive pulmonary embolism who survives but in whom recurrent embolism may be fatal.

The very rare patient who has objectively documented recurrent venous thromboembolism during adequate anticoagulant therapy.

Characteristics of an ideal filter include one that is easily and safely placed percutaneously, is biocompatible and mechanically stable, is able to trap emboli without causing occlusion of the vena cava, does not require anticoagulation, and is not ferromagnetic (does not cause artifacts on magnetic resonance images). Although there is at present no ideal filter, several devices have proved to be useful. These include the Greenfield stainless steel filter and titanium filter, the bird's nest filter, the Vena Tech filter, and the Simon–Nitinol filter. In experienced hands these devices can be quickly and safely inserted under fluoroscopic control. One novel filter can be inserted temporarily when needed, used in conjunction with thrombolytic therapy, and then removed. At present, the Greenfield filter (titanium version) has had the best performance record, and any future comparative studies should use this filter as the standard.

Studies on the neutralizing effect of protamin on unfractionated and low-molecular-weight heparin (fragmin) at the site of activation of the coagulation system in man. *Thromb Hemostas* 1995;73:439–443. *The role of protamine in neutralizing unfractionated or low-molecular-weight heparin was studied in a randomized clinical trial in healthy volunteers. They recommend doses of protamine no less than 1 mg per 100 units unfractionated heparin.*

CHAPTER

67 Pulmonary Heart Disease

Steven M. Scharf

S.M. Scharf: Pulmonary and Critical Care Division, Long Island Jewish Medical Center, New Hyde Park, New York 11042.

INTRODUCTION

The heart and the respiratory system are closely connected such that disorders of one system influence the function of the other. In the 1800s, Laennec described patients with pulmonary emphysema and associated right heart enlargement. In the 1930s, Paul Dudley White recognized that, although left heart disease is the most common cause of right ventricular enlargement and dysfunction, enlargement of the right ventricle (RV) can result from lung disease in the absence of left heart failure. He coined the term *cor pulmonale* to describe this condition, also known as *pulmonary heart disease* (PHD). With the advent of technological advances in cardiovascular physiology and diagnosis, there has been an impressive advance in our knowledge of the manner in which disordered respiratory function affects the heart, especially the RV. Uniformly accepted criteria for defining PHD do not exist; hence, precise estimates of its prevalence are difficult to ascertain. However, heart failure on the basis of PHD probably constitutes at least 15% to 20% of all cases of heart failure and 7% to 10% of all heart disease. Some 40% of patients with severe chronic obstructive pulmonary disease demonstrate clinical or pathologic evidence of PHD. This is especially important because PHD implies a grave prognosis. Only approximately one-third of patients with lung disease and PHD will be alive 4 years after diagnosis, as opposed to 64% of those without PHD.

DEFINITIONS

Pulmonary heart disease is heart disease caused by dysfunction of the lungs leading to altered pulmonary vasculature. McGinn and White used the term *acute cor pulmonale* to describe right heart strain resulting from acute pulmonary hypertension. This is in contrast to *chronic cor pulmonale,* which has been defined by the World Health Organization as an alteration in structure or function of the RV resulting from disease affecting the structures and function of the lung except when this alteration results from disease of the left heart or congenital heart disease. This definition, based on alterations in structure, has been challenged in favor of more functional definitions containing elements of clinical syndromes, i.e., right heart failure. However, these definitions are similarly imprecise, and there seems no reason to depart from the classic definition. Thus, PHD may be associated with varying degrees of clinically apparent heart failure or abnormalities in pulmonary hemodynamics or may, in many cases, be clinically silent.

In this chapter, we review some of the factors that characterize acute and chronic PHD. Because PHD is a disease of the RV, we briefly describe normal RV function and the response of the RV to imposed mechanical loads. We consider the interactions between the RV and the LV because these are so important to the normal functioning of the heart. We then consider the clinical and pathophysiological features of acute and chronic PHD. Details of pulmonary circulation and pulmonary hypertension have been reviewed in previous chapters.

NORMAL RIGHT VENTRICLE

The RV develops embryologically from two separate components of the primitive cardiac tube. The bulbus cordis is incorporated into the conus (outflow tract), and the sinus venosus is incorporated into the sinus (inflow tract). Normal RV contraction preserves the functional distinction of its dual embryologic origin. Right ventricular systole occurs by sequential contraction, beginning at the inflow tract and extending to the outflow tract, and is almost peristaltic in nature, with approximately 25 msec separating contractile activity of the two components. In fact, with increased sympathoadrenal activation, a pressure gradient can develop between the inflow and outflow tract within the ventricular cavity. This mode of contraction makes the RV ideally suited for its job as a high-volume low-pressure pump.

The RV is normally thin (less than 0.5 cm thick) and crescent shaped. Therefore, determination of its volume from limited numbers of dimensions that can be assessed using standard imaging techniques is more difficult than for the left ventricle (LV). The difficulty in measuring RV volume using simple imaging techniques (as for the LV) is further compounded by the fact that, with dilation, its shape becomes more ellipsoidal. Thus, changes in loading conditions can lead to changes in shape. This in turn may be responsible for the fact that in many circumstances there is a poor or nonexistent correlation between end-diastolic and end-systolic pressures and corresponding RV volumes.

RIGHT- AND LEFT-VENTRICLE FUNCTION COMPARED

The fact that the RV free wall may be ablated or surgically replaced with a dacron patch with no change in resting cardiac output initially led workers to believe its importance to circulatory homeostasis is minimal. However, when there is an increase in pulmonary arterial pressure or venous return, as with exercise or other stress, normal RV functioning is essential for maintenance of normal circulatory status. It is commonly stated that the RV is a “volume pump,” whereas the LV is a “pressure pump,” implying some sort of qualitative difference between the ventricles. It is certainly true that the thin-walled RV is less able to generate pressure than the muscular LV (Table 1). However, compared to its normal physiological pressure range, the RV is capable of increasing maximum pressure generation proportionally to the same degree or even more than the LV. During acute constriction of the pulmonary artery, maximum RV pressure can increase to 55 to 60 torr (almost three times the normal peak systolic pressure) before circulatory failure ensues.

TABLE 1. *Diseases that have been associated with pulmonary hypertension and/or pulmonary heart disease*

The determinants of RV function are the same as those of LV function, namely, preload, afterload, and contractility. Figure 1 illustrates the pressure–volume history of RV contraction. During diastole, the RV fills along the diastolic or relaxation pressure–volume curve. At end-diastole (EDP), isovolumic contraction occurs. The RV pressure increases until the level of pulmonary artery (PA) diastolic pressure (PADP) is reached, at which point shortening occurs. Shortening ceases when the pressure–volume point reaches the curve describing the maximum end-systolic pressure–volume relationship, at which time isovolumetric relaxation occurs. The point labeled EDP in Fig. 1 represents the stress on the RV at the onset of contraction (preload). The stress on the RV during contraction represents the afterload. The slope of the end-systolic pressure–volume curve represents a load-independent measure of contractility and is sometimes called the maximum systolic elastance. These concepts, developed and validated for the LV both in isolated load-clamped heart preparations and in *in situ* preparations, also apply to the RV with some slight modifications. First, pulmonary arterial pressure represents only part of the hydraulic load placed on the RV (afterload) during contraction. A substantial part of the total hydraulic load is represented by the elastance of the pulmonary arterial circulation. The total hydraulic load placed on the RV is more properly represented by the input impedance of the pulmonary circulation (see Chapter 64). Second, end-systole is more difficult to define for the RV than for the LV. This is because for the LV, end-ejection and end-contraction correspond fairly well. For the RV, there is dyssynchrony in that the ventricle continues to eject for a short time after end-contraction. Further, there are slight differences in end-systolic volume depending on whether contraction is isovolumetric or isotonic.

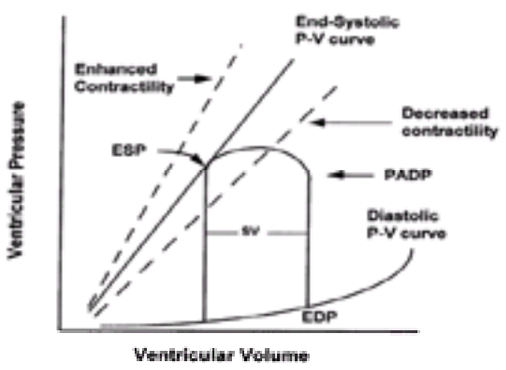

FIG. 1. Ventricular pressure–volume diagram. EDP, end-diastolic pressure; PADP, pulmonary arterial end-diastolic pressure; ESP, end-systolic pressure; SV, stroke volume. See text for explanation.

Practically speaking, however, these quantitative differences do not negate the concept of the end-systolic pressure–volume curve being an important measure of ventricular contractile function. Often the end-systolic point is defined in terms of a specified time interval, often 100 msec from end-diastole, in analyses of RV mechanics. In general, however, RV and LV contraction behave remarkably similarly. When normalized for peak pressure, the time courses of RV and LV isovolumetric pressure development are practically superimposable. Just as for the LV, RV contraction can be viewed as a series of time-varying elastances, a concept that had been developed for the LV. For the RV, as for the LV, the instantaneous pressure–volume relationship may be expressed as:

$$P_t = E_t(V_t - V_0)$$

where P_t is the pressure at any given time in the cardiac cycle, E_t is the slope of the pressure–volume curve at time *t,* V_t is ventricular volume at time *t,* and V_0 is the volume intercept of the regression line. E_t at end-systole is a measure of ventricular contractility that is relatively independent of pre- or afterload.

RIGHT-VENTRICLE RESPONSE TO ACUTELY INCREASED AFTERLOAD: THE PHYSIOLOGY OF ACUTE PHD

Investigators have assessed the ability of the RV to tolerate increased afterload by graded occlusions of the pulmonary artery or injection of glass beads or other small particles into the distal pulmonary bed. These two models are not strictly comparable because the hydraulic load produced by main pulmonary arterial constriction is greater than that produced by microvascular embolization. However, the principles governing load tolerance are the same. Relevant clinical conditions include acute massive pulmonary embolism and large increases in lung volume (high levels of positive end-expiratory pressure) in the presence of adult respiratory distress syndrome. Figure 2 illustrates the results of a typical series of experiments. The RV systolic pressure could be increased to approximately 60 torr with little evidence of circulatory decompensation, although there were decreases in cardiac output and blood pressure. However, a further small increase in the degree of pulmonary arterial constriction brought about sudden dramatic circulatory collapse accompanied by RV dilation and increased RV end-diastolic pressure. Because RV dilation occurred primarily at the time of circulatory collapse, this might suggest that the Frank–Starling mechanism plays little role in maintaining RV output against an increase in afterload. However, other studies have shown that there is a role for the Frank–Starling mechanism in RV afterload tolerance, although it is not the primary determinant. Because the right coronary artery, which supplies the RV free wall, originates in the aorta, coronary blood flow to the RV free wall depends on aortic blood pressure. One hypothesis for the sudden deterioration of the RV with increased afterload is that the balance between RV myocardial O_2 demand and supply suddenly tips in the direction of increased demand, resulting in RV ischemia. Other studies suggest that RV failure does not result from ischemia but, rather, that ischemia is secondary to circulatory collapse. Either way, RV failure with severe pulmonary hypertension appears to be the result of a vicious cycle in which decreased RV output causes decreased LV output. This in turn leads to decreased aortic pressure, which limits the degree to which coronary flow can increase commensurate with O_2 demand. With inadequate coronary flow relative to O_2 demand, RV contractility decreases, which in turn decreases cardiac output. Limitation of right coronary flow is further enhanced by increased RV intramyocardial pressure during systole, which may produce endocardial ischemia.

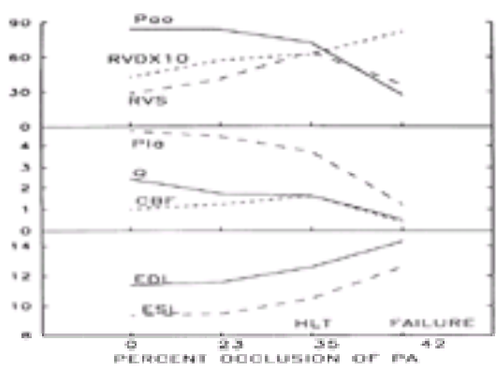

FIG. 2. Summary of hemodynamic changes with acute graded constriction of the pulmonary artery. P_{ao}, aortic pressure; RVD, RV end-diastolic pressure; RVS, RV end-systolic pressure; P_{la}, left atrial pressure; *Q,* cardiac output; CBF, coronary blood flow; EDL, RV end-diastolic segmental length; ESL, RV end-systolic segmental length; HLT, highest load tolerable; failure, circulatory collapse. SM, ed. *Cardiopulmonary Physiology in Critical Care.* New York: Marcel Dekker, 1992;239–247.)

Supportive Therapy of Acute PHD

The issues discussed above have direct clinical relevance in the assessment and treatment of acute PHD. First, sustained RV pressures greater than approximately 60 torr mean that pulmonary hypertension cannot have been acute because the normal RV cannot sustain systolic pressures greater than this level. Second, whether ischemia is involved or not, one should view RV failure in the light of the balance between myocardial O_2 supply and demand. Resuscitative maneuvers, such as the administration of isoproterenol or even massive fluid resuscitation, could act to increase RV myocardial O_2 demand and unfavorably influence the supply–demand relationship. Although we favor volume infusion in patients who are dehydrated and/or in whom the central venous pressure is low, massive volume infusion when RV afterload is severely elevated may actually worsen failure and produce circulatory decompensation. Support measures should be directed toward maintaining aortic pressure and hence coronary flow. In this setting, vasoconstrictor agents such as phenylephrine or norepinephrine are preferred over agents that increase myocardial contractility and heart rate while producing arterial vasodilation, such as isoproterenol or dobutamine. Diagnosis and specific therapy (thrombolytic agents in massive pulmonary embolism) should be instituted as rapidly as feasible while supportive measures are being instituted.

Right-Ventricle–Left-Ventricle Interactions

The ventricles exhibit two major types of interactions, “series” and “parallel.” Series interactions refers to effects of RV output on LV filling and output. Parallel interactions refers to those interactions arising from the fact that the two chambers are part of one structure, contain common muscle bands, share a common septum, and are covered by a single pericardial sac. It has been amply confirmed that the function of one ventricle depends on that of the other. Many studies have verified the diastolic interactions of the ventricles. When diastolic filling of one ventricle is increased, that of the other is impaired. This diastolic interaction is mediated largely through the interventricular septum. However, the degree of diastolic interaction is amplified approximately fourfold by the presence of the pericardium. Anything that increases the stiffness of the pericardium (pericardial fibrosis, tamponade) increases the degree of diastolic interdependence. These considerations may explain the fact that with acute massive overload of the RV, LV end-diastolic volume decreases, and LV end-diastolic pressure either remains the same or increases. Indeed, bulging of the interventricular septum into the LV is a sign of severe RV overload (see below) and is a reflection of diastolic interaction.

The ventricles also interact during systole. This interesting interaction arises because the ventricles share common fiber bundles, contract toward a common center of gravity, are found within a common pericardial sac, and share a common septum. This means that rather than impairing the function of the opposite ventricle, contraction of one ventricle actually enhances the function of the other. Although the low-pressure RV does little to enhance pressure generation in the LV, as much as 40% to 60% of the pressure generated in the RV is attributable to LV contraction! Systolic interaction is mediated largely through the septum but is substantially enhanced by increasing the elasticity of the RV free wall. This is yet another mechanism by which LV systolic pressure (arterial pressure) increases RV afterload tolerance.

CLINICAL FEATURES OF ACUTE PULMONARY HEART DISEASE

The clinical manifestations of acute PHD are nonspecific and include dyspnea, orthopnea, and cough. Physical examination may reveal distended neck veins with prominent *a* and *v* waves, pulsus paradoxus, and peripheral cyanosis. Inspection of the precordium may demonstrate RV lift, whereas palpation of the cardiac impulse may reveal a parasternal or subxyphoid heave. On cardiac auscultation, an S3 gallop and a loud pulmonic component of the second sound are usually present. A holosystolic murmur along the left parasternal border, accentuated during inspiration, suggests tricuspid regurgitation, often seen with acute or chronic pulmonary hypertension. Auscultation of the lung fields may be normal or may reveal bilateral basilar crackles. Although the patient's history and a carefully performed physical examination may suggest acute PHD, additional diagnostic studies may be necessary to confirm the diagnosis.

CHRONIC PULMONARY HEART DISEASE

Chronic PHD develops when pulmonary disease is bilateral, diffuse, and chronic. Causes of pulmonary hypertension are discussed in previous chapters. Table 1 lists many of the causes of chronic PHD. Chronic obstructive pulmonary disease is by far the most commonly seen cause of chronic PHD in the developed world. Pulmonary heart disease is especially seen in patients with the features of the so-called blue and bloated (type B) syndrome, consisting of hypoxemia, hypercapnia, and peripheral edema. Although the true incidence of chronic PHD is probably unknown, 10% to 30% of hospital admissions in the United States for congestive heart failure are caused by PHD. As discussed in previous chapters, hypoxemia and subsequent vascular remodeling are probably the most important correctable features seen in chronic PHD. Although destruction of peripheral pulmonary vessels can contribute to increased pulmonary arterial pressure, this factor appears to be minor.

Recent studies using computed tomography to quantify the extent of parenchymal obstruction have demonstrated a similar extent of emphysema in patients with the “blue and bloated” syndrome (hypoxia, hypercapnia, edema, polycythemia) as in the so-called “pink and puffing” syndrome (normoxic, breathless). Another recent study has demonstrated that RV weight correlates with peripheral airway narrowing and not with emphysema. Thus, peripheral vascular destruction probably plays a minor role in the genesis of pulmonary hypertension and PHD in patients with COPD, the major role being hypoxemia with secondary vascular narrowing and remodeling. In patients with COPD, there is a positive correlation between arterial PCO_2 and pulmonary arterial pressure. This suggests additive effects of hypercapnia and acidosis in these patients. Peripheral pulmonary vascular obstruction may be a more important mechanism for the genesis of PHD in diseases such as pulmonary fibrosis when peripheral vascular obstruction may be extensive, although these conditions have been less well studied than COPD.

Right Ventricle in Chronic PHD

Chronic PHD leads to uniform hypertrophy of the RV. The ventricular wall cross-sectional area increases, as does myocardial fiber thickness. It should be remembered that dilation of the RV may actually be associated with a greater increase in muscle mass than hypertrophy without dilation because of the increase in RV surface area. Baseline coronary flow increases in proportion to muscle mass. The RV end-diastolic pressure increases only in the later stages of pulmonary hypertension and RV hypertrophy. Because of increased muscle mass, RV myocardial O_2 demand is increased, thus rendering the RV more susceptible to demand and supply imbalance.

In contrast to acute PHD, RV systolic pressure in chronic PHD can be very high, even approaching systemic levels. Cardiac output at rest is usually normal but may be elevated in patients with chronic PHD. Patients with progressively decreasing cardiac output have a poor prognosis. This suggests that maintaining peripheral blood flow is an important adaptive response to chronic tissue hypoxemia. Polycythemia develops in many patients with chronic PHD, and this may augment peripheral O_2 delivery in the setting of a decreased cardiac output. However, polycythemia increases blood viscosity, thereby increasing pulmonary vascular resistance according to the laminar flow equation. The development of polycythemia may therefore be maladaptive, as it may contribute to further decreases in cardiac output. Patients who maintain normal or slightly elevated cardiac output with pulmonary hypertension tend to be those who do not become polycythemic, supporting the notion that polycythemia in COPD is a maladaptive response.

Patients with chronic PHD frequently experience syncope during exercise. The cause is multifactorial. Increased venous return during exercise leads to increased RV pressure and volume, thus increasing O_2 demand. This could produce RV myocardial O_2 supply–demand imbalance and even ischemia as discussed above. In addition, during exercise, systemic vascular resistance normally falls. If, because of poor RV function, cardiac output fails to increase proportionally, this will result in a fall in blood pressure, in contrast to the usual increase in systemic arterial pressure observed with exercise. Decreased systemic arterial pressure could limit RV coronary blood flow and contribute to circulatory collapse as well as lead to poor cerebral perfusion and syncope.

Pathophysiological Features

The pulmonary hemodynamics of patients with COPD has been thoroughly investigated. In the early stages, pulmonary arterial pressure is either normal or only slightly elevated. However, pulmonary arterial pressure almost invariably increases with exercise in patients with PHD. This is because of the lack of recruitable or distensible pulmonary vessels in the patient with pulmonary vasculopathy. As the disease progresses, pulmonary arterial pressure is increased even at rest. If the disease remains untreated, even with no changes in pulmonary mechanics, as hypoxemia worsens with time, pulmonary arterial pressures increase, although the rate of increase may be slow. Data on the progression of pulmonary arterial pressure in patients enrolled in the British Medical Research Council (MRC) trial on domiciliary O_2 therapy showed an increase of mean pulmonary arterial pressure of 3 torr per year. In smaller trials, other authors have found the rate of increase of pulmonary arterial pressure in untreated COPD patients to be either somewhat greater or less than this. Differences in initial disease state, degree of hypoxemia, or other patient selection factors may have accounted for the differences found.

Although pulmonary hypertension progresses slowly in patients with COPD, its presence is a poor prognostic sign. Mortality in patients with pulmonary hypertension

and PHD may be increased two- to threefold over that of comparable patients without PHD. Some studies have demonstrated that in untreated COPD, progression of pulmonary hypertension is associated with progressively worsening hypoxemia. The relationship between RV contractile function and clinical features of PHD is not clear. Some authors have found that RV function deteriorates during exercise in patients with PHD. Others have failed to show a correlation between changes in RV contractile function and clinical features of heart failure such as peripheral edema, ascites, and increased right atrial pressure. Finally, progressive decreases in systemic arterial pressure have been demonstrated in patients with pulmonary hypertension. This suggests that decreased LV afterload may help buffer the effects of pulmonary hypertension. However, as discussed above, decreased LV systolic pressure could decrease the ability of the RV to generate pressure against increased afterload. Variable results have been found regarding the changes in cardiac output with time in COPD patients with PHD.

Left-Ventricle Function in Chronic PHD

As discussed above, with RV dilation, ventricular interdependence acts to inhibit LV filling, as mediated through a leftward shift in the interventricular septum and pericardium. Indeed, decreased compliance of the LV has been demonstrated in some patients with chronic PHD. There has been a great deal of debate in the literature as to whether chronic RV overloading leads to structural and functional changes in the LV as well. In experimental studies, banding the pulmonary artery in animals led to LV as well as RV hypertrophy, supporting the concept of the whole-heart theory of PHD. Indeed, LV hypertrophy accompanies RV hypertrophy in approximately 30% of patients with COPD. Others have reported depressed LV function in patients with COPD in the absence of identifiable causes of LV failure such as coronary heart disease. On the other hand, a number of studies have failed to find evidence of LV dysfunction in patients with COPD and PHD in the absence of known causes of LV failure. More recent studies have demonstrated LV myocardial fibrosis and cellular hypertrophy in patients with COPD dying of heart failure in whom there was no identifiable cause of LV disease. It must be remembered that in addition to RV hypertrophy and dysfunction, acute-on-chronic respiratory failure is accompanied by hypoxemia, hypercapnia, and probably increased blood catecholamine levels, which could produce these changes.

There are a number of causes of impaired LV filling in patients with COPD and other obstructive airways diseases. Patients with airflow obstruction may generate large negative inspiratory swings in intrathoracic pressure, especially during exercise. Such swings increase venous return during inspiration, further dilating the RV and leading to greater diastolic interdependence effects. This may explain the early inspiratory decrease in LV preload observed in many studies. This effect is partly or wholly responsible for decreased stroke volume in early inspiration and thus contributes substantially to the pulsus paradoxus observed in many types of airway obstruction. In addition, patients with COPD often demonstrate pulmonary hyperinflation. By direct mechanical heart–lung interactions, an increased volume of the lower lobes of the lung can hinder LV filling. Finally, hypoxemia itself can impair LV relaxation.

In addition, there are factors contributing to possible LV systolic dysfunction. Large decreases in intrathoracic pressure, especially if sustained, can impair LV ejection (i.e., increase LV afterload). If intrathoracic pressure decreases more than aortic pressure during inspiration, then LV systolic transmural pressure, one measure of LV wall stress or afterload, may increase. Although sustained decreases in intrathoracic pressure increase LV afterload, the importance of this mechanism in influencing LV function with intermittent (inspiratory) exaggerated decreases in intrathoracic pressure in obstructive airways disease remains controversial.

Finally, many patients with COPD have concomitant coronary artery, valvular, or hypertensive heart disease. These conditions certainly affect LV function and contribute to further deterioration of RV function through the mechanism of backward series interaction.

Diagnosis of Chronic PHD

Both the clinical history and physical examination are critical in the diagnosis of PHD. There are several noninvasive methods that can aid in the assessment of secondary pulmonary hypertension and its cardiac complications.

Clinical Presentation

Patients with chronic PHD exhibit signs and symptoms of the underlying disease. Dyspnea is a frequent symptom and often occurs concurrently with hypoxemia and hypercapnia. However, in many patients, especially those with infiltrative or fibrotic lung disease or vascular obstruction, dyspnea is not associated with hypoxemia and is not completely relieved with oxygen therapy. In these cases, dyspnea may be caused by reflexes originating in the lungs or chest wall.

Patients with chronic PHD may present with syncope, especially during exercise, as a result of mechanisms discussed above. A type of chest pain called pulmonary artery pain has been described in patients with chronic severe PHD. This pain is anginal in character but lasts longer and is not responsive to nitrates. Stretching of the pulmonary artery or actual RV ischemia may be the cause of pulmonary artery pain. On the other hand, this type of pain may in fact represent classic coronary heart disease.

Hemoptysis may be associated with pulmonary hypertension because of leakage of blood from the vascular to the alveolar space in dilated pulmonary capillaries that rupture. It must be emphasized that hemoptysis should not be attributed to PHD until other diagnoses such as tumor, bronchiectasis, or pulmonary infarction are excluded.

Right upper quadrant fullness, early satiety, and nausea and vomiting are not uncommonly seen in patients with PHD. These symptoms are signs of chronic passive congestion of the liver. The liver may even be tender to palpation. Neurologic symptoms such as headache and mental obtundation are often seen, changes possibly attributable to decreased cardiac output and altered arterial blood gas tensions. Occasionally, hoarseness is observed, which may be caused by enlargement of the left pulmonary artery as it passes contiguous to the aorta and presses on the left recurrent laryngeal nerve.

Tachypnea at rest is often found in patients with chronic pulmonary vasculopathy, chronic pulmonary fibrosis, or infiltrative disease, but usually not in patients with stable chronic bronchitis. As in acute PHD, there may be a loud pulmonic component of the second heart sound and a RV heave and gallop. A holosystolic murmur along the left sternal border that is exacerbated on inspiration (Carvallo's sign) may be present with tricuspid regurgitation. Elevated neck veins with prominent *a* and *v* waves are associated with congestive heart failure.

Peripheral Edema in PHD

Peripheral edema is part of the congestive heart failure syndrome. Edema may extend into the abdominal wall and sacrum. The simplest explanation for edema is that elevated pulmonary artery pressure leads to elevated right atrial pressure, which in turn raises peripheral venous and capillary pressure. This leads to an increased hydrostatic gradient for fluid transudation. However, many patients with peripheral edema have normal right atrial pressures. Thus, the explanation for edema must be sought elsewhere.

There are data demonstrating that chronic hypoxia and hypercapnia can lead to abnormal renal excretion of sodium and water. Hypoxia can lead to decreased glomerular filtration and decreased filtration of sodium. Retention of bicarbonate by the kidney is a mechanism for maintaining arterial pH in cases of chronic respiratory acidosis. Because bicarbonate is retained with Na^+, this constitutes an additional edemagenic mechanism. Hypoxemia may also stimulate the production of arginine vasopressin (AVP) and lead to decreased free water excretion. Alternatively, AVP production may be stimulated by the renin–angiotensin system, specifically angiotensin II, which is activated by a reduction in renal blood flow that is seen with hypoxia. Catecholamines, often elevated in COPD patients, can also lead to renin release from the kidneys and promote sodium absorption.

Atrial natriuretic peptide (ANP) is, as expected, elevated in patients with COPD and edema. It has been demonstrated that these patients exhibit normal responsiveness to ANP following water loading. However, the response to ANP, which acts to buffer edemagenic mechanisms, is not sufficient to overcome them in the most severe patients. Finally, circulating L-dopa is filtered at the glomerulus and enters renal tubular cells under the influence of sodium. Here, L-dopa is converted into dopamine by the enzyme L-dopa decarboxylase. Stimulation of dopamine receptors promotes natriuresis and renal arterial vasodilation. Thus, dopamine may act to buffer the edemagenic effects of PHD in some patients. In summary, although the precise nature of the mechanisms leading to peripheral edema formation in PHD is not completely understood, it is clear that edema results from a complex series of interactions between pulmonary and peripheral hemodynamics along with alterations in salt and water balance at the level of the kidney.

Electrocardiogram

The electrocardiographic (ECG) abnormalities in PHD depend on its etiology. Patients with COPD have a characteristic ECG pattern as a result of major structural changes of the thorax and its contents. The resulting ECG patterns, such as shifts of the P wave and QRS axis, will then be superimposed on the changes caused by PHD. The ECG criteria for PHD listed in Table 2 illustrate the common patterns associated with COPD as well as with other parenchymal lung diseases. In general, ECG criteria are fairly specific but not terribly sensitive for the detection of PHD. The absence of all criteria for RV hypertrophy excludes approximately 95% of cases without RV hypertrophy. Esophageal electrocardiography is even more sensitive and specific for RV hypertrophy.

ECG criteria for cor pulmonale without obstructive disease of the airways
1. Right-axis deviation with a mean QRS axis to the right of +110°
2. R/S amplitude ratio in V_1 > 1
3. R/S amplitude ratio in V_6 < 1
4. Clockwise rotation of the electric axis
5. P-pulmonale pattern
6. S_1, Q_3 or S_1, S_2, S_3 pattern
7. Normal voltage QRS
ECG changes in chronic cor pulmonale with obstructive disease of the airways
1. Isoelectric P waves in lead I or right-axis deviation of the P vector
2. P-pulmonale pattern (an increase in P-wave amplitude in II, III, AVF)
3. Tendency for right-axis deviation of the QRS
4. R/S amplitude ratio in V_6 < 1
5. Low-voltage QRS
6. S_1, Q_3 or S_1, S_2, S_3 pattern
7. Incomplete (and rarely complete) right bundle-branch block
8. R/S amplitude ratio in V_1 > 1
9. Marked clockwise rotation of the electric axis
10. Occasional large Q wave or QS in the inferior or midprecordial leads, suggesting healed myocardial infarction

TABLE 2. *Electrocardiographic changesin cor pulmonale*

One problem with the ECG diagnosis of RV hypertrophy is that the electrical activity of the RV is considerably less than that of the LV. Thus, small changes in RV forces may be “lost” in the preponderance of leftward-acting forces. An increase in anteriorly directed forces may occur with RV hypertrophy, but this may also be a sign of posterior LV infarction. Mitral stenosis and PHD may meet the QRS criteria for apical, lateral, and posterior infarction. Severe RV hypertrophy may lead to Q waves in the precordial leads, falsely suggesting anterior myocardial infarction. However, if the precordial leads are moved down one interspace, Q waves will be abolished in RV hypertrophy but persist with LV anterior wall myocardial infarction.

In addition, many rhythm disturbances may be present in PHD. These range from premature atrial contractions to supraventricular tachycardia of all types, including paroxysmal atrial tachycardia, multifocal atrial tachycardia, atrial fibrillation, atrial flutter, and junctional tachycardia. Arrhythmias are frequently observed in patients undergoing acute-on-chronic respiratory failure. These are often secondary to acute RV overload, electrolyte abnormalities, hypoxemia, and acidosis or may be secondary to therapy with b-agonists, methylxanthines, or diuretics. Interestingly, red cell magnesium has been found to be decreased in patients with COPD in whom arrhythmias are observed. Although the overall incidence of arrhythmias is in the range of 20% to 70%, the range of the reported incidence of ventricular arrhythmias is considerably lower (7% to 24%). Patients with pure pulmonary vasculopathy such as primary pulmonary hypertension rarely demonstrate arrhythmias, suggesting that the increased incidence of arrhythmias in COPD is caused by other factors besides RV hypertrophy or pulmonary hypertension.

Figure 3 shows an ECG from a patient with severe pulmonary hypertension and PHD.

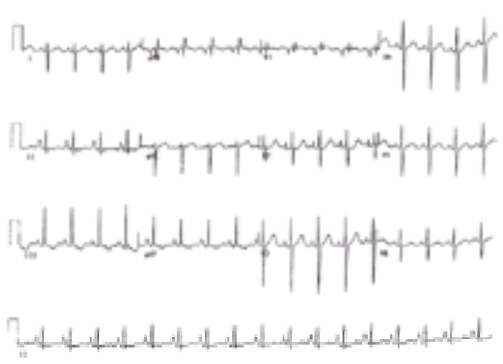

FIG. 3. Example of an electrocardiogram from a 37-year-old woman with chronic PHD related to chronic bronchiectasis. Note right-axis deviation and p-pulmonale in lead 2 along with persistent right axis forces (RS) in the lateral precordium (V_5–V_6).

Chest Roentgenogram

Routine chest radiography demonstrating a right descending pulmonary artery more than 16 mm in diameter or a left artery more than 18 mm in diameter indicates pulmonary hypertension. The RV enlargement on the posteroanterior view results in displacement of the heart shadow to the right and in an increased transverse diameter of the heart. In the lateral view, RV enlargement leads to filling of the retrosternal air space. There may be pruning of peripheral pulmonary vessels. In patients with COPD or chest wall deformity, changes in mediastinal and chest wall configuration may render the correlation of x-ray signs with RV weight unreliable. The National Institutes of Health Registry demonstrated enlarged main pulmonary arteries in 90%, enlarged hilar pulmonary arteries in 80%, and peripheral pulmonary vascular pruning in 51% of patients with primary pulmonary hypertension or chronic pulmonary thromboembolic disease. Heart size was enlarged in 94% of these patients.

Figure 4 demonstrates typical roentgenographic signs of PHD.

FIG. 4. Progression of chest x-ray in a 34-year-old woman with a primary pulmonary hypertension-like syndrome associated with human immunodeficiency virus syndrome. **A:** Chest x-ray taken in 1991. **B:** Chest x-ray taken in 1992. **C:** Chest x-ray taken in 1994. Note the progressive dilation of the main pulmonary arteries and cardiac dilation over the years.

Ultrafast Computed Tomography

Ultrafast, ECG-gated CT scanning has recently been evaluated for studying global and regional systolic and diastolic RV function. Good correlations between RV and LV stroke volumes have been obtained, and RV ejection fraction (RVEF) can been reliably estimated. Further, the stop-action mode of ultrafast CT has been shown to yield estimates of RV wall mass that correlate to actual mass in both animals and human studies. As these techniques improve, it is expected that they will be utilized increasingly in the evaluation of the progression of chronic PHD.

Echocardiography

The diagnostic application of M-mode echocardiography in evaluating the RV is limited. Because the right-sided cardiac structures are anatomically situated posterior to the echo-dense sternum, accurate assessment is technically difficult. Pulmonary hyperinflation and excessive chest motion in patients with COPD also impose

limitations to this technique.

Two-dimensional (2-D) echocardiography provides multiple cross-sectional views of the heart, improves visualization of right-sided cardiac structures, and is useful in assessing RV hypertrophy in patients with PHD. In addition, multiple cross-sectional views can be employed to obtain relatively accurate estimations of RV volume using the Simpson's rule approximation technique. Measurements of right atrial and RV size by 2-D echocardiography distinguish normal patients from those with RV volume overload and correlate with measurements made at cardiac catheterization.

There have been correlations made between indices of RV size and/or mass and pulmonary hemodynamics. One measurement called the RV index is equal to (TA × RV + AW/BSA), where TA is the inner tricuspid annulus diastolic dimension, RV is RV short-axis dimension, AW is RV anterior wall thickness, and BSA is body surface area. This index has been shown to correlate reasonably well with mean pulmonary arterial pressure.

The use of velocity measurements (Doppler echocardiography) has allowed noninvasive estimation of the pulmonary arterial pressure. One convenient method utilizes the fact that, because of dilation of the tricuspid annulus, most patients with RV overload develop some degree of tricuspid regurgitation. The pressure gradient across the tricuspid valve during systole can be estimated from the maximum velocity of the regurgitant jet and the modified Bernoulli equation:

$$PG = 4\ V^2$$

where *PG* is pressure gradient across the valve and *V* is the maximum velocity of the regurgitant jet. If right atrial pressure is measured by another technique (e.g., by neck vein distention on physical exam) or a value is assumed, then this value is added to the value for *PG.* Thus, RV and pulmonary arterial systolic pressure may be estimated. Other techniques for estimating pulmonary arterial pressure using Doppler measurements of pulmonary arterial velocity also exist and may be employed when tricuspid regurgitation is not present.

Chronic RV overload leads to RV dilation, especially during inspiration, when venous return is maximized. These changes can result in changes in RV configuration and impairment of LV diastolic filling by ventricular interdependence. Because these effects are mediated through the interventricular septum, they may be detected by echocardiogram. Normally, the septum is concave toward the LV, resulting in a relatively circular LV shape in the axial plane during diastole. During systole, there is symmetric inward motion of the ventricular walls, resulting in constriction of the LV while it maintains its circular shape. Thus, the septum functions as part of the LV during systole. With RV volume overload, the septum may become flattened or even reverse its curvature so as to become concave toward the RV. In extreme cases, the septum may bulge into the LV during diastole. During systole, the septum may demonstrate so-called paradoxic motion, defined as motion away from the LV posterolateral wall and toward the RV free wall. The septum effectively functions as part of the RV in these cases. With a sufficient degree of leftward shift of the septum, LV end-diastolic volume may become compromised enough to lead to decreased cardiac output. Finally, from echocardiographically derived estimates of wall thickness and chamber size, estimates of RV muscle mass may be made.

Figure 5 shows an example of an echocardiogram in a patient with primary pulmonary hypertension and PHD.

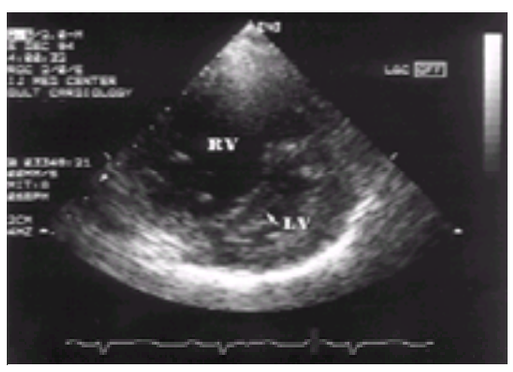

FIG. 5. Example of echocardiogram from the patient illustrated in Fig. 4 at the time of the most recent chest x-ray. This short-axis view shows severe dilation of the RV, bulging of the septum to the left in diastole, and a small LV chamber. The RV was noted to be severely hypokinetic. The *arrow* points to the interventricular septum. RV, right ventricle; LV, left ventricle. Radionuclide Techniques

The equilibrium-gated blood-imaging technique allows continuous monitoring of RV performance by tagging erythrocytes with technetium-99m. Ejection fraction is calculated by comparing counts at end-systole with those at end-diastole over approximately 10 min. Although equilibrium-gated blood pool imaging allows continuous monitoring of RV performance and provides reliable measurements of RV ejection fraction (RVEF), RV dimensions are difficult to evaluate because the ventricular borders are obscured by the presence of background counts in other cardiac chambers and the lungs. The “first-pass” technique also involves labeling with technetium-99m but is based on principles of indicator dilution theory, whereby counting is done sequentially over each cardiac chamber as a function of time. The advantage of the first-pass technique is that data are gathered over only a few heartbeats. Further, the large number of counts relative to background allows definition of the RV borders and estimates of diastolic and systolic size. Both first-pass and equilibrium-gated techniques can be used to evaluate ventricular function at rest and during exercise. The first-pass techniques allows patients to be studied in the supine or upright position, which is a major advantage. The 30° right anterior oblique position is optimal for assessing the RV. It should be noted that although radionuclide studies can detect severely elevated pulmonary arterial pressure, they cannot accurately assess mild pulmonary hypertension. The prediction of the actual level of mean pulmonary arterial pressure from radionuclide measurements is also difficult.

Right ventricle function in COPD depends on the cause, duration, and severity of PHD. The correlations between pulmonary arterial pressure and RVEF and, similarly, those between pulmonary vascular resistance and RVEF have generally been weak. Exercise studies appear to enhance the detection of decreased RVEF by radionuclide techniques.

Thallium-201 is another radionuclide used for imaging the RV. Thallium is taken up by myocardial tissue, in contrast to technetium, which images the blood pool. Although visualization of the RV at rest is not common in normals, the thickened RV myocardium present in patients with chronic PHD allows RV visualization in these patients. Thallium imaging techniques are most sensitive for detecting RV hypertrophy when mean pulmonary arterial pressure is greater than 30 torr.

Radionuclide scanning can be combined with tomographic techniques to yield images of RV blood pool and RV myocardial perfusion. Single-photon-emission computed tomography (SPECT) can be used to reconstruct three-dimensional surface images of the ventricles, which permit visualization of atrial and ventricular movements in humans. This exciting dynamic technique will undoubtedly prove to be extremely useful in the evaluation of RV function and the interactions of RV and LV function in patients during the progression of PHD.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) allows the noninvasive evaluation of RV free wall mass. With this technique, mean RV free wall mass has been shown to be greater in patients with chronic PHD than in normals. A modified short-axis section of the heart imaged by MRI appears to provide valid clinical configurational information concerning the RV on which the noninvasive diagnosis of PHD may be entertained.

In summary, with the increasing availability of noninvasive techniques for evaluating ventricular function, invasive procedures are often not indicated for the routine diagnosis of PHD. However, if unexplained RV dysfunction presents in a patient without previously diagnosed pulmonary disease, other diagnoses such as primary pulmonary vascular disease, pulmonary embolism, or left heart failure should be considered. Right heart catheterization and pulmonary angiography may be indicated in these cases.

THERAPY OF CHRONIC PHD

Of course, specific disease-directed therapy is always part of the therapeutic regimen. This may include treatment of infection and bronchodilation in COPD, treatment with steroids or other immunosuppresive agents in chronic infiltrative and fibrotic disorders, and anticoagulation in chronic thromboembolic diseases. In this section we

review some of the principles of supportive therapy that apply to cases of chronic PHD.

Oxygen Therapy

Oxygen therapy is the only mode of therapy shown to improve long-term prognosis in patients with COPD and hypoxemia. It is the only drug that causes long-term pulmonary vasodilation and halts the progression of pulmonary vasoconstriction in COPD patients with chronic PHD. However, the use of oxygen in treating causes of PHD other than COPD has not been as firmly established. There are no large randomized controlled trials of O_2 therapy in diseases such as pulmonary fibrosis and pneumoconioses as there are for COPD. However, in diseases such as pulmonary fibrosis, pneumoconioses, cardiac failure, and terminal cancer, O_2 therapy certainly appears to offer significant symptomatic relief and should not be withheld even though patients do not meet the currently accepted criteria for long-term O_2 therapy used in COPD. Further, many patients are normoxic at rest (O_2 saturation >92%) but become severely hypoxic either at night or during exercise. Although the administration of O_2 has not been unequivocally demonstrated to improve long-term prognosis in these patients, many patients derive significant functional benefit from the administration of O_2 during times of hypoxemia. For example, many patients with idiopathic pulmonary fibrosis and exercise-induced hypoxemia will demonstrate increased exercise tolerance and less exercise-induced dyspnea if portable O_2 is administered during activities of daily living.

Short-Term Effects of O_2 Therapy

Many patients presenting to the hospital with acute-on-chronic respiratory failure are hypoxemic, and treatment with oxygen leads to substantial clinical improvement, e.g., diuresis, decreased dyspnea, and improved mental functioning. Even though arterial O_2 content increases with short-term O_2 therapy, O_2 delivery to the periphery has not uniformly been reported to increase. This is because as arterial O_2 content increases, sympathoadrenal stimulation decreases, which may lead to reductions in cardiac output. However, in the most severely ill patients (P_aO_2 £ 40 torr), cardiac output may be fixed even with O_2 administration. In these patients, increasing arterial O_2 will increase peripheral O_2 delivery.

Hypoxia causes pulmonary vasoconstriction. Thus, the presence of pulmonary arterial hypertension is inversely correlated with arterial O_2 saturation in COPD. However, most clinical studies have documented either no change or only slight decreases in pulmonary arterial pressure associated with the acute administration of O_2 to COPD patients with acute-on-chronic respiratory failure. This suggests that increased pulmonary vascular resistance in most of these patients is a result of pulmonary vascular remodeling rather than hypoxic vasoconstriction. However, the demonstration that at least some of these patients respond to other vasodilators suggests that other factors such as sepsis, acidosis, and hypercapnia modulate the acute vasodilating effects of hypoxemia. Similarly, short-term O_2 therapy does not substantially change RV or LV function in most patients with acute-on-chronic respiratory failure. Therefore, the substantial clinical benefits of short-term O_2 therapy appear to derive primarily from effects on peripheral circulatory function rather than on improvement in cardiac function.

Long-Term Effects of O_2 Therapy

Modern recommendations concerning the administration of long-term domiciliary O_2 to patients with COPD derive from two major clinical trials. The British Medical Research Trial (MRC) consisted of 87 patients with severe COPD randomized to O_2 therapy (42 patients) or no therapy (45 patients). The two groups were clinically matched and had similarly severe stable pulmonary function (FEV_1 £ 1.5 liters, P_aO_2 £ 60 torr, and peripheral edema with or without hypercapnia). The treatment group was given nasal O_2, 2 liters/min or O_2 sufficient to increase P_aO_2 to at least 60 torr, for at least 15 hr per day. After 5 years, survival was 50% greater in the O_2-treated group than in the untreated group. Interestingly, pulmonary arterial pressure did not decrease in the treated group. However, the increase of 3 torr/year in mean pulmonary arterial pressure noted in the control group was not seen in the treated group. Pulmonary vascular resistance increased by 27% in the untreated patients and decreased by 11% in the treated group. However, this decrease occurred only after 6 months of treatment. This suggests that oxygen therapy reversed some of the structural changes in the pulmonary vasculature associated with chronic hypoxemia. This notion is supported by follow-up studies demonstrating less severe structural abnormalities in the pulmonary vasculature of the treated patients and is consistent with animal studies demonstrating resolution of structural abnormalities in hypoxia-induced pulmonary hypertension with removal of the hypoxic stimulus.

The nocturnal oxygen therapy trial (NOTT) sponsored by the National Institutes of Health in the United States compared 24-hr (“continuous”) and 12-hr (“intermittent”) O_2 therapy in patients with severe COPD. The study was stopped after 18 months because of the enhanced survival in the patients treated for 24 hrs (approximately double that of the 12-hr group). This continuous group actually used O_2 for a mean of 17.7 hr/day (56% took it for >19 hr). Pulmonary vascular resistance increased by 6.5% in the 12-hr group but decreased by 11% in the treated group. Long-term follow-up of patients in the NOTT trial showed that an improvement in resting and exercise RV stroke volume and a decrease in pulmonary vascular resistance predicted survival.

The conclusion from these trials was that long-term O_2 therapy in patients with hypoxic COPD can enhance survival. Little survival benefit was derived from 12 hr/day; maximum benefit was to be derived from 24 hr/day use. Table 3 presents some of the accepted criteria used by physicians and third-party payers for providing long-term domiciliary O_2 in the United States. As noted in the table, there are patients who do not meet the strictest criteria for home O_2 therapy who are nevertheless candidates for such therapy. Controlled trials of these patients do not exist, and the indications for therapy are primarily by inference, physiological considerations, and small trials. Clinical features of PHD such as secondary polycythemia, elevations in pulmonary arterial pressure and pulmonary vascular resistance, and peripheral edema are poor prognostic signs. Thus, it is reasonable to institute therapy when these are present, even though a spot check of resting P_aO_2 does not meet the strictest criteria. Often exercise testing or monitoring of O_2 saturation during sleep provides documentation of arterial desaturation to allow for the prescription of home O_2 therapy payable by third-party payers.

P_aO_2 ≤55 torr or O_2 saturation ≤88% on room air at rest in nonrecumbent position
P_aO_2 >55 torr or O_2 saturation ≤88% with evidence of secondary polycythemia (hematocrit ≥55), RV hypertrophy, impaired mental or cognitive function
P_aO_2 ≤55 torr or O_2 saturation ≤88% during exercise with demonstrable improvement in exercise performance with O_2 therapy
P_aO_2 ≤55 torr or O_2 saturation ≤88% during sleep especially associated with fragmentation of sleep, cardiac arrhythmias or ischemia, or pulmonary hypertension

TABLE 3. *Indications for long-term oxygen therapyin COPD*

Stability of Respiratory Failure and Long-Term O_2 Therapy

Long-term O_2 therapy has been shown to be of benefit only in COPD patients with stable chronic respiratory failure. Thus, the decision to institute long-term therapy should not be based on pulmonary function and arterial blood gases taken immediately after a bout of acute-on-chronic respiratory failure. Of course, this does not mean that patients presenting to the hospital who are discharged with resting hypoxemia should not be treated with O_2 for a few weeks while their pulmonary function is allowed to improve. Rather, these patients should be assessed for long-term O_2 use when they have become clinically stable. Studies have demonstrated that following acute-on-chronic respiratory failure, approximately 30% to 40% of patients will improve sufficiently with 3 weeks of standard therapy using bronchodilators and antibiotics to obviate the need for chronic O_2 therapy. There is no reliable means of predicting which patients will improve to the point of not needing O_2 therapy. Thus, at least 3 weeks of optimum standard care should be instituted in hypoxemic COPD patients before initiation of long-term O_2 therapy. Only if the accepted criteria are met after optimal standard care should therapy be instituted with O_2.

Patients who smoke should be *required* to stop smoking as a precondition for receiving a prescription for O_2. Aside from the obvious danger of having a lighted

cigarette in the flow stream of O_2 and the philosophical concerns of self responsibility, the presence of elevated carboxyhemoglobin in the blood from smoking will largely obviate the effects of O_2 on arterial O_2 content.

Nocturnal Hypoxemia

Many patients with COPD are hypoxic primarily at night and may under go severe desaturation during sleep, especially during rapid eye movement (REM) sleep. Reasons for this include nocturnal hypoventilation, ventilation–perfusion imbalance from loss of tonic skeletal muscle tone, and coexisting congestive heart failure and Cheyne–Stokes respiration and/or obstructive sleep apnea. There is no firm evidence that episodes of nocturnal desaturation *per se* lead to clinical harm; however, a number of workers believe that nocturnal desaturation may have significant clinical consequences. Nocturnal hypercapnia may lead to resetting of the central ventilatory controller and predispose to daytime hyperventilation. Nocturnal events may account for the development of clinical signs of PHD in COPD patients with daytime O_2 saturations in the normal range. Clearly, the combination of COPD and concomitant disease such as obstructive sleep apnea (overlap syndrome) predisposes to severe nocturnal hypoxemia. Both conditions must be dealt with to successfully relieve nocturnal hypoxemia.

Clinical PHD is seen in some 5% to 12% of patients with obstructive sleep apnea. Echocardiographic studies have demonstrated an association between RV hypertrophy and the occurrence of obstructive sleep apnea in children as well as adults. Figures range from 50% to 90%. Nocturnal hypoxemia and increases in pulmonary arterial pressure during apneas may contribute to PHD in these patients. Another possible mechanism is that during obstructive apneas, there are large increases in venous return during inspiration compared to expiration, which may lead to flow overload of the RV. When upper airway obstruction is relieved in these patients, improvement in RV function is almost always noted.

Other causes of nocturnal desaturation related to hypoventilation at night include chest wall deformity, severe muscle weakness or paralysis, Ondine's curse, and obesity-hypoventilation syndrome. Many of these patients will benefit greatly from nocturnal ventilation with resulting normalization of O_2 saturation.

Exercise Hypoxemia

Some relatively normoxic COPD patients become hypoxemic while exercising. Although this may not lead to increased resting pulmonary arterial pressures or increased mortality, the administration of O_2 during exercise can increase exercise tolerance and thus lead to an improved quality of life. During the NOTT trial, those patients receiving continuous O_2 may have done better not simply because they received O_2 for a greater proportion of the day but because they were better oxygenated during exercise. Similarly, in other hypoxic pulmonary conditions, O_2 administered during exercise may lead to improved quality of life. Exercise testing should be performed to document improved exercise tolerance during administration of O_2 on a case-by-case basis, and O_2 should be prescribed for patients with exercise hypoxemia in whom objective evidence of improved function can be documented.

Pulmonary Vasodilator Therapy in PHD

The demonstrated benefit of pulmonary vasodilator therapy in at least some patients with primary pulmonary hypertension has led to numerous attempts to treat PHD secondary to other conditions, most notably COPD, with vasodilator regimens. This topic has been covered thoroughly elsewhere. Various classes of vasodilators including, b-adrenergic blockers, b-agonists, calcium channel blockers, nitrates, and angiotensin-converting enzyme inhibitors have been tried. In general, vasodilator therapy has failed to demonstrate sustained therapeutic benefit in patients with COPD, and its use cannot be recommended on a routine basis. Methylxanthines lead to improved RV performance in patients with COPD, perhaps through a vasodilatory mechanism. b_2-specific agonists also act as pulmonary vasodilators in addition to their well-known effects on bronchomotor tone and mucociliary clearance. Finally, there are some individuals who will derive benefit from specific pulmonary vasodilator therapy; agents may be tried on a case-by-case basis before this form of therapy is undertaken for the long term.

Cardiac Glycosides

The utility of cardiac glycosides in PHD has been clearly documented only in the presence of concomitant LV dysfunction. There are few data to support therapeutic benefit from cardiac glycosides in isolated PHD. This, plus the fact that acute hypoxemia may increase toxicity of these agents, either directly or through secondary mechanisms such as sympathoadrenal stimulation, makes it difficult to recommend cardiac glycosides for routine treatment of PHD.

Phlebotomy and Diuretics

Reduction in intravascular volume could lead to improved function. Extravascular lung water may increase during episodes of acute-on-chronic respiratory failure associated with PHD by mechanisms discussed above. Reduction of extravascular lung water may therefore be of substantial clinical benefit. Too great a reduction in vascular volume could reduce mean circulatory pressure and lead to unwanted reductions in cardiac output and renal blood flow. In addition, care must be taken to avoid the hypokalemia that can accompany diuresis. Hypokalemia can produce metabolic alkalosis, which, when combined with possible contraction alkalosis with overdiuresis, can lead to decreased respiratory drive. Thus, adequate diuresis for clinically apparent edema is clearly beneficial, but care should be taken to maintain a normal volume state.

Blood viscosity increases sharply as the hematocrit exceeds approximately 55. This may lead to increased pulmonary vascular resistance according to the laminar flow equations and eventually to increased RV afterload. Because secondary polycythemia is a sign of hypoxemia, it should theoretically be preventable with adequate long-term O_2 therapy. However, with persistently elevated hematocrit (>55), phlebotomy should be considered. The increase in cardiac output that accompanies reduction of blood viscosity often increases peripheral O_2 delivery even though blood hemoglobin is reduced.

Almitrine Bismesylate

Almitrine bismesylate is a triazine derivative that increases the sensitivity of peripheral arterial chemoreceptors to hypoxia. Doses in the range of 50 to 100 mg twice daily have been shown to lead to increased arterial Po_2 without the need for additional O_2 therapy. Nocturnal arterial oxygenation has also been shown to be increased in patients with COPD and sleep apnea. One possible mechanism for the observed improvement in arterial oxygenation is a reduction in ventilation–perfusion mismatching. However, elevations in pulmonary arterial pressure and pulmonary vascular resistance have been reported, and it has been suggested that increasing pulmonary vasomotor tone with almitrine could worsen PHD. Further, some patients on almitrine demonstrate increased dyspnea, perhaps related to increased sensitivity to O_2. Thus, the role of this interesting agent in treating hypoxic respiratory failure and PHD remains unclear.

Lung Transplantation

Although lung transplantation was originally introduced for treatment of end-stage restrictive lung disease, the indications and eligible age range for this procedure are being widened. Patients with end-stage obstructive and vascular diseases are now considered candidates for transplantation. Patients with PHD who undergo lung transplantation may demonstrate improvement in RV function and resolution of pulmonary hypertension. Unfortunately, this mode of therapy will be limited by organ donor availability.

Lung Reduction Surgery

Currently, lung reduction surgery for patients with severe pulmonary emphysema is a promising new mode of therapy that may bring improvement in mechanical function of the lungs. Severe PHD is presently considered to be a contraindication for this surgery, primarily because of the associated increased peri- and postoperative mortality. However, the long-term effects of lung reduction surgery on pulmonary hemodynamics still need to be evaluated. Improved oxygenation and decreased mechanical distortion of pulmonary vessels postoperatively may lead to improved pulmonary hemodynamics.

CHAPTER

68 Bronchogenic Carcinoma

Gary M. Strauss

G. M. Strauss: Chief of Hematology-Oncology, Memorial Hospital, Worcester, MA, and Division of Medical Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA.

INTRODUCTION

Lung cancer is presently the most common and deadly malignancy in the United States and throughout the world. According to the American Cancer Society, bronchogenic carcinoma will be responsible for 160,400 cancer deaths in the United States in 1997. This compares with 140,890 deaths from colorectal cancer, breast cancer, and prostate cancer combined. In 1993, lung cancer was responsible for 28% of all cancer deaths in the United States, and 6.5% of all deaths. Almost 600,000 deaths from lung cancer occurred worldwide in 1995; it is projected that this figure will continue to rise well into the next century. Fifty percent more women will die of lung cancer than of breast cancer in the United States in 1997 (66,000 vs. 43,900). This is true despite the fact that breast cancer will be diagnosed this year in 225% more women than will lung cancer (180,200 vs. 79,800).

An examination of epidemiologic trends demonstrates that the sharp rise in lung cancer death rates is sufficient to account for the increase in overall mortality from cancer in this country. The only encouraging news is that the age-adjusted lung cancer mortality rates have declined 3.6% between 1990 and 1995. Nonetheless, aging of the population and increases in population size have contributed to the grim fact that the absolute number of new cases of lung cancer and the absolute number of lung cancer deaths have increased every year during at least the last half century. To date, public health measures and therapeutic advances have failed to reverse the

inexorable trend of increased lung cancer mortality in our society.

DETERMINANTS OF LUNG CANCER RISK

Cigarette Smoking

In 1604, in “A Counterblast to Tobacco,” King James I of England declared that the use of tobacco products represented “. . . a custom loathsome to the eye, hateful to the nose, harmful to the brain, dangerous to the lungs.” Although tobacco products were introduced in Europe shortly after the discovery of the New World, lung cancer was a distinctly uncommon disease until well into the twentieth century.

In 1912, Adler first suggested that inhalation of cigarette smoke might be a cause of lung cancer. However, he also made note of the fact that a “nearly complete consensus of opinion” existed “that primary malignant neoplasms of the lungs are among the rarest forms of the disease.”

In 1920, lung cancer comprised approximately 1% of all malignancies in the United States. The development of the technology to mass produce cigarettes early in this century coupled with the generosity of the American Red Cross in providing free cigarettes to those serving in World War I greatly contributed to a marked increase in smoking prevalence.

In 1938, the first scientific report appeared that pointed out an association between cigarette smoking and an increased risk for premature death. However, it was not until 1950 that Doll and Hill clearly demonstrated an epidemiologic association between cigarette smoking and increasing lung cancer mortality, an observation that was confirmed shortly thereafter by Wynder and Gardner in 1951.

Because of the indisputable link between cigarette smoking and a dramatic increase in lung cancer risk, bronchogenic carcinoma is without doubt the most preventable of the common cancers in our society. In one study of 3070 patients with lung cancer from Edinburgh, only 2% of cases occurred in lifelong nonsmokers. In the United States, current estimates indicate that 87% of all cases of lung cancer are directly attributable to cigarette smoking. This includes 90% of lung cancers in men and 79% of cases in women.

It is well-known that the relative risk for lung cancer in long-term cigarette smokers is dramatically increased versus that of lifetime nonsmokers, with estimates varying from 10- to 30-fold. The lifetime risk for development of lung cancer in a nonsmoker is probably about 1% or less. In dramatic contrast, the cumulative lung cancer risk may be as high as 30% in heavy smokers. It has been estimated that a 35-year-old man has a 9% chance of dying of lung cancer before the age of 85 if he smokes <25 cigarettes per day, and an 18% chance of dying of lung cancer if he smokes >25 cigarettes per day.

The major evidence linking cigarette smoking to human lung cancer has primarily been based on an enormous body of prospective and retrospective epidemiologic research. Well-established criteria, based on observational evidence, have been used for the attribution of causality. These criteria are based on five factors, which include (1) the consistency, (2) strength, (3) specificity, (4) temporal relationship, and (5) coherence of the association between a disease and exposure to the disease-associated variable (e.g., smoking). Applying these criteria to a huge body of observational data, the Surgeon General definitively concluded that “cigarette smoking is the major cause of lung cancer.”

Until recently, the evidence linking cigarette smoking to lung cancer has been primarily indirect. However, a direct link between tobacco and lung cancer has recently been established. Employing genetic amplification techniques, it was demonstrated that a specific metabolite of benzo[*a*]pyrene, a chemical constituent of tobacco smoke long suspected of being directly involved in carcinogenesis, damages three specific loci on the p53 tumor suppressor gene that are abnormal in about 60% of primary lung cancers. This finding was described as the “smoking gun” or “missing link” that definitively demonstrates the causal relationship between cigarette smoking and lung cancer.

Studies have demonstrated that lung cancer susceptibility in cigarette smokers can be substantially modified by a wide variety of environmental agents and host characteristics. Many of these factors have also been demonstrated to be independent risk factors for the development of lung cancer.

Occupational and Environmental Carcinogens

Asbestos

Numerous occupational and environmental carcinogens are known to increase lung cancer risk in cigarette smokers. The best-studied of these factors are asbestos and radon; additional factors include arsenic, bis(chloromethyl) ether, chromium, ionizing radiation, nickel, polycylic aromatic hydrocarbons, and vinyl chloride.

It has been demonstrated that the risk for development of lung cancer is substantially increased by previous asbestos exposure. Asbestos workers' risk for dying of lung cancer is increased 16-fold if they have smoked more than 20 cigarettes per day and 9-fold if they have smoked less than 20 cigarettes per day, compared with asbestos workers who have never smoked regularly. When cigarette smokers are considered as a group, a history of asbestos exposure increases the risk for dying of lung cancer about fivefold.

Moreover, the risk of lung cancer in those exposed to asbestos and cigarette smoking is multiplicative. If age-adjusted lung cancer death rates for those without exposure to asbestos or cigarette smoking is arbitrarily defined as 1, the relative risk for cigarette smokers not exposed to asbestos is 11. For those with asbestos exposure and no smoking history, the relative risk is 6. However, for cigarette smokers with a history of asbestos exposure, the relative risk is 59. For any individual patient, the relative risk fluctuates according to the level of smoking and degree of asbestos exposure.

The magnitude of risk for lung cancer caused solely by asbestos depends somewhat on the type of asbestos fiber. Lung cancer risk appears to be considerably higher for workers exposed to amphibole fibers than for those exposed to chrysotile fibers, controlling for the amount of exposure. The magnitude of lung cancer risk in workers with an occupational exposure to asbestos is dose-dependent.

Radon

In recent years, there has been considerable public concern about the possible risks for lung cancer caused by radon exposure. Radon is a decay product of uranium 228 and radium 226; it damages respiratory epithelium via interactions with alpha particles. It is present in soil, rocks, and groundwater, and can accumulate in homes. The risk for lung cancer related to radon exposure has been studied in underground uranium miners who were occupationally exposed to radioactive radon and its decay products. In this setting, an increased risk for lung cancer has been established. An interaction between radon exposure and cigarette smoking has also been demonstrated.

The risks associated with household exposure to radon remain uncertain. These risks have been assessed in eight case-control studies, three of which showed statistically significant associations and five of which did not. A recent meta-analysis of these eight studies reported a greater risk for lung cancer associated with higher levels of indoor radon. Moreover, the summary exposure-response trend was statistically significant, suggesting that the overall relative risk for lung cancer among those exposed to household radon was 1:14.

Family History and Genetic Determinants

Family history has received insufficient attention as a risk factor for lung cancer. One case-control study reported that relative risk for lung cancer mortality among smoking relatives of lung cancer patients was twofold to 2.5-fold greater than that of smoking relatives of controls. Even among nonsmoking relatives, lung cancer risk was higher among relatives of patients than of controls. Other studies have demonstrated that the first-degree relatives of lung cancer patients have a twofold to threefold higher risk for lung cancer.

Recent data indicate that the genetic component of lung cancer risk is greater than has been previously estimated. Indeed, there exists a genetic susceptibility to the effects of tobacco smoking that is inherited on the basis of mendelian codominance. Lung cancer risk was 2.4-fold greater among first-degree relatives of 336 deceased lung cancer probands compared with 307 controls (consisting of probands' spouses). A case-control study reported that a history of lung cancer in a parent was associated with a 5.3-fold increased risk for development of lung cancer. A recent review concluded that a consistent pattern of increased prevalence of lung cancer exists among relatives of lung cancer patients even after adjusting for the effects of age, sex, and smoking habits, with the average excess risk being about twofold.

Benign Lung Disease

The coexistence of a number of benign lung diseases increases lung cancer risk in cigarette smokers. Emphysema, bronchitis, and pulmonary fibrosis have all been demonstrated to increase lung cancer risk. Individuals with diffuse pulmonary interstitial fibrosis have a 14-fold increased risk for lung cancer, even when age, sex, and smoking history are taken into consideration. A case-control study demonstrated that chronic obstructive pulmonary disease (COPD) was associated with an overall doubling of the lung cancer risk. A statistically significantly higher risk of lung cancer has been demonstrated in a group of individuals having COPD compared with a cohort not having COPD (matched for age, sex, occupation, and smoking history).

The increased lung cancer risk in individuals exposed to asbestos has been discussed above. It appears that lung cancer is much more likely to develop in asbestos workers with asbestosis (interstitial fibrosis) than in those without asbestosis. In one study of 138 asbestos workers who died of lung cancer, fibrosis was microscopically present in the lung tissue of all sampled patients.

Dietary Factors

Dietary factors have been shown to influence lung cancer risk. An extensive body of literature suggests that certain antioxidant vitamins, particularly derivatives of vitamin A and vitamin E, may help to prevent lung cancer. Indeed, there is substantial evidence for a reduction in lung cancer risk by the regular ingestion of fruits and vegetables.

More than 100 epidemiologic surveys have demonstrated that individuals with high levels of beta carotene in their diet or blood have a lower risk for cancer in general and lung cancer in particular. Case-control or cohort studies have consistently shown that certain antioxidant vitamins decrease the risk for lung cancer. In 30 of 32 studies, the risk for lung cancer was reduced among those who consumed substantial quantities of fruits, vegetables, or both. Existing data suggest that an increase in consumption of fruit, green and yellow vegetables, and possibly some micronutrients can meaningfully decrease lung cancer risk among cigarette smokers.

Results from randomized trials have been much more inconsistent and less encouraging. The Alpha-Tocopherol Beta Carotene Lung Cancer Prevention Study, a population-based randomized trial involving almost 30,000 male cigarette smokers in Finland, suggested a possible adverse effect on lung cancer risk among those randomized to beta carotene. Similarly, the Beta Carotene and Retinol Efficacy Trial (CARET), a randomized trial comparing beta carotene and retinyl palmitate with placebo among 18,000 men and women at high risk for lung cancer, also found a higher lung cancer incidence and mortality in the experimental group. The Physicians' Health Study, which involved approximately 22,000 male physicians, reported no significant differences between groups randomized to beta carotene or placebo. A beneficial effect of beta carotene on cancer risk was suggested by the Chinese Cancer Prevention Trial, a randomized trial involving almost 30,000 participants. Finally, a trial in which patients who had undergone resection for stage I non–small-cell lung carcinoma were randomized to either retinyl palmitate or no further treatment demonstrated a reduction in the number of second primary lung cancers in those randomized to adjuvant high-dose vitamin A therapy. The definitive answer regarding the effects of dietary factors on lung cancer risk is not yet known.

Molecular Genetic Factors

The most influential determinants of lung cancer risk may be molecular genetic factors. Progress in molecular epidemiology has led to the realization that certain population subsets have a much greater risk for development of lung cancer caused by exposure to environmental carcinogens, possibly because the response to the carcinogen is modulated by genetic and acquired susceptibility factors. Unfortunately, it is not yet possible to assess the cancer risk in an individual on a molecular level. More than one genetic factor is likely important. It may soon be possible to develop a risk profile for an individual that integrates exposure to environmental carcinogens with such constitutional factors as altered proto-oncogenes and tumor suppressor genes, as well as susceptibility to DNA damage and mechanisms of DNA repair.

SMOKING AND RISK FOR LUNG CANCER

The risk for lung cancer is proportional to total lifetime cigarette consumption. The relative risk for development of lung cancer increases in proportion to the number of cigarettes smoked per day, as well as to the duration of smoking. Additional smoking-related factors that may influence risk include age at onset of smoking, degree of inhalation, tar and nicotine content of cigarettes, and use of unfiltered cigarettes. There exists no safe level of cigarette consumption, because even low levels of smoking increase lung cancer risk.

The age at which the increased risk of cigarette smokers for development of lung cancer becomes apparent is the middle to late forties. Subsequently, this age-specific relative risk increases steadily to a peak in the late seventies.

Environmental Tobacco Smoke

A great deal has appeared in the literature in recent years relating passive smoking to the risk for lung cancer. The concentration of carcinogenic constituents in environmental tobacco smoke (ETS) is far less than in smoke inhaled by a cigarette smoker. However, exposure to ETS usually begins much earlier in life than does cigarette smoking. Therefore, duration of exposure to environmental carcinogens occurs during a longer period of time.

Epidemiologic studies of nonsmokers with a history of high-level exposure to ETS demonstrates an increased risk for development of lung cancer compared with those having lower cumulative exposures. A dose-response relationship between intensity of exposure and relative risk has been reported.

Decreasing Prevalence of Smoking in Adults

Despite the increasing number of lung cancer cases, smoking prevalence among the adult population has been steadily decreasing for decades. A National Cancer Institute (NCI) survey conducted in 1955 demonstrated that nearly 60% of men and 28% of women were current cigarette smokers. When *Smoking and Health,* the first Surgeon General's report, was published in 1964, 70 million Americans used tobacco products. In the mid-1960s, 42% of adults in the United States smoked cigarettes on a regular basis. This proportion has steadily declined since that time, and was 37% in 1974, 33% in 1980, 29% in 1987, 26% in 1991, 25% in 1993, and 23% in 1995 (Fig. 1). The number of cigarette smokers in the United States was 50 million in 1965, 53 million in 1983, and 46 million in 1991. In 1993, there were estimated to be 46 million current and 46 million former smokers in this country.

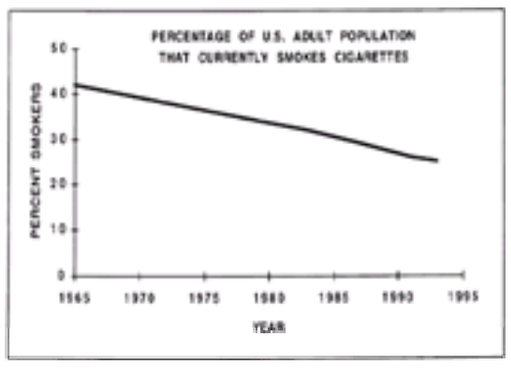

FIG. 1. Percentage of U.S. adult population that currently smokes cigarettes.

The U.S. Public Health Service had set a goal that smoking prevalence fall to 15% by the turn of the century. Unfortunately, indications are that this goal will not be reached. In the late 1980s, smoking prevalence was declining at a rate of about one percentage point per year, and in 1987 stood at 29%. However, in the 1990s, the cessation rate has slowed to about one-half percentage point per year. It has been projected that the percentage of Americans who continue to smoke will remain at 19%–20% in the year 2000.

Patterns of smoking prevalence vary markedly among different segments of the population. The prevalence of smoking in adult men in the 1930s to 1950s exceeded

50%, whereas about a third of women were regular smokers during much of that period. The percentage of men who smoke steadily declined to about 30% in the 1980s. However, there was a modest increase in the percentage of women who smoke during much of this period, with a reversal of the trend occurring only in the 1980s.

A number of surveys have demonstrated that the “quit ratio” for cigarette smoking has been steadily increasing among both men and women since 1965, although it has been consistently higher among men. In 1965, the quit ratio was 28% in men and 19% in women. In 1991, it was 52% in men and 45% in women. Nonetheless, although smoking cessation among men has been greater than among women, smoking prevalence continues to be higher in men than in women.

As white men were successful in decreasing their smoking prevalence, smoking prevalence among black men increased. This has translated into lung cancer mortality rates that in 1990 were about 30% higher among African-American men than among Caucasians. Smoking prevalence in Hispanics, particularly Hispanic women, is relatively low.

Increasing Prevalence of Smoking in Children and Adolescents

In contrast to some of the encouraging trends in smoking prevalence among adults, overall smoking prevalence among young people has not changed substantially since 1980. The prevalence of cigarette smoking among high school students in 1995 was 35% higher than in 1991 and 1993 (Fig. 2). It is estimated that 3000 children and adolescents become regular cigarette smokers every day. Nationwide, 71% of high school students have experimented with cigarette smoking. Approximately 3 million adolescents in this country currently smoke cigarettes. If current smoking trends among youth are not reversed, it is predicted that more than 5 million premature deaths may occur among those currently under 18 years of age.

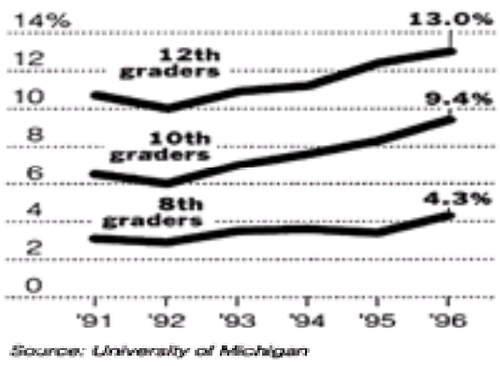

FIG. 2. Percentage of U.S. adolescents who have smoked half a pack of cigarettes a day at an early age. (Reprinted with permission from *The New York Times,* April 20, 1997.)

There are substantial racial differences in smoking prevalence in young people. A 1993 survey of smoking behavior among U.S. high school seniors reported the “phenomenal success” of black teenagers in stopping smoking; only 4% of black seniors described themselves as current smokers in 1993. This compared with 27% of blacks who smoked in 1976, an 84% drop in smoking behavior among black teens. In contrast, 23% of white high school seniors surveyed in 1993 described themselves as current cigarette smokers. This represented a 3% increase compared with 1984.

Cessation of Smoking and Lung Cancer Risk

As cigarette smoking is the major determinant of lung cancer risk, it is important to understand how smoking cessation effects risk for bronchogenic carcinoma among long-term smokers. Five large cohort studies and 10 case-control studies have attempted to quantify the magnitude of risk reduction associated with smoking cessation. Many of these data have been summarized in a 1990 Surgeon General's report.

Smoking cessation clearly decreases lung cancer risk among former smokers compared with that of persons who continue to smoke. Estimates of the extent of risk reduction vary from 20%–90%, depending on duration of abstinence. Lung cancer risk progressively declines with increasing duration of abstinence, and risk reduction is evident within 5 years of quitting. Reduction in lung cancer risk with smoking cessation is observed in both men and women and in users of both filtered and unfiltered cigarettes for all histologic subtypes of lung cancer.

There is an apparent increase in lung cancer risk within the first few years of abstinence, possibly reflecting symptoms of illness that led to smoking cessation before diagnosis. Even with a reduction in risk after quitting, former smokers continue to have a 10%–80% greater risk for development of a lung neoplasm than persons who never smoked, so that a substantial lung cancer risk remains even with prolonged periods of abstinence. This is in marked contrast to other smoking-related diseases, such as coronary artery disease, in which the beneficial effects of smoking cessation are apparent much sooner after quitting.

Although a large number of men quit smoking in the mid-1960s, shortly after the first Surgeon General's report, it took 20 years before lung cancer incidence started to decrease in men. Indeed, as smoking prevalence among adults decreases, lung cancer is increasingly becoming a disease of former smokers.

EARLY DETECTION OF LUNG CANCER

The current standard of care directed toward a reduction of lung cancer mortality in our society is well expressed by the 1980 position statement of the American Cancer Society, which did not recommend any test for the early detection of cancer of the lung but urged a focus on primary prevention. The statement added that “people with signs or symptoms of lung cancer should consult their physicians.” Between 1980 and 1995, lung cancer incidence and mortality in the United States increased by 45% and 55%, respectively (Fig. 3).

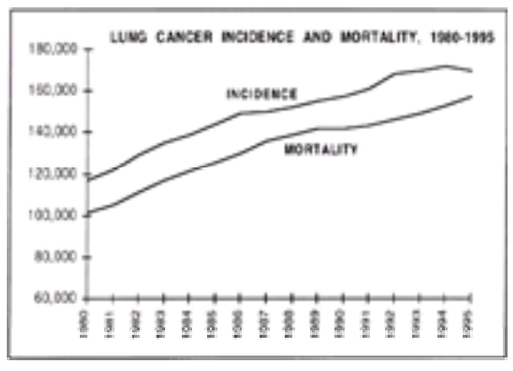

FIG. 3. Annual incidence and mortality of lung cancer based on annual statistics of the American Cancer Society, 1980–1995.

Screening for the early detection of lung cancer is not recommended. In addition to the American Cancer Society, the American College of Radiology, the National Cancer Institute, the U.S. Preventive Services Task Force, and the Canadian Task Force on Periodic Health Examination all continue to recommend that lung cancer screening not be done. The basis of this universal recommendation is that no randomized controlled trial has ever demonstrated a significant reduction in lung cancer mortality as a result of screening.

However, a reappraisal of all randomized trials on lung cancer screening raises serious questions about the proper interpretation of these trials. Although mortality reductions have not been demonstrated, significant advantages in stage distribution, resectability, survival, and fatality have been shown. Accordingly, the critical

question is related to how the benefit of screening is measured in randomized controlled trials.

It is believed that all outcome parameters other than mortality may be confounded by certain biases that are integrally related to early-detection trials. Accordingly, judgments regarding the effectiveness of screening based on parameters that include stage distribution or survival/fatality can be misleading, because of the potentially confounding influences of lead-time bias, length bias, selection bias, or overdiagnosis bias.

Unlike other outcome parameters, mortality is not subject to confounding by any of these screening biases. Accordingly, mortality is considered to represent the strongest evidence that supersedes all other outcome parameters. If a statistically significant reduction in disease-specific mortality in a randomized study were achieved, there would be general agreement that the screening strategy used should become the standard of care. However, what has been poorly understood is that mortality can be confounded by other effects in randomized controlled trials.

Randomized Trials of Lung Cancer Screening

Four randomized controlled trials including 37,724 participants have evaluated lung cancer screening. Because they were all initiated in the 1970s, before the epidemic of lung cancer in women became so obvious, each of these trials was limited to male cigarette smokers. Accordingly, no randomized controlled trial has evaluated the efficacy of lung cancer screening in women, despite the fact that lung cancer is now the most common cause of cancer death in women.

The National Cancer Institute sponsored three of the randomized controlled trials in the context of the Cooperative Early Lung Cancer Detection Program. In the Memorial Sloan-Kettering Lung Project and the Johns Hopkins Lung Project, participants were randomized at study entry to a “dual-screen” group (in which patients underwent chest roentgenography annually and a sputum cytologic examination every 4 months) or to a “single-screen” group (in which annual chest roentgenographic screening was performed).

In the Memorial Sloan-Kettering Lung Project (Table 1), 10,040 men were randomized. A total of 288 lung cancers were detected. More than 40% of the cases detected had stage I disease, and these stage I cases achieved a 76% 5-year survival. Overall, 5-year survival for all cases was 35%. Comparison of the dual-screen and single-screen groups demonstrated no differences with regard to stage distribution, resectability, survival, fatality, or disease-specific mortality. Similarly, in the Johns Hopkins Lung Project, there were no differences in outcome among 10,387 men randomized to a dual-screen or single-screen group. Eight-year survival in both groups was 20%.

Smoking status and duration of abstinence in former smokers (years)	Mortality ratio[b]			
	Men		Women	
	1–20 cigarettes/day	>21 cigarettes/day	1–20 cigarettes/day	>21 cigarettes/day
Never	1.0	1.0	1.0	1.0
Current	18.8	26.8	7.3	16.3
Former				
<1 yr	25.7	50.7	7.8	34.3
1–2 yr	22.4	33.2	9.1	10.5
3–5 yr	16.5	20.9	2.9	14.6
6–10 yr	8.7	15.0	1.0	5.1
11–15 yr	6.0	12.6	1.5	5.9
>16 yr	3.1	5.5	1.4	2.6

TABLE 1. *American Cancer Society cancer prevention study II*[a]

Accordingly, the Memorial Sloan-Kettering and Johns Hopkins Lung Projects demonstrated no benefit by adding sputum cytology to annual chest roentgenography. As randomized comparisons, these trials were designed to assess the benefit of sputum cytology rather than chest roentgenography. However, all participants in these studies did undergo annual chest roentgenographic screening for the early detection of lung cancer.

In this regard, it is perhaps noteworthy that long-term survival rates in experimental and control populations in both the Memorial Sloan-Kettering and Hopkins studies were approximately three times better than that observed in the National Cancer Institute Surveillance Epidemiology and End Results for men in whom lung cancer was diagnosed during the same epoch. Accordingly, these studies provide some support that annual chest roentgenographic screening, which was performed in all participants, contributed to the improved outcome. In any case, it is impossible to reconcile the design of these randomized controlled trials (in which all participants underwent annual chest radiographs) and the results of these trials (in which long-term survival rates were threefold higher than those observed in the general population) with existing public policy mandating no screening whatsoever.

Although the Memorial Sloan-Kettering Lung Project and the Johns Hopkins Lung Project do not directly address the effectiveness of chest roentgenographic screening for lung cancer, the Mayo Lung Project (Table 2) and the Czechoslovak Study (Table 3) do provide direct evidence regarding the efficacy of chest roentgenographic screening for lung cancer. Although neither study had an untreated control group, both studies compared regular rescreening with periodic chest roentgenography in an experimental group with infrequent, sporadic, or in some cases no rescreening in a control group.

	Dual screen group	X-ray-only group
Population	5072	4968
Incidence	144	144
Resectability	53%	51%
Five-year survival	35%	35%
Mortality	90	92

TABLE 2. *Memorial Sloan–Kettering lung project*

	Experimental group	Control group
Population	4618	4593
Incidence	206	160 ($p = 0.016$)
Resectability	46%	32%
Five-year survival (actuarial)	33%	15%
Fatality (actual)	59%	72% ($p = 0.016$)
Mortality	122	115

TABLE 3. *Mayo lung project: Incidence screening*

In the Mayo Lung Project, 10,933 participants underwent a prevalence screen, consisting of a chest roentgenogram and sputum cytology. Ninety-one prevalence cases (0.83%) were detected. Chest roentgenography detected 59 cases (of which 64% were resectable), sputum cytology detected 17 (94% resectability), and 15 cases were detectable by both chest roentgenogram and sputum cytology (20% resectability). Overall, the resection rate among these 91 prevalence cases was 54%. Although there was no control group for prevalence cases, there was a contemporary "comparison group" of 3104 patients matched for age and sex who were being treated during the same time at the Mayo Clinic. In the "comparison group," only 29% of cases were resectable. Five-year survival for all prevalence cases was 40%, which was more than double that observed in the "comparison group." Fifty-four percent of prevalence cases had either occult or stage I disease, and the 5-year survival in this subgroup was 70%.

Among those free of cancer in the prevalence screen, 4618 were randomized to an experimental group in which chest roentgenography and sputum cytology were performed every 4 months, whereas 4593 were assigned to a control group in which no specific screening was conducted (although control patients were advised to undergo annual chest roentgenography and sputum cytology).

Throughout the trial, lung cancer incidence was higher in the screened than in the control population. The trial lasted for an average of 9 years, during which time those in the experimental group underwent an average of 6 years of screening and 3 years of observation, whereas those in the control group were observed for 9 years. At the completion of the study, there were 206 cases of lung cancer detected in the experimental group, compared with 160 control cases. Accordingly, the cumulative incidence of lung cancer in the experimental and control populations was 4.5% and 3.5%, respectively, indicating a 1% incidence discrepancy. The proportion of early-stage cancers and resectability was higher in the experimental group. Moreover, actuarial 5-year survival was more than double, 33% compared with 15% (Fig. 4). Mayo investigators did not report whether survival differences were statistically significant, because they believed that these differences reflected certain screening biases. However, there was a statistically significant advantage in the lung cancer fatality rate among those randomized to screening (59% vs. 72%; $p = .016$).

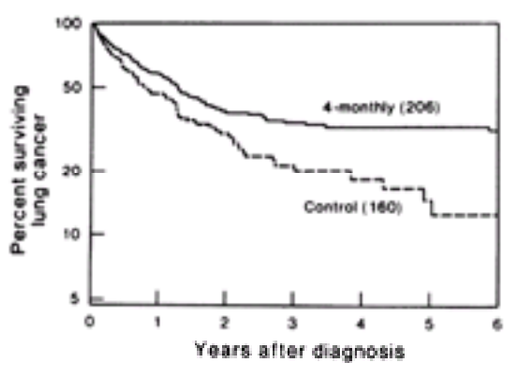

FIG. 4. Mayo Lung Project survival of patients with lung cancer diagnosed during experimental or observation period. (Reprinted with permission from Fontana R, Sanderson DR, Woolner LB, et al. Screening for lung cancer: a critique of the Mayo Lung Project. *Cancer* 1991;67:1155–1164.)

Nonetheless, despite statistically significant advantages in stage distribution, resectability, and survival/fatality, there were 122 lung cancer deaths in the screened group and 115 among the controls. Accordingly, there was a statistically insignificant mortality advantage favoring the control group.

The Czechoslovak Study on Lung Cancer Screening was a randomized trial that enrolled 6364 male smokers between the ages of 40 and 64 years. As in the Mayo study, all participants underwent a prevalence screen, consisting of a chest roentgenogram and sputum cytology. The experimental group then underwent chest roentgenography and cytology every 6 months for 3 years, whereas the control group underwent no screening until the end of the third year, when another chest roentgenogram and cytology were performed. Subsequently, both groups underwent chest roentgenography at the end of the fourth, fifth, and sixth years.

During the initial 3-year experimental period (excluding the scheduled screening at the end of the third year), 36 lung cancers were diagnosed in the study group and 19 in the control group. Resectability was 25% in the experimental group and 15% in the control group. Survival was superior in the study group, with no survivors beyond 3 years among controls and a 5-year survival of 23% in the study group, a difference that was highly statistically significant ($p = .0001$). However, there were 28 lung cancer deaths in the study group and 18 in the control group, so mortality was higher in the study group.

During the entire 6-year period of the trial, a total of 108 cancers were detected in the study group and 82 in the control group. Overall, there were 85 lung cancer deaths in the study group and 67 in the control group. Accordingly, relative mortality was 27% higher in the study population, although this difference was not statistically significant ($p = .16$).

Both the Mayo Lung Project and the Czechoslovak Study (during the experimental period) found advantages in experimental populations with regard to stage distribution, resectability, and survival/fatality. Nonetheless, there were also statistically insignificant mortality disadvantages for the screened groups in both studies.

Furthermore, in both the Mayo and Czechoslovak studies, cumulative lung cancer incidence was higher in the experimental group. In the Mayo Lung Project, the incidence difference was statistically significant at the end of this 9-year study ($p = .016$), whereas in the Czechoslovak Study it approached significance at the end of 6 years ($p = .065$). It therefore becomes important to determine why these incidence differences were observed.

Because of the relationship between mortality and incidence, it is critical to understand the nature of these incidence discrepancies. Disease-specific mortality is proportional to disease incidence and fatality. The numerator in a mortality calculation represents the number of cancer deaths. The only candidates for lung cancer mortality are those with lung cancer, who constitute the incidence group. The number of deaths then depends on the proportion of cancer deaths among these cases, which is the definition of fatality.

Screening Biases

Four screening biases, selection bias, lead-time bias, length bias, and overdiagnosis bias, which are inherent to the evaluation of screening programs, may confound proper interpretation of randomized controlled trials. It has been understood for decades, indeed before any population-based randomized controlled trials of cancer screening were initiated, that certain of these biases are likely to increase the rate of detection of cancer in an experimental group. An increased cancer detection rate in an experimental group would confound survival and fatality comparisons. Accordingly, it is assumed that one or more of the biases must provide the answer for the anomalous findings of superior survival/fatality but inferior mortality in the experimental populations of the Mayo and Czechoslovak studies. The question, however, is whether this assumption is correct.

Selection bias cannot explain differences in cumulative incidence. Although selection bias determines participation in screening trials in the first place, the process of randomization eliminates selection bias as a determinant of whether participants are assigned to experimental or control groups. Selection bias may still determine compliance with screening guidelines. It is important to understand that the elimination of selection bias in group assignment is the only direct result of randomization. Because selection bias has been eliminated, it is assumed that experimental and control populations are identical, except in regard to whether screening is conducted.

Lead-time predicts for an initial excess of cases, because cancer is detected during a preclinical phase rather than by symptomatic presentation. Indeed, if screening is to improve outcome, the opportunity provided by lead-time must be exploited. Because cancers are detected earlier on the basis of lead-time, survival and fatality are improved during this lead-time interval. This is the definition of lead-time bias. It is critical to distinguish the effects of lead-time from the effects of lead-time bias. The only effects that can be ascribed to lead-time bias are increased incidence and improved survival/fatality during the lead-time interval. Lead-time bias does not influence stage distribution, nor does it inflate long-term survival comparisons after the lead-time effect dissipates.

The concept of lead-time assumes that all cancers are clinically important lesions that eventually become life-threatening if not effectively treated. Accordingly, after screening is discontinued in the experimental group (or offered to the control group), the number of control cases should catch up to the number in the experimental group.

In the Mayo Lung Project, intensive screening in the experimental group continued for 6 years but was followed by a period of observation that on average lasted 3 years. At the end of the 6 years, there were 56 more cases in the screened group. During the first 18 months of observation, this discrepancy narrowed to 31, but by the end of observation, it had increased again to 46. The widening incidence discrepancy at the end of the observation period is not explainable on the basis of

lead-time bias.

In the Czechoslovak Study, screening in the control group at the end of the third year should have led to a compensatory number of cases that had previously been detected in the experimental group, but this did not occur. Before screening in the control group, the incidence difference was 17, but it narrowed to nine when those cases of lung cancer detected at the planned rescreening at the end of the third year were included. During the subsequent 3-year period, when both groups underwent annual screening chest roentgenography, the discrepancy in cumulative incidence increased to 26 cases. Incidence discrepancies, which increased when experimental and control groups were treated in effect as a single screened population, cannot be explained on the basis of lead-time bias.

Accordingly, lead-time bias cannot account for the cumulative incidence discrepancies noted by the completion of the Mayo Lung Project and the Czechoslovak Study. Moreover, significant advantages in stage distribution and long-term survival rates can never be attributed to the effects of lead-time bias.

Length bias refers to the tendency of screening to detect indolent tumors, which are likely to have a better prognosis. Prevalence cases are most likely to be affected by length bias, because they are likely to have been present for a considerable period of time. Comparison of case detection rates and survival of prevalence and incidence cases in the Mayo Lung Project indicates that the magnitude of length bias is small in that study. Screening the control population in the Czechoslovak Study eliminates length bias as a determinant of outcome in that trial.

That leaves only overdiagnosis, among the conventional screening biases. Overdiagnosis refers to the detection by screening of lesions that are not clinically important and would never adversely affect the lifespan of the patient. Indeed, overdiagnosis bias has been widely accepted as the most likely explanation for the observed incidence differences, at least in the Mayo Project. For example, Eddy concluded that the results of the Mayo Lung Project are “consistent with the hypothesis that many of the lesions detected by screening and labeled as cancers were not clinically important in the sense that they would never have become clinically evident during the time of the trial and follow-up.”

Although from a purely statistical point of view overdiagnosis in an experimental group can plausibly cause an increase in cumulative incidence in a corresponding control group, overdiagnosis would appear to lack biologic plausibility. As the most virulent of all the common cancers, lung cancer would appear to be an unlikely candidate for overdiagnosis through screening. Nonetheless, despite hypothetical considerations, evidence for overdiagnosis can be sought indirectly in two ways.

One is to determine if a substantial proportion of individuals have “latent” lung cancer detected incidentally at autopsy, similar to what has been documented to exist in prostate cancer. Multiple studies have repeatedly documented that approximately a third of men over the age of 50 and two thirds of men over the age of 60 have evidence of latent prostate cancer at autopsy. In contrast, the finding of lung cancer unexpectedly at autopsy is extremely uncommon. In the only series that has focused exclusively on this issue, “surprise” lung cancer was documented in 1% of 3000 autopsies conducted at Yale. Moreover, most of these “surprise” cases were not reminiscent of “latent” cancers. Indeed, two thirds of “surprise” cases were found to have metastatic disease, and up to a third of patients with “surprise” cancers may have died of lung cancer.

The second line of evidence relates to the hypothesis that if screening results in overdiagnosis of lung cancer, then many lesions detected on chest roentgenograms should remain clinically silent for prolonged periods, even if untreated. Indeed, therapy becomes irrelevant to outcome. Consequently, a substantial number of patients not undergoing resection should be long-term survivors. Data in prostate cancer might provide a model for this phenomenon. For example, a meta-analysis of six series demonstrated that 828 patients from six studies managed initially with observation enjoyed an actuarial 10-year survival of 87% among men with grade I or II tumors. However, in dramatic contrast, a pooled analysis from six studies of 239 lung cancers detected in the context of prospective screening programs that were not treated with curative resection (but were often treated by other methods) indicates that 5-year survival was 4%. Included among these six series is the report that focused on the importance of surgical resection for patients with stage I non–small-cell lung cancer identified in the context of the Mayo, Memorial, and Hopkins Lung Projects. Among 331 stage I patients, 45 did not undergo surgery (because of patient refusal or medical contraindication). Among the 45 nonsurgical patients, there were only two 5-year survivors. Among 286 resected stage I patients, actuarial 5-year survival was 70%.

The reason that “surprise” lung cancer is such an uncommon autopsy finding is that the vast majority of patients with lung cancer die of lung cancer. The only exception exists for patients with resectable early-stage disease who actually undergo curative resection. Approximately 90% of those with resectable early-stage disease who do not undergo curative resection die of lung cancer within 5 years.

In the Mayo Lung Project, higher cumulative incidence coupled with improved stage distribution, resectability, and long-term survival is, in theory, consistent with overdiagnosis. However, careful analysis of existing data conclusively demonstrates that overdiagnosis is not the answer. In the Czechoslovak Study, differences similar to those observed in the Mayo Project between experimental and control populations were observed regarding incidence, stage, resectability, and survival/fatality. However, in the Czechoslovak Study overdiagnosis cannot be implicated, because the study design incorporated regular screening in the control group during the second half of the study.

Accordingly, none of the screening biases credibly accounts for the hypothetical “missing cases” in the Mayo Lung Project and the Czechoslovak Study. This is a conclusion of enormous importance, because prevailing dogma regarding the ineffectiveness of chest roentgenographic screening for lung cancer has depended completely on these screening biases, and in particular overdiagnosis. Indeed, if screening does not lead to the overdiagnosis of lung cancer, then survival comparisons indicating that the proportion of long-term survivors is twofold to threefold higher than that observed in the general lung cancer population would indeed accurately reflect the effectiveness of screening.

Population Heterogeneity

If none of the screening biases accounts for the missing cases in the Mayo and Czechoslovak studies, what does account for them? Population heterogeneity represents the most plausible explanation for differences in cumulative incidence in these trials.

In population-based randomized controlled trials focusing on cancer, the target disease develops in only a small proportion (typically in the range of 1%–5%) of participants during the course of the study. Factors relevant to balance in such trials include population size, number of covariates influencing disease risk, and magnitude of risk modification by each variable. As previously noted, the only direct result of randomization is the elimination of selection bias.

However, when many covariates are relevant to disease risk, the elimination of selection bias may not be the obstacle to balance in population-based randomized controlled trials. Support for this hypothesis must come from an analysis of population-based randomized controlled trials evaluating screening for other diseases. In fact, analysis of 18 randomized controlled trials focusing on screening for breast cancer, colorectal cancer, and lung cancer demonstrates that substantial population heterogeneity often persists despite randomization. This in turn confounds the ability of mortality to reflect screening effectiveness accurately.

All participants in the Mayo Lung Project and Czechoslovak Study were cigarette smokers. However, there is abundant evidence that certain cigarette smokers are much more susceptible than others to the development of lung cancer. If randomization did not result in groups with equivalent lung cancer risk, mortality comparisons would not accurately reflect the benefit of screening.

Symptomatic Versus Screen-Detected Lung Cancer

The current standard of care directed toward a reduction of lung cancer mortality in our society is well expressed by the 1980 position statement of the American Cancer Society, which declared it “does not recommend any test for the early detection of cancer of the lung, but urges a focus on primary prevention.” Moreover, it added that “people with signs or symptoms of lung cancer should consult their physicians.”

Unfortunately, when patients consult their physicians because of “signs or symptoms of lung cancer,” 85%–90% already have advanced-stage disease. Moreover, 90%–95% will die of their lung cancer, usually within 2 years of diagnosis.

As early detection strategies are not advocated, it is predictable that the vast majority of patients with lung cancer are symptomatic at the time of diagnosis. Among 678 patients with lung cancer admitted to Yale-New Haven Hospital or the West Haven Veterans Administration Hospital between 1953 and 1959, only 6% were asymptomatic at the time of diagnosis. In contrast, 27% of patients had symptoms directly related to the primary tumor, 32% had symptoms of metastatic disease, and 34% had systemic symptoms of cancer. Five-year survival of these three groups of symptomatic patients was 12%, 6%, and 0, respectively. In the asymptomatic group, 5-year survival was 18%. Five-year survival for the entire group was 7%.

Among 702 patients from the Medical University Hospital and the Veterans Administration Hospital in Charleston, South Carolina, only 12% of patients were asymptomatic at the time of diagnosis. In contrast, 64% of patients presented with cough, 55% with weight loss, 53% with pain, and 44% with sputum production. Similar to the results reported from Yale, 5-year survival of the entire group was 7%.

Even in apparently early-stage disease, symptoms represent a significant determinant of prognosis. For example, the presence of symptoms at the time of diagnosis of stage I non–small-cell lung cancer adversely influenced survival among 289 resected stage I patients from Duke University. There was a 74% 5-year survival in 189 asymptomatic patients, compared with 41% in 100 patients who were symptomatic at presentation ($p < .001$).

In Japan, screening for the early detection of lung cancer is routinely practiced, and screening chest roentgenograms have been covered by health insurance by legal mandate since 1987. Outcome was compared between the 381 screen-detected and the 239 symptom-detected patients undergoing resection at Okayama University between 1980 and 1989. In the screen-detected group, 55% of patients had tumors of 3 cm, whereas in the symptom-detected group, it was 25%. In contrast, in the screen-detected group, only 11% of tumors were 5 cm, compared with 32% in the symptom-detected group. The proportion of patients with stage I and stage III non–small-cell lung cancer in the screen-detected group was 65% and 22%, respectively, whereas in the symptom-detected group, it was 32% and 48%, respectively. Overall 5-year survival in the screen-detected group was 56%, compared with 25% in the symptom-detected group ($p < .001$).

Similarly, a report from Uppsala, Sweden, indicated that lung cancers diagnosed incidentally during a general health survey, which included biennial chest roentgenographic screening for tuberculosis, had a far superior survival than those detected by symptoms. During the survey period, a total of 244 lung cancers were detected. Of these, 28 (11%) were detected on a survey chest roentgenogram, 31 (13%) were found accidentally, and 185 (76%) were noticed by symptoms. Resectability among cases detected in the survey chest roentgenogram, accidentally, and by symptomatic presentation was 75%, 74%, and 20%, respectively, whereas 4-year survival in the three groups was 39%, 33%, and 7%, respectively. If only squamous cell carcinoma or adenocarcinoma is considered, 4-year survival was 42% if the cancer was survey-detected and 10% if symptom-detected ($p < .001$). Although only a small proportion of total lung cancers were detected by survey chest roentgenogram, chest roentgenography was performed only every other year, an interval that would not be appropriate if the objective were screening for lung cancer.

In the NCI-sponsored lung screening studies, the majority of the 784 cancers detected among populations randomized to either chest roentgenography alone or chest roentgenography and sputum cytology were detected on a routine screening examination. Fifty percent of 322 lung cancers detected in groups randomized to chest roentgenography alone in the Memorial Sloan-Kettering or Hopkins studies were detected on screening radiographs, whereas the other 50% were interval cancers. Among 452 cancers detected among patients randomized to chest roentgenography and sputum cytology in the Mayo, Memorial, and Hopkins studies, 39% were detected by chest roentgenography, 13% by cytology, and 4% by both methods. Only 44% of cancers in the dual-screen groups were interval lesions detected following normal screening examinations.

Lung Cancer Screening Reconsidered

Disease-specific mortality has long been believed to be the best measure of outcome in screening trials. However, when one analyzes the data, not a single example from the 18 population-based randomized controlled trials, which included 870,593 participants, can be cited as definitive proof of the effectiveness of any screening strategy. Indeed, screening cannot be justified for any cancer on the basis of consistent reductions in mortality in randomized controlled trials.

Lead-time bias, length bias, and overdiagnosis bias may confound stage distribution and survival/fatality comparisons in randomized controlled trials. However, failure to distinguish the effects of lead-time from the effects of lead-time bias and misconceptions regarding the true nature of overdiagnosis have interfered with proper interpretation of these trials.

In lung cancer, randomized controlled trials consistently demonstrate that periodic chest roentgenographic screening is associated with statistically significant advantages in stage distribution and long-term survival. Moreover, these advantages are also clinically important, because they cannot be attributed to the effects of any conventional screening bias. Extrapolation of such long-term survival advantages from randomized controlled trials to the national stage in the 1990s would likely translate into tens of thousands of additional lung cancer survivors every year in the United States.

However, such an interpretation of the data depends completely on how screening effectiveness is measured. Because of the enormous public health importance of this issue, and the considerable fiscal implications of a change in public policy, the question of whether periodic chest roentgenographic screening should be recommended for those at high risk for lung cancer deserves reconsideration by organizations responsible for formulating public policy.

However, pending a formal reappraisal of screening guidelines, sufficient evidence currently exists to justify an annual screening chest roentgenogram among asymptomatic individuals at high risk for lung cancer. Early detection leading to early treatment is of key importance if we are to impact favorably on the appalling epidemic of lung cancer mortality among cigarette smokers and the growing population of former smokers in our society.

PATHOLOGY AND CLASSIFICATION

The histologic classification for primary lung cancer was originally developed by the World Health Organization (WHO) in 1967 and modified in 1981. It remains the international standard at the present time, and is currently undergoing its third revision (Table 4). The four major histologic subtypes of lung cancer, which cover approximately 95% of all primary bronchogenic carcinomas, include squamous cell (epidermoid) carcinoma, adenocarcinoma, large-cell carcinoma, and small-cell (or oat cell) carcinoma. Bronchoalveolar cell carcinoma is classified as a subtype of adenocarcinoma. Although a specific histopathologic classification is highly desirable, the distinction between small-cell carcinoma (SCLC) and non–small-cell lung carcinoma (NSCLC) is most critical in guiding therapy.

	Experimental group	Control group
Population	3172	3174
Incidence	36	19
Resectability	25%	15%
Five-year survival (actuarial)	23%	0% ($p = 0.0001$)
Mortality	28	18

TABLE 4. *Czechoslovak study: Incidence screening*

Today, pathologists most frequently make an initial diagnosis of lung cancer by cytologic techniques alone. More than 80% of all lung cancers are diagnosed by bronchial brushings, washings, or directed fine-needle aspiration (FNA). Thus, as thoracoscopic techniques have improved, the role of cytology and FNA has dramatically increased during the past decade, gradually replacing the less sensitive induced sputum cytology as a method of diagnosis. These methods of obtaining cellular specimens suitable for definitive diagnosis are safe and inexpensive compared with the cost and morbidity of invasive surgical techniques. The diagnostic yield of cytologic specimens can be enhanced with such techniques as immunocytochemistry and electron microscopy.

Relationship of Histologic Type to Smoking

Although the relationship between cigarette smoking and squamous cell carcinoma and small-cell carcinoma has long been clear, the relationship between smoking and adenocarcinoma and large-cell carcinoma has been more ambiguous. Although the older literature suggests that smoking is unrelated to adenocarcinoma of the lung, more recent data indicate that each of the major histologic subtypes is directly related to smoking, although to differing degrees. The degree of lung cancer risk as a function of total exposure to tobacco differs with cell type and is strongest for small-cell carcinoma, less strong for squamous cell carcinoma, weaker still for adenocarcinoma, and absent for large-cell carcinoma. Adenocarcinoma is the most common histologic type seen in nonsmokers.

The role of cigarette smoking in the pathogenesis of bronchoalveolar carcinoma has been less clear, although more recent studies do support a clear-cut association between smoking and bronchoalveolar carcinoma. Two case-control studies suggest an association between smoking intensity and bronchoalveolar carcinoma. In one case-control study of 87 patients with bronchoalveolar carcinoma, only 10% of men and 25% of women were lifelong nonsmokers.

Squamous Cell Carcinoma

In the past, squamous cell carcinoma was the most common histologic subtype of all lung cancers. In the 1970s, squamous cell carcinoma comprised approximately half of all lung cancers, but by the mid-1980s, the percentage had decreased to approximately 30%–40%. These cancers occur almost exclusively in cigarette smokers and are much more common in men than in women. The decrease in frequency appears in part to be related to the decreased prevalence of smoking in men.

About two thirds of squamous cell carcinomas occur centrally in the lung; most of the rest present as peripheral or subpleural masses (Fig. 5). They tend to be relatively slow-growing neoplasms and spread along the bronchial wall, directly invading the peribronchial lymph nodes and adjacent pulmonary parenchyma. Peripheral squamous cell carcinomas often invade the chest wall. Central tumors tend to arise at the bifurcation of segmental or subsegmental bronchi. Squamous cell cancers have a tendency to become necrotic and cavitary.

FIG. 5. Central squamous cell carcinoma of left lung with cavitation. This tumor eroded into the adjacent pulmonary artery (*probe*), causing fatal hemorrhage. (Reprinted with permission from Morgan WKC, Hales MR. Bronchogenic carcinoma. In: Baum GL, Wolinsky E, eds. *Textbook of Pulmonary Diseases.* 3rd ed. Boston: Little, Brown; 1983.)

Squamous cell cancer is frequently preceded by a preinvasive lesion of squamous dysplasia or carcinoma *in situ* and can be detected by biopsy and cytology. These tumors tend to be relatively slow-growing (Fig. 6 and Fig. 7). It has been estimated that the average time from the development of carcinoma *in situ* to clinically apparent tumor is approximately 3 to 4 years.

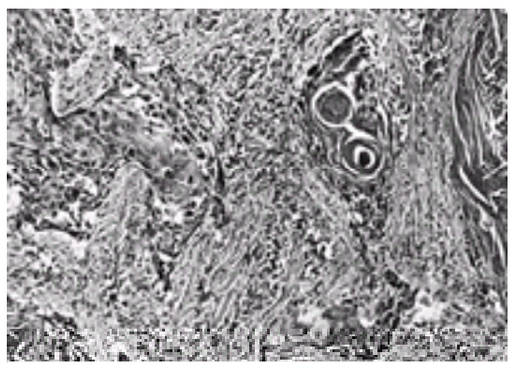

FIG. 6. Well-differentiated squamous cell carcinoma with two keratinized epithelial pearls. There are numerous lymphocytes and plasma cells in the desmoplastic stroma. Adenocarcinoma

During the past two decades, adenocarcinoma has emerged as the most common histologic subtype of all lung cancers. Adenocarcinomas arise predominantly in the periphery of the lung, often in relation to focal scars or in regions of interstitial fibrosis. Adenocarcinoma usually does not arise within the bronchi, and it involves the bronchi only through local invasion or submucosal lymphatic spread. Because of their peripheral location, adenocarcinomas are associated with pulmonary symptoms less commonly than centrally located squamous cell carcinomas. Although often presenting as a solitary pulmonary nodule, they are not infrequently multicentric.

Although adenocarcinomas are the most common histologic subtype in women and nonsmokers, most adenocarcinomas occur in persons with a smoking history. Adenocarcinomas tend to be slow-growing. However, they invade lymphatic and blood vessels relatively early in their natural history, and for this reason they have a higher propensity for distant metastasis than squamous cell carcinomas. This property helps explain why they are associated with a poorer survival than are squamous cell carcinomas.

Adenocarcinomas are characterized by glandular formation, the development of papillary structure, or the production of mucin (Fig. 8). Well-differentiated adenocarcinomas are characterized predominantly by acinar formation, whereas poorly differentiated adenocarcinomas may appear as solid sheets of tumor cells that may exhibit a slight tendency to form small acini and less prominent glandular differentiation. Immunohistochemically, adenocarcinomas express low-molecular-weight cytokeratins, carcinoembryonic antigen (CEA), and epithelial membrane antigen. The major value of determining CEA levels is to distinguish adenocarcinomas, which are usually CEA-positive, from mesotheliomas, which are CEA-negative.

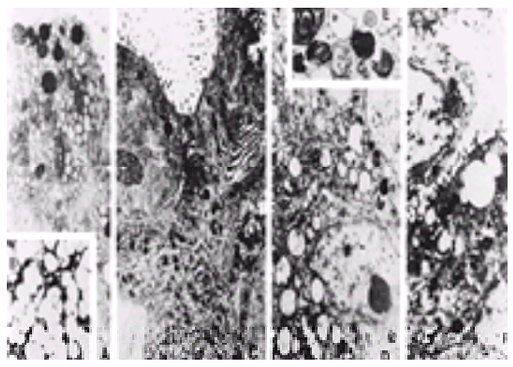

FIG. 8. Adenocarcinomas. **A:** Note the poorly formed surface microvillous border and the collections of coalescent mucin vacuoles. ×13,000. **B:** Coalescent mucin vacuoles are better illustrated at this magnification. ×22,000. **C:** Note the dark, electron-dense granules, typical of Clara cell adenocarcinomas. Also note the better-developed microvillous border. ×10,000. **D:** Note the collections of typical lamellar bodies, indicative of pneumocyte type II differentiation. ×7500. **E:** Note the details of the lamellar bodies. ×28,000. **F:** Note a combination of coalescent mucin vacuoles and Clara cell granules within the same cell, indicative of a mixed adenocarcinoma. ×13,000. (Reprinted with permission from Herrera, et al. Ultrastructural characterization of pulmonary neoplasms. *Surv Synth Pathol Respir* 1984;3:520.)

The WHO classification divides adenocarcinoma into four subtypes: acinar, papillary, solid tumor with mucin production, and bronchoalveolar cell carcinoma. When these tumors are resectable, solid tumor with mucin production is associated with the poorest prognosis, and bronchoalveolar carcinoma with the most favorable. Bronchoalveolar carcinoma tends to occur in younger patients than do other histologic NSCLC subtypes.

Large-Cell Carcinoma

Large-cell carcinoma constitutes approximately 10% of all lung cancers. These tumors tend to occur as bulky masses and are most often located in the periphery of the lung. They usually present as solitary masses with associated necrosis and no cavitation. They tend to metastasize widely, in a manner similar to that of adenocarcinomas.

Large-cell carcinoma is so classified because at the level of the light microscope it lacks both the glandular formation of adenocarcinomas and the keratinization or intracellular bridges indicating squamous differentiation (Fig. 9A and Fig. 10). By electron microscopy, some large-cell carcinomas contain intracytoplasmic tonofilaments, mucin droplets, or electron-dense granules, which indicate neuroendocrine differentiation. Most large-cell carcinomas have ultrastructural features consistent with either poorly differentiated squamous cell carcinomas or adenocarcinomas.

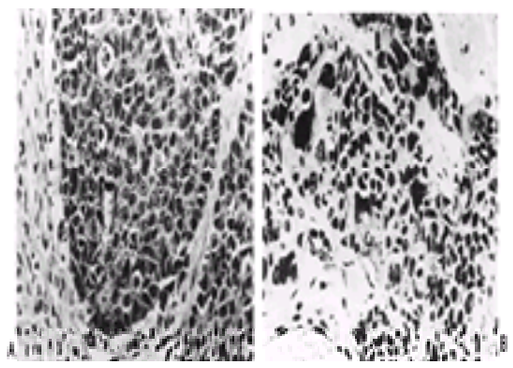

FIG. 9. A: A large-cell carcinoma not showing any mucin production or stratification, an example of group 4 in the WHO (1981) classification of undifferentiated large-cell carcinomas. **B:** A tumor with large, pleomorphic cells. This is another area from the tumor, illustrated as an example of a small-cell carcinoma of intermediate type. Such large-celled areas do not preclude the diagnosis of small-cell carcinoma, but they may pose problems when a diagnosis is based on small biopsy specimens. H&E stain, ×320. (Reprinted with permission from Smith JF. *The Management of Lung Cancer.* London: Edward Arnold; 1984.)

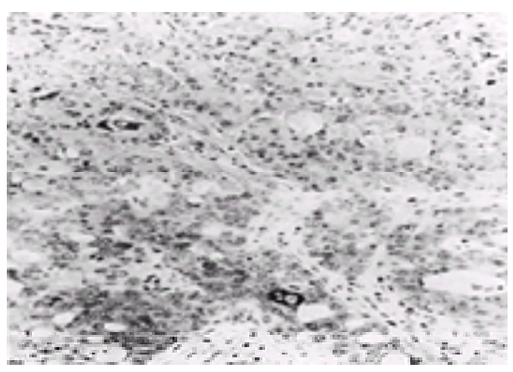

FIG. 10. Photomicrographs of a large-celled anaplastic carcinoma with mucin production. **A:** Most of the mucin was cytoplasmic or in pools, as shown by period acid-Schiff staining after diastase digestion. No clear ductal structures or acini were formed. **B:** The same tumor stained immunocytochemically for keratin. Most cells contained keratin-like immunoreactive material, and occasional mononuclear and multinucleated cells were strongly positive. ×250. (Reprinted with permission from Carter RL. *Precancerous States.* New York: Oxford University Press; 1984.)

In recent years, the entity of large-cell neuroendocrine carcinoma has been the focus of considerable interest. It has been recognized that tumors that are otherwise typically squamous cell carcinomas, adenocarcinomas, or large-cell carcinomas may show evidence of neuroendocrine differentiation when examined by electron microscopic or immunohistochemical techniques. Large-cell neuroendocrine carcinomas cannot be distinguished from large-cell carcinomas without the use of these techniques. The prognostic significance of this entity is presently unclear, but there is some evidence that they may respond better to chemotherapy than other large-cell carcinomas. Giant cell carcinoma is recognized as another distinct clinical entity with a very adverse prognosis.

Small-Cell Carcinoma

In the past, small-cell carcinoma represented about 25% of all cases of lung cancer. However, the proportion of lung cancers classified as SCLC has declined in recent years in the United States, and SCLC currently represents approximately 20% of primary lung neoplasms. However, SCLC remains relatively more prevalent in other parts of the world. There is a very strong relationship between SCLC and cigarette smoking.

The majority of SCLCs are located centrally, arise in the peribronchial tissues, and infiltrate the bronchial submucosa (Fig. 11). SCLC is believed to arise from basal neuroendocrine Kulchitsky cells. As with adenocarcinoma of the lung, a preinvasive form of SCLC has not been identified.

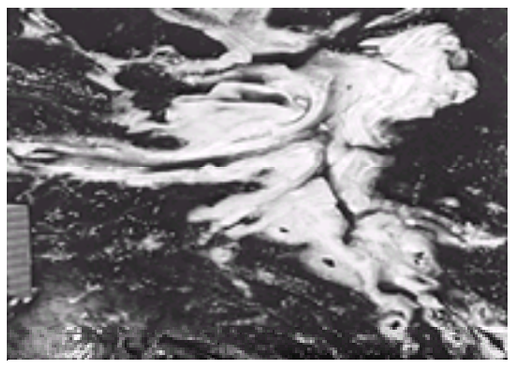

FIG. 11. Small-cell anaplastic carcinoma arising in the distal portion of the right intermediate bronchus and extending both proximally and distally along the bronchial vascular rays. Although small in mass, this tumor was responsible for widespread metastases, causing inappropriate secretion of ACTH, adrenal cortical hyperplasia, and death from severe, intractable hypokalemia. (Reprinted with permission from Morgan WKC, Hales MR. Bronchogenic carcinoma. In: Baum GL, Wolinsky E, eds. *Textbook of Pulmonary Diseases.* 3rd ed. Boston: Little, Brown; 1983.)

SCLC disseminates early and widely into regional lymph nodes, and this histologic subtype is the most common cause of superior venal cava syndrome in adults. SCLC behaves much more aggressively than other lung cancers, exhibiting very rapid growth and early dissemination.

These tumors are characterized by a proliferation of highly malignant small cells, about two to three times the size of lymphocytes (Fig. 9B). They contain hyerchromatic nuclei with finely dispersed chromatin, indistinct nucleoli, and scanty cytoplasm. The nuclei of these cells mold or conform to the cytoplasm of adjacent cells in well-preserved specimens. There is often extensive smearing of the fine chromatin of these delicate cells, producing a characteristic “crush”-like artifact in poorly preserved specimens. Mitotic figures are common, and the tumor grows in sheets without a specific pattern.

Small-cell carcinoma has traditionally been subdivided into a classic oat cell and intermediate cell types. Oat cell carcinomas consist of lymphocyte-like cells growing in sheets or nests in a sparse connective-tissue stroma. The intermediate cell type is comprised of polygonal or fusiform cells that are much larger in size, with more abundant cytoplasm. These cells form rosettes.

Two other, less common histologic subtypes have also been described. One is the mixed small-cell and large-cell variant, which comprises about 4% of SCLCs. Some early studies had demonstrated that this subtype had a lower response rate to chemotherapy and a lower survival compared with “pure” small-cell subtypes, although this claim has been disputed. The other subtype that has been described is combined small-cell with squamous cell or adenocarcinoma. The significance of this subtype is not completely clear. In one series, 2% of SCLCs also had histologic features of adenocarcinoma or squamous cell carcinoma, and such tumors tended to be more localized, were occasionally resectable, and seemed to be associated with a better prognosis than pure SCLC.

However, the predominance of evidence at the present time suggests that there are no real differences in outcome between the four SCLC subtypes. Accordingly, stage distribution, metastatic potential, response to therapy, and survival appear to be similar when the oat cell or intermediate cell subtype is considered on the one hand, and the mixed cell or combined subtype on the other.

PROGNOSTIC FACTORS IN NSCLC

The anatomic extent of the cancer, as reflected by the stage of disease, is the most important determinant of prognosis in NSCLC. Indeed, the objective of cancer staging is to provide a prognostically useful classification based on the anatomic distribution of disease. In NSCLC, patients with resectable stage I or II disease have a prognosis superior to that of patients with more advanced disease. The significance of most nonanatomic determinants of prognosis is not as important, especially in the setting of overt distant metastases, because stage IV NSCLC is invariably fatal.

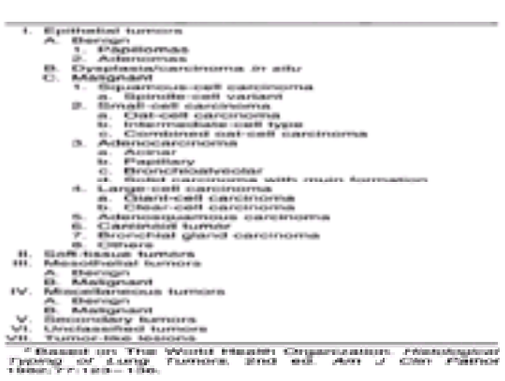
Nonetheless, a variety of clinical and pathologic factors can significantly contribute to an assessment of prognosis, particularly in patients with resectable disease. Moreover, numerous biologic or molecular markers of prognosis have been identified in recent years. Because a substantial proportion of patients with resectable NSCLC have biologically virulent cancers, the use of prognostic factors can contribute to an assessment of outcome among those with early-stage disease.

Performance Status and Weight Loss

Although many clinical factors have been reported to be predictive of outcome in lung cancer, the two most important variables are weight loss and performance status. It has long been established that poor performance status predicts a short survival in those with localized stage I and II NSCLC. A multivariate analysis of 651 patients demonstrated that weight loss and poor performance status were significant adverse indicators of outcome independent of stage, histology, and treatment.

Lymph Node Involvement

The critical importance of regional node involvement in NSCLC is recognized in the International Staging System (ISS) for NSCLC, which was introduced in 1986 and modified in 1997 (Table 6 and Fig. 12). In this system, the definition of stages I, II, IIIA, and IIIB largely depends on the presence or absence of nodal involvement at specific sites. The prognostic significance of the level and extent of nodal involvement in NSCLC has led to the development of a thoracic lymph node map (Fig. 13). Involvement at specific nodal stations has great prognostic significance.



I. Epithelial tumors

[illegible] on the World Health Organization Histological Typing of Lung Tumors. 2nd ed. Am J Clin Pathol 1982; 77:123–136.

TABLE 5. *WHO II lung cancer classification*[a]

Primary tumor (T)
TX: Tumor [illegible] or [illegible] by presence of malignant cells in [illegible] but not visualized by imaging or bronchoscopy
T0: No evidence of primary tumor
Tis: Carcinoma in situ
T1: Tumor [illegible] in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than lobar bronchus (i.e., not in the main bronchus)
T2: Tumor with any of the following features of size or extent:
More than 3 cm in greatest dimension
Involves main bronchus, 2 cm or more distal to the carina
Invades visceral pleura
Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T3: Tumor of any size that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium
Associated with atelectasis or obstructive pneumonitis of the entire lung
Separate tumor nodule(s) in the same lobe
T4: Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina
Separate tumor nodule(s) in a different ipsilateral lobe
Associated with malignant pleural or pericardial effusion

Regional lymph node (N)
NX: Regional lymph nodes cannot be assessed
N0: No regional lymph node metastasis
N1: Metastasis to ipsilateral peribronchial and/or ipsilateral hilar nodes and intrapulmonary nodes involved by primary tumor extension
N2: Metastasis to ipsilateral mediastinal and/or subcarinal lymph node(s)
N3: Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene or supraclavicular lymph node(s)

Metastasis (M)
MX: Distant metastasis cannot be assessed
M0: No distant metastasis
M1: Distant metastasis present

Stage groupings of TNM subsets

Stage 0	Tis	N0	M0
Stage IA	T1	N0	M0
Stage IB	T2	N0	M0
Stage IIA	T1	N1	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T3	N1	M0
	T1,2,3	N2	M0
Stage IIIB	any T	N3	M0
	T4	any N	M0
Stage IV	any T	any N	M1

[illegible] on Staging of Lung Cancer. Chest 1997; 111:1710–1717.

TABLE 6. *International staging systemfor lung cancer*[a]

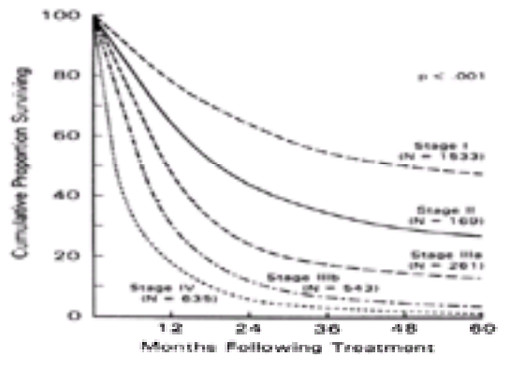

FIG. 12. Cumulative proportion of patients surviving 5 years by clinical stage of disease. (Reproduced with permission from Mountain CF. A new international staging system for lung cancer. *Chest* 1986;89:225S.)

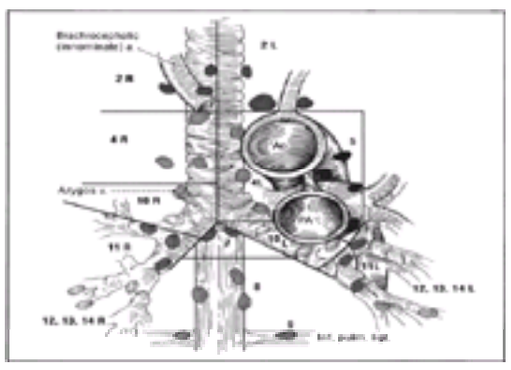

FIG. 13. Classification of mediastinal lymph nodes. (Reprinted with permission from the Lung Cancer Study Group, courtesy of Bristol-Myers Squibb.)

Stage I disease is defined by the absence of regional nodal involvement. In stage II disease, lymph node involvement is limited to ipsilateral intrapulmonary (hilar, peribronchial, lobar) nodes. A modification of the ISS, introduced in 1997, subdivides stages I and II into IA/IB and IIA/IIB subcategories, primarily based upon tumor size (Table 6). Stage IIIA is defined by the presence of ipsilateral mediastinal nodes or subcarinal lymph nodes. Stage IIIB disease is defined by the presence of contralateral mediastinal or hilar nodal involvement, or ipsilateral or contralateral supraclavicular nodal involvement by tumor.

In patients with stage II NSCLC, the number and/or location of involved N1 nodes is a significant determinant of outcome. At Memorial Sloan-Kettering, the overall 5-year survival was reported to be 39% in stage II NSCLC, and the number of involved N1 lymph nodes was an important predictor of survival. In a Japanese series, overall 5-year survival was 49% in stage II disease, but survival was 65% in patients whose N1 involvement was limited to lobar nodes, compared with only 40% when hilar nodes were involved ($p > = .014$).

The location of specific involved nodal groups may also have prognostic significance in patients with stage IIIA or IIIB disease. It appears that patients with resected right-sided lung cancers have a worse prognosis if the involved N2 nodes include superior mediastinal nodes compared with inferior mediastinal nodes. For left-sided tumors, involvement of inferior mediastinal nodes by tumor carries a worse prognosis. Patients with single-level mediastinal nodal involvement do better than those with multilevel metastases.

In addition to the location of nodal involvement, the size and number of involved nodes have been demonstrated to be important prognostically. Moreover, the presence of extracapsular extension outside involved nodes has adverse prognostic significance.

Tumor Size

Tumor size has consistently been an important determinant of outcome in stage I NSCLC. Nine studies of stage I NSCLC have shown that T1 tumors are associated with superior survival compared with T2 tumors (Table 6). Survival in patients with T1N0 tumors varies from 64% to 85% and is more variable in those with T2N0 tumors, ranging from 36%–68%. The magnitude of survival differences between T1 or T2 subsets in individual studies is quite variable, ranging from 8%–38%. The modification to the ISS, introduced in 1997, subdivides stage I into stage IA (TIN0M0) and stage IB (T2N0M0) subcategories.

Despite the consistency of the finding that tumor size is an important prognostic factor, T status may not be the dominant prognostic factor in stage I NSCLC. Other important factors include the degree of tumor differentiation (well, moderate, poor) and DNA ploidy (diploid, aneuploid).

In stage II or II NSCLC, one study from Memorial Sloan-Kettering did demonstrate that patients whose tumors were <3 cm had a significantly superior survival compared with those whose tumors were >5 cm. However, tumor size has not consistently been an important prognostic variable in stage II and III NSCLC. Once the tumor has progressed beyond the primary site, the existence of nodal or distant metastases represents the major determinant of outcome.

Histologic Subtype

There is conflicting information relating to the prognostic importance of histologic subtype in resectable NSCLC. Two studies from the Lung Cancer Study Group (LCSG) reported that squamous cell carcinoma had a superior outcome compared with other histologic types. In one series of 392 stage I patients, long-term survival was 77% in squamous cell carcinoma and 66% in adenocarcinoma and large-cell carcinoma ($p = .014$). Similarly, in 572 patients with T1,N0 lesions, the recurrence rate was 12% in squamous cell carcinoma, compared with 26% in those with adenocarcinoma, large-cell carcinoma, or bronchoalveolar cell carcinoma. When only squamous cell carcinoma and adenocarcinoma were compared, the probability of recurrence was significantly lower in patients with squamous cell carcinoma ($p < .001$). However, studies from the Mayo Clinic, Memorial Sloan-Kettering, Duke University, and Japan reported no significant differences in survival based on histologic subtype of NSCLC. In the Japanese series, 5-year survival trends favored those who had nonsquamous histologies over those with squamous cell carcinoma (71% vs. 77%; $p = .076$).

Finally, a report on the prognostic significance of histopathologic subtyping of adenocarcinoma of the lung based on the WHO classification indicated that those with solid carcinomas and mucus formation had a significantly worse outcome than those with the three other histologic subtypes. In 137 patients, the median survival was only 10 months in the 14% of patients classified as having “solid carcinoma with mucus formation.” In contrast, the median survival was 31 months in the 57% of patients with “acinar adenocarcinoma” and 32 months in the 12% with “papillary adenocarcinoma.” The most favorable survival was observed in the 18% of patients with “bronchoalveolar cell carcinoma,” in whom median survival was 44 months.

Tumor Differentiation

Conflicting reports exist on the prognostic significance of tumor differentiation. A report from Johns Hopkins indicated that lack of tumor differentiation was a associated with a 24% 5-year survival, compared with 42% in those whose tumors were better differentiated. Similarly, a Japanese study of resected adenocarcinomas of the lung 2 cm in diameter reported that the 5-year survival was 78% for patients with well-differentiated tumors, 54% in those with moderately differentiated tumors, and 28% in those with poorly differentiated tumors ($p = .001$). In another Japanese study of stage I NSCLC, 5-year survival in patients with well-differentiated tumors was

significantly superior to survival in those with moderately or poorly differentiated tumors (83% vs. 72% and 76%, respectively). In contrast, a study from Duke University reported no significant survival differences as a function of degree of tumor differentiation.

Other Pathologic Markers

Lymphatic and Blood Vessel invasion

Lymphatic vessel invasion (LVI) and blood vessel invasion (BVI) have each been reported to be a significant determinant of prognosis, although results of different trials have been somewhat inconsistent. Some of these discrepancies may be explained by variations in pathologic definitions of these features and by the lack of statistical power in some of the trials.

A Veterans Administration study involving 685 resected NSCLCs concluded that LVI was a significant determinant of prognosis, whereas BVI was not. Three-year survival was significantly better among those without LVI than among those with LVI (61% vs. 42%). In a report of 151 stage I NSCLC patients from Japan, the 5-year survival among patients without LVI was 82%; it was 71% in patients with LVI (p = .045). Similarly, the 5-year survival in patients without BVI was 78%, compared with 52% in those with BVI (p = .061). In the Duke University series, only BVI was reported to be a significant determinant of survival in 289 stage I patients. Five-year survival was 68% in patients without BVI, compared with 35% among patients with BVI (p < .001).

Tumor Proliferation

The rate of tumor proliferation can be estimated pathologically by measuring the mitotic index, reported as the number of mitotic figures per 10 high-power fields (HPF) by light microscopy. The 5-year survival of patients with stage I NSCLC was 67% in those with 15 mitoses per HPF and 46% in those with 15 mitoses per 10 HPF (p .02). Similarly, in each of two reports limited to patients with T1N0 adenocarcinomas of the lung, the presence of a high mitotic index was a significant adverse determinant of survival.

Giant Cells

A series from Johns Hopkins reported that the presence of tumor giant cells adversely affected survival in early-stage NSCLC. In contrast, the identification of a brisk plasma cell infiltration within the tumor favorably influenced survival.

Serum Tumor Markers

Serum tumor markers have been extremely useful in evaluating prognosis and/or response to therapy in a number of malignancies, including germ cell tumors, ovarian cancer, colorectal cancer, and breast cancer. The utility of serum markers in NSCLC has been considerably less impressive. Although numerous serum tumor markers have been reported to be elevated in NSCLC, no marker has been shown to have any reasonable degree of specificity for lung cancer. The two serum markers most widely utilized in NSCLC, CEA and CA-125, are more commonly associated with colorectal and ovarian cancer, respectively.

In NSCLC, elevations of serum tumor markers are much more common in stage IV disease than in early-stage disease. Serum markers have not been demonstrated to predict survival in patients with disseminated NSCLC.

Limited data exist on the prognostic significance of serum tumor markers in resectable NSCLC. An LCSG report on resected stage I NSCLC concluded that preoperative CEA levels are prognostically important. Recurrences were observed in 12% of patients with preoperative CEA levels of 2.5 ng/mL, and in 42% of those with CEA levels of 2.5 ng/mL (p = .009). In 152 patients with NSCLC and CEA levels ³10 ng/mL who underwent an attempt at surgical resection, preoperative CEA levels increased as stage increased from I to IIIA (p .05). The preoperative CEA did not predict resectability. Preoperative CEA levels of 30 ng/mL were associated with a significantly shorter survival compared with lower values (p < .05). Nonety-two percent of patients whose preoperative CEA was 50 ng/mL died within 2 years of resection. Patients with resectable NSCLC who had CA-125 levels exceeding 15 U/mL were more than three times more likely to relapse and more than four times more likely to succumb to metastatic disease than those with lower values. Three-year survival was 67% for patients with preoperative CA-125 levels of 15 U/mL, compared with only 20% for those with CA-125 levels of 15 U/mL (p < .001). It appears that very high levels of CEA and/or CA-125 are associated with a poor outcome.

Molecular Markers

A variety of biomarkers expressed by tumor tissue have been reported and may be clinically useful. These can be classified as molecular genetic markers, metastatic propensity markers, differentiation markers, and proliferation markers.

Molecular Genetic Markers

The prognostic importance of mutation and/or protein product overexpression of five distinct oncogenes has been shown to be important in NSCLC. These include the *ras* oncogene, the p53 tumor suppressor gene, the c-*erbB*-2 proto-oncogene, bcl-2 protein, and retinoblastoma (Rb) protein (Table 7).

TABLE 7. *Prognostic significance of tumor size in surgical–pathologic stage I NSCLC*

K-ras Oncogene and p21 Expression

The *ras* oncogenes are believed to be important to cell growth by regulating signal transduction pathways. They are expressed in virtually all mammalian cells, and mutations in any of three distinct *ras* genes, H-*ras,* N-*ras,* and K-*ras,* can lead to malignant transformation. In lung cancer, almost all mutations affect the K-*ras* gene. Most reports indicate that *ras* mutations are predominantly associated with adenocarcinoma, although a slightly higher proportion of such mutations in squamous cell carcinoma has been reported. The *ras* genes encode for a group of proteins (p21 proteins) associated with the surface of cell membranes.

Activation of the K-*ras* oncogene has been reported to be associated with an adverse prognosis in resectable lung adenocarcinoma. In one series, 63% of patients with the K-*ras* mutation had died, compared with only 32% of those without the mutation, after a median follow-up of 3 years (p = .002). Two other reports have confirmed that K-*ras* mutations adversely affect survival in resectable NSCLC.

Similarly, overexpression of p21, the protein product of K-*ras,* has been reported to affect survival adversely. In one series of 116 resected NSCLC patients, 5-year survival was 64% in patients with negative p21 immunostaining, 38% for those with moderate immunostaining, and 11% in those with strong immunostaining. Multivariate analysis indicated that the association between p21 and survival was independent of stage, histology, and nodal status.

The p53 Tumor Suppressor Gene

The p53 tumor suppressor gene has been more commonly associated with human cancer than any other gene. Although most reports of p53 expression in NSCLC suggest that it carries an adverse prognosis, the opposite has also been found. Abnormalities of p53 in NSCLC have been reported both in terms of gene mutation and protein expression. The relation between survival and p53 gene abnormalities was evaluated in 85 resected NSCLC patients; p53 overexpression was detected in 55%, and mutations were noted in 54%. However, concordance was observed in only 65% of all patients. A significant reduction in survival was noted when p53 was overexpressed, but not when a gene mutation was identified. Similar results were reported in several other studies. It has been stated that p53 oncoprotein expression is “a favorable prognostic factor” in NSCLC. In a group of 156 resected patients, median survival for those with a high level of immunostaining for p53 was 65 months, compared with 26 months for those with low levels of immunostaining and 33 months for those with negative immunostaining.

On the other hand, no significant survival differences could be found in 125 resected NSCLC patients based on p53 immunostaining. Similarly, no significant overall association between p53 expression and survival could be demonstrated in 208 resected NSCLC patients. In another study, of 100 patients with adenocarcinoma, those with p53 expression had a worse survival than those without p53 expression. In contrast, in 88 patients with squamous cell carcinoma, no significant survival differences were observed, although survival trends suggested that p53 might predict for a better outcome.

The prognostic significance of p53 mutations has also been the subject of conflicting reports. No significant associations with gene mutations and survival in NSCLC have been reported; a significantly inferior 3-year survival for patients with p53 mutations compared with patients without mutations has been found (28% vs. 51%; p = .010) in 120 resected patients with NSCLC. Similarly, the presence of a p53 mutation led to a significant shortening of survival in 71 cases of resectable NSCLC (p = .014). The reasons for these conflicting reports are unclear but are likely to be multifactorial. Differences in experimental techniques and specific anti-p53 antibodies likely provide a partial answer.

The c-erbB-2 Oncogene and p185^{neu} Expression

The c-*erbB*-2 oncogene encodes for an epidermal growth factor receptor (erbB-1, EGFr). Three studies have reported that overexpression of its protein product, p185^{neu}, is associated with an adverse outcome in certain patient subsets. Kern reported that patients with adenocarcinoma of the lung who overexpressed p185^{neu} had a significantly worse survival compared with those who did not. In contrast, p185^{neu} expression did not influence survival in squamous cell carcinoma. Tateishi reported on the prognostic importance of p185^{neu} expression in 119 patients with adenocarcinoma and 84 patients with squamous cell carcinoma. Overall, 28% of adenocarcinomas were positive for p185^{neu}, compared with only 2% of the squamous cell cancers. Overexpression of p185^{neu} adversely affected 5-year survival (30%, compared with 52% for patients with tumors that were p185^{neu}-negative; $p < .01$). Finally, Harpole demonstrated p185^{neu} expression in 21% of 271 resected patients with stage I NSCLC. Surivival was significantly worse in those who expressed p185^{neu} than in those who did not ($p < .001$).

The bcl-2 Protein

The *bcl*-2 gene encodes for a protein that inhibits apoptosis. Expression of bcl-2 protein in 122 resected patients with stage I or II NSCLC was evaluated; the protein was detected by immunohistochemical analysis in 25% of patients with squamous cell carcinoma and 12% (5/42) with adenocarcinoma. Patients with tumors positive for bcl-2 protein had a superior survival at 5 years, although the differences reached statistical significance only for those with squamous cell histology (p .02). Similarly, survival was improved in patients with resectable NSCLC who expressed bcl-2 protein.

Retinoblastoma Protein

Loss of expression of the retinoblastoma (Rb) protein has been associated with an adverse prognosis in several human cancers. In lung cancer, no Rb protein expression was identified in 24% of 101 patients with resected NSCLC; median survival was significantly worse for patients with Rb-negative than with Rb-positive tumors (18 vs. 32 months; p = .007). A second study, involving 159 patients with resected NSCLC, reported 18% with Rb-negative tumors; these patients exhibited a trend toward inferior survival, although differences did not reach statistical significance (28 vs. 48 months; p = .37).

Markers of Metastatic Propensity

Although metastatic propensity has traditionally been evaluated by a number of pathologic parameters (lymphovascular invasion, degree of tumor differentiation), a number of markers can provide insights into the likelihood of metastatic spread. These include detection of isolated tumor cells in lymph nodes or bone marrow, cathepsin B expression, intensity of angiogenesis, and basement membrane deposition (Table 8).

Variable	Favorable	Unfavorable
K-ras oncogene activation	No point mutation	Point mutation at codon 12
p21–K-ras protein product expression	Absent p21 staining	Strong p21 staining
p53 tumor suppressor gene	No mutation	Gene mutation present
p53 protein product expression	Normal p53 expression	Overexpression of p53
p185^{neu} expression, the protein product of the C-erbB-2 oncogene	No expression of p185^{neu}	Overexpression of p185^{neu}
bcl-2 protein expression	bcl-2 positive	bcl-2 negative
Retinoblastoma (Rb) protein expression	Rb positive	Rb negative

TABLE 8. *Molecular genetic markers in early-stage NSCLC*

Isolated Tumor Cells in Lymph Nodes

It has been demonstrated that in a substantial percentage of patients with histologically negative lymph nodes, occult nodal metastases are revealed with the use of sensitive immunohistochemical techniques employing tumor-specific monoclonal antibodies. In one report of 60 patients with resected stage I NSCLC, 63% of patients with histologically negative lymph nodes had occult nodal metastases demonstrated by immunostaining with a polyclonal antikeratin antibody using the avidin-biotin complex immunoperoxidase technique. Lymph nodes closest to the primary tumor were most likely to contain occult micrometastases. There was a trend toward decreased median survival among those with occult nodal metastases (5.4 years vs. 6.7 years), although the difference did not reach statistical significance.

In another series, immunostaining with the Ber-Ep4 monoclonal antibody was performed in 72 patients with stage I NSCLC (all of whom had histologically negative nodes). The Ber-Ep4 antibody reacts with two glycoproteins present on the surface and in the cytoplasm of epithelial cancer cells. Individual cells positive for Ber-Ep4 were detected in 15% of patients. Recurrences were observed in 50% of patients with occult lymph nodes metastases and in 14% of those who had negative nodes (p = .005) during a 26-month median follow-up period. Moreover, 30% of patients with nodal micrometastases died of lung cancer during the observation period, compared with 7% without nodal involvement (p = .048).

Isolated Tumor Cells in Bone Marrow

The presence of occult metastases in bone marrow, detected by monoclonal antibody CK2 directed against cytokeratin polypetide 18 (CK18), has been evaluated in a series of 139 patients with resected NSCLC. CK18 was present in only 6 of 215 control patients without epithelial cancer. Overall, isolated bone marrow metastases were detected in 60% of patients. Among 66 node-negative patients, CK18 positivity was a strong predictor for recurrence and survival. During the median follow-up of 39 months, 75% of 12 node-negative, CK18-positive patients relapsed, compared with 35% of 54 patients who were CK18-negative (p = .023). On the other hand, the initial bone marrow status did not predict recurrence in 62 patients with positive regional nodes at the time of primary surgery.

Cathepsin B Expression

Cathepsin B, a lysosomal cysteine proteinase, regulates the catabolism of a variety of intracellular proteins. Cathepsin B is able to degrade extracellular matrix, thereby promoting tumor invasion and metastasis. Fairly extensive literature in breast cancer indicates that a high level of cathepsin B expression is associated with an adverse prognosis. Cathepsin B expression was assessed immunohistochemically using a polyclonal antibody in 108 resected NSCLC patients. A high level of expression was

associated with a statistically significant shortened survival ($p < .01$) in patients with squamous cell carcinoma or adenocarcinoma of the lung.

Intensity of Angiogenesis

An inverse relationship between the intensity of angiogenesis and prognosis has been demonstrated in stage I NSCLC. The intensity of angiogenesis was assessed by counting microvessels and grading their density in a population of 87 patients with resected T1,N0,M0 NSCLC. Microvessels were identified by antibody staining for factor VIII as well as by routine hematoxylin-eosin (H&E) staining. Those in whom recurrence developed had a statistically significantly higher mean number of microvessels and density grade than those in whom metastatic disease did not develop.

Basement Membrane Deposition

The presence of basement membrane deposition, determined by immunohistochemical staining with polyclonal antibodies to human type IV collagen, has been reported to predict for a favorable outcome in stage I and II squamous cell carcinoma of the lung. In 68 patients with early-stage squamous cell carcinoma, those with extensive basement membrane deposition had a significantly longer survival than those with moderate or limited deposition ($p = .02$).

Markers of Differentiation

Expression of certain cell membrane proteins is altered during the process of malignant transformation. Two related cell membrane proteins with reported prognostic significance have been evaluated in NSCLC (Table 9).

Variable	Favorable	Unfavorable
Isolated tumor cells in lymph nodes	Negative immunostaining with polyclonal antikeratin antibody	Positive immunostaining with polyclonal antikeratin antibody
Isolated tumor cells in lymph nodes	Negative immunostaining with the Ber-Ep4 monoclonal antibody	Positive immunostaining with the Ber-Ep4 monoclonal antibody
Isolated tumor cells in bone marrow	Negative immunostaining for cytokeratin polypeptide 18 (CK18)	Positive immunostaining for cytokeratin polypeptide 18 (CK18)
Cathepsin B expression	Low cathepsin B expression	High cathepsin B expression
Intensity of angiogenesis	Low microvessel count and density grade	High microvessel count and density grade
Basement membrane deposition (squamous-cell carcinoma)	Extensive deposition	Limited deposition

TABLE 9. *Markers of metastatic propensity in early-stage NSCLC*

Blood Group Antigens

ABH blood group antigens are present on the surface of most epithelial cells, in addition to being expressed on the surface of erythrocytes. Expression of ABH blood group antigen may be altered on the surface of tumor cells, and such alterations may be associated with prognostic significance. The prognostic significance of blood group antigen A expression in 164 patients with resectable NSCLC has been evaluated. The blood was type A or AB in 71 patients, and 61% of these patients expressed the A antigen on their tumor cells. Median survival of antigen-positive patients was superior to that of antigen-negative patients (71 months vs. 15 months; $p < .001$). In 93 patients whose blood group was O or B, survival was intermediate (39 months; $p = .002$). Expression of blood group antigen B or H on the surface of tumor cells did not correlate with survival.

A second study correlated expression of ABH blood group antigens with survival in 89 patients with resectable NSCLC. Loss of expression of blood group antigens was observed in 54%, whereas the other 46% demonstrated conserved expression. A superior survival was demonstrated in those with conserved expression (p .05). Loss of expression predicted for hematogenous metastases. Loss of expression of blood group antigen B was associated with the most significant decrease in survival (p .05). In contrast, loss of expression of A or H antigen was not associated with a significant survival decrement. A third trial failed to confirm any of these findings, so that the relationship between blood group antigens and prognosis remains unclear.

Expression of Lewis-Related Antigens

Expression of the H/Le^y/Le^b antigen on the surface of the cancer cells occurs only in the context of deletion of A and B blood group antigens, which are precursor antigens. H/Le^y/Le^b expression is detected by immunostaining using migration-inhibiting antibody (MIA) 15-5. In a series of 149 patients with resectable NSCLC, 5-year survival was superior for 58 MIA-negative compared with 91 MIA-positive tumors (59% vs. 21%; $p < .001$). Five-year survival differences were more pronounced in squamous cell carcinoma (62% vs. 11%; $p < .001$) than in adenocarcinoma (61% vs. 37%; $p = .015$). MIA-15-5 status was an important determinant of survival in patients with blood groups A and AB; it was not important for those with blood groups B and O.

In another report, expression of three Lewis-related antigens--Le^y, sialyl Le^x, and sialyl Le^a--was examined in 133 patients with resected stage I NSCLC. Expression of any of the Lewis-related antigens was associated with a significant decrease in survival, although expression of both the Lewis and sialyl Lewis antigens more strongly predicted for an adverse outcome. An association between expression of Lewis antigens and BVI was reported in this population.

Markers of Proliferation

A number of molecular techniques have been used to identify potentially more aggressive, rapidly dividing neoplasms. Biomarkers that correlate with cellular proliferation include DNA ploidy and percent S-phase (measured by flow cytometry), KI-67 proliferation index, and proliferating cell nuclear antigens (Table 10). The mitotic index may also be classified as a proliferation marker.

Variable	Favorable	Unfavorable
Expression of blood group antigens on tumor cells	Conserved expression of blood group antigens on tumor cells	Altered expression of blood group antigens on tumor cells
Expression of H/Le^y/Le^b antigens	Negative staining with MIA-15-5	Positive staining with MIA-15-5

TABLE 10. *Differentiation markers in early-stage NSCLC*

Flow Cytometry

Flow cytometry measures proliferative activity by determining the fraction of cells in the synthetic or S-phase of the cell cycle. Furthermore, it also measures DNA content, or ploidy status. By definition, diploid tumors have a normal DNA content and aneuploid tumors have an abnormal DNA content.

The DNA content of resectable NSCLC has been reported in nine studies. Only two of these trials also reported on cell cycle analysis. Five studies reporting on the

prognostic significance of DNA content in resected NSCLC found that tumor aneuploidy adversely affected survival. Four studies found no significant differences in survival when aneuploid and diploid tumors were compared. Accordingly, despite an extensive literature, the prognostic importance of DNA content in resectable NSCLC is uncertain.

Only two studies have addressed the prognostic significance of percent S-phase in early-stage NSCLC. One study indicated that a high S-phase fraction predicted a poor survival, whereas the other found no survival differences on the basis of cell cycle analysis. Accordingly, the prognostic importance of S-phase fraction in resectable NSCLC remains unknown.

KI-67 Nuclear Antigen

Immunohistochemical analysis for the proliferation-associated nuclear antigen KI-67 can identify rapidly dividing tumors. In a group of 61 patients with resectable NSCLC, the survival of patients with a proliferation index of 5% was significantly inferior to survival of those with a proliferation index of 5% (*p* .04). In a much larger population (271 patients) with resected stage I NSCLC, a continuous effect of the magnitude of KI-67 immunostaining on recurrence and survival was demonstrated. The median proliferation index was 5.3%, and the range varied from 0.1%–71%. Results indicated that the higher the proliferation index, the greater the risk for recurrence and death from lung cancer.

Proliferating Cell Nuclear Antigen

Proliferating cell nuclear antigen (PCNA), a nuclear protein that binds to DNA polymerase, is a marker of cellular proliferation. A highly significant relationship between the magnitude of staining with PCNA and survival has been found; PCNA was defined as positive when 5% of tumor cells stained with the antibody.

CLINICAL PRESENTATION OF LUNG CANCER

As previously discussed, screening for lung cancer is neither recommended nor widely practiced. Accordingly, the vast majority of patients are symptomatic at the time of clinical presentation. In one population-based series of 1539 lung cancer patients from New Hampshire and Vermont, only 2% (28 patients) were asymptomatic. Most asymptomatic patients present incidentally when chest roentgenography is performed for other reasons. The symptoms and signs of lung cancer are often divided into three general categories, according to whether they are related to local manifestations of the tumor, to metastatic disease, or to paraneoplastic syndromes. Many more patients present with signs and symptoms in the first and second categories than in the third.

Symptoms

The most common symptom of lung cancer is cough, which occurs in 45%–75% of all patients. Although cough, often associated with sputum production, is extremely common, it is a nonspecific symptom, because a high proportion of patients with lung cancer have pre-existing emphysema or bronchitis, in which similar symptoms may be found. However, a change in the character of an established chronic cough should raise the suspicion of a superimposed process. The production of large amounts of sputum, termed *bronchorrhea,* occurs in about 15% of patients with bronchoalveolar cell carcinoma. Bronchorrhea is extremely rare in other histologic subtypes.

Dyspnea occurs in about a third to half of all patients. It is also a nonspecific symptom and may be related to underlying COPD. Shortness of breath in the context of lung cancer may be attributable to multiple factors, including airway obstruction, obstructive pneumonitis or atelectasis, lymphangitic spread, pleural or pericardial effusion, or thromboembolic disease.

Hemoptysis has been reported in 27%–57% of patients with lung cancer. It should be noted that bronchitis is still the most common cause of hemoptysis, but lung cancer is diagnosed in 19%–29% of all patients who present with hemoptysis. In such cases, the volume of blood in the sputum tends to be small. In rare cases, tumor erosion into a bronchial artery can produce massive hemoptysis and death from asphyxiation.

Chest pain occurs in about a quarter to half of all patients. Some patients have dull, intermittent pain in the hemithorax in which the tumor is located; this does not necessarily indicate invasion to adjacent structures and does not preclude resection. On the other hand, severe, persistent pain often indicates invasion of the chest wall or mediastinum and portends locally advanced disease. Such pain is often associated with rib erosion.

Unilateral, localized wheezing is uncommon, but when it occurs it should raise suspicion of an underlying bronchogenic carcinoma producing fixed obstruction of a major airway. Tracheal obstruction may produce stridor. These symptoms are usually associated with severe dyspnea.

Weight loss has been reported in 8%–68% of patients with lung cancer. It may reflect symptoms of local or metastatic disease, or symptoms of a paraneoplastic syndrome. Almost all studies demonstrate that weight loss is a negative prognostic factor in lung cancer.

Metastatic Disease

About 70% of patients with lung cancer present with symptoms that reflect intrathoracic or extrathoracic metastasis. Pleural effusions are generally caused by pleural extension of the tumor. Pericardial effusion can occur by direct extension of the tumor to the pericardium and epicardium.

Hoarseness, when caused by lung cancer, is most often caused by compression of the recurrent laryngeal nerve; it has been reported in 2%–18% of cases. It is more common in left-sided tumors, because of the circuitous route of the left recurrent laryngeal nerve around the aortic arch.

Superior vena cava syndrome may result from either compression or direct invasion of the great veins of the thoracic inlet by mediastinal nodes or by the tumor itself. It is most common caused by small-cell carcinoma. Symptoms of superior vena cava syndrome include headache, with a sense of fullness in the head, and dyspnea. Physical signs include swelling of the face or upper extremity, plethora, dilated neck veins, and a prominent venous pattern on the chest. Superior vena cava syndrome was noted in 4% of 2000 patients in one series.

Brachial plexopathy is often caused by tumors in the superior sulcus of the lung. This entity, first described by Pancoast, is characterized by pain in the distribution of the C-7, T-1, and T-2 nerve roots, Horner's syndrome, rib destruction, and atrophy of hand muscles.

The most common organs involved by distant metastases from lung cancer are the brain, bones, liver, adrenal glands, and skin. Lung cancer can metastasize to virtually any bone, although vertebrae are most commonly involved. Ribs and pelvic bones are also very commonly involved. Symptoms include severe pain that may have a pleuritic component when the ribs are involved. Hepatic metastases most commonly produce symptoms of weakness and weight loss and carry a very poor prognosis. Headache, nausea and vomiting, focal neurologic symptoms, seizures, confusion, and personality changes may all be manifestations of brain metastases. The lung is the primary site of approximately 70% of cancers that initially present with symptomatic brain metastases.

Paraneoplastic Syndromes

Symptoms of the third category represent nonmetastatic systemic manifestations of the lung cancer (paraneoplastic syndromes) and are not directly related to tumor dissemination. Such manifestations may be caused by the production of biologically active substances by the tumor or by the body's response to the tumor. Often, the mechanism is poorly understood. Overall, clinically significant paraneoplastic syndromes occur in about 10%–20% of patients with bronchogenic carcinomas.

Some paraneoplastic phenomena are related to specific tumor cell types. Hypercalcemia is most strongly associated with squamous cell carcinoma. Digital clubbing and hypertrophic pulmonary osteoarthropathy (HPO) are most often associated with adenocarcinomas. Small-cell carcinoma is most commonly associated with syndromes related to the production of ectopic hormones, including the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and ectopic Cushing's syndrome resulting from production of corticotropin (ACTH) by the tumor. A variety of poorly understood neurologic syndromes also occur, including Eaton-Lambert syndrome (seen almost exclusively in small-cell lung cancer), peripheral neuropathy, and cortical cerebellar degeneration.

ESTABLISHING THE DIAGNOSIS

The existence of an underlying lung cancer is usually suspected on the basis of abnormal findings on a chest roentgenogram (Fig. 14 and Fig. 15). A definitive diagnosis may be made from an examination of tissue or exfoliated cells obtained from the tumor. Specific diagnostic techniques include sputum cytology, flexible fiberoptic bronchoscopy, pleural biopsy and fluid analysis, fine-needle aspiration (FNA), mediastinoscopy, and open thoracotomy. All patients undergoing a workup for

lung cancer should have a computed tomographic (CT) study of the thorax, with contrast when possible, for staging purposes and evaluation of the mediastinum. Magnetic resonance imaging (MRI) of the chest (with gadolinium) should be performed if there is any question of invasion of blood vessels by the tumor. Proper staging requires that imaging of the head (CT, MRI) and bones (bone scan) be performed to rule out metastatic disease. Appropriate workup also includes full pulmonary function studies and a cardiac evaluation if symptoms or signs warrant.

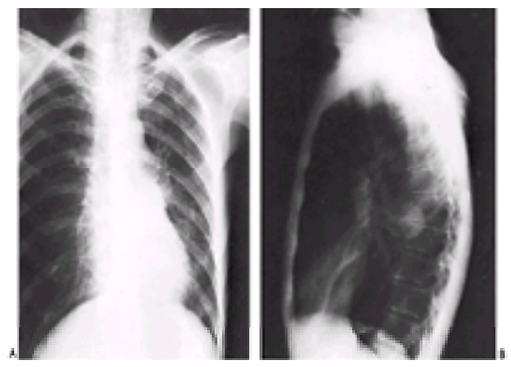

FIG. 15. A: Carcinoma of the lung hidden behind the cardiac silhouette on posteroanterior roentgenogram. **B:** Lateral view of the chest reveals the carcinoma. (Reprinted with permission from Morgan WKC, Hales MR. Bronchogenic carcinoma. In: Baum GL, Wolinsky E, eds. *Textbook of Pulmonary Diseases.* 3rd ed. Boston: Little, Brown; 1983.)

Computed Tomography of the Chest

The use of CT in the evaluation of hilar or mediastinal lymphadenopathy is controversial. CT is quite sensitive for imaging nodes >1.0 cm; sensitivity ranges from 64%–79%, with a specificity of 62%–66%. The false-negative rate is substantial, with adenocarcinomas having the highest rate of false-negatives. Thoracic CT is usually extended to include the liver, adrenals, kidneys, and upper abdominal lymph nodes, as it is the most effective tool in delineating metastatic disease in these sites.

Sputum Cytology

The diagnosis of central lesions can be made in approximately 80% of cases by the cytologic analysis of freshly expectorated and appropriately prepared sputum (Fig. 16). A specific cell type can be diagnosed 85%–95% of the time if malignant cells are seen.

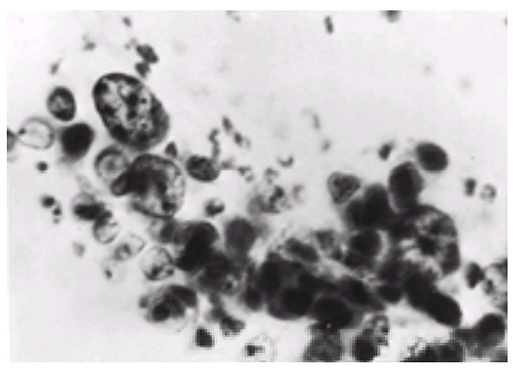

FIG. 16. Photomicrograph of bronchial washings stained by the Papanicolaou technique showing malignant cells. Note the hyperchromatic nuclei with irregularly placed chromatin particles. ×900. (Reprinted with permission from Morgan WKC, Hales MR. Bronchogenic carcinoma. In: Baum GL, Wolinsky E, eds. *Textbook of Pulmonary Diseases.* 3rd ed. Boston: Little, Brown; 1983.)

Flexible Fiberoptic Bronchoscopy

Fiberoptic bronchoscopy is a well-tolerated technique that makes possible visualization of the central tracheobronchial tree and permits brushings, washings, and biopsy specimens to be taken from any visible lesion. Bronchoscopy performed under fluoroscopic guidance permits biopsies of more peripheral lesions. The diagnostic yield is 90% when six to 10 biopsy specimens of endoscopically visible carcinomas are obtained. The diagnostic yield of nonvisualized, peripheral lesions is about 60% if both biopsy specimens and brushings are obtained. In addition, bronchoscopy is a staging procedure that can be used to exclude contralateral endobronchial (M status) lesions and define the proximal extent of an endobronchial lesion in relation to the main bronchi and trachea (T status). Transtracheal and transbronchial thin-needle aspirations (Wang procedure) can be performed to evaluate the involvement of paratracheal, precarinal, and subcarinal nodes (N status).

Analysis of Pleural Fluid and Pleural Biopsy

In a patient with suspected or documented lung cancer and a pleural effusion, analysis of the fluid and also pleural biopsy are required, either to make the initial diagnosis or help define the stage. Cytologic accuracy of pleural fluid examinations in the diagnosis of malignant pleural effusion varies from 40%–87%, depending on the tumor cell type. Accuracy can be increased by examining at least three independently obtained samples. Cytopathologic analysis of both pleural fluid cell blocks and smears should be performed.

Biopsy of the pleura is indicated whenever the cytology of an exudative pleural effusion is nondiagnostic. It will be positive for malignancy 39%–75% of the time. Analysis of pleural fluid will provide the diagnosis of malignancy more often than pleural biopsy.

The presence of a malignant pleural effusion automatically classifies the patient as having an unresectable T4 lesion. Not all malignant effusions are secondary to pleural involvement by tumor. If analysis of multiple pleural fluid and biopsy samples is nondiagnostic and the fluid is exudative, thoracoscopic examination of the

pleural surface should be performed to help make a diagnosis and stage the patient. A transudative, nonbloody effusion should not be considered in the determination of stage if results of the cytopathologic examination are negative.

Fine-Needle Aspiration

FNA is usually performed under CT or fluoroscopic guidance to obtain cells from lesions not accessible by other means. The most common complications of this procedure are pneumothorax (25%–35%) and minor hemoptysis (1%–10%). The diagnostic sensitivity of FNA in lung cancer is 85%. False-negatives result from inadequate sampling or the sampling of necrotic tissue. The false-positive rate of transthoracic needle aspiration is 0.1%–0.5% and is most commonly caused by the presence of an inflammatory process, such as pneumonia, abscess, or active tuberculosis, or fibrosis.

FNA is very useful in determining cell type in patients who are not candidates for surgery, or for staging purposes when either upstaging or downstaging would influence management. The procedure should not be performed in patients who are surgical candidates, because the finding of malignant cells will not affect therapy and because FNA is not a reliable test for diagnosing benign lesions.

Mediastinoscopy/Anterior Mediastinotomy (Chamberlain Procedure)

These invasive surgical procedures are the most accurate methods for staging the mediastinum and identifying patients with unresectable disease: contralateral nodal involvement, extranodal extension of cancer, high paratracheal involvement, or cell type not amenable to surgery (small-cell carcinoma). Many centers use CT as a screening tool to assess the mediastinum, as mentioned above.

Lymph nodes 1.0 cm in the short axis are considered abnormal and require sampling by mediastinoscopy. Patients with an abnormal mediastinum on chest CT should undergo mediastinoscopy or anterior mediastinotomy so that tissue can be obtained to document the presence of malignancy before definitive surgical resection. Cervical mediastinoscopy permits direct imaging and sampling of paratracheal, tracheobronchial, and anterior subcarinal lymph nodes. Anterior mediastinotomy and extended cervical mediastinoscopy allow assessment of the aortic pulmonary window and anterior mediastinal nodes. Mediastinoscopy will exclude from thoracotomy 30%–40% of patients initially thought to have surgically resectable disease.

Direct Lymph Node Biopsy

Palpable cervical or scalene lymph nodes in the setting of suspected lung cancer should be sampled. Evidence of metastasis will usually preclude thoracotomy. In patients with documented lung cancer and palpable scalene nodes, biopsy results have been positive in 83% of cases; only 20% of nonpalpable nodes were positive for malignancy after biopsy.

Thoracotomy

Surgical exploration of the chest is the gold standard for determining the final T and N status of the cancer and permits decisions to be made regarding the surgical procedure required. Thoracotomy should be performed in any patient with a normal mediastinum on CT. All lymph node stations not sampled during mediastinoscopy should be assessed at thoracotomy regardless of appearance on CT. Samples of nodes from the superior mediastinum and subcarinal, subaortic, peribronchial, and intrapulmonary nodes adjacent to the planned site of bronchial resection should be obtained. N status often can be determined only at this time.

STAGING OF LUNG CANCER

Once the diagnosis of lung cancer has been established, a determination of extent of disease, as reflected by surgical pathologic staging, must be made to guide appropriate therapy and determine prognosis. A TNM (tumor, node, metastasis) staging system for lung cancer has been in use for more than two decades, predominantly for NSCLC. The T status (T1-4) describes the size, location, and extent of the primary tumor; the N status (N0-2) delineates lymph node involvement, and the M status (M0-1) represents distant metastases. A three-stage staging system of the American Joint Committee on Cancer (AJCC) was widely utilized until 1986. In this system, stage I included T1,N0,M0 and T2,N0,M0 as well as T1,N1,M0 tumors, whereas stage II consisted exclusively of T2,N1,MO lesions. Patients identified as having regionally advanced disease (consisting of T3 and/or N2 disease) or distant metastatic (M1) disease were grouped together within a single stage III category.

In 1986, the International Staging System (ISS) for lung cancer was introduced and adopted by the AJCC (Table 6 and Fig. 12). This system, like the older AJCC system, is based on the principal of TNM groupings and comprises five stages. In 1997, the ISS was modified, so that stages I and II were divided into IA/IB and IIA/IIB subcategories. This is predominantly related to tumor size, although T3N0M0 lesions were moved from stage IIIA to stage IIB (Table 6).

In stages I, II, and IIIA NSCLC, the stages in which resection plays a therapeutic role, prognosis is better when staging is based on surgical pathologic criteria (pTNM) rather than clinical criteria alone (cTNM) (Fig. 17 and Fig. 18). This is because a significant proportion of patients are found to be understaged at surgery, despite extensive preoperative workup. In a prospective validation of the International Union Against Cancer TNM evaluation involving 3824 patients, concordance between TNM and clinical stages was 61% for stage I disease.

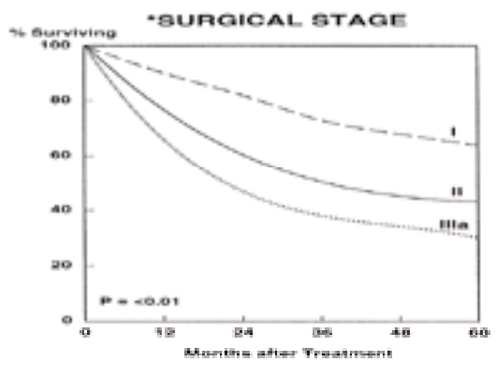

FIG. 18. Cumulative survival according to surgical-pathologic stage of disease. This evaluation of disease extent is based on pathologic examination of resected specimens. (Reproduced with permission from Mountain CF. Staging classification for lung cancer. *Clin Chest Med* 1993;14: 43–51.)

Stage I (T1-2,N0) represents local disease without regional node involvement. Stage II (T1-2,N1) encompasses lymph node involvement that is limited to nodes within

the substance of the lung itself (peribronchial, lobar, and/or hilar nodes). The current standard therapy for stages I and II NSCLC consists of surgical resection. Postoperative radiation may reduce the risk for local recurrence in resected stage II disease.

Stage III comprises regionally advanced disease and is subdivided into stage IIIA and stage IIIB subcategories. Stage IIIA disease consists of regionally advanced disease that is nonetheless technically resectable for cure. It comprises T3,N1 or T1-2-N2 disease. While by definition stage IIIA NSCLC is technically resectable, the efficacy of surgery is controversial. Stage IIIB consists of regionally advanced, technically unresectable (with intent to cure) disease (T4 and/or N3 disease). Modern treatment for both stage III categories is evolving, but most investigative strategies have utilized multimodality approaches consisting of chemotherapy, radiation, and surgery.

Stage IV consists of distant metastatic disease (M1). Treatment generally consists of chemotherapy and palliative radiation, or no treatment is undertaken.

Proportional stage distribution in NSCLC varies enormously among different series and depends very much on the method of detection. Among 3753 patients reported by Mountain, whose staging information was used to formulate the ISS, 1533 (41%) had stage I disease. In this series, stage I was by far the most common stage of disease at presentation and was almost two and a half times as frequent as any other stage grouping. The most accurate data regarding proportional stage distribution at the present time comes from the National Cancer Data Base (NCDB), which contains information on 58,653 lung cancer patients. The anatomic classification of extent of disease employed by the NCDB is neither the AJCC nor ISS classification. Rather, patients are classified into local, regional, or distant categories. After stratification by race and socioeconomic status, the percentages of patients classified with local, regional, and distant disease were 17%–18%, 31%–33% and 35%–39%, respectively (the remainder being not further classified). These data are much more consistent with the current perception that most patients with lung cancer have metastatic disease at presentation. They are also consistent with the current overall 5-year survival of 13% for all lung cancer patients in the United States.

Although the optimal staging system for SCLC remains uncertain, a simple two-stage system dividing patients into those with limited or extensive disease has been widely used. Limited disease refers to disease that is either confined to the hemithorax of origin or is encompassed within a single radiation portal. Extensive disease refers to cancer that has spread beyond the hemithorax of origin.

MANAGEMENT OF STAGE I AND STAGE II NSCLC

Therapeutic management of all stages of NSCLC depends on the stage of disease at clinical presentation. Surgical resection is widely recognized as the most effective therapy for patients with stages I and II NSCLC. By and large, only patients who have undergone complete resection are likely to achieve a cure. The adjunctive role of radiation therapy and chemotherapy is still under investigation.

Surgery

Stage I NSCLC is the only stage of NSCLC in which it is agreed that surgical resection alone constitutes standard treatment, even though its value has never been established by a randomized trial. Nonetheless, the favorable results reported in selected surgical series, and the infrequency of long-term survival among patients treated with nonsurgical means, clearly establishes surgery as the treatment of choice in resectable early-stage NSCLC.

Lobectomy has generally been accepted as the procedure of choice in both stages I and II NSCLC. It is usually possible to remove all known disease with lobectomy, while preserving pulmonary function. Full pneumonectomy may be required with large proximal tumors. Sleeve resection should be considered when the tumor mass is 2 cm from the main carina.

In recent years, advances in video optics have facilitated the development of video-assisted thoracoscopic surgery (VATS). This minimally invasive procedure is associated with a reduction in surgical morbidity, including postoperative pain. VATS has been employed for diagnostic and staging purposes, and for wedge or segmental resections in selected individuals, particularly elderly patients with significant medical comorbidities. Limited resection has been found to be inferior to lobectomy as a definitive cancer operation in patients with small, peripheral, stage I lesions. The efficacy of VATS is therefore not clear.

The reported success of surgical therapy for stages I and II NSCLC varies widely. Success clearly depends on the extent of staging. In Mountain's series, approximately 50% of patients with clinical stage I and 30% of patients with clinical stage II NSCLC survived for 5 years following diagnosis. For patients with pathologic stages I and II NSCLC, 5-year survival was 64% and 45%, respectively. Among patients with pathologic stage I disease, 5-year survival was 69% and 59% for those with T1,N0 and T2,N0 tumors, respectively. In one series of 289 stage I patients treated at Duke University, the 5-year survival was 63%, whereas in a series of 495 patients from the Mayo Clinic, the 5-year survival was 69%.

Probably the most impressive results regarding surgical therapy for stage I NSCLC comes from Memorial Sloan-Kettering, where 598 stage I patients underwent resection. The histologic distribution included 39% with squamous cell carcinoma and 59% with adenocarcinoma (including 16% with bronchoalveolar carcinoma). Interestingly, only 2% of patients had large-cell carcinomas. The overall 5- and 10-year survivals in this series were 75% and 67%, respectively.

Of these patients, 49% were classified as T1 and 51% as T2. As expected, patients who had T1 tumors enjoyed a superior survival compared with those who had T2 tumors (5- and 10-year survivals: T1, 82% and 74%; T2, 68% and 60%; $p < .0004$). Tumor size significantly influenced survival when stratified as <1 cm, >1 to 3 cm, >3 to 5 cm, and >5 cm. For example, 10-year survival for patients with tumors <3 cm, >3-5 cm, and >5 cm was 74%, 62%, and 47%, respectively. Virtually all series confirm the importance of tumor size in pathologic stage I NSCLC.

Surgical therapy consisted of a lobectomy in 85% and pneumonectomy in 4% of patients, whereas 11% underwent wedge resection or segmentectomy. Mediastinal lymph node dissection was performed in 94% and lymph node sampling or no formal dissection in 6%. The 5- and 10-year survivals were 77% and 70%, respectively, among those who underwent lobectomy or pneumonectomy. Patients treated with lesser resection had 5-and 10-year survivals of 59% and 35%, respectively ($p = .026$).

In many series, stage II NSCLC is the least common of any stage of lung cancer. The results of surgical resection among patients with stage II NSCLC are considerably less favorable than the results for patients with stage I disease. The LCSG has reported on 1000 patients with stage II disease and found the histologic subtype to be an important determinant of survival. In patients with T1,N1 disease, the 5-year survival was 75% for squamous cell carcinoma and 52% for adenocarcinoma ($p = .04$). For patients with T2,N1 tumors, the 5-year survival was 53% for squamous cell carcinoma and 25% for adenocarcinoma ($p < .01$).

For patients who undergo complete resection for stage II (T1,N0,M0 or T2,N0,M0) NSCLC, the 5-year survival has been reported to be as high as 47%, based on a study of 214 patients from Memorial Sloan-Kettering Cancer Center. A T2,N1 tumor was present in 84% of all patients in this series. Lobectomy was performed in 68% and pneumonectomy in 31%. The number of involved N1 nodes was a very important determinant of outcome in this series, and patients who had a single nodal site did better than those with multiply involved nodes. Whereas the distinction between T1 and T2 was not significant, there was a significantly better survival in patients with tumors <3 cm than in those with tumors <5 cm.

Radiation Therapy

Radiation treatment has been employed in the management of early-stage NSCLC in nonsurgical candidates, and in the postoperative management of patients with resected stage II disease. Radiation therapy has also been used as a primary alternative to surgery in patients with technically resectable early-stage disease. These individuals usually are elderly, refuse surgical intervention, or have significant medical comorbidities.

The results of 347 patients with clinical stage I NSCLC, treated at the Queensland Radium Institute between 1985 and 1992 with radiation alone, were retrospectively reviewed. All patients received at minimum a 50-Gy tumor dose in 20 fractions during 4 weeks. Overall 5-year survival was 27%, and median survival was 27.9 months. The 5-year survival among the 167 patients with T1,N0 tumors was 32%, and it was 21% for the 180 patients with T2 tumors ($p < .01$).

Another series, of 84 “medically inoperable” patients with early-stage disease, reported a 5-year survival of 31% for clinical stage I and 19% for clinical stage II NSCLC. Most patients received 40 Gy to the primary tumor and mediastinum and a subsequent boost, bringing the dose to 60 to 74 Gy. Tumor size was the most important factor predicting both local-regional failure and survival. Local-regional recurrence occurred in 24% of patients with tumors 5 cm and in 53% of those with larger tumors. Similarly, the 5-year survival was 29% for tumors <5 cm, compared with 14% for those <5 cm. Thus, a substantial minority of patients with early-stage NSCLC may achieve prolonged survival and even cure with radiation alone, but results achieved with this modality are clearly inferior to the results achieved with surgical resection.

With regard to postoperative adjuvant radiation therapy following resection, randomized trials exist both for stage I and stage II disease. The role of postoperative radiation has been studied in a French trial involving 132 patients with T2,N0 lesions. Patients were randomized to surgery alone or to surgery followed by 45 to 60 Gy

of postoperative radiation centered on the hilum and upper mediastinum. The results of the trial demonstrated no advantage for the group undergoing postoperative radiation therapy. In fact, trends in disease-free survival (p = .11) and overall survival (p = .049) favored the nonirradiated group. Overall 5-year survival was 44% in both groups. The proportion of patients who had local recurrence was 15% in the radiation group and 17% in the control group. The proportion with distant metastases was 37% in the irradiated group and 25% in the group with surgery alone.

Similarly, a trial from Belgium studied the role of postoperative radiation in 175 evaluable patients who had completely resected lung cancer without nodal involvement. In this trial, 92 patients were randomized to surgery alone and 83 to surgery and 60 Gy of postoperative radiation delivered to the mediastinum. All histologic subtypes were eligible, and seven patients with SCLC were included in each arm. Like the French trial, this was a negative study, and survival trends at 5 years also favored the nonirradiated group (24% vs. 43%; p = NS). For patients with T2,N0 tumors, there was actually a significant survival detriment associated with postoperative radiation (p < .05). Postoperative radiation did alter the pattern of recurrence. In 25 (of 83) patients in the radiation arm in whom recurrences developed, the percentages of recurrences that were exclusively regional, both regional and distant, and exclusively distant were 4%, 12%, and 84%, respectively. In contrast, among 36 (of 92) patients in the surgery arm who had recurrence, 28% of recurrences were regional only, 25% regional and distant, and 47% distant only. Accordingly, radiation did decrease the risk for regional recurrence in this trial.

In stage II NSCLC, the role of postoperative radiation therapy has been best evaluated by the Lung Cancer Study Group in LCSG protocol 773. In this trial, 230 patients with completely resected squamous cell carcinoma were randomized to no further therapy or to 50 Gy of postoperative radiation. Two thirds of participants had stage II disease, and the remainder had ipsilateral mediastinal nodal involvement (stage IIIA). Overall, recurrences were observed in 37% (38/102) in the radiation group and 47% (51/108) in the group with surgery only (p = .17). Postoperative radiation also led to a striking change in the pattern of recurrence. There was a dramatic reduction in the risk for recurrence to the ipsilateral lung and mediastinum in the radiation group (3% vs. 41%; p < .001) but an increase in distant recurrences (97%). Of recurrences in the group with surgery alone, 59% were at distant sites. Survival analysis demonstrated no difference in overall survival between the groups. Accordingly, the results of this trial demonstrated that postoperative radiation could reduce the risk for local recurrence following resection of squamous cell carcinoma, although overall recurrence rate and survival were not improved. The results underscore the need for effective systemic therapy to control distant metastatic disease.

Adjuvant Chemotherapy

As the most common pattern of failure following curative resection of stages I and II NSCLC is distant metastatic disease, adjuvant chemotherapy represents the most rational therapeutic strategy to diminish this risk. Although numerous adjuvant chemotherapy trials in resectable NSCLC have been conducted during the past several decades, no patient subset has been identified in whom an undisputed benefit from adjuvant chemotherapy has been achieved. Accordingly, adjuvant chemotherapy is not a standard of care for any patients with resected stage I or stage II disease.

A meta-analysis of chemotherapy in NSCLC has been published, with data included from 14 randomized trials comparing surgical resection alone with surgery plus adjuvant chemotherapy. These trials comprised a total of 4357 patients; there were 2574 deaths. Five of the trials evaluated adjuvant chemotherapy based on the use of long-term alkylating agents. In these trials, the hazard ratio favored surgery alone, and this risk for death was 15% *higher* among those randomized to chemotherapy (p = .005).

For studies that utilized a cisplatin-based chemotherapy regimen, the hazard ratio estimates favored adjuvant chemotherapy. Overall, there was a 13% reduction in the risk for death among treated patients in these eight trials, which translated into an absolute 5% improvement in the probability of long-term survival (p = .08).

Although conflicting data exist, a number of studies do support the conclusion that adjuvant chemotherapy in resectable NSCLC is associated with some biologic effect. Nonetheless, adjuvant chemotherapy remains experimental at the present time and is recommended only in the context of a clinical trial.

The availability of newer and potentially more effective agents provides an opportunity to re-evaluate the role of chemotherapy in the adjuvant setting. Newer drugs with encouraging activity include carboplatin, paclitaxel (Taxol), docetaxel (Taxotere), vinorelbine tartrate (Navelbine), gemcitabine (Gemzar), and irinotecan (CPT-11). Adjuvant trials including some of the newer agents have already been initiated. Two ongoing North American adjuvant chemotherapy trials in patients at high risk for recurrence following complete resection of NSCLC deserve mention.

The National Cancer Institute of Canada is conducting a phase III study comparing surgery alone with surgery followed by adjuvant chemotherapy with cisplatin and Navelbine (NCIC BR10). Eligible patients include those with T2,N0 stage I disease and those with stage II (T1,N1 or T2,N1) disease. Tissue is being collected to study molecular markers on a prospective basis. The presence of a *ras* mutation will be utilized as a stratification factor before randomization. Groups in the United States are planning to cooperate in this study, so it will be conducted as an intergroup study.

The Cancer and Leukemia Group B is sponsoring an intergroup study in patients with high-risk stage I NSCLC (CALGB 96-33). Eligible patients must have a T2,N0 primary lesion. A total of 500 patients will be randomized to surgery alone or to surgery followed by adjuvant chemotherapy with carboplatin and Taxol. The rationale for defining “high risk” exclusively on the basis of T status is based on the consistency of individual reports indicating that tumor size is an important predictor of outcome in stage I NSCLC. In this study, it is felt that there is insufficient information to permit treatment decisions to be based on any constellation of molecular and/or pathologic prognostic markers.

Response rates in advanced NSCLC observed with combination chemotherapy regimens employing cisplatin and Navelbine (NCIC adjuvant trial) or carboplatin and Taxol (CALGB trial) exceed the response rates observed with 5-fluorouracil (5-FU) and leucovorin in advanced colorectal cancer or cyclophospamide, methotrexate, and 5-FU (CMF) in advanced breast cancer. Accordingly, there is a strong basis for optimism that the current adjuvant trials in resectable NSCLC will provide definitive evidence that adjuvant chemotherapy contributes to long-term survival in resectable NSCLC. Nonetheless, until such evidence becomes available, adjuvant chemotherapy in resectable early-stage NSCLC remains investigational.

MANAGEMENT OF STAGE IIIA AND STAGE IIIB NSCLC

The management of regionally advanced NSCLC has evolved rapidly during the last decade. The older AJCC staging system had grouped regionally advanced NSCLC along with distant metastatic disease in a single stage III category. However, the ISS subdivides regionally advanced stage III disease into stage IIIA and IIIB categories. Stage IIIA disease is characterized by circumscribed extrapulmonary extension of the primary tumor, implied by the T3 designation or by the presence of N2 nodes. Stage IIIB is characterized by extensive extrapulmonary (although intrathoracic) extension, implied by the T4 designation or nodal disease outside the ipsilateral hemithorax.

Conceptually, stage IIIA was intended to describe regionally advanced yet potentially resectable disease, whereas stage IIIB was intended to described regionally advanced, categorically unresectable disease. Criteria for resectability have changed somewhat, and these distinctions are not absolute. Moreover, in this era of multimodality therapy, surgery may play a cytoreductive role in the management of cancer.

Stage IIIA disease appears to be associated with a better prognosis than stage IIIB disease. According to data presented when the ISS was introduced, stage IIIA is associated with a median survival of 12 months and a 5-year survival of 15%, whereas stage IIIB is associated with a median survival of 8 months and a 5-year survival of <5%.

Radiation Therapy in Stage III NSCLC

Radiation therapy alone has traditionally been considered the “standard” therapy for regionally advanced NSCLC. However, the literature on radiation alone in the treatment of regionally advanced stage III NSCLC consistently demonstrates that the median survival achieved is <1 year in duration, and 5-year survival rates range between 5% and 8%. Radiation is an effective palliative measure in terms of relief of symptoms, but it is not associated with long-term survival in the vast majority of treated patients.

There has been little effort to distinguish stage IIIA from stage IIIB prospectively in patients treated with radiation therapy alone. A designation of stage IIIA or IIIB was retrospectively assigned to 306 patients treated at Fox Chase Cancer Center between 1978 and 1987 with standard radiation alone. No significant differences in outcome were found between the 166 IIIA patients and 140 IIIB patients in median survival time (9.4 vs. 9.8 months) or 2-year survival rates (17% vs. 18%). Although this analysis is limited, because only 28% of patients underwent surgical staging of the mediastinum, the authors concluded that stratification of patients into a stage IIIA or IIIB category has little clinical importance when radiation therapy is used alone.

Local control remains a major problem. A 75% local failure rate at 3 years, even among patients with relatively small tumors treated with >65 Gy of radiation, has been reported. Local control is not enhanced by increasing radiation dose with conventional radiation techniques. Two series have shown that severe radiation pneumonitis increases as the radiation dose is raised.

The ineffectiveness of conventionally fractionated radiation in providing long-term survival for the vast majority of patients raises the question of whether radiation should continue to be considered “standard” therapy of regionally advanced NSCLC. Two randomized trials have suggested that “immediate” radiation therapy delivered at the time of diagnosis provides little if any prolongation of survival compared with “delayed” radiation (given when symptoms supervene) or no radiation at all.

There is some evidence that hyperfractionation radiation, in which multiple daily fractions of radiation are employed, may be superior to conventionally fractionated radiation. The Radiation Therapy Oncology Group (RTOG), in protocol 83-11, performed a randomized trial in which 848 patients with stage III NSCLC were randomized to one of five different hyperfractionated treatment arms in which 60.0 Gy, 64.8 Gy, 69.4 Gy, 74.4 Gy, or 79.2 Gy of radiation was administered. A survival advantage was reported for a retrospectively identified subgroup of “favorable” patients (defined as those with Karnofsky performance status of 70%–100% and <6% weight loss). Such “favorable” patients assigned a dose of 69.4 Gy had a median survival of 13 months and a 2-year survival of 29%, both statistically significantly better than median survival at the lower dose levels. There was no further advantage with the higher dose levels, and no survival advantage was seen in those patients who were not “favorable.” The role of hyperfractionated radiation in stage III disease is still being evaluated.

Surgery in Stage III NSCLC

Because the vast majority of patients with NSCLC who achieve long-term survival have undergone resection, surgery is believed to be the most effective modality in NSCLC. In stage III NSSCLC, most patients with stage IIIA are technically resectable, and even certain subsets of stage IIIB patients are amenable to resection. Considerable data support the conclusion that from a surgical standpoint, stage IIIA NSCLC should be stratified based on the presence of a T3 primary lesion or the presence of N2 regional adenopathy.

Until 1997, T3N0 tumors were classified as stage IIIA disease. Clearly, T3N0 and T3N1 tumors are biologically distinct from those associated with N2 disease. The evidence that surgical resection plays a major role in the treatment of stage IIIA disease is strongest with respect to these categories. Patients with T3N0 tumors have a superior prognosis compared to other stage IIIA subgroup. It is for this reason, the T3N0 tumors were reclassified as stage IIB, according to the 1997 revision of the ISS.

Patients with T3 tumors comprise a heterogeneous group with varying prognoses that depend on the basis for the T3 designation. Patients with T3 tumors based on involvement of the chest wall probably have the most favorable outlook with surgical resection. Reports from the Mayo Clinic and the Brigham and Women's Hospital indicate 5-year survival 50% for resected T3,N0 tumors involving the chest wall.

Similarly, patients who have superior sulcus (Pancoast) tumors without regional nodal involvement enjoy respectable long-term survival rates when surgical resection is employed. In Paulson's series of such patients treated with preoperative radiation followed by resection, the 5-year survival rate was 31%.

In contrast, results of surgical resection for tumors that invade the mediastinum are quite different. In a group of 225 such patients from Memorial Sloan-Kettering Cancer Center who underwent thoracotomy, median survival was 12 months and 5-year survival was 7%. Patients with overt mediastinal invasion would be classified at having T4 primary tumors by the ISS system.

Several series have demonstrated that 5-year survival rates range from 15%–29% among highly selected groups of patients undergoing resection of N2 disease. A number of factors have been identified that adversely affect survival in resected N2 disease. These include the presence of T3 tumors, nonsquamous histology, the presence of high mediastinal nodes, or multiple involved N2 sites.

The largest experience on the role of surgery in N2 disease comes from the Memorial Sloan-Kettering Cancer Center. Of 706 patients judged to have N2 disease by either clinical or pathologic criteria (mediastinoscopy was not routinely performed), 404 underwent thoracotomy, and the disease of 151 of these (37% of thoracotomy patients and 21% of all N2 patients) was completely resectable. The bulk of mediastinal nodal involvement significantly affected the likelihood of complete resection. Of 224 patients who were felt by clinical criteria to have NO or N1 disease but were found to have otherwise inapparent N2 disease encountered at thoracotomy, the disease of 119 (53%) was resectable. In contrast, 179 patients had obvious clinical N2 disease, and the disease of only 32 of them (18%) was resectable. Approximately 90% of all patients who underwent resection also received postoperative radiation to the ipsilateral hilum and mediastinum (40 to 45 Gy). The overall 5-year survival for the entire group of N2 patients who underwent resection was 30%. For those who were clinically NO or N1, the 3- and 5-year survivals were 47% and 34%, respectively. For those with clinically overt N2 disease, the 3- and 5-year survivals were each 9%; the 9% figure is not very different from that achievable with radiation alone.

A report from Toronto General Hospital on the surgical treatment of 141 patients with stage IIIA disease demonstrated that cervical mediastinoscopy is extremely useful in selecting patients for surgical resection. In contrast to the experience cited above from Memorial Sloan-Kettering, all patients in the Toronto report underwent preoperative cervical mediastinoscopy for surgical staging of the mediastinum. In 62 patients, findings at mediastinoscopy were negative, but mediastinal nodal involvement was found at the time of resection. The actuarial 5-year survival in this group was 24%. In contrast, among 79 patients, mediastinoscopy findings were positive. In this group, 67 patients underwent resection, but their 5-year survival was only 9%.

Accordingly, the data support the conclusion that surgical “response rates” (resectability) are impressive in certain N2 subsets. Moreover, long-term survival may be achieved in some patients. It remains uncertain whether surgery is the most effective modality in stage IIIA NSCLC, particularly in patients with clinically overt N2 disease.

Combined Surgery and Radiation in Stage III NSCLC

The rationale for combining radiation and surgery is to improve local-regional control. In theory, an improvement in local control would lead to an improvement in overall survival, although this has not been the case in most solid tumors in adult patients. Studies have been carried out in which radiation was utilized preoperatively as well as postoperatively.

Two large, randomized trials comparing preoperative radiation therapy followed by surgery with surgery alone were conducted in the 1960s and 1970s. The first was the Veterans Administration Study, in which patients were randomized to receive preoperative radiation at 40 to 50 Gy or immediate surgery. The second was a study conducted by the NCI in which patients were randomized to preoperative radiation with a minimum of 40 Gy or to surgery alone. Both trials failed to demonstrate any benefit for preoperative radiation, either in terms of decreased mortality or recurrence. Patients with SCLC were eligible to participate in these trials.

Sherman reported the results of a phase II trial of preoperative radiation followed by surgical resection in stage III NSCLC. Fifty-three patients received 30 to 40 Gy preoperatively followed by resection and postoperative radiation. Forty-six patients underwent thoracotomy; the disease of 38 was resectable. Five-year survival was 18% for the entire cohort of 53 patients and 27% for the 38 patients who underwent successful resection.

The role of postoperative radiation was most definitively evaluated by the Lung Cancer Study Group in LCSG protocol 773. Patients with completely resected stage II or III squamous cell carcinoma were randomized to receive 50 Gy of postoperative radiation or no further therapy. About a third of the patients had stage III NSCLC. As previously discussed, postoperative radiation significantly reduced the incidence of local-regional recurrences to the ipsilateral lung and mediastinum from 41% to 3%. However, this did not translate into a survival advantage, but rather shifted recurrence patterns from local-regional to distant.

Induction Chemotherapy and Radiation Versus Radiation Alone in Stage III NSCLC

The use of systemic chemotherapy before definitive local-regional therapy (radiation and/or surgery) is generally referred to as *induction chemotherapy* or *neoadjuvant chemotherapy.* The term *induction chemotherapy* will be employed here.

The role of induction chemotherapy combined with thoracic radiation has been extensively investigated in stage III NSCLC. Numerous phase II and III studies have been completed. Indeed, the role of induction chemotherapy is perhaps better supported by randomized studies in NSCLC than in any other solid tumor of adults.

There are a number of theoretical advantages for the use of induction chemotherapy. These include stage reduction to facilitate improved local control by radiation and/or surgery. Micrometastases are addressed early in the course of treatment. Finally, some studies suggest that induction chemotherapy is better tolerated than chemotherapy administered later in the course of treatment.

The most influential phase III trial in stage III NSCLC is the trial conducted by the Cancer and Leukemia Group B (CALGB 84-33). Eligibility for this trial was limited to patients with prognostically favorable pretreatment characteristics, including favorable performance status (Eastern Cooperative Oncology Group performance status of

0 or 1) and minimal weight loss (5% of body weight in the preceding 3 months). Patients were randomized to receive 60 Gy of radiation in 6 weeks or two cycles of induction chemotherapy with cisplatin and vinblastine followed by identical radiation treatment.

A recent update of this trial has been published, which includes 7-year follow-up information. A total of 78 patients were randomized to chemotherapy and radiation, whereas 77 were randomized to radiation alone. The objective response rate was 56% to combined treatment and 43% to radiation alone (p = .092). The group randomized to induction chemotherapy achieved a significant improvement in median survival (13.7 vs. 9.6 months; p = .012), and a higher proportion of patients undergoing induction chemotherapy survived 1, 2, 3, 5, and 7 years (54%, 26%, 24%, 17%, and 13% vs. 40%, 13%, 10%, 6%, and 6%, respectively).

The Radiation Therapy Oncology Group (RTOG) and the Eastern Cooperative Oncology Group (ECOG) have conducted a three-arm trial involving 452 eligible patients who were randomized to the same two treatment arms employed in CALGB 84-33 and to a third arm that included hyperfractionation radiation to a total dose of 69.6 Gy. The hyperfractionation arm had been shown to produce a survival advantage for favorable patients in RTOG protocol 83-11. Preliminary results of this trial indicate that 1-year and median survivals were superior in the group randomized to induction chemotherapy compared with the other two groups (p = .03). The 1-year and median survivals for the three groups are as follows: induction chemotherapy and radiation therapy, 60% and 13.8 months; hyperfractionation radiation therapy, 51% and 12.3 months; standard radiation therapy, 46% and 11.4 months.

The results of a multicenter French study involving 353 patients who were randomized to 65 Gy of radiation or three cycles of induction chemotherapy with cisplatin, vindesine, cyclophosphamide, and CCNU (chloroethyl-cyclohexyl-nitrosourea) given before radiation followed by three additional cycles of chemotherapy have been reported. The response rate to induction chemotherapy was 27%. For combined chemotherapy and radiation, the 1-, 2-, and 3-year survivals were 50%, 21%, and 11%, respectively; for radiation alone they were 41%, 14%, and 5%, respectively (p = .08). There was a very high rate of local-regional failure in both groups. Local control was 17% in the radiation arm and 15% in the combined modality arm in this trial. However, the distant failure rate was significantly reduced in the combined modality arm (22% vs. 46% failure at 1 year; p < .001); with a mean follow-up of 61 months, there was a statistically significant improvement in survival associated with combined modality treatment (p < .02).

The European Organization for Research and Treatment of Cancer (EORTC) conducted a three-arm study in 331 patients; 50 Gy of thoracic radiation in one arm was compared with two other arms utilizing concurrent cisplatin and radiation on one of two schedules. In one arm, cisplatin was administered daily (6 mg/m^2) along with radiation, whereas in the other arm it was administered weekly (30 mg/m^2). There was a significant improvement (p = .009) in survival for daily cisplatin and radiation compared with radiation alone (2- and 3-year survivals, 26% and 16% vs. 13% and 2%, respectively). For weekly cisplatin and radiation, survival was intermediate (2- and 3-year survivals, 19% and 13%) but was not significantly different from either of the other arms. The survival benefit observed with daily cisplatin and radiation appeared to be result of improved local control (p = .003).

The results of an Italian randomized trial in 95 patients comparing 50.4 Gy of radiation alone with the same radiation given in conjunction with weekly low-dose cisplatin (15 mg/m^2) have been reported. Although there was a trend favoring the combined arm in regard to progression-free interval (9 months vs. 7 months) and median survival (16 months vs. 11 months), neither of these differences was statistically significant. There were 12 intrathoracic relapses in the combined arm, compared with 23 in the radiation alone arm, a difference that was of borderline significance (p = .053). There was no difference between the two groups with regard to distant relapse rates.

The Finnish Lung Cancer Study Group compared split-course radiotherapy (55 Gy) with or without CAP (cyclophosphamide, Adriamycin, cisplatin) chemotherapy in 238 patients with “inoperable” stage III NSCLC. No significant differences in survival were found; the median and 1- and 2-year survivals were 311 days, 41%, and 17%, respectively, for the radiation alone group and 332 days, 42%, and 19%, respectively, for the combination group. In addition, no effect of chemotherapy on local control or relapse patterns was detected.

The North Central Cancer Treatment Group compared 60 Gy of radiation alone or two cycles of MACC (methotrexate, Adriamycin, cyclophosphamide, and CCNU) chemotherapy followed by radiation and two additional cycles of MACC in 107 patients with stage III disease. The median and 1- and 2-year survivals for patients treated with radiation alone were 292 days, 43%, and 12%, respectively; for those who received induction therapy, the figures were 317 days, 47%, and 23%, respectively (p = .59). This was the only study in which there was absolutely no suggestion of benefit by the addition of induction chemotherapy. It was also the only trial in which a cisplatin-based regimen was not utilized during induction.

A meta-analysis included data from 14 randomized trials comparing chemotherapy and radiation with radiation alone in regionally advanced stage III NSCLC. A total of 2589 patients participated in these trials. Overall, the meta-analysis revealed that the use of combination chemotherapy and radiation reduced the risk for death by 12% at 1 year, 13% at 2 years, and 17% at 3 years. This corresponds to a mean gain of life expectancy of about 2 months. The magnitude of benefit was similar whether sequential or concurrent chemotherapy and radiation were utilized.

At this time, despite encouraging data of the advantages of combined chemotherapy and radiation, many important questions remain unanswered. The optimal induction chemotherapy regimen has not been established. The optimal sequence of chemotherapy and radiation remains unknown. The role of hyperfractionation radiation has not been firmly established. Most importantly, the vast majority of patients continue to have recurrence and eventually succumb to metastatic disease, despite the use of chemotherapy and radiation for regionally advanced NSCLC. Local-regional recurrence remains a major problem. In CALGB 84-33, the group treated with chemotherapy and radiation had an 80% incidence of local-regional failure, whereas 90% of those randomized to radiation therapy alone had local-regional failure. Green has emphasized that despite the use of induction chemotherapy and radiation, patterns of failure indicate a need for better control of both macroscopic intrathoracic disease and distant micrometastatic disease in the setting of regionally advanced NSCLC.

Phase II Trials of Induction Chemotherapy and Surgery in Stage IIIA NSCLC

In the last decade, many phase II trials have investigated multimodality treatment strategies that include induction chemotherapy and surgical resection in regionally advanced stage III NSCLC. Considerable variability in the design of these trials makes interpretation of results difficult. Some studies incorporated modern surgical staging of the mediastinum, whereas others did not. Some included induction radiation as well as chemotherapy. Of the trials that utilized radiation, some incorporated sequential chemotherapy and radiotherapy, and others employed concurrent administration. The definitions of resectable disease also vary considerably.

Table 11 lists phase II trials that employed induction chemotherapy and surgery with or without radiation in stage IIIA NSCLC (although two trials also included IIIB patients). Perhaps three times as many trials have been conducted as are listed on the table. Each of the trials listed utilized a cisplatin-based regimen in combination with other agents. Seven of the trials used preoperative radiation (given concurrently with chemotherapy in six and sequentially in one), one trial used only postoperative radiation, and two did not employ radiation at all.

Variable	Favorable	Unfavorable
DNA content (flow cytometry)	Diploid	Aneuploid
S-phase fraction (flow cytometry)	Low	High
Proliferation index using Ki-67 nuclear antigen	PI < 3.5	PI > 3.5
Proliferating cell nuclear antigen (PCNA)	<5% of tumor cells stained with PCNA	>5% of tumor cells stained with PCNA
Mitotic index (pathologic marker)	<13 mitoses per 10 high powered fields	≥13 mitoses per 10 high powered fields

TABLE 11. *Proliferation markers in early-stage NSCLC*

Overall, response rates to induction therapy were quite impressive, varying from 39%–77%. Most responses to induction therapy were partial, although complete responses were observed in some trials. Resectability rates exceeded 50% in each of these trials. The highest resectability rate (93%) was noted in a trial that utilized hyperfractionation radiation concurrently with induction chemotherapy. Many trials have noted that a substantial fraction of resected specimens, often in the range of 10%–20%, do not contain viable tumor following induction therapy.

Median survival times have varied considerably, ranging from 13 to 32 months. Long-term survival rates have also varied significantly, from 17%–37%. Nonetheless, all

these trials support the conclusion that a substantial minority of patients treated achieved long-term survival.

Although none of these trials was designed to evaluate the therapeutic role of surgery in the context of regionally advanced disease, several of the trials reported that those who underwent successful resection enjoyed longer survival times than those in whom resection could not be achieved. In the CAP II study from the Dana-Farber Cancer Institute, median survival was 31 months in patients who underwent resection and 13 months in those who did not (p = .001). In the Memorial Sloan-Kettering trial, median and 5-year survivals for patients with complete resection were 27 months and 26%, compared with 12 months and 5% for those with incomplete or no resection (p = .00002). In CALGB 89-35, median and 3-year survivals were 21 months and 46% among those undergoing complete resection, 18 months and 25% for those with incomplete resection, and 8 months and 0% for those with no resection. Similarly, in the Toronto trial, median and 3-year survivals were far superior in the group with complete resection (30 months and 40%).

Surgery improves local control of the tumor. These phase II trials demonstrate a shift in recurrence patterns from local-regional to distant, compared with what is observed in trials utilizing induction chemotherapy and radiation without surgical resection. Local recurrence has generally been observed in 50% of patients in whom recurrence develops after trimodality therapy. This contrasts with an 80%–90% rate of persistent or recurrent local-regional disease in patients with no resection.

Phase II Trials of Induction Chemotherapy and Surgery in Stage IIIB NSCLC

Each of the studies included in Table 12 focused on groups of patients with stage IIIA NSCLC (although stage IIIB patients were included in the Rush study but considered ineligible for surgery). Conceptually, the stage IIIA designation implies regionally advanced yet potentially resectable disease. Such patients have extrapulmonary but intrathoracic disease. As the stage IIIB designation implies extrathoracic disease, the disease of such patients has been considered categorically unresectable for cure. However, the recent report of the results of a Southwestern Oncology Group phase II study, SWOG protocol 88-05, documents a potential role for aggressive local-regional therapy, even in the context of IIIB NSCLC.

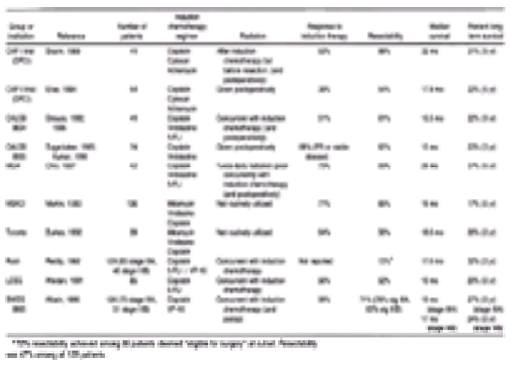

TABLE 12. *Phase II trials on induction chemotherapy and surgery in stage IIIA disease*

In this study, 126 evaluable patients were treated with concurrent induction chemotherapy and radiation, and were then considered for surgical resection. The chemotherapy consisted of cisplatin and etoposide (VP-16). Among evaluable patients, 75 had stage IIIA NSCLC, all with N2 adenopathy. However, 51 patients had stage IIIB NSCLC: 27 with N3 disease, 17 with T4,N0 or N1, and 7 with T4,N2 disease.

Resection was achieved in 85% of patients with stage IIIA disease and 80% of patients with stage IIIB disease. There was no significant survival difference for IIIA and IIIB subsets (p = .81). The median and 2- and 3-year survivals for IIIA patients were 13 months, 37%, and 27%, respectively, whereas for stage IIIB patients the figures were 17 months, 39%, and 24%, respectively.

The strongest predictor of long-term survival in patients with either IIIA or IIIB disease was the absence of mediastinal nodes at the time of surgery. In patients with negative mediastinal nodes at surgery, median survival was 30 months and 3-year survival was 44%, compared with a median survival of 10 months and a 3-year survival of 18% in those with positive nodes (p = .0005).

Moreover, local-regional control was improved in this trial. Only 11% of 65 relapses were local-regional, whereas 61% were distant. The single most common site of disease recurrence was the brain; 26 such relapses were observed, and central nervous system relapse was the sole cause of death in 19 of these cases.

Randomized Trials of Induction Chemotherapy and Surgery Versus Surgery in Stage IIIA NSCLC

Despite encouraging phase II data on the role of induction chemotherapy (with or without radiation) and surgery, randomized trials are believed to be essential to provide definitive proof for the effectiveness of a new treatment strategy. Reports of three randomized trials comparing induction chemotherapy followed by surgical resection with resection without systemic treatment have been influential in modifying the perception of the role of chemotherapy in the management of regionally advanced NSCLC. Indeed, the report by Roth of a randomized trial from M.D. Anderson Hospital declared that induction chemotherapy should now be considered as a standard treatment for this group of patients.

In the M.D. Anderson trial, the group randomized to induction chemotherapy received three cycles of cyclophosphamide, etoposide, and cisplatin followed by resection; the control group received surgical resection alone. The group that received combined therapy achieved an estimated median survival that was almost sixfold greater than that of patients randomized to surgery alone (64 months compared with 11 months; p < .008). Similarly, 2- and 3-year survivals were 60% and 56% for the induction chemotherapy group, compared with 25% and 15% for the surgery alone group.

The report from M.D. Anderson closely followed a similarly designed randomized study reported by Rosell from Barcelona, Spain, which also showed a dramatic threefold survival advantage for patients randomized to induction chemotherapy followed by surgery. In the group randomized to induction chemotherapy, median survival was 26 months; it was 8 months in the surgery alone group (p < .001). In this trial, the chemotherapy regimen consisted of cisplatin, mitomycin C, and ifosfamide.

A third randomized trial from the NCI had preceded the other two. In this trial, the experimental group, treated with induction chemotherapy of cisplatin and etoposide, had a better survival than a control group randomized to primary surgical resection (28.7 vs. 15.6 months).

Although these three prospective randomized studies demonstrate that groups randomized to induction chemotherapy followed by surgical resection achieved an improved survival compared with groups randomized to surgical resection alone in stage IIIA NSCLC, the results should be interpreted with caution. The major problem relates to the fact that each of the trials enrolled small numbers of patients. Only 60 patients were enrolled in both the M.D. Anderson and the Barcelona studies. Because of the huge differences in survival observed in each of these trials, both were discontinued before their projected accrual goals were reached, following accepted rules for early stopping.

The other problem is that the sheer magnitude of the survival differences were far greater than could be reasonably expected from the modestly effective chemotherapy regimens employed in these studies, particularly in the M.D. Anderson trial. The median survival in the experimental group in the M.D. Anderson study, which exceeded 5 years in the 28 patients randomized to induction chemotherapy, has not been approached in any other phase II or phase III study evaluating multimodality therapy in regionally advanced NSCLC. In contrast, the unimpressive response rate associated with induction chemotherapy in this trial is fairly typical of what chemotherapy usually accomplishes in NSCLC. The response rate was 32%, including eight partial responses and one complete response, in the 28 patients in the induction chemotherapy arm of the M.D. Anderson trial. This modest response rate translates into almost a sixfold increase in median survival, and almost a fourfold increase in 3-year survival. Johnson and Piantadosi appropriately caution that “because the outcome of this trial is not entirely consistent with biologic expectations and other evidence, we should be cautious in accepting the results.”

It was shown in the Barcelona study that the group of patients randomized to surgery alone had a higher fraction of tumors associated with more virulent characteristics. For example, many trials have demonstrated that point mutations in the K-*ras* oncogene and aneuploidy are associated with an adverse prognosis in patients with resectable NSCLC. In the Barcelona trial, patients in the surgery alone arm had a higher fraction of tumors with K-*ras* mutations (42% vs. 15%) and DNA aneuploidy (70% vs. 29%). Accordingly, it is possible that an excess of biologically virulent tumors in the group randomized to surgery alone in the Barcelona study contributed significantly to the observed outcome differences, rather than the induction chemotherapy *per se.* In this trial, the response rate to induction chemotherapy

was 60% (16 partial responses and two complete responses among 30 patients).

In addition to the three randomized trials just discussed, a fourth randomized trial, conducted by the CALGB, has been reported by Elias. In this trial (CALGB 91-34), 57 patients with stage IIIA N2 NSCLC were randomized to one of two treatment strategies. One group received two cycles of induction chemotherapy with cisplatin and high-dose VP-16 with granulocyte colony-stimulating factor (G-CSF) support] before surgery, which was followed by two additional cycles of chemotherapy and radiation. The other group received induction radiation (40 Gy) before surgery, which was followed by postoperative radiation. Response to induction chemotherapy was 38% in the induction radiation arm and 47% in the chemotherapy arm. Median disease-free and overall survivals were 9 months and 19 months for the group undergoing induction chemotherapy, compared with 12 months and 23 months in the group receiving preoperative radiation. Although the trend toward reduced survival in the group receiving induction chemotherapy was not statistically significant, the results of CALGB 91-34 conflict with the results of the other three randomized trials, which suggest a dramatic benefit for the use of induction chemotherapy.

Cumulatively, these four phase III studies evaluating the role of induction chemotherapy before surgery have included a total of 204 patients. Although we can learn a great deal from these trials, it is perhaps debatable whether the most important lesson relates to the efficacy of multimodality therapy in stage IIIA NSCLC or to the limitations of small, randomized studies.

Ten phase II studies included 747 patients. Although the results of these trials vary, a greater consistency is seen in the results of the phase II trials than of the randomized trials. The phase II trials provide no hint that the real effect of induction chemotherapy in stage IIIA NSCLC is to produce a 64-month median survival and a 3-year survival of 56%. The implausible and conflicting results of the phase III trials suggest that small, randomized trials may receive greater credibility than they deserve, for the simple reason that they are randomized.

Conclusions Regarding Multimodality Therapy in Stage III NSCLC

Despite the limitations of the randomized surgical trials in stage IIIA NSCLC, they do lend considerable support to the hypothesis that induction chemotherapy followed by surgical resection does improve disease outcome compared with surgical resection alone. Although the magnitude of the survival advantages are very likely to have been exaggerated, particularly in the M.D. Anderson trial, numerous phase II trimodality studies support a similar conclusion, although with a modest degree of effectiveness. Moreover, these results are consistent with numerous phase III studies that have demonstrated that induction chemotherapy and definitive radiation improve outcome when compared with thoracic radiation therapy alone.

Whether induction chemotherapy is now standard therapy for this disease is debatable, and additional clinical trials evaluating such as approach will be difficult to accomplish. CALGB 91-34 was closed because of difficulty in accruing patients following publication of results of the other trials.

The role of resection in stage IIIA and stage IIIB disease remains unproven, but local control appears to be improved in multimodality programs that include resection. A phase III trial designed to evaluate the efficacy of surgical resection in the context of induction chemotherapy and radiation in stage IIIA NSCLC is currently being performed by several cooperative groups under the leadership of SWOG.

The recent results of both phase II and phase III trials have provided a basis for optimism that real therapeutic progress is finally being achieved in regionally advanced NSCLC. Further study of therapeutic strategies that incorporate aggressive systemic therapy and maximal local-regional therapy in both stage IIIA and stage IIIB NSCLC are clearly warranted.

MANAGEMENT OF STAGE IV NSCLC

Stage IV NSCLC is almost invariably a fatal disease. Accordingly, it should generally be approached with strictly palliative intent. No standard therapy exists, but systemic chemotherapy and supportive care are the treatment approaches most often considered.

An exception to such a palliative approach exists for patients who present with a solitary site of metastatic disease. For such patients, consideration of an aggressive local-regional approach to treatment may be appropriate. This approach has been best documented in patients with a solitary brain metastasis, although it has also been used in cases of a solitary adrenal metastasis.

Surgical resection (as well as stereotactic radiosurgery) has been widely utilized in patients with a solitary brain metastasis. The data justify its use in selected patients who present with a solitary brain metastasis that develops after successful therapy for early-stage NSCLC, or who present with a solitary brain metastasis together with an otherwise localized stage I NSCLC. A number of reports have suggested that long-term survival is possible with a combined surgical approach to primary and metastatic sites in approximately 20% of patients with a solitary brain metastasis associated with what is otherwise stage I NSCLC.

However, successful systemic treatment is essential to the effective management of the vast majority of patients with stage IV NSCLC. Unfortunately, NSCLC has proved to be remarkably resistant to chemotherapy. In 1988, in a review of 134 phase II trials of single agents in advanced NSCLC, only five agents (among 48 that had been studied up to that time) could be identified that had a response rate exceeding 15%. These agents included cisplatin, mitomycin C, ifosfamide, vinblastine, and vindesine. The traditional benchmark of success for chemotherapy in advanced NSCLC has been the proportion of patients who survive 1 year from the time of treatment for metastatic disease.

Chemotherapy Versus Best Supportive Care

Because of the limited activity of combination chemotherapy in stage IV NSCLC, many physicians believe that chemotherapy should not necessarily be utilized in the setting of advanced disease. Indeed, stage IV NSCLC is unique in that numerous randomized trials have been conducted comparing combination chemotherapy with best supportive care. Eight such trials have been performed. Five of them have been criticized for using substandard chemotherapy. The two individual trials that are most widely known both employed a similar cisplatin-based chemotherapy regimen. The Canadian study, reported by Rapp, found a statistically significant prolongation of survival from 17 weeks in the control arm to 32.6 weeks in the group receiving cisplatin (100 mg/m^2) and vindesine. An Australian study also reported a 17-week median survival in the best supportive care arm, whereas the group receiving cisplatin and vindesine had a median survival of 27 weeks. However, in this study the survival advantage in the chemotherapy group did not reach statistical significance.

Three meta-analyses have been published comparing chemotherapy with best supportive care. Each of the meta-analyses supports the conclusion that combination chemotherapy is associated with a small but significant improvement in the duration of survival. In one meta-analysis, median survival for patients treated with best supportive therapy was 3.9 months, whereas survival was 6.7 months for those receiving combination chemotherapy.

Prolongation of life is usually the primary objective of chemotherapy, and survival is very simple to quantify. However, there are other important goals in the setting of advanced disease. Improvement in the quality of life is an equally valuable end point as overall survival. One study reported that independently of initial Karnofsky score, 75% of patients treated for advanced NSCLC reported an improved quality of life. Similarly, the meta-analyses suggest that chemotherapy favorably impacts on quality of life.

Nonetheless, the effect of chemotherapy in the setting of advanced disease is modest for most patients. Although chemotherapy may be a reasonable option for many patients, it is not mandatory as the standard of care in all patients. Still, it should be offered to patients with good performance status and minimal weight loss, who are most likely to respond in the setting of advanced disease.

Active Chemotherapeutic Agents in NSCLC

Chemotherapeutic agents that have activity in NSCLC (Table 13) include the platinum compounds (cisplatin and carboplatin), ifosfamide, mitomycin C, etoposide, and vinblastine. During the 1990s, a number of newer chemotherapeutic agents have been identified that are also active in NSCLC. These include Navelbine (a new vinca alkaloid), the taxanes (Taxol and Taxotere), the camptothecins (irinotecan and topotecan), and gemcitabine.

Chemotherapeutic agent	Response rate (%)
Cisplatin	20%
Carboplatin	8–16%
Ifosfamide	21%
Etoposide	5–15%
Mitomycin C	25–30%
Vinblastine	11–28%
Vinorelbine (navelbine)	30%
Taxol	21–24%
Taxotere	20–30%
Irinotecan	32–41%
Topotecan	0–15%
Gemcitabone	20–26%

TABLE 13. *Single agents in advanced NSCLC*

Cisplatin and Carboplatin

Traditionally, cisplatin has been felt by many investigators to be the single most active chemotherapeutic agent in metastatic NSCLC. Its single-agent response rate is about 20%, based on 10 phase II studies of advanced NSCLC including more than 500 patients. Cisplatin-based combination chemotherapy has been associated with higher response rates, up to 40%–50%, and has produced median survivals ranging between 30 and 50 weeks in nonrandomized, predominantly single-institution studies. The vast majority of responses are partial with cisplatin-based chemotherapy, and very few studies have produced more than an occasional complete response.

Cisplatin has a well-established toxicity profile, which can make it a difficult agent to utilize. Toxic effects include severe nausea and vomiting, renal dysfunction, and neurotoxicity. It is not particularly myelosuppressive.

The importance of dose intensity for cisplatin in advanced NSCLC remains uncertain. One randomized trial in which a fixed dose of vindesine was combined with cisplatin at doses of either 60 mg/m^2 or 120 mg/m^2 revealed identical response rates, although there was a significant survival advantage for the responders to the high-dose regimen. Randomized trials by SWOG and EORTC failed to reveal any significant differences in either response rate or survival when low-dose and high-dose cisplatin combination regimens were compared.

Carboplatin is a second-generation derivative of cisplatin; it is believed to form intrastrand and interstrand DNA cross-links, like the parent compound. Single-agent carboplatin has an overall response of 8% in a mixture of previously treated and untreated patients with advanced NSCLC. In a randomized study by ECOG comparing single-agent carboplatin with four other regimens that employed either cisplatin analogues or combinations, carboplatin alone had a 9% response rate but had the lowest frequency of severe or life-threatening toxicity. Furthermore, this agent was associated with the most favorable survival (median, 31 weeks) of the five regimens tested.

The only randomized trial directly comparing carboplatin with cisplatin in NSCLC (in which etoposide was also employed in both treatment arms) demonstrated that response and survival were equivalent and that toxicity was less in the carboplatin arm. It has been recommended that comparative data of platinum analogues justify carboplatin as a replacement for cisplatin in therapy of advanced cancer delivered with noncurative intent.

Carboplatin, in contrast to the parent drug, cisplatin, produces little renal impairment. Its major toxic effect is myelosuppression, particularly thrombocytopenia, and toxicity of carboplatin is closely related to renal function. Approximately 65% of carboplatin is recovered in the urine within 24 hours of intravenous administration, and 32% of the excreted dose is unchanged carboplatin; the plasma half-life is approximately 30 hours. The renal excretion of carboplatin approximates the glomerular filtration rate, with little excretion or reabsorption by the renal tubules. Because of the renal excretion of carboplatin, any impairment in renal function could result in increased toxicity.

Ifosfamide

Ifosfamide is an oxazaphosphorine analogue of cyclophosphamide; it provides more effective DNA crosslinking distance between two independent functional alkylating moieties. Like cyclophosphamide, ifosfamide is activated by liver P_{450} microsomes via hydroxylation of the No. 4 ring carbon to yield 4-hydroxyifosfamide. It is one of the most potent alkylating agents in vitro.

Ifosfamide has considerable single-agent activity in stage IV NSCLC. In 326 patients with advanced NSCLC from multiple series treated with single-agent ifosfamide, the overall response rate was 21% and median survival was 9 months. In the absence of uroprotection, hemorrhagic cystitis is dose-limiting, with an overall incidence of 18%–40%. Cystitis may be exacerbated by the antidiuretic effect of ifosfamide and the resulting fall in urine output. Sodium-2-mercaptoethanesulfonate (mesna), a sulfhydryl compound, prevents hemorrhagic cystitis by inactivating toxic metabolites, thereby allowing administration of larger doses of ifosfamide. The dimeric and inactive form of mesna, dimesna, circulates in the blood and has poor tissue penetration, but it becomes active when reduced to mesna in the kidney. Perhaps for these reasons, mesna does not appear to interfere with the antitumor effect of ifosfamide and protects both upper and lower genitourinary tracts. Because of its short half-life ($t_{1/2}$ of 1.5 hours), mesna should be given for a longer period than ifosfamide ($t_{1/2}$ of 6 to 8 hours). With uroprotection, the predominant toxicity becomes myelosuppression. Thrombocytopenia is much less of a problem.

Etoposide

Etoposide (VP-16) is a semisynthetic, epipodophyllotoxin derivative with significant single-agent activity in NSCLC. By interfering with topoisomerase II activity (the enzyme responsible for creation and repair of breaks in DNA double strands), etoposide prevents DNA repair. Single-agent dose-limiting toxicity is myelosuppression, which develops when etoposide is given at standard daily doses of 75 to 100 mg/m^2 per day as an intravenous bolus for 3 to 5 days.

Because inhibition of topoisomerase II by etoposide is reversible when the drug is no longer present, prolonged exposure may be more effective than short-term infusion. Clinically, the drug has known to be markedly schedule-dependent and is generally given by bolus administration during 3 to 5 consecutive days. Single-agent VP-16 has been shown to produce response rates in the range of 5%–15% when a multiple-day bolus schedule is used in advanced NSCLC.

Mitomycin C

Single-agent mitomycin has long been recognized as having considerable activity in advanced NSCLC. Multiple phase II studies involving 207 patients treated with mitomycin C at doses of 10 to 20 mg/m^2 every 3 to 6 weeks have produced response rates that average 25%. A more recent study reported a 30% response rate in 64 patients with metastatic squamous cell lung cancer treated with single-agent mitomycin C.

Toxicity, including cumulative myelosuppression, can be severe with this agent. Pulmonary toxicity and thrombotic microangiopathy have been well described, although infrequent. Both appear to be related to the cumulative dose of mitomycin C.

Vinblastine and Vinorelbine

Vinblastine, a vinca alkaloid available since the 1960s, has considerable single-agent activity in NSCLC. Vindesine is another vinca alkaloid identified as an active agent in NSCLC, although it has never become commercially available in the United States. Vinca alkaloids inhibit normal microtubule disassembly. Response rates to vinblastine and other vinca alkaloids have ranged from 11%–28% in single-agent trials.

Recently, vinorelbine (Navelbine) has emerged as a new semisynthetic vinca alkaloid with significant activity in NSCLC. It has been approved specifically for use in NSCLC. Its optimal administration schedule appears to be weekly, and response rates have been in the range of 30% in advanced NSCLC. Neutropenia is the dose-limiting toxicity. Although it also causes neurotoxicity, like all vinca alkaloids, it has been shown to spare the axonal microtubules, which translates into less neurotoxicity than occurs with other vinca alkaloids.

Taxol and Taxotere

The taxoids, Taxol and Taxotere, are diterpene plant products derived from the bark of the Western yew (*Taxol brevifolia*). These agents have a unique mechanism of action. Unlike other antimitotic agents, which inhibit microtubule assembly, the taxanes promote microtubule assembly, stabilize microtubules, and inhibit depolymerization to free tubulin.

A number of studies in advanced NSCLC demonstrate that both agents have response rates in excess of 20%. Two initial studies employing Taxol in advanced NSCLC as a 24-hour infusion reported response rates of 21% and 24%. Subsequent studies have demonstrated that Taxol is also active in lung cancer in 3-hour and even 1-hr infusion schedules.

Dose-limiting toxicity of Taxol is reversible myelosuppression. Other toxicities include severe allergic reactions, alopecia, arthralgia/myalgia, and peripheral neuropathy. Severe hypersensitivity reactions are well-known, although they occur in 5% of patients who are premedicated with corticosteroids and H_1 and H_2 blockers. An advantage of shorter infusion schedules is less myelosuppression, although neurotoxicity may be greater.

Taxotere has been employed in four phase II studies in previously untreated advanced NSCLC. At a dose of 100 mg/m^2 given during 1 hour every 3 weeks, the response rate was 30%. Moreover, in two studies in which Taxotere was given to cisplatin-refractory patients, the response rate was 20% and median survival was 9 months. Neutropenia is the dose-limiting toxicity; hypersensitivity reactions and skin rashes may also be seen. A reaction involving fluid retention, which can be associated with pleural effusions, ascites, and weight gain, has been well described and is prevented with prophylactic corticosteroids.

Irinotecan and Topotecan

The camptothecin compounds, derived from the oriental plant *Camptotheca acuminata,* inhibit topoisomerase I and induce DNA strand breaks at the replication fork. Two analogues have been studied in advanced NSCLC.

Irinotecan (CPT-11) has been studied in 161 patients with advanced NSCLC in three trials in Japan. The response rates varied from 32%–41%. Major toxicities include neutropenia and diarrhea, which can be severe. Reversible pulmonary toxicity is also occasionally observed.

A related compound, topotecan, has also been tested in advanced NSCLC, although its activity appears to be less encouraging. In one study, there were no responders among 20 patients. In another trial, the response rate was 15% in 40 patients with advanced NSCLC, with the suggestion of a higher response rate in squamous cell carcinoma. Toxicity has predominantly been reversible myelosuppression.

Gemcitabine

Gemcitabine (22-difluorodeoxycytidine) is a pyrimidine antimetabolite that is closely related to cytosine arabinoside. It possesses considerable single-agent activity in a variety of solid tumors, including advanced NSCLC. It is generally administered on a weekly schedule and has a very attractive toxicity profile. At lower doses, the side effects include influenza-like symptoms, fever, and occasionally hypotension. At higher doses, the major toxicity is myelosupresssion. Peripheral edema, rash, and liver function abnormalities have also been observed.

Seven studies of this drug enrolling a total of 577 evaluable patients with advanced NSCLC have been reported. These studies have consistently reported response rates in the range of 20%–26%. Usual doses are in the range of 800 to 1200 mg/m^2 per week for 3 of every 4 weeks. Higher doses can be given, although it is unclear whether this provides any advantage.

Combination Chemotherapy in Advanced NSCLC

Although combination chemotherapy has been extensively investigated in NSCLC, no single combination has emerged as a standard regimen in advanced NSCLC. Cisplatin has formed the basis of many of the most effective combination regimens, but carboplatin has recently found an increasing role, because of an activity level that is similar to and a toxicity profile that is more attractive than that of the parent compound. Combination cisplatin and etoposide therapy has been widely used; a 38% response was observed in one study of 94 patients with advanced NSCLC, whereas other trials demonstrated a pooled response rate of 28%. The combination of carboplatin with etopside has a reported response rate of 29%–38% (8% complete response).

In recent years, combination regimens incorporating some of the newer chemotherapeutic agents have begun to be reported. Reponse rates in excess of 60% were reported in two studies in advanced NSCLC with the combination of Taxol and carboplatin. A study from Fox Chase Cancer Center reported a response rate of 63% (9% complete response) in 54 patients with stage IIIB and stage IV NSCLC treated with carboplatin and Taxol as a 24-hour infusion. Because myelosuppression was dose-limiting, G-CSF support was used. The 1-year median survival of 51% is superior to that usually reported in advanced NSCLC.

An identical response rate was reported among 40 patients with advanced NSCLC from the University of Southern California. In this study, Taxol was used as a 3-hour infusion along with carboplatin. The overall response rate was 63%, which included two complete responses and 15 partial responses. There was very little significant hematologic toxicity in this study, and G-CSF was not used. The dose-limiting toxicities were myalgias, arthralgias, and cumulative sensory neuropathy.

The combination of cisplatin and gemcitabine was reported to have a 54% response rate in 48 patients with advanced NSCLC. Median survival was an impressive 61.5 weeks for all patients. The main toxicity was thrombocytopenia, which was severe in more than half of patients but was invariably reversible and short-lived. No febrile neutropenia was observed.

Two recent randomized trials in advanced NSCLC have generated considerable interest. The ECOG conducted a three-arm randomized trial comparing cisplatin and etoposide with two other regimens, both utilizing cisplatin and Taxol. Taxol was given by 24-hour continuous infusion, either at a standard dose of 135 mg/m^2 or a higher dose of 250 mg/m^2 (with G-CSF support). A total of 560 patients were enrolled. Response rates and median survival were superior for the two Taxol-containing regimens than for the etoposide arm. There were no differences between the higher- and lower-dose Taxol-containing regimens with respect to response rate (32.1% vs. 26.5%) or median survival time (10.0 months vs. 9.6 months).

A randomized trial has also been reported by SWOG comparing cisplatin alone with cisplatin and Navelbine in advanced NSCLC. A total of 412 eligible patients participated in the trial. There was an advantage for the Navelbine-containing arm with regard to response rate (25% vs. 10%), median survival (7 months vs. 6 months), and 1-year survival (33% vs. 12%). Toxicity was predominantly myelosuppression and was worse for the Navelbine-containing arm.

Conclusions Regarding Systemic Management of Stage IV NSCLC

So what can be recommended regarding chemotherapy in advanced NSCLC? In a situation in which cure is not possible, patient preferences are critical to the development of any appropriate treatment plan. In the author's opinion, patients with poor performance status and those who have had significant weight loss are best managed conservatively. As such patients are unlikely to benefit from chemotherapy, they should be made aware of the fact that best supportive care is an appropriate management option. Palliative radiation for symptomatic sites of metastatic disease should always be considered.

For patients who express a desire to “try something,” single-agent chemotherapy or one of the newer, better-tolerated combination regimens can be offered. Improvements in supportive therapy, which include better antiemetics and prophylactic antibiotics as well as hematologic growth factors, make it more likely that such patients can tolerate chemotherapy than was true in the past, even if they are still unlikely to respond.

For patients with good performance status, chemotherapy should be offered. As an unequivocally best chemotherapy regimen does not exist, patients should ideally be enrolled in a clinical trial. If such a trial is unavailable, or if patients decline participation, one of the newer combination chemotherapy regimens would be reasonable. At the present time, reasonable chemotherapy regimens include carboplatin and Taxol, carboplatin and etoposide, cisplatin and Navelbine, and cisplatin and gemcitabine. However, the field is changing rapidly, and other combinations or single-agent chemotherapy can also be given.

Second-line chemotherapy can also be considered in highly selected patients, preferably with single agents not previously utilized. The best candidates for second-line therapy include patients who previously responded to first-line therapy and those whose performance status remains good at the time of progression.

SMALL-CELL CARCINOMA OF THE LUNG

SCLC represents a clinicopathologic entity that is biologically and clinically distinct from NSCLC. It is distinguished from NSCLC by its characteristic of rapid growth with early development of widespread metastases. It is also extremely sensitive to both chemotherapy and radiotherapy, although relapse usually occurs within 2 years despite treatment. The overall 5-year survival is approximately 3%–8%.

SCLC comprises approximately about one fifth of all lung cancer. It occurs almost exclusively in cigarette smokers, and in one series only 2% of 500 SCLC patients did not have a smoking history. SCLC is also the most common histologic subtype among uranium miners; it is probably caused by exposure to radioactive radon, a byproduct of uranium decay.

Clinical Presentation, Staging, and Prognostic Factors

Because SCLC tends to be a centrally occurring neoplasm, patients typically present with a large hilar mass and bulky mediastinal adenopathy. Typical symptoms tend to be similar to those of other lung neoplasms and include cough, dyspnea, weight loss, and manifestations of postobstructive pneumonia.

Approximately 10% of patients with SCLC present with the superior vena cava syndrome. Indeed, SCLC is the most common malignant cause of superior vena cava syndrome. Survival in SCLC does not appear to be significantly compromised by the presence of superior vena cava syndrome.

Because the tumor tends to arise submucosally, hemoptysis is less common than in squamous cell carcinoma. Cavitation is very uncommon in SCLC. A small cohort of patients with SCLC can present with an apparently solitary pulmonary nodule, although this tends to be uncommon.

SCLC is more commonly associated with certain paraneoplastic syndromes than any other tumors. Syndromes that have been specifically associated with SCLC include SIADH, ectopic Cushing's syndrome, and Eaton-Lambert syndrome (myasthenia-like syndrome). It is much more common to detect polypeptide hormone immunologically, because available immunoassays detect both inactive precursors as well as the active hormones. SCLC is frequently associated with elevated levels of polypeptide hormones, although the clinical syndromes associated with these hormones are much less common. In one series, 11% of patients had laboratory evidence of SIADH at the time of clinical presentation, whereas 27% of patients had symptomatic hyponatremia. The presence of SIADH is not related to the stage of disease or prognosis in SCLC.

About 4% of patients with SCLC present without any obvious primary tumor in the lung or associated hilar or mediastinal adenopathy. The most common primary sites for extrapulmonary small-cell cancers include the uterine cervix, esophagus, larynx, pharynx, colorectum, prostate, and paranasal sinuses. A small fraction of patients present with nodal and visceral metastatases without an evident primary tumor at any site. Histologically, these tumors often resemble SCLC and often contain neurosecretory granules. They behave aggressively and are usually treated with chemotherapy regimens similar to those used for SCLC. There is little question that these neoplasms represent a heterogeneous group of tumors.

The majority of patients with SCLC already have distant metastatic disease at the time of clinical diagnosis. This is underscored by the classic study of Matthews, in which autopsies were performed on patients who had succumbed to a non–cancer-related illness <30 days after apparently curative resection. Among 19 patients with SCLC, 63% had distant metastases, in comparison with 17% of 131 patients with squamous cell carcinoma, 40% of 30 patients with adenocarcinoma, and 14% of 22 patients with large-cell carcinoma.

In the staging system currently utilized in SCLC, patients are simply categorized as having limited disease (LD) or extensive disease (ED). LD is defined as disease confined to the hemithorax of origin or within a single radiation portal. It general, it corresponds to ISS stages I–IIIB. ED refers to overt extrathoracic metastatic disease. Overall, approximately 70% of patients with SCLC present with overt ED. The most common sites of metastastic involvement are the liver, adrenals, bone, bone marrow, and brain.

Adverse determinants of prognosis in SCLC include poor performance status, weight loss, elevated lactate dehydrogenase (LDH), and male sex. However, the worse prognostic feature by far is the presence of clinically apparent distant metastases. In patients with ED, central nervous system or hepatic involvement is particularly unfavorable compared with other sites of metastatic disease. The presence of paraneoplastic syndromes is generally believed to be associated with an adverse outcome.

The diagnosis of SCLC is usually by histologic or cytologic examination of tissue or cells obtained via bronchoscopy, FNA, or mediastinoscopy. Tests for determining the extent of disease include CT of the chest and abdomen (with particular attention directed toward imaging the liver and adrenals), bone scan, CT or MRI of the brain, and unilateral or bilateral bone marrow aspiration and biopsy. Bilateral bone marrow aspiration increases the diagnostic yield by 10% in comparison with unilateral testing. Because SCLC progresses rapidly, staging should proceed quickly; long delays in initiating chemotherapy must be avoided. Although extensive staging procedures are often carried out, it is not at all clear that these are associated with any benefit; there is probably no advantage in conducting more extensive staging than necessary to document the presence of ED.

A possible exception is a CT or MRI of the brain. Approximately 15% of patients with SCLC have central nervous system involvement at the time of diagnosis, and approximately one third of these patients have no symptoms. Early treatment of brain metastases is associated with a reduced rate of chronic neurologic disability.

Chemotherapy in SCLC

The mainstay of treatment for all patients with SCLC is systemic chemotherapy, because SCLC is highly responsive to chemotherapy. Historical data indicate the futility of managing this disease with local-regional modalities alone.

In the 1960s, before the introduction of systemic chemotherapy for SCLC, median survivals for patients with LD was approximately 12 weeks and was 5 weeks for patients with ED. A British Medical Research Council study from the 1960s, in which 144 patients with apparently resectable SCLC were randomized to surgery or radiation therapy, demonstrated that survival was extremely poor in both treatment arms. The median and 1- and 5-year survivals were 6.5 months, 21%, and 1%, respectively, for those randomized to surgery. Among those treated with definitive radiation, the figures were 10 months, 22%, and 4%, respectively.

Martini reported that among patients with SCLC seen at Memorial Sloan-Kettering Cancer Center between 1931 and 1971, only 7% had resectable tumors, and only two patients survived for a minimum of 5 years. Similarly, among 368 surgically treated patients with SCLC reported by Mountain in the 1960s, only a single patient survived 5 years following resection. This contrasted with a 15%–25% 5-year survival for the other three major histologic subtypes. A review of patients felt to have surgically resectable SCLC could find absolutely no advantage for the inclusion of surgery in the treatment regimen.

As SCLC is almost invariably a disseminated disease even in patients with LD clinically, chemotherapy is mandatory for all subsets of patients. Compared with NSCLC, SCLC shows a much higher level of responsiveness to chemotherapy. Moreover, complete responses are quite common in SCLC, as opposed to NSCLC, in which complete responses are distinctly uncommon.

The first report of an improvement in survival in SCLC with the use of chemotherapy was reported by the Veterans Administration Lung Cancer Study Group in 1969, when it reported that three cycles of cyclophosphamide could more than double median survival in comparison with supportive care alone in extensive SCLC. Subsequently, many studies were able to document that chemotherapy improved survival significantly compared with the use of surgery or radiation therapy alone. The results of these trials rapidly established combination chemotherapy as the mainstay of therapy for both limited and extensive SCLC by the early 1970s.

Numerous single agents have been demonstrated to possess activity in SCLC. The most active single agents in SCLC include the alkylating agents (ifosfamide and cyclophosphamide), the epipodophyllotoxins (etoposide and teniposide), the platinum agents (cisplatin and carboplatin), vincristine, and doxorubicin (Adriamycin). Moreover, among the newer chemotherapeutc agents introduced over the last decade, the taxanes (Taxol and Taxotere), the topoisomerase I inhibitors (topotecan, irinotecan), Navelbine, and gemcitabine have all been shown to be possess significant single-agent activity in this disease.

Although few randomized trials have been conducted to address this point, the results with combination chemotherapy are much better than the results that can be achieved with single-agent chemotherapy. A consensus report in the early 1980s concluded that optimal results in the treatment of SCLC could be achieved only with the use of combination chemotherapy. At the present time, the superiority of combination chemotherapy is firmly established for SCLC. Impressive response rates and improved survival have been reported for elderly patients treated with oral etoposide alone. Single-agent chemotherapy is a reasonable option for patients who are elderly or have poor performance status.

The results with multiple combination chemotherapy for SCLC depends on the stage of disease. In patients with LD, modern regimens produce overall response rates of 85%–95%, which include complete response rates of 50%–60%. Median survival times of 12 to 16 months have been regularly observed, and 2-year survival times of 15%–25% are possible.

In ED, response rates and median survival are clearly inferior to those observed in limited disease. The overall response rates of 75%–85% are not substantially inferior to those observed in LD, but complete response rates are considerably lower, in the range of 15%–25% in most trials. Median survival times vary from 7 to 11 months, whereas 2-year survival is seen in 5% of patients with ED. As is discussed below, thoracic radiation improves local control rates from 10% to about 40%–60% in patients with LD and is associated with improved survival.

The optimal combination chemotherapy regimen in SCLC is still not clear. No single regimen is clearly superior to all other regimens at the present time. The combination of cyclophosphamide, Adriamycin (doxorubicin), and vincristine (the CAV regimen) was widely used in the late 1970s and 1980s and was considered to be the “standard regimen,” with which other regimens should be compared.

When etoposide became established as an active agent in SCLC, trials were conducted to determine if the addition of etoposide to CAV (CAVE) or the substitution of etopside for vincristine (CAE) led to improvements in outcome. Some studies have shown modest advantages with the newer regimens, although it remains unclear to what extent these regimens offer real outcome advantages.

In recent years, regimens based on etopside and cisplatin (EP) have become the most widely used combination for the treatment of SCLC. This combination has been shown to be highly synergistic in preclinical studies, and it has been shown to be highly effective in numerous clinical trials, both as first-line therapy and as a salvage regimen. Response rates as high as 95% have been reported. A pooled analysis of 294 previously treated patients with SCLC who were treated with EP produced an overall response rate of 47%. Regimens substituting carboplatin for cisplatin in combination with etoposide in SCLC appear to have similar efficacy.

Although other regimens appear to be comparable with EP in efficacy, none has been proved superior. A number of strategies have been employed in an effort to develop more effective chemotherapy programs. One such strategy has been to use alternating, non–cross-resistant chemotherapy regimens. These have been investigated in SCLC as a method of potentially overcoming drug resistance by exposing the tumor to an increased number of active cytotoxic agents. Some studies have suggested that this strategy may have some merit, but randomized trials have not consistently demonstrated an improvement in response rates or survival. A consensus conference concluded that alternating chemotherapy regimens could not be recommended on the basis of existing results of randomized trials. Accordingly, this approach has not gained wide acceptance in SCLC.

Another approach has been to increase the dose intensity of chemotherapy to enhance response rates and survival. Although a few studies have suggested that this approach may be worthwhile, the preponderance of evidence from randomized comparisons indicates that “high-dose” regimens provide no consistent survival advantages over “standard-dose” regimens employing the same agents, and that toxicity, particularly myelosuppression, is greater with the dose-intense regimens. A meta-analysis of 60 trials showed no demonstrable effect on response rate or survival when dose intensity was increased.

Because SCLC is so highly responsive to chemotherapy, it is an appropriate disease to study in the context of high-dose chemotherapy and autologous bone marrow support. Only a single, small, randomized trial has compared conventional therapy with high-dose therapy and marrow support in SCLC. In this trial, 45 patients who had responded to induction chemotherapy were randomized to conventional or high-dose chemotherapy as intensification. In the dose-intense arm, nine of 12 patients (75%) achieved a complete response, compared with none of eight patients given conventional-dose treatment. Trends toward higher median and long-term survival favored the high-dose arm, but failure of local control remained a major problem. Chest radiation was not employed in this trial.

Elias reported the preliminary results of a phase II study conducted at the Dana-Farber Cancer Institute, in which patients with limited SCLC who had achieved a complete (or nearly complete) response with conventional “induction” chemotherapy were given high-dose chemotherapy and autologous bone marrow transplant. The high-dose therapy, intended to consolidate the remission, consisted of cyclophosphamide, carmustine, and cisplatin with hematopoietic stem cell support. The high-dose therapy was followed by thoracic and prophylactic cranial radiation. Of the first 25 patients treated who had achieved complete (or nearly complete) remission following induction therapy, 57% remained disease-free 2 years after the completion of protocol treatment. These highly encouraging preliminary observations justify the continued study of this approach for highly selected patients with limited SCLC.

In summary, the introduction of combination chemotherapy as standard therapy for SCLC in the 1970s has contributed to significant improvements in survival in both limited and extensive disease. Although a number of chemotherapy regimens may be equivalent to EP or etoposide and carboplatin, alternating regimens or dose-intense regimens have not gained widespread acceptance. Four to six cycles of EP without maintenance therapy appears sufficient. Moreover, high-dose chemotherapy with autologous bone marrow support warrants further study in patients under the age of 60 years who achieve complete remission with conventional combination chemotherapy.

Thoracic Radiation in SCLC

Although disseminated extrathoracic metastasis has traditionally been the most frequent form of failure in SCLC, local and regional failure within the chest occurs in up to 80% of patients with LD treated with chemotherapy alone. This high rate of local failure provides a rationale for the use of thoracic radiation in patients with SCLC. The objective of thoracic radiation is to improve local control and survival. Results from a number of randomized studies have demonstrated that the use of thoracic radiation significantly decreases the rate of local failure in SCLC. It remains unclear whether this improvement is associated with a survival advantage.

The largest individual randomized trial was a study conducted by the CALGB involving 399 patients. They were randomized either to chemotherapy alone or to two concurrent chemotherapy and radiation arms, in which 50 Gy of radiation was either given early, with the first cycle of chemotherapy, or delayed until the fourth cycle of chemotherapy. The chemotherapy consisted of cyclophosphamide, etoposide, and vincristine, with doxorubicin substituted for the etoposide in alternate cycles beginning with the seventh cycle. The rate of local failure was 90% in the chemotherapy alone group and 60% in each of the chemotherapy and radiation groups. Median survival was improved only slightly in the group receiving delayed radiation compared with early or no radiation (14.6 vs. 13.1 vs. 13.6 months). However, 2-year survival was 25% in the delayed radiation group, compared with 15% in the early radiation group and 8% in the chemotherapy alone group.

The role of thoracic radiation in SCLC has best been clarified by two meta-analyses published in 1992. Thirteen randomized trials, including >2100 patients, were evaluated in the larger meta-analysis. Chemotherapy regimens and radiation doses and schedules differed between studies. Both reports demonstrated that the addition of thoracic radiation was associated with a small but significant improvement in 2- and 3-year survival rates, which averaged 5%–7%. Local control rates were improved by 25%. Overall, local control was observed in 23% (172/737) of patients receiving chemotherapy alone, compared with 48% (376/784) of patients who were treated with chemotherapy and radiation. The improvement in long-term survival was greatest for patients who were 55 years of age. The survival benefit was achieved at the cost of increased toxicity. Accordingly, treatment for limited SCLC should include both combination chemotherapy and thoracic radiation for optimal management. Unanswered questions relate to the optimal sequencing of chemotherapy and radiotherapy.

As there is evidence that radiotherapy given after chemotherapy may be associated with inferior local-regional control, radiation should probably be initiated relatively early, although not necessarily at the very beginning of chemotherapy. A randomized trial reported by the National Cancer Institute of Canada showed that early radiation was associated with improved local control and survival and suggested that greater delays may produce significantly inferior results. The CALGB study suggests that administering radiation with the fourth cycle of chemotherapy is reasonable.

An additional questions relates to radiation volume. It is uncertain whether radiation portals should be designed based on the original tumor volume or on the shrinking volume that follows a response to chemotherapy. Available evidence suggests that relatively tight radiation portals appear appropriate, particularly for lesions with substantial postobstructive infiltrates.

Finally, questions about dose and fractionation schedule continue. A number of phase II studies have suggested that hyperfractionation schedules, in which radiation is given two or (or even three) times daily, may have an advantage in terms of local control and survival compared with standard, once-daily fractionation schedules. A randomized trial to prove this point in ongoing.

Prophylactic Cranial Radiation in SCLC

Shortly after the introduction of successful chemotherapy in SCLC, it was recognized that the central nervous system represented an extremely common site of first relapse and was frequently the sole site of failure. This is because most of the commonly used chemotherapeutic agents do not effectively penetrate the blood-brain barrier; accordingly, the brain serves as a sanctuary site.

In a retrospective study of 48 patients achieving a complete response to chemotherapy, central nervous system metastases developed in 38%, none of whom had

received prophylactic cranial irradiation (PCI). In 17% of patients, the brain represented the only site of failure. Others have reported that the brain may be a first or solitary site of failure in 9%–14% of patients with SCLC who achieve complete remission. Moreover, the probability of brain metastases increases with increasing length of survival. Cumulative risk of central nervous system metastases has been estimated to be 58%–80% at 2 years following diagnosis.

Based on these observations, the use of PCI to decrease the rate of central nervous system failure and improve survival has been extensively studied in SCLC in 13 randomized trials. These studies have varied greatly in regard to number of patients entered, dose and schedule of central nervous system radiation, whether PCI was employed only in patients with LD or whether patients with ED were also eligible, and whether only complete responders to chemotherapy were studied.

With reasonable consistency, these studies demonstrate that PCI leads to a definite reduction of the risk of central nervous system metastases. In a pooled analysis including 716 patients in nine randomized studies, it was demonstrated that doses of PCI ranging from 20 to 40 Gy reduced the rate of central nervous system recurrence from 22%–6%.

Two large, multicenter, randomized trials of the value of PCI have been published recently. In a French trial, 300 patients with limited SCLC achieving a complete response to chemotherapy were studied. At 2 years, the rate of central nervous system failure was 67% for those not undergoing PCI, compared with 40% for those who did. The percentage of cases in which the central nervous system was the first site of relapse fell from 45% to 19%. Although survival trends favored the group receiving PCI, there were no significant differences at 2 years (29% vs. 21%; $p = .14$). Similarly, in another multicenter study involving 314 patients, central nervous system failure at 3 years was 55% in those not receiving PCI, compared with 37% in those who did. Although survival trends favored the PCI group in this trial, there were no statistically significant differences in survival. Accordingly, a large body of literature based on randomized comparisons demonstrates that PCI decreases the rate of central nervous system recurrence but has no significant impact on overall survival. All patients in whom central nervous system metastases develop eventually succumb to their disease.

Perhaps the most powerful argument against the routine use of PCI in patients with limited SCLC is related to the toxicity of PCI, particularly the potentially disabling late neurologic and intellectual impairment that occurs. Not all approaches to central nervous system radiation treatment are equally likely to be associated with neurologic sequelae. The probability of significant neurologic problems developing is much more likely when radiation is given concurrently with systemic chemotherapy and/or when a radiation fraction size of 400 Gy is used.

Each of the two recent randomized studies of PCI in SCLC prospectively monitored for the development of central nervous system toxicity by neuropsychologic assessment. The French trial also performed CT. Significant cognitive impairment related to PCI was not documented in either study. It was found that up to 25%–60% of patients had pre-existing cognitive impairments before PCI.

The author believes that because radiation is a local-regional treatment modality, its effectiveness should be judged on the basis of its ability to maintain local control and improve quality of life. This is true unless radiation is being administered with curative intent in the primary management of a particular neoplasm. There are virtually no other examples in oncology in which noncurative radiation has become standard therapy on the basis of survival advantages in randomized trials. In the author's opinion, PCI should be incorporated into the primary management of limited SCLC, because it significantly diminishes the risk for central nervous system recurrence and because recent evidence suggests that it can be safely administered without a substantial risk for significant neurologic disability. There is little question that the development of symptomatic brain metastases has a negative impact on quality of life, particularly if the brain is the sole site of recurrence. Moreover, it is also reasonable to consider PCI for patients with extensive SCLC and good performance status who achieve a complete remission with systemic chemotherapy.

The use of PCI should be limited to complete responders to chemotherapy. It should be given in sequential fashion, after chemotherapy; concurrent chemotherapy and PCI should be avoided. Although the proper dose and schedule of PCI continue to be debated, a relatively low daily fraction size of 2 to 3 Gy and a total dose of 30 to 36 Gy may be optimal

Surgery in the Treatment of SCLC

Surgical resection alone is not a reasonable option for the management of SCLC. SCLC is a highly virulent neoplasm that is presumed to be a systemic disease, even when apparently localized. The question, however, is whether surgery should be considered in the context of combined modality therapy for this disease. A moderate amount of data exist regarding the use of surgery followed by adjuvant chemotherapy, and induction chemotherapy followed by surgery. Most of the data are uncontrolled.

Surgery may be an option for SCLC presenting as a single pulmonary nodule, defined as a single lesion 6 cm in diameter. It has been reported that 4%–12% of lung cancers presenting as a solitary pulmonary nodule turn out to be SCLC. Conversely, a solitary pulmonary nodule was the presentation in 4% (15/408) of patients with SCLC seen at McGill University between 1979 and 1984. About two thirds of SCLC solitary pulmonary nodules are of the “intermediate cell” histologic subtype; in marked contrast, about two thirds of SCLCs presenting in the usual manner are of the classic “oat cell” subtypes.

No controlled data exist, but the long-term survival rates of patients with SCLC solitary pulmonary nodules who have undergone surgical resection are impressive in comparison with those of other groups of patients with SCLC. Kreisman pooled available studies and reported that among patients with stage I SCLC who had solitary pulmonary nodules treated with surgical resection, 40%–53% survived for 5 years.

The role of postoperative therapy in such patients is somewhat unclear. Although most patients undergoing resection receive postoperative chemotherapy, some do not and still enjoy prolonged disease-free survival. Nonetheless, in recognition of the systemic nature of most SCLC, most authorities recommend that patients with resected SCLC solitary pulmonary nodules should receive adjuvant chemotherapy with an established combination regimen. There are no data regarding the efficacy of thoracic radiation or PCI in this setting, although it is reasonable to consider such therapy in the context of potentially curative therapy for these patients.

Other studies have also reported impressive long-term survival rates for patients with SCLC undergoing surgical resection. The data suggest that patients with stage I or stage II SCLC have a 27%–42% chance of 5-year survival after resection. Shepherd reviewed the data and suggested that approximately 50% of patients with stage I SCLC could be cured with surgery followed by adjuvant chemotherapy. Long-term survival was much less common in patients with more advanced SCLC.

Whether the encouraging trends in resectable SCLC reflect a beneficial effect of the surgery itself or a reduced tumor burden in patients in whom resection is possible remains unknown. Nonetheless, such data support continued investigation of the role of surgical resection followed by chemotherapy (and possibly radiation) in early-stage SCLC.

What about surgical resection following induction chemotherapy? Most of the available data come from small phase II trials. Shepherd reviewed the results of nine such trials including 260 patients with limited SCLC treated by induction chemotherapy, after which resection was considered for responders. Overall chemotherapy response rates were at least 88% in eight of the nine trials. Approximately 60% of patients were taken to surgery, and about 80% of these patients underwent complete resections (approximately 50% of those entering the trials). The vast majority of patients undergoing resection had viable residual SCLC in the resected specimens, with pathologic complete response rates averaging about 10%. For patients with pathologic stage I SCLC in whom complete resection was achieved, 5-year survival approached 70%. For patients with stage II or stage IIIA SCLC, survival was less favorable, but there were cohorts who achieved long-term disease-free survival.

These results led to a randomized study by the LCSG to evaluate the role of resection following induction chemotherapy in limited SCLC. All patients with LD were eligible, which translates into ISS stages I, II, IIIA, and IIIB. Patients received five cycles of chemotherapy consisting of cyclophosphamide, doxorubicin (Adriamycin), and vincristine (CAV). All patients were restaged after induction therapy. Patients judged to be suitable for resection were then randomized to surgery followed by thoracic radiation and PCI, or to an identical regimen of radiation treatment without surgery. A total of 340 patients were registered in the trial. Overall, 66% achieved a response to induction chemotherapy (28% complete and 38% partial responses). A total of 144 (42%) patients were randomized, 68 to the surgery arm and 76 to no surgery. Fifty-eight resections took place, including 54 complete resections (77%). Unfortunately, no significant differences in median or overall survival were observed between the surgery and no surgery groups. Median survival of all patients was 14 months; it was 18 months for those patients who were randomized. Actuarial 2-year survival was 20% in both arms. Accordingly, the study failed to provide any support for the use of surgical resection in limited SCLC.

At the present time, surgery cannot be considered standard for any subgroup of patients with SCLC. However, available evidence from nonrandomized studies does support the conclusion that resection is beneficial in well-staged SCLC patients with ISS stage I, and possibly also in some patients with stage II disease. Among patients with limited SCLC, surgery should not be included in the management of those with ISS stage IIIA or stage IIIB disease. Unfortunately, such patients represent the vast majority of those with limited SCLC.

Conclusions Regarding the Management of SCLC

Combination chemotherapy is the mainstay of standard treatment for virtually all patients with SCLC, including those with LD and ED. Although no consensus for “best” chemotherapy regimen exists, four to six cycles of a standard combination, such as etoposide and cisplatin (EP), is reasonable. However, given the high degree of

sensitivity to chemotherapy of SCLC, consideration of the use of a more intensive combination regimen or an alternating regimen is also reasonable, even outside the context of a clinical trial. An important objective is to maximize the possibility of complete remission.

Thoracic radiation should now be considered to represent standard therapy for patients with LD. Existing data would support that thoracic radiation should be given concurrently with chemotherapy, preferably following two to four cycles of chemotherapy.

PCI should be considered for patients with LD who achieve a complete response to chemotherapy or to chemotherapy and radiation. It can also be considered for patients with ED who achieve a complete remission. PCI should not be given concurrently with chemotherapy.

Both surgical resection and high-dose chemotherapy with autologous bone marrow transplant remain experimental treatment strategies for SCLC at the present time. However, both approaches warrant consideration in specific situations. Surgical resection should be considered for patients with LD who present with stage I SCLC. Experimental protocols employing high-dose chemotherapy and autologous bone marrow transplant warrant consideration for patients 60 years of age who achieve complete remission with conventional chemotherapy and radiation. The objective of both strategies is to enhance the cure rate in a disease in which long-term survival is achieved in only a small minority of patients.

CHAPTER

69 Tumors of the Lung Other Than Bronchogenic Carcinoma

Scot H. Merrick

S.H. Merrick: Department of Surgery, University of California at San Francisco, San Francisco, California 94143.

INTRODUCTION

Other than bronchial carcinoid and bronchoalveolar carcinoma, the pulmonary tumors discussed in this chapter are exceedingly rare and collectively comprise approximately 2% of all lung tumors. Many of these tumors are benign; some are malignant; and others exhibit locally aggressive behavior.

With the introduction of electron microscopy, immunohistology, and cell culture techniques (and with some ongoing controversy), the commonly accepted World Health Organization classification of these tumors has undergone major changes. One of the more useful classification schemes, devised by Spencer, segregates these tumors according to the cell of origin, as far as possible, as follows:

1. Tumors of APUD cells, neural cells, or of unknown origin:
   a. Bronchial carcinoid tumor
   b. Neurofibroma and neurofibrosarcoma of the lung
   c. Myoblastoma of the bronchus
   d. Malignant melanoma of the bronchus
   e. Pulmonary "chemodectoma"
   f. Benign clear-cell tumor of the lung
2. Tumors derived from bronchial epithelium or bronchial mucous glands:
   a. Bronchial papillomatous tumors
   b. Bronchial cystadenoma, monomorphic and pleomorphic
   c. Pleomorphic bronchial gland adenomas
   d. Oncocytic bronchial gland adenoma
   e. Bronchial mucoepidermoid adenoma
   f. Adenoid cystic carcinoma of the bronchus
   g. Mucinous, multilocular cystcarcinoma of the bronchus
3. Tumors of pulmonary connective tissue origin:
   a. Chondroma of the bronchus
   b. Bronchial and subpleural lipomatous tumors
   c. Fibroma and myxoma of the lung
   d. Pulmonary fibroleiomyoma
   e. Pulmonary sarcoma
   f. Pulmonary rhabdomyosarcoma
   g. Embryonal pulmonary sarcoma
   h. Intravascular and sclerosing bronchoalveolar tumor (IVSBAT)
   i. Tumors of vascular origin:
      i. Angioma
      ii. Lymphangioma
4. Lung tumors of chronic granulomatous or uncertain origin:
   a. Plasma cell granuloma, benign and malignant histiocytoma of the lung
   b. Sclerosing angioma
5. Hamartomas of the lung:
   a. Chondromatous
   b. Fibroleiomyomatous
6. Blastoma and teratoma of the lung
7. Pulmonary reticuloses:
   a. Lymphoid hyperplasia
   b. Hodgkin's disease
   c. Lymphosarcoma and histiocytic sarcoma
   d. Plasmacytoma of the lung
   e. Leukemia
   f. Giant intrathoracic lymph nodes
   g. Histiocytosis X diseasete

The term *bronchial adenoma* has been used for some time to describe fleshy, polypoid tumors of the tracheobronchial tree. Recently, however, in recognition of their malignant potential, the most common types of adenomas have undergone name changes. Cylindromas are now called adenoid cystic carcinoma, mucoepidermoid tumors are now called mucoepidermoid carcinoma, and a suggestion has been made to change the name of bronchial carcinoid tumors to low-grade APUD carcinoma or Kulchitzky cell carcinoma. Bronchoalveolar cell carcinoma is also discussed in this chapter. The illustrative reviews of Dail and Mackay are recommended for further reading.

In general, tumors that originate within a bronchus tend to be discovered earlier because of signs and symptoms of bronchial stenosis and obstruction: wheezing, cough, atelectasis, obstructive pneumonitis, and distal bronchiectasis. Tumors originating in the periphery of the lung, on the other hand, may attain large size before they produce symptoms. They are discovered either incidentally on routine chest x-ray or when they have involved adjacent structures within the chest, at which point

they may be inoperable.

Careful bronchoscopy, fine-needle biopsy, computed tomography, and magnetic resonance imaging (MRI) may provide useful information in the evaluation of these tumors. Positron-emission tomography may be useful in distinguishing benign from malignant lesions. However, in some cases the diagnosis will only be made postoperatively by the pathologist because (lipomas and chondromatous hamartomas excepted) there are no diagnostic roentgenologic signs, and even bronchoscopic biopsy can be misleading. With few exceptions, surgery is the treatment of choice to remove potentially lethal lesions and to relieve symptoms. In general, conservative resection is the rule, employing modern bronchoplastic techniques. Many lesions can now be resected thoracoscopically, without formal thoracotomy.

BRONCHOALVEOLAR CELL CARCINOMA OF THE LUNG

Bronchoalveolar cell carcinoma is a primary tumor of the lung arising within alveoli and terminal bronchioles and spreading along the surface of the airways to involve other parts of the lung. It is also called alveolar cell carcinoma, bronchiolar cell carcinoma, bronchioloalveolar cell carcinoma, and pulmonary adenomatosis because of a controversy concerning the cell of origin. Previously, this tumor comprised approximately 5% of all lung tumors, although recent evidence suggests that the incidence may be much higher. Formerly, the production of mucus by these tumors suggested bronchiolar cell origin, but it has since been shown that alveolar cells also can differentiate into cells capable of mucus secretion. It is now agreed that the tumor arises from type II alveolar pneumocytes and Clara cells. Clinically, two separate entities have been described. Focal bronchoalveolar carcinoma usually presents as a solitary peripheral nodule characterized by slow growth (tumor-doubling time approximately 300 days) and infrequent regional lymph node metastases (Fig. 1). A diffuse form of the disease is less common but more aggressive and is characterized by multiple nodules or consolidation (Fig. 2). Prognosis for focal disease treated by complete resection is excellent; however, if left untreated, some of these cases may progress to the diffuse form, presumably by aerogenous dissemination. A multiclonal theory of cell origin may also play a role.

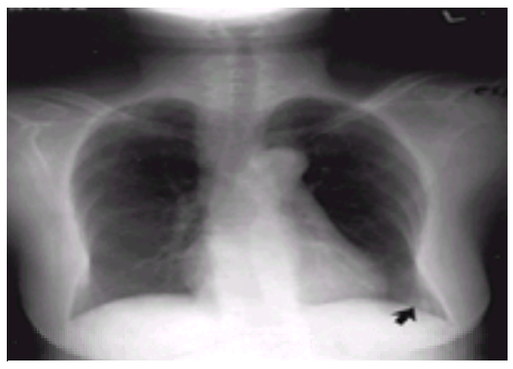

FIG. 1. Asymptomatic focal bronchoalveolar carcinoma of the left lower lobe (*arrow*).

FIG. 2. Diffuse or pneumonic form of bronchoalveolar carcinoma with bilateral patchy tumor infiltrates.

The etiology is unknown, but bronchoalveolar cell carcinoma bears a striking resemblance histologically and in mode of spread to an infectious (presumably viral) disease of animals (primarily sheep) in South Africa called *jaagsiekte.*

The hallmark of the histologic diagnosis is the pattern of growth of flat or columnar malignant cells along alveolar and bronchiolar walls, with frequent intraalveolar projections but with preservation of the general interstitial framework of the lung (Fig. 3). Electron microscopy commonly shows dense cytoplasmic granules and nuclear inclusions (Fig. 4). Immunohistochemical techniques have shown these inclusions to represent a portion of the surfactant molecule.

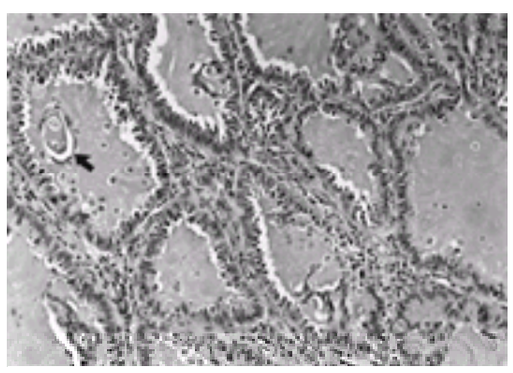

FIG. 3. Bronchoalveolar carcinoma showing tall columnar cells and small nests of tumor floating within mucin (*arrow*) (H&E, ×50). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

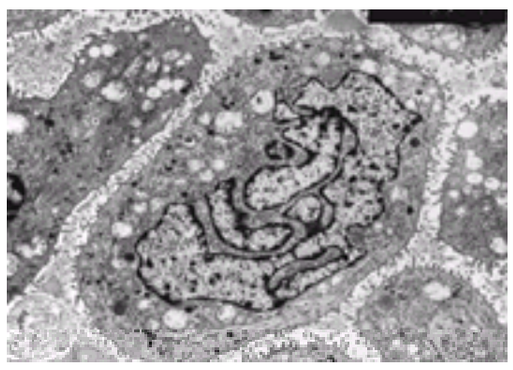

FIG. 4. Electron micrograph of bronchoalveolar cell carcinoma of the Clara-cell type. Note the prominent electron-dense granules, which are characteristic. (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

Compared to bronchogenic carcinoma, bronchoalveolar tumors are less likely to be associated with smoking or chronic lung disease. Approximately 40% of patients present with advanced disease (TNM stage III, IV) and are usually symptomatic. Cough, copious watery sputum, dyspnea, and constitutional symptoms and signs such as malaise, fatigue, and clubbing are characteristic of this disease. The diagnosis can occasionally be made by sputum cytology and more often by bronchoscopic brushing and biopsy. Fine-needle biopsy is positive in 75% to 80% of patients.

The treatment of bronchoalveolar cell carcinoma is surgical, and lobectomy is the procedure of choice. Data from the Lung Cancer Study Group have shown a 5-year survival rate of approximately 60% following surgical resection. For tumors more advanced than T_1N_0, the yearly recurrence rate may exceed 20%. Because the disease spreads by local extension, the plane of a segmentectomy or wedge resection is likely to cut across invisible extensions of tumor, making conservative surgery inappropriate. Even for more advanced disease, lobectomy or pneumonectomy should be considered (provided that there is no evidence of spread to the opposite lung), because there is no other suitable treatment. The tumor is not particularly responsive to chemotherapy or radiation therapy. Although the disease tends to spread slowly, untreated bronchoalveolar carcinoma proceeds inexorably to pulmonary insufficiency and death by inanition. Although it is considered experimental, isolated lung perfusion with chemotherapy may be useful.

BRONCHIAL CARCINOID

Although originally classified as bronchial adenomas, bronchial carcinoids should now be categorized as neuroendocrine neoplasms of the lung, which include tumorlets and small-cell carcinoma. Carcinoids comprise approximately 2% of primary lung tumors and usually present in the fifth decade of life as a reddish polypoid mass within view of a bronchoscope, occurring in a main, lobar, segmental, or subsegmental bronchus. Peripheral tumors may occur in 20% of cases, and rare tracheal occurrences have been reported. Because of their location and tendency to expand into the bronchial lumen, carcinoids frequently produce partial or complete bronchial obstruction (see Fig. 5). Wheezing and hemoptysis are common signs, and intermittent lobar or segmental atelectasis is a hallmark of the tumor. Mucopurulent sputum and distal bronchiectasis occur in cases of long-standing obstruction. The majority of patients are symptomatic, but as many as 20% may present with an asymptomatic pulmonary nodule. Smoking, occupation, and environmental factors do not appear to play a role in the genesis of this tumor.

FIG. 5. Bronchial carcinoid tumor causing complete atelectasis of the lower lobe of the right lung.

Cytologic examination of the sputum, bronchial washings, and brushings is not productive, as the tumor is enveloped by normal mucosa. However, fine-needle biopsy may be useful in a small number of cases. Because the tumor is highly vascular, direct biopsy has been avoided in the past for fear of major bleeding. Today, with use of a “microbiopsy” forceps through a fiberoptic bronchoscope, direct biopsy can be performed safely with a diagnostic sensitivity of 60% to 80%.

Many hormones have been reported to be secreted by bronchial carcinoids, including ACTH, ADH, gastrin, somatostatin, calcitonin, and growth hormone. The most common is 5-hydroxytryptamine, or serotonin, but only a very small fraction of patients with bronchial carcinoids exhibit the “carcinoid syndrome,” and only when hepatic metastases have occurred. When present, the syndrome can be controlled effectively with somatostatin analogs.

The tumor usually presents as a polypoid mass, but the base of the “polyp” varies from a pedicle to a broad attachment. In fact, the stalk invariably penetrates through the bronchial wall to the extent that the bulk of the tumor is extrabronchial. Endobronchial resection is, therefore, not a definitive treatment, although in extremely poor-risk patients it may be reasonable to restore airway patency by laser resection.

Microscopically, the typical carcinoid tumor is made up of small, uniform argyrophilic cells with central nuclei and eosinophilic cytoplasm within a vascular stroma (Fig. 6). The cells may form clusters, cords, or tubules or grow in solid sheets. They arise from Kulchitzky cells, which belong to the APUD system. These cells, which are seen under the electron microscope to contain neurosecretory granules, also give rise to small-cell carcinoma of the lung. Previously thought to originate from neural crest cells, Kulchitzky cells are now believed to originate from bronchial germinal epithelium. Immunohistochemical studies may be very useful, as bronchial carcinoids have been shown to express a number of epithelial and endocrine markers such as cytokeratin, neurofilament proteins, neuron-specific enolase, and chromogranins. Of these, chromogranin is the most useful marker, being demonstrated in 86% of specimens.

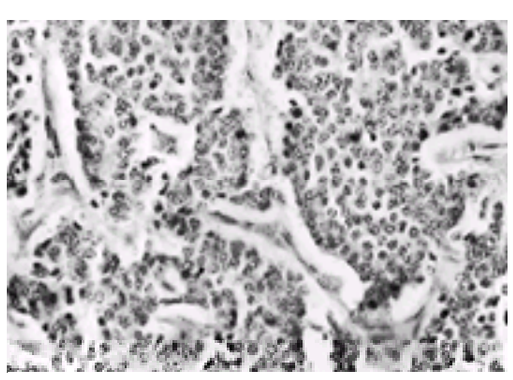

FIG. 6. Bronchial carcinoid tumor. Nests of uniform cells are separated by a delicate connective-tissue stroma. There are round nuclei with evenly dispersed, coarse chromatin and pale cytoplasm (H&, ×400). (Courtesy of Dr. Miriam Lurie, Department of Pathology, Carmel Hospital, Haifa, Israel.)

The typical carcinoid tumor is relatively benign: mitoses are rare in the tissue; regional lymph node metastases are almost never present at the time of thoracotomy; and the 5-year survival rate approaches 100%.

The atypical carcinoid tumor (also termed neuroendocrine carcinoma) is characterized histologically by mitoses, cell necrosis, aneuploid DNA content, and pleomorphism. It is useful to group these tumors into three categories, based on cell size and degree of differentiation: (1) well-differentiated type, (2) intermediate type, and (3) small cell. Types 1 and 2 invariably express neuron-specific enolase and synaptophysin on immunohistologic stains, and a high percentage are in stage II or III at the time of surgery. Type 3 is well known for clinical overproduction of hormones, particularly ADH and ACTH, and for a proclivity for early metastases.

The treatment of typical carcinoids is conservative resection, sparing pulmonary parenchyma where feasible unless the lung has been destroyed by bronchiectasis beyond the point of bronchial obstruction. Bronchoplastic procedures and sleeve resections can be performed even with surgical margins close to the tumor. Atypical carcinoids, on the other hand, should be treated with more aggressive resection (lobectomy or pneumonectomy) to insure adequate margins, and lymph node excision should be performed. A 5-year survival of 60% can be expected; interestingly, both survival and recurrence seem to be dependent more on cell type than on nodal status. The treatment of small-cell carcinoma is in evolution. Because the majority of patients have widely metastatic disease at the time of presentation, chemotherapy is the most appropriate option. However, selected patients with “limited” disease may benefit from surgery before or after multimodality therapy. For further discussion

of small-cell carcinoma of the lung, refer to Chapter 68 and Chapter 71.

NEUROGENIC TUMORS

Primary neurogenic tumors of the lung, which include benign neurofibromas, neurilemmomas, and neurofibrosarcomas, are quite rare, with fewer than 100 cases reported. Intrapulmonary neurofibromas are the most common and are more likely to occur in association with von Recklinghausen's disease. In this situation, the lung tumors may be multiple, causing significant arteriovenous shunting and hypoxemia. Benign neurilemmomas (Schwannomas) are more likely to arise sporadically. These tumors are consistently related to a bronchus, either within the lumen (more commonly) or outside the bronchial wall. Both neurofibroma and neurilemmomas originate from nerve sheath cells; however, their histology may be confused with those of neuroblastomas, leiomyomas, fibromas, and mesotheliomas. Immunostaining for neuron-specific enolase and protein S-100 will help establish nerve sheath origin. Most primary neurogenic tumors of the lung are asymptomatic and therefore may attain a large size over a long period of time. Cough and hemoptysis are caused when a bronchus becomes obstructed or compressed by the mass of a large tumor. Endobronchial lesions may appear as polypoid lesions projecting into the lumen of a bronchus and can be resected successfully with a YAG laser. Parenchymal lesions can be cured by conservative resections, and recurrences are rare.

Malignant Schwannomas (neurosarcomas, neurofibrosarcomas) are often accompanied by the finding of benign neurofibromas in other parts of the tumor. Invasiveness, hemorrhage, and necrosis of the tumor are characteristic. These tumors may grow very large and metastasize late in their natural history. Many patients have been cured by surgical resection, and adjuvant chemotherapy, particularly with Adriamycin, may be useful for extensive tumors.

GRANULAR CELL TUMOR OF THE BRONCHUS

Although granular cell tumors occur in nearly all anatomic sites, they are found predominantly in the tongue and skin and are extremely rare in the lungs. Previously termed myoblastoma, this tumor is now believed to originate from Schwann's cells. The tumor is found in the lung as a benign sessile or polypoid growth within the trachea or a central bronchus and is usually associated with obstructive pneumonitis. Multiple tracheobronchial lesions occur in 20% of patients. Ulceration of pedunculated lesions may produce hemoptysis. The tumor may be multicentric; coexisting lesions outside of the respiratory tract may be frankly malignant. Histologically, the tumor is composed of clusters of polygonal cells with small hyperchromatic nuclei and abundant cytoplasm containing numerous fine, acidophilic granules. These granules appear similar to lysosomes under electron microscopy.

Although benign, these tumors are locally invasive and are associated with squamous metaplasia, simulating malignant tumors of the bronchus. Larger lesions may have extensive submucosal infiltration, making bronchoscopic or laser removal useful only for palliation. Definitive treatment is by surgical resection, with sleeve resection or a bronchoplastic procedure used if feasible.

Oncocytomas and oncocytic carcinoids can be confused with granular cell tumors. Immunohistochemical stains for protein S-100, neuron-specific enolase, and vimentin may be useful in differentiating ambiguous cases. *Mycobacterium avium-intracellulare* should also be considered in the differential diagnosis.

MALIGNANT MELANOMA OF THE BRONCHUS

Cutaneous and ocular malignant melanoma frequently spreads to the lungs, presenting as multiple, bilateral parenchymal nodules. Approximately 2% of malignant melanomas will metastasize to the bronchus, making the diagnosis of primary malignant melanoma of the bronchus a diagnosis of exclusion. Because a complete examination to exclude all other possible primary sites can only be done postmortem, diagnosis before death can only be presumptive (Fig. 7 and Fig. 8). Nevertheless, several authors have suggested the following diagnostic criteria: (1) absence of past or present atypical or malignant pigmented skin lesions from any site, (2) a solitary lung lesion centered on a bronchus with no evidence of other organ involvement, and (3) *in situ* melanocytic change of bronchial mucosa adjacent to or overlying the major tumor mass (the so-called “junctional” or “lentiginous” change). On the basis of these criteria, a small number of reported cases may benefit from surgical resection.

FIG. 7. Lung tomogram showing adenoid cystic carcinoma of the right mainstem bronchus (*arrows*).

FIG. 8. Primary fibrosarcoma arising from the left mainstem bronchus.

PULMONARY CHEMODECTOMA

Minute, multiple chemodectomas are occasionally found at autopsy in patients who have died from cardiovascular disease, especially pulmonary thromboembolism. Over 80% of cases occur in women. Grossly, these tumors appear as 1-mm to 3-mm nodules on the pleura or within the pulmonary parenchyma. Microscopically, the tumors consist of nests of large cells in the interstitial tissues near or surrounding small pulmonary veins. The tumor cells are large, spindled, or elongated with regular nuclei, eosinophilic cytoplasm, and indistinct cell borders. Immunohistochemical stains for epithelial membrane antigen and vimentin are usually positive. Chemodectomas were formerly thought to have developed from chemoreceptor cells in the lung, but Churg and Warnock failed to find neurosecretory granules ultrastructurally, as would have been expected in paraganglion cells. They suggested that these tumors have characteristics related to meningiomas.

BENIGN “CLEAR-CELL” TUMORS OF THE LUNG

Also known as “sugar” tumors because of their high glycogen content, these tumors present as isolated, asymptomatic, solitary pulmonary nodules on chest x-ray. They are exceedingly rare, occurring mainly in middle-aged adults. Successful diagnosis by fine-needle aspiration has been reported. Grossly, the tumors are not encapsulated. Nevertheless, they remain distinct from surrounding tissue. They are not associated with bronchi. Histologically, these tumors resemble “clear-cell carcinoma” of the kidney, both expressing melanoma antigens, and so are confused with metastatic lesions. However, frequent mitoses should be observed in the

latter. In general, immunohistochemical stains may be helpful. Conservative resection should be considered curative.

BRONCHIAL PAPILLOMATOUS TUMORS

These are benign lesions of the larynx, trachea, and bronchi, usually multiple and only rarely solitary. The tumors are multicentric and are usually caused by human papilloma virus (HPV). These tumors are more common in infants and children, in whom the disease is self-limiting and extends beyond the larynx in only 2% of cases. During the course of cellular proliferation, however, airway obstruction may occur from the florid overgrowth. Disease extending into the bronchopulmonary tree is more virulent, often presenting with symptoms and signs of obstruction and requiring multiple resections for recurrent disease. Endobronchial resection, conventional or laser, is live saving, although many patients will require chronic tracheostomy.

In adults, the prognosis is poorer, especially in the form that spreads to the parenchyma. In most cases, laryngotracheal papillomas always appear first, followed by progressively lower airway involvement. In cases of bronchoalveolar spread, nodules form in the lung and then cavitate to form cysts. Distal bronchiectasis is common, and frank lymphangitic invasion has been described. The lesions tend to increase in number and size with time, and these patients usually die of progressive pulmonary insufficiency. Bronchoscopic and laser resection are the mainstays of therapy; good results have also been reported with photodynamic therapy and interferon-a.

Microscopically, a connective tissue stroma is covered by a cuboidal or squamous epithelium in varying degrees of differentiation and keratinization. Because of cytologic atypia, papillomas may be difficult to distinguish from squamous cell carcinoma. Frank malignancy has been described and is associated with HPV serotypes 16 and 18.

BRONCHIAL MUCOEPIDERMOID ADENOMA

Mucoepidermoid tumors of the bronchus are the third most common type of bronchial adenoma but comprise only 0.1% of all lung tumors as a whole. This is a pedunculated polypoid tumor arising from excretory duct reserve cells of mucous glands. It is usually located in the lobar or mainstem bronchi and, rarely, in the trachea. The tumor is coated with mucus and is capable of producing a large mucocele beyond the point where it causes bronchial obstruction. Histologically, the tumor consists of large cells growing in sheets (“epidermoid,” without keratinization), scattered among which are numerous mucus-containing glands. Tonofibrils and mucin granules are common ultrastructural findings, and tumors are usually immunopositive for epithelial markers. These tumors have been found in virtually all age groups, characteristically producing symptoms of cough, wheezing, hemoptysis, and recurrent pneumonias.

There appear to be a spectrum of mucoepidermoid tumors ranging from benign and completely curable to a malignant and highly lethal variety. The latter are characterized by cytologic atypia, pleomorphic cells, greater mitotic activity, and infiltration into adjacent lung parenchyma. Although exceptions have been reported, in general, the disease is nearly always benign in children. Conservative resection should be employed in this age group. In adults, on the other hand, many of these tumors are highly malignant histologically and very aggressive clinically, with a tendency to local invasiveness and early metastases. Conservative lung resection for low-grade tumors has been suggested, with no evidence of recurrent disease at a mean follow-up of 4.7 years. High-grade lesions, which may be difficult to distinguish from poorly differentiated squamous cell carcinomas, are typically unresectable, and survival is less than 2 years.

BRONCHIAL ONCOCYTOMATOUS ADENOMA

This is a rare benign polypoid tumor that arises from bronchial mucous glands and ducts. Oncocytes are epithelial cells with abundant eosinophilic cytoplasm and small nuclei. Ultrastructurally, they contain abundant mitochondria but no neurosecretory granules, which distinguishes them from carcinoid tumor cells, which they may resemble histologically. Demonstration of chromogranin by immunostaining may be useful. Most cases occur in adults; the tumors rarely exceed 4 cm in size and are benign.

MUCOUS GLAND ADENOMA

These are rare, benign tumors of the bronchial glands that can produce obstructive symptoms or asthma. This tumor, which has also been reported in the trachea, has also been termed *bronchial cystadenoma* and *adenomatous polyp.* The basic histology is that of mucus-filled spaces lined by well-differentiated bronchial gland epithelium. Several subtypes have been proposed (tubular, papillary, mucoepidermoid-type; monomorphic, pleomorphic) based on the predominant cell type. Conservative resection is the treatment of choice.

ADENOID CYSTIC CARCINOMA OF THE BRONCHUS

These tumors originate from mucous glands throughout the body. In the tracheobronchial tree, adenoid cystic carcinoma occurs primarily in the trachea or mainstem bronchus, more central than carcinoid tumors in general (Fig. 7). Although they constitute a small proportion of all primary bronchial neoplasms, they account for approximately 40% of primary tumors of the trachea. Most patients are in their fourth decade.

These are sessile growths, and, like other bronchial tumors, they may present as obstructing lesions, often causing atelectasis of an entire lung.

Histologically, the tumor is composed of duct-lining cells of mucous glands that form into duct-like tubules (hence the older name “cylindroma”) and glands and cysts that contain mucin. The stroma is also myxomatous. This tumor typically immunostains for keratin and vimentin.

These tumors are low-grade adenocarcinomas that spread by local extension through the tracheal wall and metastasize to lymph nodes. Perineural invasion is characteristic.

Treatment is by local wide excision, dictated by anatomic constraints. In some circumstances, sleeve resection of the trachea or of the main bronchus or a bronchoplastic procedure may be feasible. In other instances, tracheal carinal resection or standard lobectomy or pneumonectomy may be required. Local recurrences may occur, usually because of underestimation of intramural spread. Even though adenoid cystic carcinoma is relatively radioresistant, postoperative radiation should be administered when lymph node metastases have occurred or invasion of perineural lymphatics has been demonstrated in the surgical specimen.

CHONDROMA OF THE BRONCHUS

Chondromas grow directly from bronchial or tracheal cartilage into the lumen of the airway as a purely cartilaginous mass unlike hamartomas, which, in addition, contain other elements from the tissues of the bronchial wall. A chondroma has a very smooth, lobulated surface and may grow to be very large. It may be removed by local excision (through a bronchotomy incision) or, preferably, by sleeve resection. Bronchial chondromas may accompany extraadrenal paragangliomas and gastric leiomyosarcomas in Carney's syndrome.

SARCOMAS OF THE LUNG

The most common sarcoma of the lung is metastatic. In general, these tumors are small, multiple lesions that may arise after a long interval after treatment of a primary site. Removal of metastatic lung sarcomas may carry a favorable prognosis, which is discussed in a later section.

In contrast, primary sarcomas of the lung are rare as a group, and some of the varieties are exceedingly rare. These tumors may account for 0.2% to 0.4% of all lung cancer cases and are usually large, solitary, and asymptomatic. The most common primary lesions are malignant fibrous histiocytoma (MFH), fibrosarcoma, and leiomyosarcoma. Kaposi's sarcoma of the lung, associated with acquired immunodeficiency syndrome (AIDS), is now the most common sarcoma affecting the lung. Chondrosarcomas, liposarcomas, myxosarcomas, and rhabdomyosarcomas also occur in the lung. Often the tumor is undifferentiated and referred to simply as a sarcoma or spindle-cell sarcoma of the lung. In general, these tumors do not contain calcium on roentgenograms and do not exfoliate cells into the bronchial tree, making cytologic tests of little value. Grossly, these tumors are not encapsulated and rarely metastasize outside the lung, but local recurrence following resection can be a problem. Differential diagnosis should include plasma cell granuloma, hemangiopericytoma, carcinosarcoma, blastoma, and hypernephroma. Immunohistochemistry (particularly CEA and cytokeratin) may be a useful diagnostic tool.

Pulmonary sarcomas may originate within a mainstem or lobar bronchus (Fig. 8) or peripherally within the pulmonary parenchyma or may arise from major vessels. Fine-needle biopsy and fiberoptic bronchoscopy may be diagnostic for some lesions (e.g., MFH and Kaposi's sarcoma, respectively), and CT or MRI scans may be useful for others. In general, a generous biopsy is needed to secure the diagnosis.

Malignant fibrous histiocytoma of the lung is a particularly aggressive type of sarcoma. It is usually found in middle-aged men and may occur more frequently in patients who have undergone radiation therapy. The tumor is characterized by a mixture of fibroblasts and histiocytes with giant cells and inflammatory cells interspersed. Approximately 50% of patients have local or distant metastases, and the recurrence rate may approach 40%. Not surprisingly, the prognosis is poor; a combination of surgery, radiotherapy, and chemotherapy may improve survival.

Endobronchial fibrosarcomas and leiomyosarcomas have a much better prognosis than their intrapulmonary counterparts, probably because they produce symptomatic bronchial obstruction relatively early in their course and are therefore smaller when resected. Intrapulmonary sarcomas tend to have a highly malignant histologic appearance and metastasize early to hilar and mediastinal lymph nodes. Paradoxically, some fibrosarcomas attain very large size without metastases, but the great majority of these are inoperable because of involvement of adjacent intrathoracic structures.

Chondrosarcomas are rarer. Despite the presence of radiographic calcification, these lesions are not benign. An intrabronchial chondrosarcoma may appear benign on bronchoscopic biopsy only to be found to be invasive at surgery. Intrabronchial chondrosarcomas also have a better prognosis than intraparenchymal tumors. However, the overall prognosis is poor, with most patients surviving only 6 to 12 months from the time of diagnosis.

Pulmonary rhabdomyosarcomas are very rare but may be seen in congenital cystic malformation. Typically, these tumors become extremely large and invasive. They compress the surrounding parenchyma into a fibrous pseudocapsule. Histologically, rhabdomyosarcomas consist of strap-like cells with cross-striations. There are also undifferentiated round and spindle-shaped cells with cross-striations and nonstriated giant cells. The presence of desmin by immunohistochemical staining is diagnostic. The origin of striated muscle cells in the lung is a source of speculation.

Kaposi's sarcoma can be a particularly virulent tumor. Spontaneous occurrence in the lung is rare; however, it has been estimated that 35% of patients with AIDS will develop pulmonary involvement. Many patients present with hemoptysis and may have a bloody pleural effusion. Approximately 50% of patients will have a coexisting opportunistic infection. In contrast to other sarcomas in the lung, Kaposi's follows lymphatic pathways, often resulting in nodal spread. Rapid progression is not uncommon, although chemotherapy may reverse fulminant respiratory failure.

LIPOMAS OF THE BRONCHUS AND LUNG

These are among the least common of benign tumors, consisting of lobules of mature fat cells supported by a delicate fibrous stroma arising from the submucosal or interstitial adipose tissue. They can occur anywhere along the entire tracheobronchial tree. For unknown reasons, these tumors typically occur in middle-aged males.

Many patients present with obstructive symptoms. The diagnosis is difficult to establish by bronchoscopy because the pliable capsule resists the biopsy forceps. A CT scan, however, can accurately make the diagnosis based on the density coefficient of fat; distal bronchiectasis may be seen in long-standing bronchial obstruction.

Removal of the tumor through the bronchoscope may be hazardous because the bronchial wall may be perforated in the process. This technique should be limited to pedunculated lesions. Laser resection may be possible in some cases, but open bronchotomy or sleeve resection is preferable.

Even more rare is the subpleural lipoma, a tumor that may attain great size.

PULMONARY FIBROMA AND MYXOMA

Fibromas of the lung are rare and may occur endobronchially, extrabronchially, or within the lung itself. They are composed of fibrous connective tissue and may become large enough to cause bronchial obstruction, either intraluminally or by extrinsic compression. Sections of gross tumors often show trabeculae. In children, fibromas may be found in the cervical trachea. Recurrences may occur after endoscopic removal. Broad-based, sessile lesions should be removed surgically.

Pulmonary myxomas are extraordinarily rare. They look like fibromas grossly but have a gelatinous and glistening appearance on the cut section. Microscopically, there is abundant extracellular mucin between stellate cells.

PULMONARY LEIOMYOMA

These tumors are some of the most common soft-tissue tumors found in the lungs. In order of frequency, the tumors are found in the peripheral lung, small bronchi, central bronchi, and trachea. Parenchymal tumors are usually asymptomatic and may attain a large size before discovery. Lesions of the airway tend to produce obstructive symptoms and bronchiectasis. In consistency, the peripheral tumor is similar to a hamartoma; it is tough and fibrous and is readily “shelled out” of the parenchyma. Histologically, spindle-shaped cells containing smooth muscle are seen, but immunohistochemical studies and electron microscopy may be necessary to distinguish these tumors from fibromas, neurofibromas, and neurilemmomas. In general, conservative resection using bronchoscopy, laser, or sleeve resection is curative.

There have been many reports of pulmonary leiomyomata occurring in women with similar tumors of the uterus. Whether or not the pulmonary lesions represent “benign metastases” is subject to controversy, as low-grade smooth muscle metastases and primary leiomyomas are difficult to distinguish. Nevertheless, in women with pulmonary leiomyomata, a careful pelvic examination is recommended.

EPITHELIOID HEMANGIOENDOTHELIOMA

Previously known as intravascular bonchioloalveolar tumor (IVBAT), this rare, malignant tumor usually presents as small, asymptomatic, bilateral pulmonary nodules. Over 80% of patients are female, and most are less than 40 years of age. Most patients are asymptomatic, although alveolar and intrapleural hemorrhage may occur (Fig. 9). Sputum cytology is usually negative, although fine-needle biopsy may be suggestive of the diagnosis. Tumor cells typically demonstrate reactivity for factor-VIII-related antigen by immunohistochemistry, and pinocytotic vesicles are present on electron microscopy. Hence, most believe this tumor to be derived from the endothelial cell (Fig. 10).

FIG. 9. Epithelioid hemangioendothelioma in a 39-year-old woman presenting with hemoptysis and intrapleural hemorrhage.

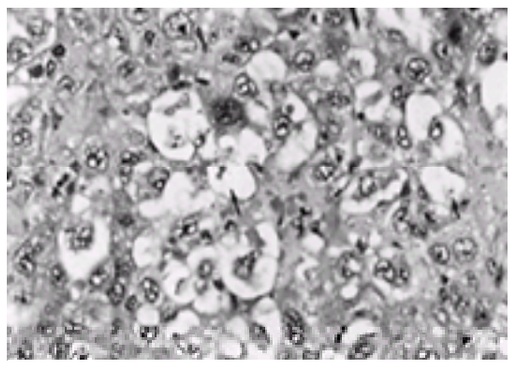

FIG. 10. Epithelioid hemangioendothelioma exhibiting irregular nests of large cells showing hyperchromatic nuclei and frequent mitotic activity. Hemorrhagic, cystic cavities are present (*arrows*); immunostaining for factor VIII was positive (H&E, ×1000). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

These tumors tend to have an indolent but progressive course. Intrapulmonary spread is not uncommon, and extension of tumor to the pleura and pericardium may occur. No effective therapy is available, although radiotherapy may provide some palliation. Hormonal therapy has been suggested, but efforts to substantiate expression of estrogen and progesterone receptors in this tumor have not been successful.

PULMONARY ANGIOMA (ARTERIOVENOUS FISTULA)

These are congenital lesions of mesodermal origin. Developmentally, this tumor may be a vascular type of pulmonary hamartoma. In 30% to 40% of cases, hereditary telangiectasia (Rendu–Osler–Weber syndrome) is present. In a number of cases, the pulmonary lesions are multiple and bilateral. These tumors have a predilection for the lower lobes and are highly variable in size, ranging from minute telangiectasis to cavernous aneurysms with a large right-to-left intrapulmonary shunt (with dyspnea, cyanosis, clubbing, and polycythemia). Diagnostic evaluation should include computed tomography and angiography.

As a result of intrapulmonary shunting, systemic thromboembolism and cerebral abscesses may occur. Furthermore, the lesions tend to increase in size with time; subpleural aneurysm formation may result in free intrapleural rupture. Surgical resection should be conservative (wedge resection or segmentectomy) because other lesions may become manifest later on. Multiple lesions have been successfully treated by angiographic embolization.

There is an acquired form of pulmonary arteriovenous fistula that results from the development of abnormal vessels in chronic liver disease and in AIDS in the form of Kaposi's tumors around the walls of intrapulmonary blood vessels. Arteriovenous malformations may also result from lung trauma.

PULMONARY HEMANGIOPERICYTOMA

Fewer than 100 cases of this tumor have been reported in the literature. They tend to occur in older patients and affect both sexes with equal frequency. Approximately one-third of patients are asymptomatic; radiographic manifestations are nonspecific, although these tumors tend to be found in the left lower lobe and have sharp contours (probably because of the presence of a fibrous capsule in many patients) (Fig. 11).

FIG. 11. Asymptomatic hemangiopericytoma of the left lower lung in a 70-year-old man.

This tumor arises from pericytes within the basement membranes of capillaries. Microscopically, “antler-like” vascular spaces are characteristic (Fig. 12). The usual size is less than 5 cm; larger tumors tend to have extensive central necrosis. Necrotic tumors over 5 cm in size, with a mitotic rate over 3 per 10 high-power fields and the presence of pleural, bronchial, or vascular invasion, are predictive of a poor prognosis, and metastases may occur in 21% of patients. Surgical resection is the treatment of choice, as radiation and chemotherapy are ineffective. The differential diagnosis should include pulmonary fibromas, metastatic sarcomas, and bronchial carcinoids.

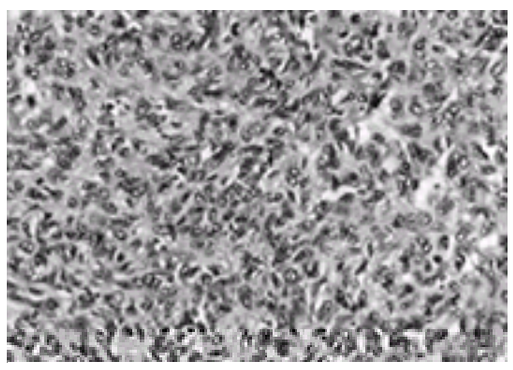

FIG. 12. Hemangiopericytoma exhibiting a fairly uniform population of spindle cells arranged in small whorls and fascicles. Intricate vascular channels that stain positive for factor VIII are present (*arrows*). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

GLOMUS TUMOR

This interesting tumor is usually seen in the extremities (particularly the nail beds) and is thought to be derived from cells of a special arteriovenous shunt, the Sucquet–Hoyer canal, which may be a temperature-sensitive regulator of blood flow. Ectopic tumors from these cells have been described in the lungs and, occasionally, the trachea. Microscopically, the tumor appears similar to carcinoids and hemangiopericytomas. A variable nuclear cytoplasmic border resembling a “chicken-wire” pattern is characteristic. Electron microscopy is helpful, as neurosecretory granules are absent.

PULMONARY PLASMA CELL GRANULOMAS (HISTIOCYTOMAS)

Also known as inflammatory pseudotumor, xanthoma, fibroxanthoma, and mast-cell granuloma, this tumor is known for its controversial nosology. Most authorities

believe this tumor to be reactive; others feel the tumor to be neoplastic, with the originating cell either a myofibroblast or a low-grade B-cell lymphoma. Nearly half of the patients with this disease have a history of prior lung infections. Men and women of all ages tend to be afflicted with equal frequency. The lesions are usually solitary, asymptomatic, and commonly appear either as a circumscribed nodule or an ill-defined mass on chest x-ray. Bronchoscopy and fine-needle biopsy are not useful. Rarely, these lesions may become very large and invade the pleura, mediastinum, diaphragm, chest wall, or vertebral bodies. Metastases do not occur.

Microscopically, plasma cell granulomas contain mature plasma cells and lymphocytes within a framework of granulation tissue. Mast cells may also be present, but true giant cells are rare. Although plasma cell granuloma has been associated with multiple myeloma, immunohistochemical studies show a polyclonal infiltrate.

Treatment is primarily surgical, although some lesions have been known to regress spontaneously. Conservative resection is curative, and recurrences are rare.

SCLEROSING HEMANGIOMA OF THE LUNG

This rare but fascinating tumor has been reviewed extensively by Dail. It is usually a benign lesion presenting as a solitary nodular (less than 5 cm in 90% of cases) density with some predilection for the lower lobes. Over 80% of the patients are female, and the majority are asymptomatic. Hemoptysis is the most common presenting sign. There are no specific radiographic features.

Grossly, these tumors are well circumscribed and can be shelled out from adjacent lung parenchyma. Microscopically, the pattern may be variable but most commonly consists of tumor surrounded by extensive fibrosis and dilated vascular spaces that are filled with blood. Cholesterol clefts and hemosiderin-laden macrophages may also be seen. Originally, this histology led to a theory of endothelial cell origin. However, there have been many immunohistochemical and electron microscopic studies that do not support endothelial differentiation. Instead, many of these studies have demonstrated the presence of surfactant apoprotein in the tumor cells, and most now believe this tumor to be epithelial in nature, originating from type II pneumocytes. In the past, sclerosing angioma has been confused with plasma cell granulomas (histiocytoma), which are also called fibroxanthomas because of fibrosclerotic tissue, cholesterol spaces, and fat-filled macrophages. These degenerative changes occur in both tumors. The difference is the absence of plasma cells in sclerosing angiomas.

Sclerosing hemangiomas may involve adjacent lymph nodes, but they do not metastasize. Malignant variants have been reported and are usually multiple lesions. As a rule, conservative resection is curative, and recurrences are unusual.

PULMONARY RETICULOSES

Lymphoproliferative disorders usually involve the lung secondarily. Primary lesions do occur (Fig. 13), as the lung contains an extensive system of lymphoid tissue. Although generalization is difficult, one concept proposes that the lung contains a specific, bronchial-associated lymphoid tissue (BALT) that has the capacity to form a spectrum of lymphoid proliferations. This spectrum includes follicular hyperplasia of the bronchial wall, nodular hyperplasia (“pseudolymphoma”), and diffuse lymphoid hyperplasia (“lymphoid interstitial pneumonitis”). The latter has been associated with a viral etiology, particularly Epstein–Barr virus and human immunodeficiency virus. Primary lymphomas of the lung are usually low-grade and originate from B-cell lines. Symptoms, signs, and radiographic features are nonspecific. Examination of sputum cytology or fine-needle aspirates for various immunologic markers may be diagnostic. Grossly, primary lung lymphomas usually do not involve the hilar lymph nodes and tend to be surrounded by cytologically benign infiltrates. Large lesions usually exhibit extensive necrosis. Solitary, circumscribed lung lesions may benefit from resection with excellent long-term survival.

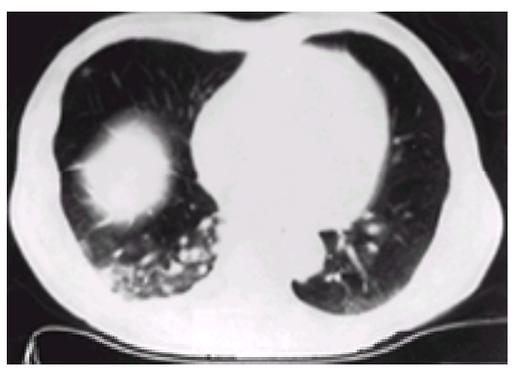

FIG. 13. Primary pulmonary lymphoma presenting as a bilateral nodular infiltrate in the lower lobes.

Pseudolymphomas have true lymphoid germinal centers within a massive infiltrate of well-differentiated lymphocytes and other inflammatory cells. In contrast to malignant lymphomas, the bronchus is spared, leading to characteristic air bronchograms on chest x-ray. Lymphomas, on the other hand, show a uniform cellular infiltrate of poorly differentiated lymphocytes without true germinal centers (Fig. 14).

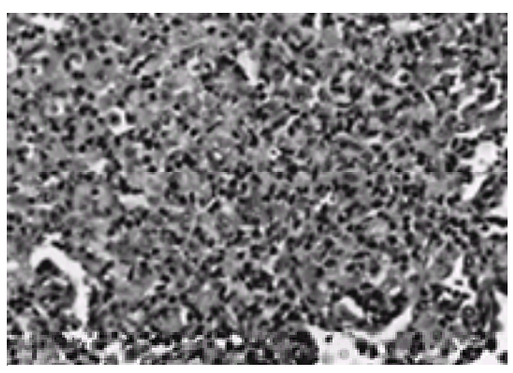

FIG. 14. Open-lung biopsy specimen showing pulmonary lymphoma of a mixed small cleaved and large cell type (material from the patient in Fig. 13). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

Subpleural lymph nodes may become enlarged (lymphoid hyperplasia), to be visualized on chest x-ray. The presence of dust-laden histiocytes suggests an environmental etiology. A rare form of diffuse benign intrapulmonary lymphoid hyperplasia also has been described.

Giant intrathoracic lymph nodes occasionally arise at the pulmonary hilum without coexisting pulmonary or mediastinal disease. They may be associated with fever or anemia. In the past, they have been mistaken for thymomas on chest x-ray and histologically.

The lung is also frequently involved with other generalized diseases of the reticuloendothelial system, such as leukemia and histiocytosis X. The latter has a characteristic ring-like appearance on high-resolution chest CT. Lung biopsy may be required to establish the diagnosis in these conditions.

HAMARTOMAS OF THE LUNG

A pulmonary hamartoma is a noninvasive malformation originating from elements normally found in lung tissue. Although the histogenesis is unclear, most investigators feel that hamartomas are not congenital and are true neoplasms. As a group, these tumors are perhaps the most common benign tumors of the lung, accounting for over 60% of benign lesions in one series and estimated to be present in 0.25% of the general population. Men are afflicted more commonly than women, and over 80% are asymptomatic. These tumors are usually found in the periphery of the lung; radiographically, their borders are lobulated and sharp, and speckled calcifications may be seen, giving the appearance of “popcorn.” Some 20% may be endobronchial, resulting in obstructive symptoms (Fig. 15 and Fig. 16). Chest CT scans may be

useful by demonstrating fat within the tumor, and fine-needle aspiration is diagnostic in a high percentage of cases.

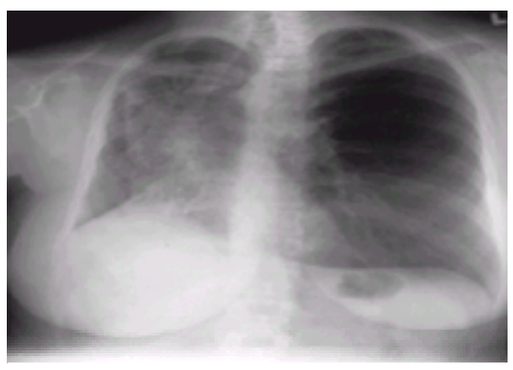

FIG. 15. Endobronchial hamartoma originating in the right middle lobe, resulting in near-complete obstruction of the right mainstem bronchus.

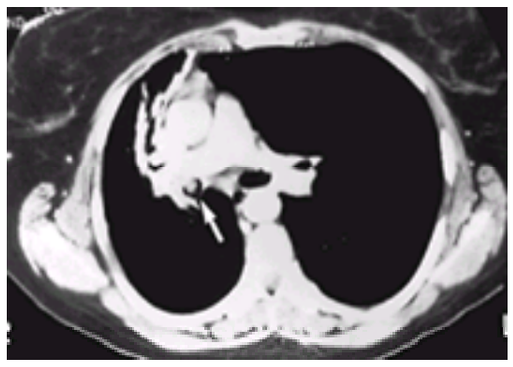

FIG. 16. Endobronchial hamartoma occupying the right mainstem bronchus (*arrow*).

The typical hamartoma contains a mixture of cartilage, fat, smooth muscle, epithelial, and mesenchymal cells (Fig. 17). Growth is slow, with an estimated doubling time of 14 years. Although malignant transformation has been reported, it is exceptional. However, typical bronchial carcinoma may coexist, particularly in high-risk individuals. Excision of hamartomas is recommended if carcinoma cannot be excluded or if growth rates on serial radiographs are excessive. The majority of tumors can be enucleated or removed by conservative resection.

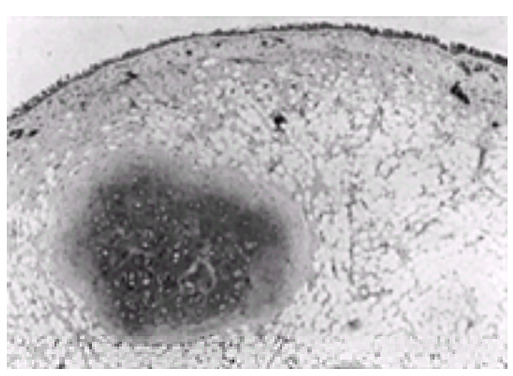

FIG. 17. Section of an endobronchial hamartoma showing typical features of epithelial border and smooth muscle and fat cells. A focus of cartilage is seen centrally (H&E, ×100). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

There is a special instance of a very aggressive tumor, adenomatous hamartoma of infancy, also known as cystic adenomatoid formation, in which an entire lobe or lung is filled with cystic spaces lined with bronchiolar epithelium, with a disorganized arrangement of dilated bronchioles and alveolar spaces. Air trapping within cysts may produce dramatic distention of the opposite lung. Pulmonary resection is urgently indicated in these infants.

PULMONARY BLASTOMA (EMBRYOMA)

Pulmonary blastomas are rare, malignant tumors of mixed epithelial and mesenchymal composition that are believed to recapitulate the fetal lung at 10 to 16 weeks of gestation. A bimodal age distribution is apparent, with an initial peak during the first decade and a later peak in the seventh decade. The tumor may be found in a peripheral or central location, with occasional endobronchial extension. Over 40% of patients are asymptomatic, and radiographic findings are not specific. Diagnosis by fine-needle aspiration has been described.

Grossly, these tumors are usually sharply circumscribed but may contain areas of extensive necrosis. Histologically, the tumor consists of undifferentiated embryonic connective tissue lined by vacuolated columnar epithelium, simulating fetal bronchioles. The epithelial component may form cell balls or “morulae,” which appear similar to squamous metaplasia. Theories of histogenesis must explain how these tumors involve two germ-cell lines. Most pathologists believe that the tumor arises from a single cell type that then differentiates in several directions.

The overall prognosis is poor, with only 50% of patients surviving 5 years. Most patients die of extrathoracic metastases. Combination chemotherapy may be useful in pediatric patients.

INTRAPULMONARY TERATOMAS (DERMOID CYSTS OF THE LUNG)

True, primary intrapulmonary teratomas are exceedingly rare; one must first exclude direct extension from the mediastinum or metastasis from germ-cell tumors in other locations (particularly the testes). Most lesions are found in the left upper lobe, and growth is very slow. They may be solid or cystic and contain tissue derived from all germ layers. They contain hair, sebum, pancreatic, and other tissue. One-third to one-half of these tumors have been classified as malignant on the basis of histologically immature cells. However, pulmonary teratomas rarely behave aggressively.

CARCINOSARCOMA

Carcinosarcoma is a rare tumor, accounting for 0.2% of all pulmonary neoplasms. It is composed of both carcinomatous and sarcomatous elements and is usually found in older men, commonly in the upper lobes. Many patients present with evidence of metastatic disease in patterns similar to traditional lung carcinoma. Endobronchial spread is very common.

Histologically, the epithelial component is usually squamous cell carcinoma, under which there is a cellular, spindle-cell stroma with bone or cartilage. The prognosis is poor, with death occurring within a year of initial diagnosis in the majority of patients.

TUMORS METASTATIC TO THE LUNGS

The lungs are the most frequent site of metastases from nearly all organs, and up to 20% of patients dying of pulmonary metastases have no tumor elsewhere. Carcinoma of the colon, kidney, breast, testis, uterus, head and neck, and ovary, as well as sarcomas and melanomas, are especially prone to metastasize to the lungs. Except for abdominal visceral organs whose venous drainage is directly through the portal system, the lungs are the first organ to filter venous blood. Blood-borne metastases account for the majority of secondary pulmonary malignancies. Tumor also may reach the lungs through lymphatic spread or by direct extension.

Over 80% of patients are asymptomatic; typically, peripheral lung nodules are found on screening chest films obtained during follow-up of the original tumor. The tumors are commonly multiple and bilateral. However, isolated lesions may occur, and it is important to distinguish these from benign lesions and/or primary bronchogenic carcinoma. Fine-needle biopsy can be helpful in these situations, but sputum cytology, bronchoscopy, and mediastinoscopy are usually low-yield. In general, new solitary lesions found in patients with a history of breast or head and neck cancers are most likely primary lung carcinomas. New lung lesions in patients with previous colon cancer are equally likely to represent primary lung carcinoma or metastatic disease, whereas new lung nodules in patients with prior sarcomas or melanomas are almost always metastatic. Rarely, tumors of the breast, colon, or kidney may present as endobronchial metastases, producing obstructive symptoms.

In order to consider resection of metastatic pulmonary nodules, one must first establish that the primary tumor is under control. Second, there must be no evidence of extrapulmonary metastases, and third, resection must not severely compromise lung function. Once these criteria have been satisfied, a chest CT scan should be obtained to investigate the number and laterality of the lesions (Fig. 16 and Fig. 17). Although the number of metastatic lesions, the disease-free interval, tumor histology, and tumor-doubling time have been positively correlated with overall survival, patient selection should not be absolutely dependent on these factors. The overall 5-year survival following resection of pulmonary metastases is approximately 35%.

Because one-third of patients with unilateral disease of chest CT scan are found to have bilateral nodules during surgery, many investigators recommend a median sternotomy approach so that both lungs can be evaluated. Functional disability may be less with this incision, and it may facilitate resection of future recurrences. However, overall survival is not affected by the type of incision. Wedge resection of the metastatic deposits is satisfactory in the majority of patients. More aggressive resections (e.g., pneumonectomy) are sometimes indicated for complete local control of disease. Should recurrent disease develop, some patients, particularly those with metastatic soft-tissue sarcomas, may benefit from repeat resection.

Approximate 5-year survival rates according to tumor histology are presented in Table 1. One particularly interesting metastatic tumor is the so-called benign metastasizing giant-cell tumor. This lesion usually contains a mixture of mono- and multinucleated giant cells and is characteristically found in the distal radius. Although histologically benign, the tumor may spread to the lungs, particularly after a local recurrence of the primary lesion (Fig. 18 and Fig. 19). Spontaneous regression of the pulmonary lesions has been reported; however, surgical resection is indicated for definitive diagnosis and to prevent complications of local growth.

Histology	5-year survival (%)
Teratoma	84
Uterus	54
Kidney	54
Head and neck cancer	47
Osteosarcoma	46
Soft-tissue sarcoma	33
Breast	27
Carcinoma	24
Colon	23
Melanoma	4

TABLE 1. *Actuarial survival according to tumor histology*

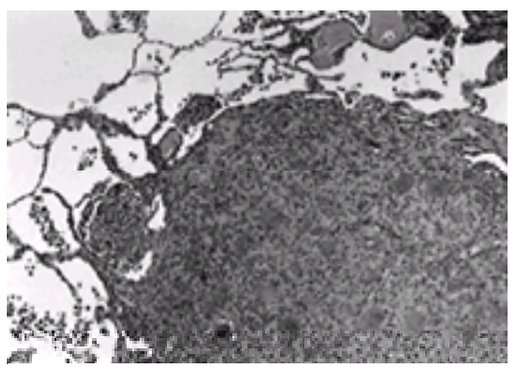

FIG. 19. Metastatic pulmonary giant-cell tumor showing prominent multinucleated cells within a benign architecture. (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

Despite optimistic results for several tumors, surgical resection for pulmonary metastases should still be considered palliative. Most patients will die of local recurrence or systemic spread of the primary lesion. The role of adjuvant chemotherapy is not yet clearly defined, but patients with metastatic osteosarcoma may benefit.

CHAPTER

70 Tumors of the Mediastinum, Pleura, Chest Wall, and Diaphragm

Scot H. Merrick

S.H. Merrick: Department of Surgery, University of California at San Francisco, San Francisco, California 94143.

TUMORS AND CYSTS OF THE MEDIASTINUM

The embryologic development of the mediastinum produces a number of closely opposed structures of different germ layer origins. Mediastinal masses may therefore have distinctly different histologies and predilections for specific locations. There are also major differences in the patterns of occurrence between adults and children. Advances in radiographic imaging techniques, isotope scanning, and tumor markers have made important contributions to the management of mediastinal masses over the past decade.

The mediastinum consists of all structures between the two pleural cavities and is bounded superiorly by the thoracic inlet and inferiorly by the diaphragm. For purposes of discussion, it is customary, by drawing lines on the lateral projection of a chest x-ray, to divide the mediastinum into three compartments (Fig. 1). This compartmentalization is clinically useful because of the predilection of certain tumors to arise within circumscribed areas. The posterior compartment is delineated by a line drawn along the posterior pericardial border and continued upward along the anterior borders of the thoracic vertebral bodies. A second line may be drawn along the anterior pericardial border and continued upward along the anterior surface of the tracheal air shadow in order to create two additional compartments, the anterior mediastinum and the middle mediastinum. In some texts, the anterior mediastinum is further subdivided into superior and inferior subcompartments, but the overlap of tumors such as thymomas between these subdivisions is so great as to limit the usefulness of this refinement.

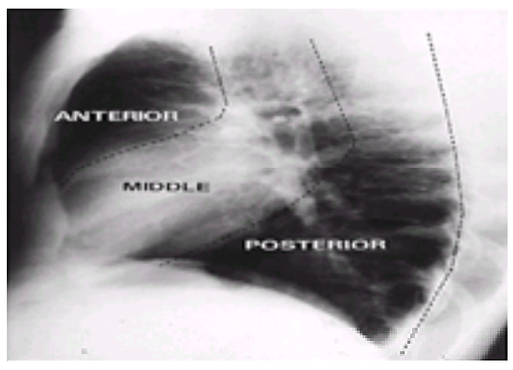

FIG. 1. Lateral chest x-ray film demonstrating the three compartments of the mediastinum. (Reproduced from Sabiston DC Jr, Oldham HN Jr, The mediastinum. In: Sabiston DC Jr, Spencer FC, eds. *Gibbon's Surgery of the Chest,* 4th ed. Philadelphia: WB Saunders, 1983.)

The anterior compartment contains the thymus, ascending aorta, innominate artery and vein, superior vena cava, fat, and lymph nodes. Over 50% of mediastinal masses occur in this compartment. The middle mediastinum contains the heart, pericardium, aortic arch and branches, bronchi, upper esophagus, trachea, and mediastinal lymph nodes. The posterior mediastinum contains the lower esophagus, descending aorta, sympathetic chain, and intercostal nerves and accounts for 25% of all mediastinal masses.

The most common lesions of the anterior mediastinum are thymic neoplasms, lymphomas, and germ-cell tumors, which account for nearly 60% of tumors in this compartment. It is not uncommon for these tumors to enlarge and occupy the middle compartment as well. Masses in the middle mediastinum are primarily cystic; 25% of lesions are metastatic malignancies to lymph nodes (lymphoma, carcinoma). In most reports, 70% of lesions within the posterior compartment are either neurogenic in origin or cystic. In children, neurogenic tumors are more common, and thymomas are rare.

Approximately 30% of mediastinal masses are malignant, with lymphomas, primary carcinomas, malignant thymomas, and malignant germ-cell tumors representing the majority. Malignant lesions are more common in children and between the ages of 20 to 40; several authors have reported increasing numbers of malignant mediastinal lesions coinciding with the increased incidence of lymphomas. The presence of symptoms is also predictive of malignancy.

Approximately 60% of patients with a mediastinal mass will have symptoms. Nevertheless, a large proportion of patients will have benign lesions discovered on routine x-rays. Chest pain, dyspnea, cough, and fever are the most common presenting symptoms. Many tumors will produce systemic syndromes as the result of hormone secretion. For example, excessive ACTH production by mediastinal carcinoids can produce Cushing's disease, and mediastinal pheochromocytoma may produce hypertension. In addition, thymomas have a poorly understood association with myasthenia gravis, red-cell aplasia, and collagen vascular disorders.

In addition to a careful history and physical examination, patients with a suspected mediastinal mass should have a routine chest x-ray and contrast-enhanced computed tomography. These two studies will identify the size, location, and composition of the lesion in the majority of cases. Magnetic resonance imaging (MRI) may help to distinguish vascular from soft-tissue masses in some cases and radiation fibrosis from neoplastic lesions. Several radioisotope scans may accurately localize occult, functional mediastinal tumors. Examples include ^{131}I-*meta*-iodobenzylguanidine (MIBG) to detect pheochromocytomas and technetium–thallium studies for the localization of ectopic parathyroid adenomas. Numerous mediastinal tumor markers have been reported, but only a-fetoprotein (nonseminomatous germ-cell tumors) and human chorionic gonadotropin (teratomas) are clinically useful.

Fine-needle biopsy has been used with accuracy to diagnose mediastinal masses. Occasionally, mediastinoscopy is required to provide sufficient tissue for definitive

diagnosis (e.g., lymphoma). In selected patients, video-assisted thoracoscopy may be diagnostic and therapeutic.

Although they also occur within the boundaries of the mediastinum, tumors and aneurysms of the thoracic aorta, trachea, esophagus, and heart are traditionally discussed as separate topics.

Classification of Mediastinal Tumors

Davis, Oldham, and Sabiston classify mediastinal tumors according to tissues of origin as follows:

1. Neurogenic tumors
    a. Neurofibroma
    b. Neurilemmoma
    c. Neurosarcoma
    d. Ganglioneuroma
    e. Ganglioneuroblastoma
    f. Neuroblastoma
    g. Chemodectoma
    h. Pheochromocytoma
2. Thymomas
    a. Benign
    b. Malignant
3. Lymphomas
    a. Hodgkin's disease
    b. Lymphoblastic lymphoma
    c. Large-cell diffuse growth pattern
        i. T-immunoblastic sarcoma
        ii. B-immunoblastic sarcoma
        iii. Sclerosing follicular cell
4. Germ-cell tumors
    a. Teratodermoid tumors
        i. Benign
        ii. Malignant
    b. Seminoma
    c. Nonseminomas
        i. Embryonal carcinoma
        ii. Choriocarcinoma
        iii. Endodermal
5. Primary carcinomas
6. Mesenchymal tumors
    a. Fibroma/fibrosarcoma
    b. Lipoma/liposarcoma
    c. Myxoma
    d. Mesothelioma
    e. Leiomyoma/leiomyosarcoma
    f. Rhabdomyosarcoma
    g. Xanthogranuloma
    h. Mesenchymoma
    i. Hemangioma
    j. Hemangioendothelioma
    k. Hemangiopericytoma
    l. Lymphangioma
    m. Lymphangiomyoma
    n. Lymphangiopericytoma
7. Endocrine tumors
    a. Intrathoracic thyroid
    b. Parathyroid adenoma
    c. Carcinoid
8. Cysts
    a. Pericardial
    b. Bronchogenic
    c. Enteric
    d. Thymic
    e. Thoracic duct
    f. Nonspecific
9. Giant lymph node hyperplasia
    a. Castleman's disease
10. Chondroma
11. Extramedullary hematopoiesis

A number of nonneoplastic lesions, particularly of the middle and posterior compartments, must be considered in the differential diagnosis of mediastinal masses. These include hiatal hernias, esophageal diverticula, meningoceles, and infections (mediastinitis, paravertebral abscess). An accurate differentiation should be possible in the majority of cases.

Neurogenic Tumors

Tumors that arise from intercostal nerve sheaths (neurilemmoma, neurofibroma), autonomic ganglia (ganglioneuroma, ganglioneuroblastoma), or paraganglionic nervous system (chemodectoma, pheochromocytoma) account for 20% to 25% of all mediastinal tumors in adults and 35% to 50% of mediastinal tumors in children. The etiology of these tumors is unknown, and most are thought to occur spontaneously. However, approximately 25% to 40% of patients with neurofibromas will have von Recklinghausen's disease. Ninety percent of neurogenic tumors arise in the posterior mediastinum, typically along the paravertebral gutter, where the sympathetic chains and the origins of intercostal nerves are located. Seventy-five percent of all posterior mediastinal tumors are neurogenic.

Although the great majority of neurogenic tumors in adults are benign, approximately 1% to 4% are malignant. Neurogenic tumors associated with von Recklinghausen's disease are more likely to be malignant. In contrast, most neurogenic tumors in children are malignant.

Approximately half of all benign and malignant neurogenic tumors are asymptomatic, being discovered incidentally on chest x-rays. The classic appearance is that of a round, smooth, homogeneous mass with sharp margins lying in the posterior mediastinum abutting the vertebral bodies (Fig. 2). The part that reaches the chest wall is flattened, lending a “D” shape to the tumor, a feature that is best appreciated on the lateral or appropriate oblique projection. The benign forms of these tumors usually increase in size slowly over a long period, whereas the malignant tumors tend to enlarge rapidly. Pain and cough are symptoms of local extension and compression. Some tumors enlarge sufficiently to cause dyspnea (Fig. 3). Catecholamine secretion from paraganglionic tumors may produce hypertension, headaches, sweating, and palpitations. Secretion of vasoactive intestinal polypeptide by ganglioneuromas and neuroblastomas may produce profuse, watery diarrhea.

FIG. 2. Chest computed tomographic scan showing a neurilemmoma of the posterior mediastinum *(arrows)* in a 44-year-old man with back pain.

FIG. 3. Operative photograph of a large ganglioneuroma occupying most of the pleural space and producing dyspnea.

Approximately 10% of neurogenic tumors will extend medially through the intervertebral foramen to form “dumbbell” tumors (Fig. 4). These are almost always symptomatic, with back pain, intercostal radicular pain, or signs of spinal compression. Typically, a CT scan will demonstrate erosion of the intervertebral neuroforamen, pedicles, and facets. In this situation, MRI scanning is indicated, as it will more effectively demonstrate intraspinal extension of tumor and spinal cord involvement. If MRI is not available, then myelography should be performed. Current treatment of dumbbell tumors consists of a single-stage combined laminectomy and thoracotomy for complete removal of tumor.

FIG. 4. Chest computed tomography scan showing a neurogenic tumor extending into the intervertebral foramen, forming a “dumbbell” *(arrow)*.

Neurofibromas and *neurilemmomas* account for the great majority of all neurogenic tumors. The former is thought to represent a metaplastic derivative of Schwann cells; it occurs sporadically and in association with phacomatoses (von Recklinghausen's disease, tuberous sclerosis, von Hippel–Lindau disease, etc.) and may arise from any nerve in the thorax. Neurofibromas contain all of the elements of the nerve trunk, including axons and connective tissue. Grossly, a true capsule is usually absent, and on histologic examination, cellular palisading is absent. Immunohistochemical stains will demonstrate S-100 protein, indicating a nerve sheath origin. Because of the propensity for continued slow growth and malignant potential, surgical resection is recommended for all neurofibromas. Complete removal should be considered curative; a plexiform variant may be locally aggressive and difficult to control.

Neurilemmomas are derived from Schwann cells, which encase each axon cylinder of peripheral nerves. In addition to von Recklinhausen's disease, this lesion is also associated with Noonan's syndrome. Histologically, two separate morphologies have been described. Antonio type A is characterized by palisading nuclei within a dense cytoplasmic stroma. Antonio type B typically reveals a loose, myxomatous stroma with areas of hemorrhage (Fig. 5). As with neurofibromas, surgical resection is recommended, and the prognosis is excellent.

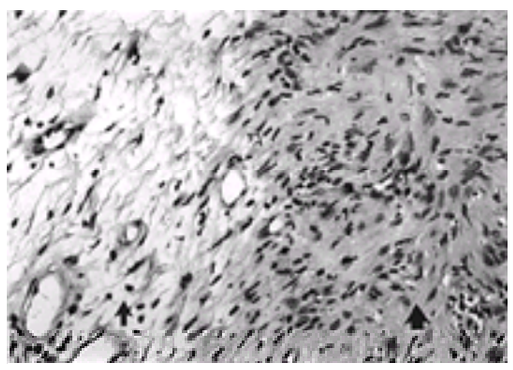

FIG. 5. Neurilemmoma showing Antonio type A *(large arrow)* and type B *(small arrow)* (H&E stain, ×660). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

Rarely, malignant degeneration of either neurofibromas or neurilemmomas may occur, giving rise to a neurosarcoma (malignant schwannoma). This lesion may synthesize an insulin analog capable of producing hypoglycemia. Complete resection is possible in only 50% of patients; local recurrence is common, and long-term survival is rare. Radiotherapy may be useful for palliation.

Ganglioneuromas are common benign tumors that arise from peripheral nerve cells of the sympathetic chain (Fig. 6). They occur more frequently in children. Microscopically, they consist of ganglion cells containing three or four nuclei within a stroma of medullated and nonmedullated nerve fibers, connective tissue, and Schwann cells (Fig. 7). Ganglioneuromas may undergo malignant degeneration either into a partially differentiated *ganglioneuroblastoma,* which contains immature sympathetic nerve cells and mature ganglion cells, or into a completely undifferentiated neuroblastoma, which is composed of small lymphocyte-like cells frequently arranged into rosettes. Neurosecretory granules are present on electron microscopy. Although both lesions are seen most often in children, neuroblastomas are much

more common, accounting for 15% of annual pediatric cancer deaths. Only a minority of patients have disease confined to the chest at the time of presentation. In addition to cough, pain, and dyspnea, neuroblastomas can produce catecholamines (which cause hypertension and sweating) or vasoactive intestinal polypeptide (resulting in watery diarrhea) and have been associated with an autoimmune condition known as “opsoclonus-polymyoclonus syndrome.” Serum ferritin levels correlate with the presence of active tumor.

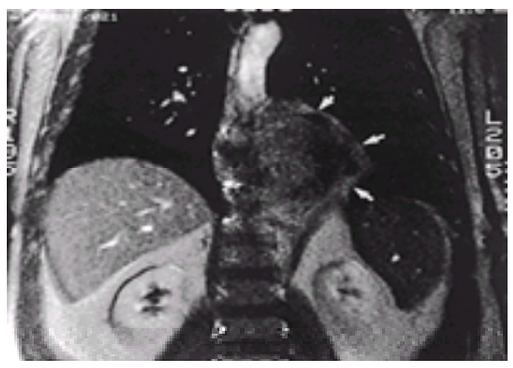

FIG. 6. Magnetic resonance image of a large, smptomatic ganglioneuroma *(arrows)* in a 47-year-old man. Figure 70-3 shows the operative picture.

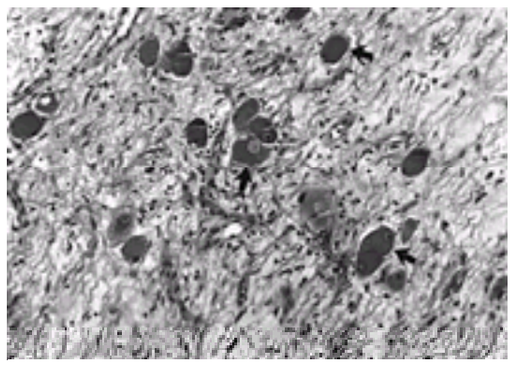

FIG. 7. Ganglioneuroma showing prominent ganglion cells *(arrows)* within a background of loose connective tissue stroma (H&E stain, ×500). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

The treatment of minimally invasive ganglioneuroblastomas is primarily surgical, with an expected 5-year survival of nearly 90%. For neuroblastomas, prognosis is dependent on the age of the patient, the histologic grade of the tumor, tumor location (better prognosis for disease limited to the chest), tumor DNA content, and the presence of certain biological markers (e.g., *N-myc* gene amplification). There is evidence to suggest genetically different subtypes of neuroblastomas, which may explain observed differences in prognosis. For early-stage lesions, resection can effect a cure; only 10% of patients with disseminated neuroblastoma will be disease-free at 2 years. Combination chemotherapy and radiotherapy can achieve good response rates for advanced disease. Autologous bone marrow transplantation has also been used with some success. On rare occasions, neuroblastomas have regressed spontaneously.

Mediastinal paragangliomas are rare lesions, accounting for approximately 1% of all mediastinal tumors. Included in this group are carotid body tumors, chemodectomas, glomus tumors, and pheochromocytomas. All are capable of storing catecholamines intracellularly; pheochromocytomas are best known for their secretory function. Multiple lesions may be present in the 10% of patients with the multiple endocrine neoplasia syndrome (MEA types II, III). Pathologically, these tumors are quite vascular, and immunohistochemical staining will distinguish them from neurogenic tumors. For secretory lesions, symptoms of catecholamine excess are characteristic. Measurement of urinary catecholamines will establish the diagnosis. Chest CT scans and ^{131}I-MIBG scans will localize the majority of pheochromocytomas. Surgical resection is curative for benign paragangliomas; even with benign histology, some lesions will behave aggressively, and 5-year survival approaches 50%.

Thymoma

Several neoplastic conditions may involve the thymus gland, including thymoma, thymic carcinoma, and carcinoid. Of these, thymoma is by far the most common. The normal thymus gland is composed of a mixture of epithelial cells and lymphocytes. Although the great majority of thymomas contain a mixture of these cell types, and though the lymphocytes are predominant, it is the epithelial cells that are neoplastic. It is true that a lymphoma also may occur in the thymus gland as a primary tumor or as a part of systemic disease, but in those cases the lymphocytes and not the epithelial elements are neoplastic. Several schemes have been proposed for the classification of thymomas, based on the degree of invasion (stages I to IV; Table 1) and histology (cortical, medullary, mixed; Table 2). The former is most widely accepted, but both have prognostic utility.

Stage	Descriptor	Proportion of cases	5-year survival (%)
I	Completely encapsulated tumor without evidence of capsular invasion	40	96–93
II	Gross or microscopic extracapsular extension of tumor into adjacent fat or pleura	14	70–85
III	Gross invasion of 3/4 adjacent organs (pericardium, great vessels, etc.)	34	58–72
IVa	Diffuse, metastatic disease involving the pleura or pericardium	9	50–60
IVb	Distant metastases	3	24

TABLE 1.*Staging system for thymoma based on tumor spread*

Histopathology	Proportion of patients (%)	5-year survival (%)
Cortical	41	52
Medullary	12	100
Mixed	46	85

TABLE 2.*Staging of thymoma basedon tumor histopathology*

Thymomas comprise 10% to 20% of all mediastinal tumors. Rare in childhood, thymomas increase in incidence with age. There is an equal sex distribution. Most of these tumors are located centrally in the anterior mediastinum (Fig. 8), but they also may occur laterally in the middle mediastinum when a tumor in the inferior pole of the gland enlarges and descends along the border of the pericardium.

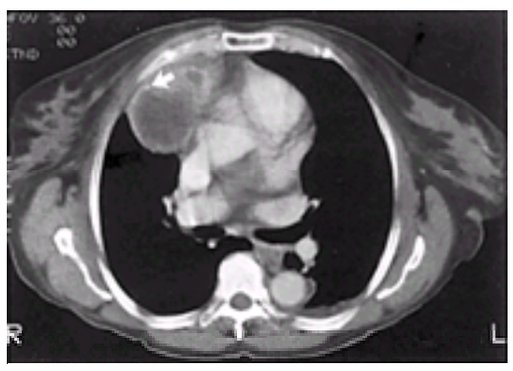

FIG. 8. Invasive thymoma in a patient with chest pain and arthralgias. Calcium is present within the mass *(arrows).*

Fifty percent of patients are asymptomatic. Approximately 25% have cough, dyspnea, or chest pain. Superior vena caval obstruction is usually a sign of malignancy. Approximately 25% to 35% have an associated paraneoplastic syndrome, and myasthenia gravis is the most frequent.

From 10% to 50% of thymomas are associated with myasthenia gravis, whereas approximately 10% to 15% of patients with myasthenia will be found to have a thymoma at surgery. In the past, the occurrence of myasthenia in patients with a thymoma was thought to have a negative impact on survival. With improvement in drug therapy and plasmapheresis, this is no longer true. Myasthenia has been observed more frequently with certain histologic types of thymoma. A number of other autoimmune or immune phenomena have been associated with thymomas. Among the most common are red cell hypoplasia (virtual absence of erythroblasts and reticulocytes in the bone marrow), hypogammaglobulinemia, systemic lupus erythematosus, and Cushing's syndrome. Red cell hypoplasia occurs in 5% of thymomas. However, 50% of all cases of red cell hypoplasia are associated with thymoma. Hypogammaglobulinemia occurs in a smaller percentage of thymomas, but approximately 10% of patients with this condition also have a thymoma. Cushing's syndrome is associated with carcinoid tumors of the thymus.

Standard chest radiographs in patients with thymomas typically show a smooth, lobulated mass located in the anterior mediastinum. Calcification within the mass may be present. Retrospective examination of serial roentgenograms suggests that thymomas usually enlarge slowly over a long period. Thymomas associated with myasthenia gravis are usually smaller than average. In fact, many are discovered incidentally during thymectomy intended for the relief of myasthenic symptoms. Magnetic resonance imaging is useful in determining the relationship of large tumor to the great vessels; a lobulated internal architecture may be associated with malignancy. One must always be aware of the “thymic rebound” phenomenon, which typically occurs after chemotherapy for lymphoma. The chest CT scan reveals symmetric thymic enlargement, consistent with hyperplasia. Biopsy may be necessary in these situations.

Grossly, thymomas are encapsulated, lobulated tumors. Degenerative changes are often found, including focal hemorrhage, calcification, and cyst formation. On cut section, the grayish-tan tumor is frequently compartmentalized by fibrous septa. Although thymomas are commonly adherent to adjacent structures, frank invasion occurs in only 20% to 40% of patients.

Microscopically, a mixture of epithelial cells and lymphocytes may be found. The epithelial cells are either round, oval, or elongated, with vesicular nuclei and indistinct cell margins (Fig. 9), whereas the lymphocytes are normal in appearance. Rosettes are formed in 20% of cases, and Hassal's corpuscles (keratinized epithelial cells) are frequently present. With a predominance of epithelial cells, the lesion is called an epithelial thymoma; when the epithelial cells assume a fusiform shape, the lesion is termed a spindle-cell thymoma; a predominance of lymphocytes is termed a lymphocytic thymoma. These groups occur with equal frequency; however, myasthenia is more commonly seen in association with lymphocytic thymomas, and red cell hypoplasia is more common in association with spindle lesions.

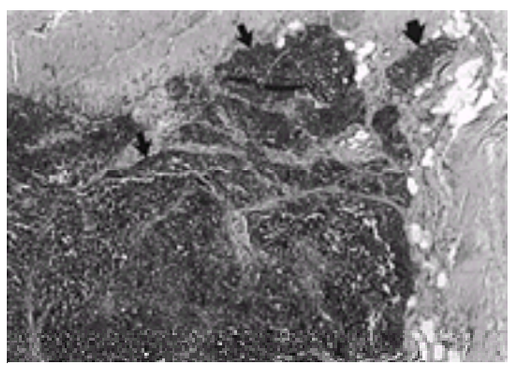

FIG. 9. Invasive lymphocytic thymoma showing characteristic tumor lobules *(small arrows).* A focus of invasive tumor is seen *(large arrow)* (H&E stain, ×132). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

Surgical resection is recommended for most thymomas. *En bloc* removal of the tumor and surrounding tissue through a sternotomy incision is the most common practice, although thoracoscopic approaches have been used. Often, the distinction between a benign and malignant lesion is made at operation, with the finding of tumor invasion. Even without gross evidence, microscopic invasion is seen in 20% of tumors. The 5-year survival for stage I disease is approximately 90% (Table 1). Several studies have shown that oncogene protein expression or tumor DNA content may predict outcome. However, the most accurate indicator of long-term prognosis is the degree of tumor invasion. For advanced lesions or recurrences, radiotherapy and/or cisplatin-based chemotherapy can extend survival. Thymectomy improves the symptoms of myasthenia in a approximately 25% of patients with thymomas; nearly twice as many myasthenic patients without thymomas will improve with thymectomy. Red cell hypoplasia is rarely helped by thymectomy, and hypogammaglobulinemia never is.

Lymphomas

As a group, the lymphomas represent approximately 20% of all adult mediastinal malignancies; this number doubles in children. The incidence of malignant mediastinal lesions has increased, primarily as a result of an increase in the number of lymphomas. The majority of mediastinal lymphomas are found in the anterior and middle compartments, arising from nodal tissue in association with systemic disease. Occasionally, the primary tissue of origin is the thymus, thyroid, or heart. The classification of lymphomas is based on the cell of origin (B cell, T cell), cellular histology, degree of maturation, and cell surface antigen marker. Hodgkin's lymphoma, lymphoblastic lymphoma, and diffuse large-cell non-Hodgkin's lymphoma account for 90% of primary mediastinal lymphomas. The tumor biology, clinical presentation, and response to therapy varies according to the type of lymphoma.

The mediastinum is usually involved as part of generalized systemic lymphoma. These patients suffer from fever, fatigue, weight loss, lymphadenopathy, hepatosplenomegaly, etc. The diagnosis can be made by biopsy of lymph nodes or bone marrow and by study of the peripheral blood.

However, approximately 10% of lymphomas present with disease apparently confined to the mediastinum (Fig. 10 and Fig. 11). In addition to systemic symptoms, mediastinal lymphomas may cause pain, cough, and dyspnea. In advanced stages, involvement of adjacent structures may result in pleural and pericardial effusions, tracheal obstruction, and superior vena caval obstruction.

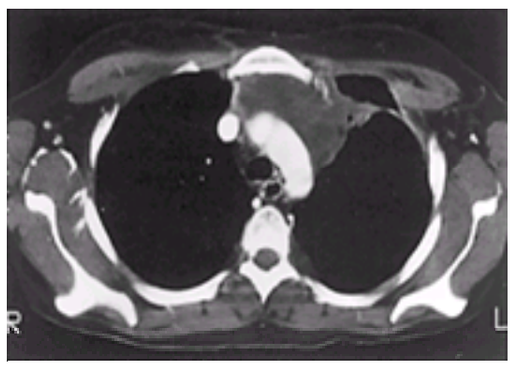

FIG. 10. Anterior mediastinal Hodgkin's lymphoma in a 24-year-old woman.

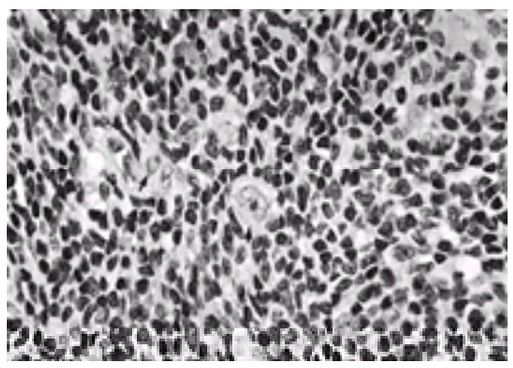

FIG. 11. Typical Hodgkin's lymphoma showing a background of benign lymphocytes and prominent Reed–Sternberg cells *(arrows)* (H&E stain, ×600). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

There are no specific radiographic features that define mediastinal lymphomas. However, CT and MRI scans are essential to determine the extent of disease, invasion into contiguous structures, and to establish a baseline for therapeutic response. Thymomas, germ-cell tumors, and Castleman's disease (a benign lymph node hyperplasia seen in the mediastinum) should be considered in the differential diagnosis.

Because many lymphomas require electron microscopy and immunohistochemical stains for definitive diagnosis, open biopsy techniques are frequently required to provide sufficient tissue for examination. Anterior mediastinal masses can be accessed by mediastinoscopy. Middle and posterior lesions can be biopsied during thoracoscopy. There are no serum markers specific for lymphomas, although serum lactate dehydrogenase is elevated in many patients.

The treatment of patients with mediastinal lymphomas is based on primary radiotherapy (stage I, II Hodgkin's disease) or radiation with combination chemotherapy (non-Hodgkin's lymphomas). Early-stage Hodgkin's disease has a 10-year survival of over 90%. Modern cure rates for non-Hodgkin's lymphomas are approximately 50%. Recurrences are more frequent with “bulky” mediastinal disease. Although surgical resection of isolated lesions and tumor “debulking” have been reported with good results, this approach has limited application.

Germ-Cell Tumors of the Mediastinum

These tumors can be divided into benign teratodermoid tumors and malignant tumors, which include seminomas, embryonal carcinomas, choriocarcinomas, and endodermal sinus (yolk sac) tumors. Germ-cell tumors are thought to originate during abnormal migration of germ cells during embryogenesis. Fewer than 1% represent metastases from a gonadal primary. Approximately 50% to 70% of all extragonadal germ-cell tumors occur in the anterior mediastinum; other locations include the pineal gland, retroperitoneum, and sacrococcygeal areas. Germ-cell tumors are more common in men with Klinefelter's syndrome.

Teratodermoid Tumors

The term teratoma indicates that a tumor is composed of tissues derived from all three germ layers and that all those tissues are foreign to the organ in which they are found. Dermoid cysts, the name applied to the simplest form of teratoma, is a misnomer because tissue elements other than skin are also present in the cyst lining.

Approximately 10% of mediastinal tumors are teratomas; which is the most common germ-cell neoplasm of the mediastinum. Essentially all mediastinal teratomas develop within the anterior compartment in connection with the thymus gland and sometimes within it.

Mostly asymptomatic, they are usually discovered on routine chest x-ray as a mass in the anterior mediastinum projecting into either hemithorax. Symptoms of pain and dyspnea are related to compressive effects. In infants and children, compressive symptoms occur earlier because there is less space for tumor enlargement. Occasionally, these tumors erode, by pressure necrosis or infection, into adjacent organs such as the lung, pericardium, pleura, or superior vena cava, into which the cyst's contents may be discharged. A patient may, for example, cough up hair from a cyst that has eroded into the lung. Typically, chest CT scans show a cystic structure that may contain calcium, bone, and fat (Fig. 12).

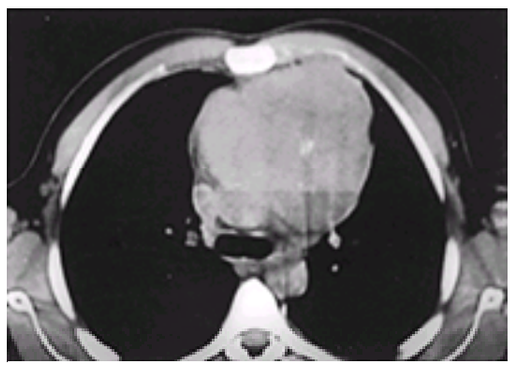

FIG. 12. Teratoma of the anterior mediastinum with central calcium deposits.

Benign teratomas tend to be smooth and rounded, whereas their malignant counterparts are usually lobulated. Grossly, most benign mediastinal teratomas are multicystic, whereas the malignant forms tend to be solid. Microscopically, benign teratomas contain cystic structures lined by tall mucus-secreting cells and a large number of different types of tissue attempting to form organs. Teratomas may be extremely complex and contain a great variety of tissues, including skin, hair, teeth, sebum, muscle, bone, cartilage, fat, respiratory epithelium, pancreas, nerve tissue, and others in various stages of embryologic development. Eighty percent of teratomas are composed of mature tissue elements and are therefore considered benign. Immature tissue elements in a teratoma constitute a sign of malignancy, especially in an adult.

Except for areas of inflammatory reaction or malignant invasion, teratomas have no real tissue attachment and can practically be shelled out of the mediastinum once the overlying pleura has been incised. Because the diagnosis is usually not known beforehand, it is probably good practice to approach the tumor through a median sternotomy, regardless of whether it projects more to one side than the other, and to remove the contiguous thymus *en bloc* with the tumor. All fistulous connections to

other organs (e.g., bronchocystic fistulas) must be interrupted and properly sealed. Care must be exercised to avoid damaging the phrenic nerve, which is frequently stretched over the tumor. Resection of benign teratomas should be considered curative. For malignant lesions, chemotherapy may prolong survival.

Seminoma

Seminoma, also known as *dysgerminoma,* is a rare primary malignant tumor that almost invariably arises in the anterior mediastinum. It occurs almost exclusively in men, between the ages of 20 to 40 years, and accounts for half of all mediastinal germ-cell tumors. Chest pain, cough, dyspnea, and hoarseness are the most common symptoms. The superior vena cava syndrome may be present in 10% to 20% of patients. Typically, a large, homogeneous anterior mediastinal mass is seen on chest CT, but there are no specific radiographic signs; metastatic spread tends to be local into the adjacent lung and/or great vessels. A small number of patients will have elevations of b-human chorionic gonadotropin (b-HCG). This tumor is histologically identical to seminoma of the testis, but the testicular tumor rarely metastasizes to the anterior mediastinum. In the absence of testicular enlargement and retroperitoneal adenopathy on CT scan, a seminoma in the mediastinum may be considered to be a primary extragonadal germ-cell tumor.

Seminomas are solid, nonencapsulated tumors adjacent to the thymus and sometimes enclosed within the gland. On cut section, they are homogeneous, pale tan to yellow, and firm in consistency. On microscopic examination, the tumor is typically divided into numerous islands by fine reticulum fibers. The cells have large, dense nuclei, and the abundant cytoplasm contains glycogen (in contrast to thymomas, which they may resemble). Noncaseating granulomas are also frequently found in the tumor.

Surgery, radiotherapy, chemotherapy (usually cisplatin, bleomycin, and etoposide), and combinations of these have been used as the primary treatment for seminomas. Operative resection is indicated only for small, localized lesions because the recurrence rate for larger lesions is high. Because the tumor is usually very radiosensitive, radiotherapy (4500 to 5000 cGy) has been used extensively, and approximately 60% of patients will be cured with this approach. For large, bulky lesions and in patients with extrathoracic spread or recurrence, the addition of cisplatin-based combination chemotherapy can produce complete remission rates of 80% to 90%.

Nonseminomatous Germ-Cell Tumors of the Mediastinum

Embryonal carcinoma, choriocarcinoma, and teratocarcinoma of the mediastinum are quite rare, and endodermal sinus (yolk sac) tumor of the mediastinum is extremely rare. As a group, they comprise approximately 3% to 10% of all mediastinal tumors. Nonseminomatous germ-cell tumors of the mediastinum almost always occur in men between the ages of 20 and 50. Rapid growth and invasive behavior are the rule. Symptoms include pain, cough, hemoptysis, dyspnea, fever, and weight loss. Approximately 20% of patients develop signs of superior vena caval obstruction. Gynecomastia develops in a significant percentage of nonseminomatous germ-cell tumors and is associated with high levels of b-HCG; b-HCG and/or a-fetoprotein (AFP) is produced by the majority of these tumors. Assays of these biomarkers are an extremely useful way to assess the efficacy of chemotherapy.

Almost all patients with nonseminomatous germ-cell tumors have one or more foci of metastatic disease at the time of diagnosis. Tumors tend to be large, with invasion into local structures, and, in contrast to seminomas, the response to radiotherapy is poor. Multiagent cisplatin-based chemotherapy is the treatment of choice. With this approach, approximately 50% to 70% of patients will achieve complete remission, and half may be long-term survivors. A significant number of patients will have normalization of tumor markers, but residual disease is visible on x-ray studies. Although 70% of these residua contain scar or mature teratoma, active tumor persists in the remainder. In this situation, surgical resection of the remaining tumor may be of benefit.

Mesenchymal Tumors of the Mediastinum

Mesenchymal tumors may arise from connective tissue, muscle, blood vessels, fat, and lymphatic tissue. As a group, they account for approximately 6% of all mediastinal tumors, and about half are benign. These tumors include fibroma (benign mesothelioma), lipoma, and liposarcoma. Myxoma, leiomyoma, leiomyosarcoma, rhabdomyosarcoma, xanthogranuloma, and mesenchymoma occur so rarely that there are few recent reports. In addition, there are tumors of vascular and lymphatic origin, including hemangiopericytoma, lymphangioma, cystic hygroma, and lymphangiomyoma (lymphangiopericytoma). All these are relatively more common in other parts of the body than in the mediastinum. Some of these tumors are of mixed cell type. Swanson has provided a comprehensive review of these tumors.

Fibromas occur more frequently in the pleura (benign pleural mesothelioma) than in the mediastinum. Some cases of mediastinal fibromas have been associated with hypoglycemia and may degenerate into fibrosarcomas. Lipomas account for 2% of all primary mediastinal tumors and are found predominantly in the anterior mediastinum. They must be differentiated from mediastinal lipomatosis, the excessive fat accumulation caused by excessive corticosteroid stimulation, herniated omentum, and thymolipoma (a histologically normal hyperplasia of thymus and fat cells). The diagnosis of a lipoma can be made on CT scan by the low specific coefficient of attenuation (-30 to -100 Hounsfield units) of fat. Lipomas in the lower mediastinum are usually asymptomatic, but large cervicomediastinal lipomas can produce tracheal obstruction. Over 50 cases of liposarcoma of the mediastinum have been reported. Typically, this lobulated tumor may become quite large and infiltrate soft tissues and organs, producing symptoms of airway compression and chest pain. Most of these tumors are “low grade” but have a propensity to recur following resection.

Lesions of vascular origin, hemangiomas, hemangioendotheliomas, and angiosarcomas may arise anywhere in the mediastinum and are extremely rare. Hemangiomas may be quite vascular and may rupture into a pleural space. Complete resection may be difficult but is usually curative. Hemangioendotheliomas and angiosarcomas behave more aggressively. Thirty percent are malignant. Direct extension of tumor into adjacent bone may occur, and local recurrence is common.

Mediastinal lymphangiomyoma (lymphangiopericytoma) is a noninvasive benign tumor closely associated with the thoracic duct, derived from perilymphatic smooth muscle of the lung. The tumor oozes chyle and produces chylothorax. Many mediastinal lymphangiomas begin in the neck (“cystic hygroma”) and descend into the mediastinum. They are composed of multilocular thin-walled cysts lined by endothelium and filled with clear fluid. These tumors are surrounded by a vascular and fibrous reaction and grow in a budding fashion, making surgical resection difficult. Nevertheless, recurrence is rare following removal. Radiotherapy is not recommended, as malignant transformation has been described.

Intrathoracic Thyroid

This is a common lesion, estimated to occur in 0.02% of the general population. More frequent in women, intrathoracic goiter frequently arises as an extension from the isthmus or inferior pole of the cervical thyroid gland and descends into the mediastinum between the trachea and prevertebral fascia. The mass may present either anterior to the trachea or in the posterior mediastinum, partially overlying the trachea. Approximately half of patients complain of respiratory distress. Typically, inspiratory stridor or a choking sensation is aggravated by leaning forward. Venous engorgement of the neck and arm may result from compression of the innominate vein. Hyperthyroidism may be present in 13% of patients. On the chest x-ray, the trachea is usually displaced laterally, and the lumen is reduced. Esophageal compression can be appreciated on barium swallow. Findings of chest CT scan are characteristic, consisting of a nonhomogeneous mass with distinct borders containing course calcifications (Fig. 13). Prolonged enhancement of the mass after injection of iodinated contrast is typical. Radioactive iodine scans (^{131}I) are invariably positive.

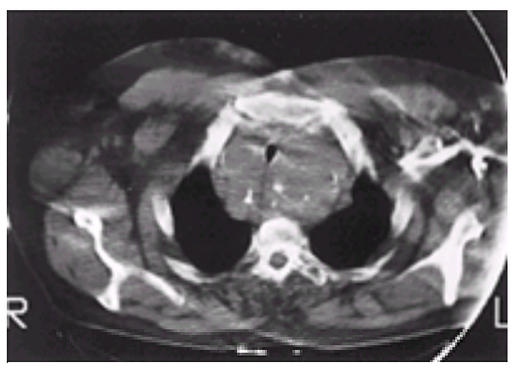

FIG. 13. Computed tomographic scan of a large intrathoracic thyroid causing severe airway compression and stridor.

Histologically, intrathoracic thyroid tumors are usually multinodular goiters. Follicular adenoma may be present on occasion, and approximately 3% to 5% will contain

occult carcinoma.

True ectopic thyroid tissue is a very uncommon condition. The tissue is usually found in the anterior mediastinum adjacent to the thymus. The blood supply is from the mediastinum rather than from the neck. Symptoms are infrequent. Rarely does this tissue represent the only functioning thyroid tissue in the body.

The use of L-thyroxine to suppress an intrathoracic goiter will do little to change the size of the mass. Because of the propensity for airway compromise, either acutely or from tracheomalacia, and the possibility of occult carcinoma, most clinicians recommend surgical resection. This can be accomplished through a cervical incision in most cases.

Intrathoracic Parathyroid Adenoma

Approximately 10% of parathyroid adenomas are found in the anterior mediastinum, where they produce symptoms only by parathormone secretion. These adenomas are often embedded within the thymic tissue because they share a common embryologic origin (third branchial cleft). They are rarely visible on a chest x-ray and are usually the subject of an intensive search in a patient with persistent or recurrent hyperparathyroidism. High-resolution CT scanning, MRI, ultrasonography, thallium–technetium scintigraphy, and selective venous sampling in combination will localize the lesion in 80% to 90% of cases. Angiographic ablation may provide long-term control in 60% of patients; surgical removal is curative.

Thymic Cysts

Cysts develop as a result of a persistent thymopharyngeal duct and therefore may be found anywhere from the mandible to the lower anterior mediastinum, often in the lateral neck. An acquired inflammatory process may be required to produce cyst formation in ductal epithelium. They are usually discovered incidentally, although they occasionally produce tracheal compression.

Cysts are round in the mediastinum and tubular in the neck. They have a thin, fibrous wall, a smooth inner lining, and are filled with straw-colored fluid. They are prone to hemorrhage and hence may contain old blood and cholesterol crystals.

Microscopically, they are lined by columnar, cuboidal, or stratified squamous epithelium. In order to make the diagnosis of thymic cysts, it is necessary to identify thymic tissue in the wall of the cyst, which may be difficult in an atretic thymus gland. The differential diagnosis includes cystic thymoma or lymphoma, making resection of all thymic cysts advisable.

Thoracic Duct Cysts

These cysts are very uncommon. Although thay are usually asymptomatic, the larger cysts may compress the esophagus or adjacent structures. A fatty meal may exacerbate symptoms. The principal diagnostic feature is the observation that the thoracic duct enters and leaves the cystic mass. This can be demonstrated by lymphangiogram. Symptomatic lesions are usually excised, but chylothorax may result.

Enteric Cysts

Also known as *enterogenous cysts, reduplication cysts, inclusion cysts,* or *gastric cysts,* these cysts originate from the dorsal foregut that develops into the gastrointestinal tract. Approximately 15% of all mediastinal cysts are enteric in origin and are more frequent in children. They may be found at any level in the posterior mediastinum (Fig. 14).

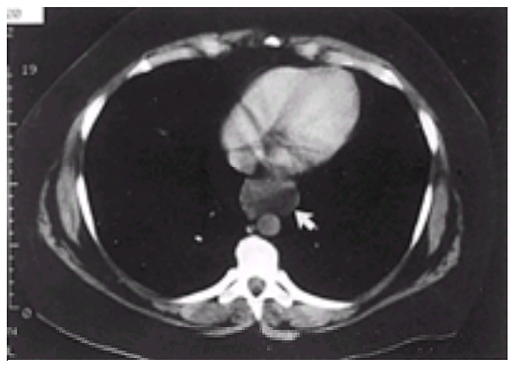

FIG. 14. Enteric cyst of the posterior mediastinum *(arrow)* causing dyspnea and chronic cough in a 32-year-old woman.

Although most patients are asymptomatic, children frequently present with cough, dyspnea, and recurrent pulmonary infections. In adults, dysphagia from esophageal compression is the most common symptom.

Grossly, enteric cysts are smooth-walled structures attached to the wall of the esophagus or completely embedded within the muscle (Fig. 15). Characteristically, a two-layer muscularis is present (Fig. 16). The mucosa may resemble that of esophagus, stomach, or small intestine. Gastric mucosa is capable of acid secretion and may result in peptic ulceration with perforation into adjacent esophagus or bronchus. Rarely, adenocarcinoma may arise from chronic cysts.

FIG. 15. Operative photograph of the woman shown in Fig. 70-14, showing the cyst originating from the esophageal wall.

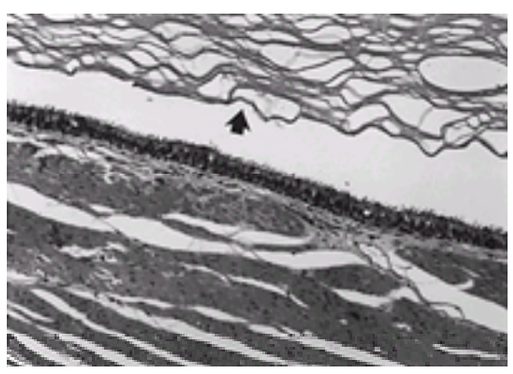

FIG. 16. Enteric cyst with ciliated columnar epithelium, bands of smooth muscle, and mucous debris *(arrow)* (H&E stain, ×500). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

There are no specific radiographic findings, although technetium-pertechnetate scans may localize gastric mucosa. Chest CT scans typically show a low-attenuation mass with smooth borders. Endoscopic and thoracoscopic decompression of these cysts has been described, but recurrence is likely if the cyst wall remains intact. Complete excision is the treatment of choice in symptomatic patients and to prevent the complications of infection and hemorrhage.

Bronchogenic Cysts

Originating as duplication cysts of the ventral foregut that forms the respiratory system, these cysts are usually located in the lung parenchyma (most common) or in the mediastinum (immediately posterior to the carina) (Fig. 17). They account for approximately 10% of mediastinal tumors and represent the most frequent mediastinal cyst. They are round, frequently multilocular, and are lined by pseudostratified ciliated columnar epithelium. The cyst wall may contain cartilage, smooth muscle, fibrous tissue, and mucous glands. Communication with the tracheobronchial tree is uncommon, but they are nearly always attached either intimately or by a cartilaginous band to the trachea.

FIG. 17. Chest computed tomographic scan showing mediastinal bronchogenic cyst *(arrows)* posterior and inferior to the carina.

The majority of patients are symptomatic from bronchial or tracheal compression or cyst infection. In infants and children, these symptoms may be life-threatening. Hemorrhage, rupture, and malignant degeneration of bronchogenic cysts have been reported. Therefore, excision of these lesions is recommended.

Pericardial Cysts

These are round, usually unilocular, fluid-filled cysts that sit on the diaphragm in contact with the pericardium and anterior chest wall. Embryologically, they represent a failure of fusion of the mesodermal elements that form the pericardium. The majority of pericardial cysts are located in the right cardiophrenic angle and are asymptomatic. Occasionally, cysts have been observed to change in size with respiration. This correlates with the finding at surgery in approximately 5% of cases of a communicating tunnel between the cyst and the pericardium through which the cyst contents are reducible. On CT scans, pericardial cysts classically have smooth borders and water density (Fig. 18). The differential diagnosis includes hydatid cyst, localized anterior exenteration of the diaphragm, pleural tumors, peripheral right middle lobe or lingular tumors, foramen of Morgagni hernias, and extraperitoneal fat hernias. Large cysts have been managed successfully with needle aspiration.

FIG. 18. Pericardial cyst located in the right cardiophrenic angle *(arrow).*

TUMORS OF THE PLEURA

The majority of pleural tumors are metastatic, with carcinoma of the lung or breast and lymphoma accounting for 75% of cases. Benign primary tumors such as lipomas, endotheliomas, and cysts do occur but are very rare. The most common and clinically important primary pleural neoplasms are mesotheliomas. Chest films, chest CT scans, cytologic analysis of pleural fluid, and pleural biopsy should lead to a diagnosis in most patients with pleural tumors.

Mesothelioma

Pleural mesotheliomas are tumors derived from the serosal surface of the lung. They may be classified as benign or malignant; malignant forms can be further classified as localized or diffuse. Benign lesions, also known as pleural fibromas, tend to be pedunculated tumors attached by a narrow stalk to the visceral or parietal pleural surface of the lung (Fig. 19 and Fig. 20). They represent approximately 10% of all mesotheliomas and may become very large before producing symptoms. Grossly, these tumors consist of fibrous tissue and are well encapsulated. Patients may present with pulmonary osteoarthropathy or hypoglycemia. These symptoms resolve after resection of the tumor.

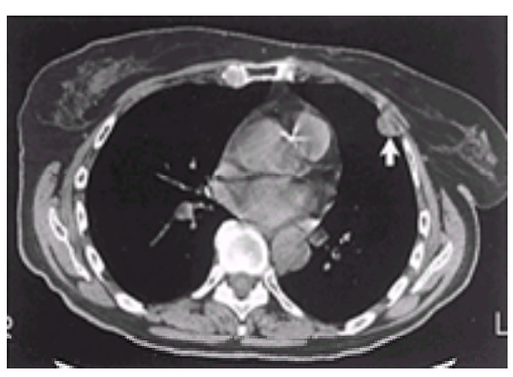

FIG. 19. Chest computed tomographic scan of an asymptomatic fibrous mesothelioma *(arrow)* arising from the visceral pleura.

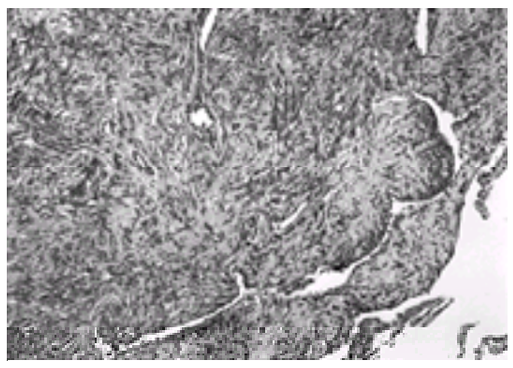

FIG. 20. Fibrous mesothelioma, characterized by bland spindle cells without mitoses (H&E stain, ×250). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

Malignant mesothelioma is a rare tumor, accounting for 1% of cancer deaths. The majority of cases are of the diffuse form and are unilateral. This disease usually presents between the ages of 50 to 70 years and is seen more frequently in men. Shortness of breath and nonpleuritic chest pain are the most common complaints, and a pleural effusion is often present, which may cause significant compression of the lung.

Malignant mesothelioma may develop at the site of pleural injury from a number of causes. The inhalation of asbestos fibers, especially crocidolite, is carcinogenic and is associated with the development of mesothelioma in 5% to 7% of exposed workers. A latent period of 20 to 40 years between the time of exposure and the development of disease is not uncommon. Inhalation of other mineral fibers, such as zeolites, is also associated with the development of mesothelioma.

Grossly, the entire lung often becomes encased within a mass of fibrous tissue, which also invades the chest wall, diaphragm, and mediastinum (Fig. 21). Some areas of the tumor are hard, like scar tissue, and other areas may be soft and gelatinous or necrotic. Histologically, mesotheliomas are classified with soft-tissue sarcomas, although a number of types are described (epithelial, sarcomatoid, transitional). The distinction between the epithelial type (most common) and metastatic adenocarcinoma is often difficult and requires electron microscopy and immunohistochemical stains (particularly cytokeratin and CEA).

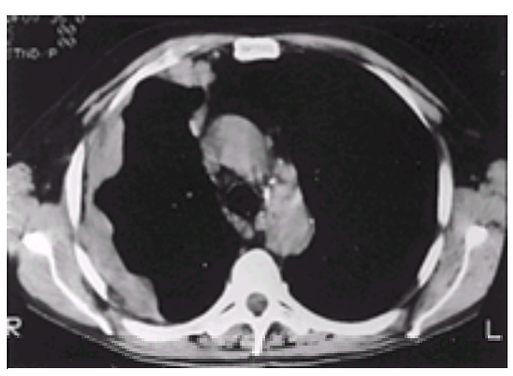

FIG. 21. Diffuse malignant mesothelioma showing the characteristic lobulated pleural mass.

Cytologic diagnosis from pleural fluid is frequently inadequate; usually only hyperplastic mesothelial cells are retrieved. Needle biopsy of the pleura is equally unrewarding due to insufficient cellular material; seeding of the biopsy tract with tumor is a recognized problem. Thoracoscopy or thoracotomy is often required to obtain sufficient material for analysis.(Fig. 22).

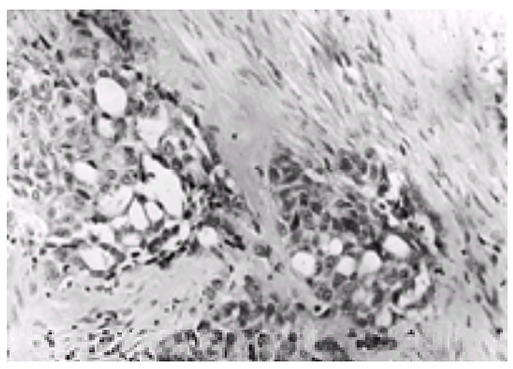

FIG. 22. Malignant pleural mesothelioma, mixed type, showing mesothelial and spindle cells (H&E stain, ×400). (Photomicrograph courtesy of Dr. Miriam Lurie, Department of Pathology, Carmel Hospital, Haifa, Israel.)

At the present time, the treatment of malignant pleural mesothelioma is palliative. Conservative strategies include chemical pleurodesis for control of pleural effusions. Aggressive radiation and/or chemotherapy or photodynamic therapy may control symptoms, but no survival benefit has been documented. Similarly, radical pleurectomy and extrapleural pneumonectomy have not been shown to significantly alter survival, which averages 8 to 12 months.

Endometriosis of the Lung and Pleura

This is a very rare condition characterized by extragenital deposits of endometrial tissue on the visceral or parietal pleural surfaces. Symptoms of hemoptysis and pleuritic chest pain tend to be cyclical and more pronounced during menses. Some cases have been associated with recurrent pneumothorax and hemorrhagic pleural effusions, with endometrial cells in the pleural fluid samples. One theory proposes that hormonally active endometrial implants obstruct small bronchioles, resulting in bulla formation. Treatment with synthetic androgens or gonadotropin-releasing hormone agonists may be useful.

TUMORS OF THE CHEST WALL

Tumors may originate in the soft tissue (skin, subcutaneous tissue, muscles, nerves, and blood vessels) or in the bony skeleton of the thoracic cage. Signs and symptoms depend on the location, size, and degree of malignancy of the neoplasm. In general, chest wall tumors usually present as a slowly enlarging mass causing localized, dull pain. Radicular pain indicates intercostal nerve involvement. Occasionally, an asymptomatic mass is palpated by the patient or seen incidentally on a routine chest x-ray. A chest wall tumor also may project inward and involve the lung as it expands. Approximately 60% of chest wall tumors are malignant.

Benign tumors include chondroma, fibrous dysplasia, osteoblastoma, eosinophilic granuloma, lipoma, giant-cell tumor, fibroma, neurofibroma, osteochondroma, desmoid tumor, hemangioma, cystic hygroma, lymphangioma, and pigmented nevus. Aneurysmal bone cysts are benign lesions found in the ribs but are generally thought to represent a nonneoplastic response to injury. Malignant tumors include fibrosarcoma, chondrosarcoma, solitary plasmacytoma, Ewing's sarcoma,

liposarcoma, osteogenic sarcoma, reticulum cell sarcoma, rhabdomyosarcoma, hemangiopericytoma, and melanoma.

It should be noted that 40% to 50% of chest wall tumors are metastatic in origin. Tumors of the genitourinary tract, thyroid, colon and soft tissue sarcomas are particularly likely to spread to the chest wall. Also, the chest wall may be invaded by direct extension from intra- and extrathoracic tumors such as a superior sulcus tumor, bronchogenic carcinoma, breast carcinomas, and pleural mesotheliomas.

The evaluation of patients with a chest wall tumor should include conventional chest radiographs as well as computed tomography. The latter is particularly important in delineating the pleural, mediastinal, and pulmonary involvement of the lesion. Bone scans should be performed if metastatic disease is suspected. There is little utility in fine-needle or incisional biopsy for primary chest wall lesions, as the tissue is usually insufficient for diagnosis. Exceptions include Ewing's sarcoma and plasmacytoma, where chemotherapy and/or radiation may be the primary therapy.

Benign Tumors

Chondromas, also known as enchondromas, are the most common benign lesions of the chest wall, occurring at the costochondral or sternochondral junctions. They usually present between the ages of 35 and 55. These tumors are rubbery and multicystic, with a gelatinous center. On x-ray, the medullary mass thins but does not penetrate the cortex. These tumors may undergo malignant degeneration into chondrosarcomas. Hence, radical excision is warranted.

Fibrous dysplasia (osteitis fibrosa) accounts for approximately 15% of benign chest wall tumors. They are usually situated in the posterior or lateral rib. The rib appears locally expanded and filled with small cysts (Fig. 23). This tumor can become very large and may be locally aggressive. Histologically, the lesions consists of fibrous tissue and incompletely mineralized bone lacking a rim of osteoblasts (Fig. 24). Pathologic fractures are common. Osteochondroma is a small, hard, painless tumor. In the rib it appears as an excrescence of cartilage with a cap projecting out of the rib. Lipomas are usually found superficially in the chest wall. Neurofibromas occur as isolated sessile or pedunculated skin tumors or as part of generalized neurofibromatosis (von Recklinghausen's disease).

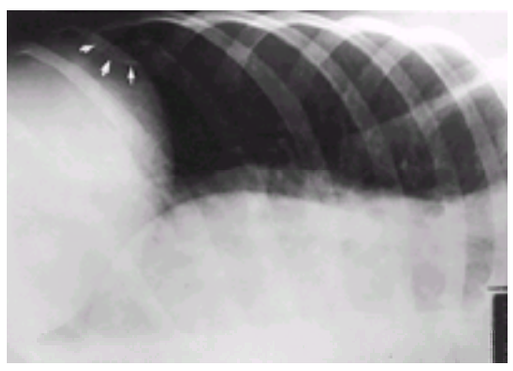

FIG. 23. Standard x-ray film of the rib showing fibrous dysplasia *(arrows).* The cortex is expanded, and a lytic core is prominent.

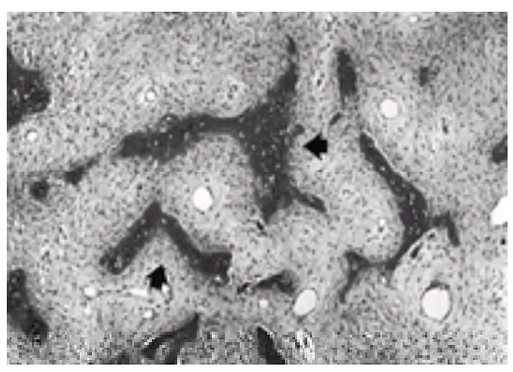

FIG. 24. Fibrous dysplasia showing the characteristic “Chinese characters” pattern *(arrows)* of bone formation. A background of bland fibrous reaction has replaced the marrow tissue (H&E stain, ×250). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

Osteoblastoma is a benign lytic lesion originating in the medulla of bones, affecting the ribs in 4% of cases. The great majority occur in patients less than 30 years of age. Characteristically, CT scans show a lytic lesion with a thin bony shell that concentrates technetium on bone scans (Fig. 25). Abundant osteoblasts and giant cells may be present on light microscopy (Fig. 26). Surgical removal is the treatment of choice.

FIG. 25. Technetium bone scan of osteoblastoma involving the right ninth rib.

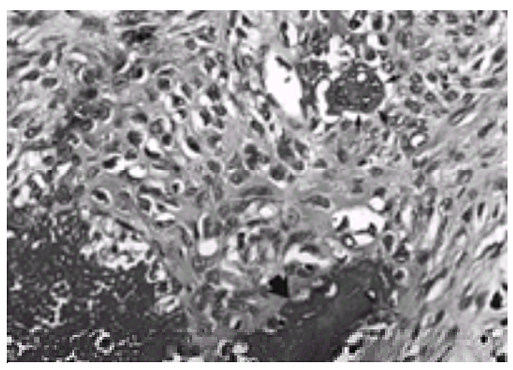

FIG. 26. Osteoblastoma, characterized by osteoblasts, prominent giant cells *(small arrows),* and oteoid formation *(large arrow)* (H&E stain, ×500). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

Eosinophilic granulomas are well-defined lytic lesions that can occur in the ribs. They represent 10% of benign chest wall lesions. These tumors are composed of histiocytes and eosinophils with occasional giant cells, fibroblasts, and plasma cells. Surgical resection is curative, although radiation therapy can be effective in poor-risk patients.

Desmoid tumors are slow-growing hard masses occurring most often in the soft tissues of the abdomen and extremities; approximately 20% to 50% have been reported on the chest wall. Women are affected more frequently than men. These tumors are low-grade fibrosarcomas but lack cellular pleomorphism and mitotic activity. Because tumor cells tend to infiltrate along muscle bundles, recurrence after surgical resection is a significant problem, averaging 30%. Low-dose radiotherapy can control local recurrences.

Cystic hygromas originate in the neck but may extend into the axilla. *Lymphangiomas* are more extensive, growing through the muscles of the chest wall into the mediastinum and lung. They cause pleural effusions and, occasionally, chylothorax (for which thoracic duct ligation may be required). *Hemangiomas* are seen in infancy and early childhood and spontaneously regress after the first 2 years of life.

Malignant Tumors

Fibrosarcomas usually occur in young adults, frequently near the scapula. It is the most common soft-tissue sarcoma of the chest wall and may account for 20% to 50% of all malignant chest wall neoplasms. These tumors are slow growing and metastasize to regional lymph nodes and to the lungs. Wide local resection is the treatment of choice, although local recurrence may develop in a significant number of patients. Prognosis depends on the grade of the tumor; in general, a 5-year survival rate of 50% to 60% can be expected for low-grade lesions. For high-grade lesions, large tumors, and for incomplete resection, the addition of adjuvant chemotherapy and/or radiotherapy may be beneficial.

Chondrosarcoma is the most common chest wall neoplasm. In order of frequency, these tumors are found in the ribs, scapula, and sternum. Most patients are over 40 years of age. A presumptive diagnosis can often be made radiographically, with the finding of a large, lobulated mass with poorly defined margins and cortical bone destruction. Mottled calcification of the mass is commonly seen. These are indolent lesions characterized by slow growth and local recurrence (Fig. 27). Patients with recurrent tumors often have metastatic disease involving local lymph nodes and the lung. Prognosis depends on tumor size, location, and grade as well as the extent of primary resection. Complete resection should achieve a 60% to 70% 5-year survival rate. Incomplete resection and/or recurrence is ominous, as there is no effective role for chemotherapy or radiation.

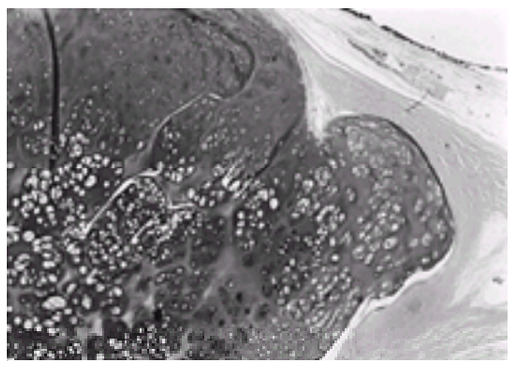

FIG. 27. Chondrosarcoma showing a lobular tumor with a hypercellular matrix (H&E stain, ×250). (Courtesy of Dr. Gordon Honda, Department of Pathology, University of California, San Francisco.)

Solitary *plasmacytomas* are uncommon in general but account for approximately 30% of malignant chest wall neoplasms. Most patients complain of a mass or pain in the ribs, and the characteristic radiographic finding is that of a punched-out, lytic lesion. Grossly and microscopically, this disease is indistinguishable from multiple myeloma. Local control of solitary plasmacytoma can be achieved with radiotherapy or chemotherapy in the majority of patients, with an expected 5-year survival of 40%. However, most patients will eventually develop multiple myeloma, which is usually fatal despite chemotherapy.

Ewing's sarcoma occurs during the first three decades of life and involves ribs, scapula, clavicle, or vertebrae. Approximately 7% will involve the ribs primarily. The disease usually presents as a painful mass and is associated with fever and leukocytosis. X-rays typically show evidence of rib destruction or bone lysis. Occasionally, there is widening and sclerosis of the bony cortex with multiple layers of new bone formation, producing an “onion peel” appearance. Histologically, Ewing's sarcoma requires electron microscopy to distinguish it from other round-cell tumors such as neuroblastoma and lymphoma. Disease located primarily in the chest wall is more aggressive than primary tumors of the extremities, probably because of a higher incidence of metastatic disease at presentation. Treatment for isolated rib lesions is surgical resection; combination chemotherapy and radiation has been used successfully for more advanced lesions. Five-year survival rates of 50% have been recently reported.

Osteogenic sarcoma is one of the rarest tumors of the ribs or sternum. Patients usually complain of a painful mass, and a significant number have received previous radiation for treatment of other diseases. The x-ray typically shows dense cortical sclerosis with radiating calcified subperiosteal spicules, producing a “sunburst” effect (Fig. 28). Thirty percent of patients will have synchronous metastases, usually to the lung. The overall 5-year survival following surgical resection for primary chest wall lesions is 15%. Adjuvant chemotherapy may improve survival.

FIG. 28. Osteosarcoma of the rib showing the classic “sunburst” pattern.

Rhabdomyosarcomas are rare and highly malignant. The tumor spreads along fascial planes and metastasizes early by hematogenous spread. It is resistant to irradiation; surgical resection should be combined with adjuvant chemotherapy to achieve the best survival. *Liposarcomas,* in contrast to benign lipomas, which are superficial, tend to develop in deep fascial planes. Resection of low-grade lesions is followed by excellent survival. *Reticulum cell sarcoma* and *hemangiopericytoma* occur extremely rarely in the chest wall.

The mainstay of treatment of malignant tumors of the chest wall, especially fibrosarcomas and chondrosarcomas, is wide local excision. Maintaining 4-cm margins around the tumor will provide the lowest recurrence rates and best survival. Tumors of the sternum should all be regarded as malignant. In lesions involving the manubrium, the head of the clavicle and costal cartilages also should be removed. Reconstruction of large chest wall may be accomplished by the use of muscle flaps, myocutaneous flaps, rib grafts, Marlex mesh, and molded acrylic plates. Operative mortality is less than 5% in most series, and there is little effect on pulmonary function.

TUMORS OF THE DIAPHRAGM

Although the diaphragm is frequently invaded by tumors arising from adjacent stomach, esophagus, liver, colon, ribs, and vertebrae, primary tumors of the diaphragm are extremely rare. Fewer than 100 cases have been reported; of those, approximately 60% are malignant.

Benign tumors include lipoma, fibroma, mesothelioma, angiofibroma, neurofibroma, and neurilemmoma. Congenital and acquired cysts also have been found in the diaphragm.

Malignant tumors are primarily of mesenchymal origin: fibrosarcoma (most common), liposarcoma, rhabdomyosarcoma, and neurogenic sarcomas. A few leiomyosarcomas have also been reported.

Benign lesions are usually asymptomatic. Malignant lesions give rise to pain in the lower chest and flank. Phrenic nerve involvement causes cough, hiccups, and shoulder pain. Large tumors may produce dyspnea. Clubbing has occasionally been noted.

The differential diagnosis includes peripheral pulmonary parenchymal tumors, an elevated portion of hemidiaphragm, loculated subpulmonic pleural effusions, and hiatal hernia. A subdiaphragmatic mass may indent a portion of the diaphragm, which consequently protrudes superiorly simulating a tumor of the diaphragm itself.

Diagnostic tests to differentiate among these entities include CT scan and artificially induced pneumothorax and pneumoperitoneum. Computed tomographic scanning is particularly useful in diagnosing lipomas, which have a very low specific coefficient of attenuation.

Diaphragmatic tumors should be excised. The resulting diaphragmatic defect can be repaired either directly with sutures or with a prosthetic patch, if necessary.

CHAPTER

71 Extrapulmonary Syndromes Associated with Tumors of the Lung

Catherine B. Niewoehner

C.B. Niewoehner: Endocrinology and Metabolism Section, VA Medical Center, and Department of Medicine, University of Minnesota, Minneapolis, Minnesota 55455.

INTRODUCTION

In 1928, Brown described unexpected adrenal hyperactivity in a bearded woman with diabetes who had an oat-cell carcinoma of the lung. Clearly, she had a tumor producing adrenocorticotropin (ACTH). More case reports of hormone activity associated with lung cancer followed, but it was not until 1941 that Albright and Reifenstein suggested a possible mechanism for the association. They proposed that tumors secrete hormone-like substances producing clinical syndromes. This was confirmed 20 years later when high ACTH concentrations were discovered in the plasma of patients with adrenal hyperactivity and bronchogenic carcinoma. Syndromes resulting from production of unexpected or “inappropriate” substances by tissues not normally associated with hormone production were termed ectopic hormonal syndromes.

Initially, ectopic hormone secretion was thought to be a rare event, but now we know that peptide hormone production is characteristic of all cancers and that these peptides are produced by the normal tissues from which the tumors are derived. Increased peptide hormone production by lung neoplasms is quantitatively abnormal but not truly ectopic. Many of the hormones are secreted as inactive large-molecular-weight polypeptide precursors because of either abnormal posttranslational modification or an alternative process of secretion. Recognizable clinical syndromes result only if neoplastic tissue is able to metabolize the precursor to a bioactive hormone.

Lung cancers, particularly small-cell carcinomas and bronchial carcinoid tumors, have the highest reported incidence of tumor expression of neuroendocrine peptides. However, evidence that a circulating hormone is actually produced by the tumor often is not available. Criteria for establishing tumor hormone production are (1) the presence of both the tumor and a hormonal syndrome or elevated blood or urine concentration of the hormone; (2) failure of normal feedback mechanisms to suppress hormone levels in plasma or urine; (3) demonstration of the polypeptide in tumor tissue or tissue extracts; (4) increasing hormone concentrations across the tumor capillary bed; (5) decreased hormone concentrations if therapy directed toward the tumor is successful; (6) demonstration of hormone synthesis and release by the tumor *in vitro;* (7) cell-free translation of tumor peptide messenger RNA; and (8) exclusion of other sites of significant hormone production. An invasive procedure and a research laboratory are required to obtain tissue and perform the analyses to fulfill these criteria.

It is unlikely that hormone production by tumors occurs as a result of random activation of areas of the genome that normally are repressed. This concept does not account for the strong association of some hormonal syndromes with specific lung and other carcinomas. Baylin and co-workers developed an elegant model suggesting that the different types of bronchogenic carcinoma arise through a continuum of differentiation events occurring in cells of common cellular origin. The less differentiated cells secrete many peptide hormones and growth factors, whereas more differentiated cells, which are more rigorously regulated, secrete only a few.

The true incidence of hormone production associated with lung carcinomas is difficult to determine for many reasons. Surveys probably reflect the minimum incidence. Tumors secrete peptides sporadically. Changes in tumor metabolism and peptide production occur with time, but tumor markers frequently are measured only once. Metastases may produce peptides that are different from those in the primary neoplasm. Excess hormone secretion frequently occurs only in response to a stimulus, and provocative tests for hormone responsiveness usually are not done. Finally, the presence of a hormone usually is assessed by radioimmunoassay, and the antibodies used vary from laboratory to laboratory.

Many tumors produce an array of peptide hormones, and no peptide is specific for a given bronchogenic carcinoma. This is as expected if different neoplasms arise from common precursors. Fluctuations in the concentration of peptides elaborated by bronchogenic carcinomas sometimes reflect the clinical course of these tumors, but not always. Peptide production may be better correlated with the state of tumor differentiation than with tumor mass, but changes in tumor peptide concentrations can signal changes in tumor metabolism or malignant potential. It is important to recognize hormone-induced extrapulmonary syndromes to avoid unnecessary procedures and to provide appropriate treatment.

HORMONAL AND METABOLIC SYNDROMES

Adrenocorticotropin and Cortocotropin-Releasing Hormone

Gewirtz and Yalow were the first to show that tissue extracts from lung carcinomas of all types contain a large-molecular-weight, biologically inactive form of ACTH (pro-ACTH) that can be converted to bioactive ACTH. Normal lung and all lung carcinomas also contain the precursor peptide proopiomelanocortin (POMC) and its component peptides: pro-ACTH and b-lipotropin, a hormone with weak lipotrophic and melanocyte-stimulating activity. In normal lung the concentration of POMC mRNA is only 0.008% to 0.08% of that in the pituitary gland, and smaller forms of POMC mRNA predominate. These do not code for a signal sequence, so the POMC peptides cannot be secreted. The ACTH concentration in normal lung is only 0.000003% to 0.00005% of that in the pituitary gland. However, lung carcinomas contain larger amounts of full-length POMC mRNA and can secrete enough POMC-derived peptides to produce clinical syndromes. The POMC also is cleaved to melanocyte-stimulating peptide fragments, b-endorphin, and corticotropin-like intermediate-lobe peptide (CLIP), which has no known function.

Why so many tumors, especially lung carcinomas, produce excess pro-ACTH, ACTH, and other POMC-derived peptides remains an enigma. Luster and co-workers found that the ACTH produced by a small-cell carcinoma induced an increased rate of growth of the tumor *in vitro* and suggested that ACTH might play an autocrine role. If so, it might be important to suppress tumor ACTH as early as possible.

Some patients with high plasma ACTH concentrations have no clinical manifestations, even though morning cortisol concentrations are high and the normal diurnal variation of cortisol is absent. Plasma 11-deoxycorticosterone and dehydroepiandrostenedione sulfate concentrations and urinary free cortisol, 17-hydroxysteroids, and 17-ketosteroids are increased as well. Either the circulating cortisol concentrations are not high enough to produce symptoms or death ensues before there is sufficient time for symptoms and signs of hypercortisolism to develop.

Other patients with ectopic ACTH production are markedly symptomatic. Most of these patients have small-cell carcinoma or bronchial carcinoid tumors. The classic signs of Cushing's seldom occur in patients with small-cell carcinoma because progression of the disease is so rapid. Because the effects of high ACTH on electrolyte flux develop more rapidly than the effects on lipid and carbohydrate metabolism, these patients present with weight loss, severe proximal muscle weakness, pretibial and ankle pitting edema, polyuria, and hypokalemic alkalosis (serum bicarbonate usually $^{3}30$ mmol/liter and pH ^{3} 7.45), which may be very resistant to treatment. Hyperpigmentation (Fig. 1) is the result of the excess lipotropin or the melanocyte-stimulating fragments of POMC. Cortisol excess fosters opportunistic infections, which frequently are fatal, and also is responsible for the poor response to chemotherapy, even in patients who are not neutropenic. In patients with small-cell carcinoma, the prognosis is terrible.

FIG. 1. (A) This patient with carcinoma of the lung complained of darkening of the skin. Note the hyperpigmentation under his eyes and around his mouth. **(B)** His chest film revealed an area of infiltration along the left cardiac border. Scalene node biopsy was positive for anaplastic carcinoma. The patient had increased 17-ketosteroids, total 17-ketogenic steroids, and 17-hydroxycorticosteroids but no clinical Cushing's syndrome. **(C)** Small-cell anaplastic carcinoma arising in the left lower lobe bronchus was found at postmortem examination. Note the marked variation in the size and shape of the deeply staining nuclei (×450).

Patients with more slowly progressive bronchial carcinoid tumors do develop classic features of Cushing's syndrome, including moon facies, truncal obesity, purple abdominal striae, hirsutism, psychosis, hypertension, edema, osteoporosis, and hyperglycemia (Fig. 2). Differentiating pulmonary tumor ACTH production from pituitary tumor ACTH production in these patients can be difficult. Plasma ACTH and cortisol concentrations usually are not suppressed by high-dose dexamethasone administration in patients with lung cancers, but partial suppression can occur with carcinoid tumors. Ectopic ACTH-producing tumors usually do not respond to corticotropin-releasing hormone (CRH), and serum 11-deoxycortisol levels usually do not rise after metyrapone administration, but there are exceptions. Because excess CLIP is produced by lung carcinomas but not by pituitary tumors, the CLIP/(CLIP + ACTH) ratio could be used to confirm ectopic origin of the ACTH if the CLIP assay were readily available.

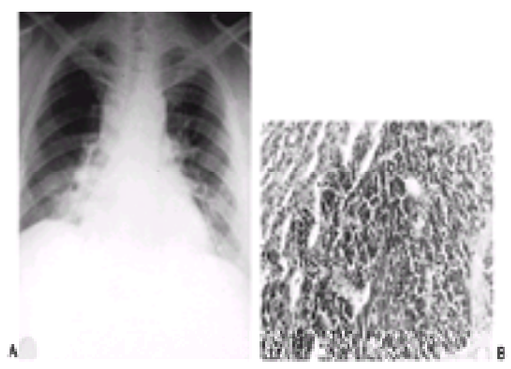

FIG. 2. (A) Chest roentgenogram showing an area of increased density along the right cardiac border. The patient was a 34-year-old man with truncal obesity, edema, hypertension, hypokalemic alkalosis, polycythemia, and the typical urinary steroid values of Cushing's syndrome. **(B)** A liver biopsy was obtained at abdominal exploration. A large nest of anaplastic carcinoma cells metastatic from the lung is seen adjacent to cords of liver cells (×450).

Occasional patients with bronchial carcinoid tumors develop Cushing's syndrome because of tumor CRH, which induces pituitary hyperstimulation and bilateral adrenal hyperplasia. These tumors are even more difficult to differentiate from pituitary adenomas by biochemical testing than are carcinoids producing ACTH.

In several series of patients with Cushing's syndrome secondary to small-cell carcinoma, the only ones who achieved a remission were those in whom cortisol levels were controlled before chemotherapy was begun. Inhibitors of steroid biosynthesis such as ketoconazole, metyrapone, and aminoglutethimide can be used to treat Cushing's, but all have serious side effects. Patients with small-cell carcinoma usually require high doses of these drugs, sometimes in combination. RU-486, a drug that blocks steroid action at the receptor level, has been used successfully. The adrenocorticolytic drug *o',p'*-DDD is not useful because its onset of action is slow, and several weeks is required to control cortisol secretion. Potassium and spironolactone can be given to control hypokalemia.

The same drugs can be used for patients with Cushing's syndrome caused by the more indolent carcinoid tumors; smaller doses or drug combinations are required in those individuals. The somatostatin analog octreotide also has been used for these patients, although paradoxic increases in ACTH following octreotide and lanreotide, the slow-release somatostatin analog, have been reported. There is one report of carcinoid tumor ACTH suppression by bromocriptine. Bilateral adrenalectomy is effective if medical therapy fails.

Antidiuretic Hormone (Arginine Vasopressin) and Atrial Natriuretic Factor

Winkler and Cranshaw described a patient with the combination of lung cancer, hyponatremia, and excessive urinary sodium loss in 1938. Twenty-two years later, Schwartz and colleagues observed that despite an increased extracellular fluid volume and hypotonic plasma, the urine of similar patients was hypertonic. They proposed that the fluid and electrolyte imbalance seen in these patients was a consequence of inappropriate secretion of antidiuretic hormone (ADH; also arginine vasopressin, AVP). Since then, inappropriately elevated ADH concentrations have been found in 50% to 68% of patients with small-cell carcinoma and somewhat less

often with other types of lung cancer. Inappropriate ADH secretion may precede evidence of the tumor mass by several months. The highest and most persistent ADH concentrations occur in patients with extensive or rapidly progressing tumors. Pituitary ADH is stored attached to another polypeptide, a neurophysin, and the two peptides are secreted together. Tumor neurophysin is detectable in only 70% of patients with small-cell lung cancer. Radioactive neurophysin antibodies are being tested to see if they can be used for localizing tumors or to follow the response to therapy.

The clinical response to tumor-produced ADH depends on the degree of water loading and other therapies. Hyponatremia is also exacerbated by chemotherapy, particularly cyclophosphamide, radiation therapy, or prostaglandin inhibitors (prostaglandins of the E_2 series are inhibitors of ADH action). Most patients are asymptomatic if the serum sodium is at least 120 mmol/L, and no treatment is necessary. If the serum sodium falls below 120 mmol/L, patients are likely to develop headache, lethargy, generalized weakness, confusion, and somnolence. If severe hyponatremia develops rapidly, patients may present with nausea and vomiting. When the serum sodium falls below 110 mmol/L, the risk of seizures, hypothermia, coma, and death increases markedly.

Fluid restriction to an intake less than insensible water loss often restores the sodium concentration. If the hyponatremia is severe, hypertonic saline infusion can be coupled with furosemide administration and replacement of urinary electrolyte losses until the serum sodium concentration increases. Demeclocycline, which produces reversible ADH resistance, can be added if fluid restriction alone is not sufficient. Lithium also produces nephrogenic ADH resistance, but the side effects of lithium are greater, and the effects, which may be permanent, are unpredictable.

Lung cancer patients with hyponatremia also have abundant atrial natriuretic factor (ANF). It is usually impossible to determine whether tumor production of ANF is the primary cause of the hyponatremia or whether ANF is increased in response to an expanded plasma volume caused by inappropriate ADH.

Calcium Metabolism and Bronchogenic Carcinoma: Humoral Hypercalcemia of Malignancy

Hypercalcemia without evidence of bony metastases is associated with solid tumors of many kinds. The syndrome is known as “humoral hypercalcemia of malignancy” (HHM). In the lung, HHM is associated most often with squamous cell tumors and sometimes with adenocarcinomas and bronchial carcinoid tumors. Most hypercalcemia associated with small-cell carcinoma probably reflects unidentified bone metastases or concomitant parathyroid hyperplasia or adenoma.

The hypercalcemia results primarily from increased bone resorption relative to bone formation, and increased renal tubular resorption of calcium contributes also. In patients with lung cancer, these usually are caused by tumor production of parathyroid hormone-related protein (PTHrP). Eight of the 13 amino acids of the N-terminal region of PTHrP and parathyroid hormone (PTH) are identical, and the two hormones bind to the same receptors; the remaining structure of each is unique. The function of PTHrP in normal tissues is unknown. Concentrations are especially high in epidermis, breast milk, and amniotic fluid, so PTHrP might be an important regulator of fetal calcium homeostasis. PTHrP increases osteoclast activity, bone resorption, nephrogenous cyclic AMP, and renal phosphate wasting just as PTH does but has less effect on renal calcium retention. PTHrP does not activate the renal hydroxylase that converts 25-hydroxyvitamin D to the active 1,25-dihydroxyvitamin D, so intestinal calcium absorption is decreased in HHM.

Most patients with mild hypercalcemia are asymptomatic. Even serum calcium concentrations of 3.0 to 3.25 mmol/L (12 to 13 mg/dl) or more often are associated with surprisingly mild anorexia, constipation, myalgias, or lethargy. Patients with decreased mobility and patients receiving chemotherapeutic drugs toxic to bone cells have increased bone resorption and are at high risk for worsening hypercalcemia, as are patients with fever, anorexia, or vomiting who become dehydrated. If hypercalcemia is severe, patients develop nausea and vomiting, abdominal pain, polyuria, dehydration, and weakness and become confused or obtunded. Patients with bronchogenic carcinoma who have a serum calcium ³2.63 mmol/L (³10.5 mg/dl) are likely to have large tumor masses and a poor outcome. Symptoms improve with treatment, but median survival is only 4 to 6 weeks. Patients do not live long enough to develop band keratitis, uremia, and renal calculi.

Patients with HHM have high ionized serum calcium levels, hypercalciuria, low serum phosphorus, and low or low-normal PTH levels because PTH is suppressed when plasma calcium is high. It is usually unnecessary to order a PTHrP level because the malignancy is obvious, and a good history and the low PTH level eliminate most other causes of hypercalcemia. Plasma levels of 1,25-dihydroxyvitamin D are low or low normal.

If rapid treatment is required, intravenous saline and furosemide lower serum calcium acutely. Dietary calcium restriction, oral phosphate, glucocorticoids, and indomethacin are effective only transiently, if at all. This is not surprising because calcium absorption from the gastrointestinal tract is decreased in HHM, and prostaglandins are not responsible for the hypercalcemia. The effect of calcitonin is short-lived (24 to 48 hr), perhaps because of down-regulation of receptors. Mithramycin (plicamycin) inhibits osteoclastic bone resorption, but its use is limited by renal and hepatic toxicity and bone marrow suppression.

Bisphosphonates are potent inhibitors of osteoclast activity by mechanisms that are still uncertain. When they are given intravenously to patients with HHM, the plasma calcium concentration begins to fall within 48 hr; the calcium nadir is reached at 5 to 7 days. In good responders, normocalcemia can persist for 14 to 30 days. Two bisphosphonates that are available at the present time are etidronate disodium and pamidronate. Pamidronate is more effective than etidronate disodium (normocalcemia in 70% versus 41% and longer duration of action). Slight fever (1°C), asymptomatic hypocalcemia, hypophosphatemia, hypomagnesemia, and small increases in creatinine occur transiently in some patients.

Gallium nitrate also inhibits bone resorption and has been shown to lower serum calcium when administered as a continuous infusion with concomitant hydration and diuresis. Gallium nitrate also is more effective than etidronate disodium (normocalcemia in 82% versus 43%, median duration 8 days versus 0 days).

Oncogenic Osteomalacia: Renal Phosphate Wasting

The association of renal phosphate wasting, osteomalacia with bone pain, muscle cramps and weakness, and cancer has been known for many years. Patients with oncogenic osteomalacia also have a 1,25-dihydroxyvitamin D deficiency. Usually oncogenic osteomalacia occurs with small mesenchymal tumors, which are notoriously difficult to locate, but it has been found in several patients with small-cell carcinoma of the lung. All of these patients had marked hypophosphatemia with renal phosphate wasting (low tubular resorption of phosphorus and TmP/GFR), inappropriately low or low-normal 1,25-dihydroxyvitamin D concentrations, elevated alkaline phosphatase, and osteomalacia or increased osteoid on bone biopsy.

The biochemical picture is very similar to that of X-linked hypophosphatemic rickets. Tumor production of a substance that causes proximal renal tubule phosphate wasting and inhibition of renal 25-hydroxyvitamin D 1a-hydroxylase is thought to be responsible. A substance with these properties that is heat labile, lipid insoluble, and presumed to be a peptide has been found in tumor extracts. The substance is not PTH or a PTH-related protein, even though tumor extracts stimulate PTH-responsive renal adenylate cyclase. Serum calcium is normal or only slightly decreased; this substance may not react with bone receptors. Serum 25-hydroxyvitamin D and calcitonin levels are normal too.

Renal phosphate handling improves only if chemotherapy induces a remission. Patients may have a partial response to calcium, phosphate salts, and 1,25-dihydroxyvitamin D.

Calcitonin and Calcitonin Gene-Related Peptide

Calcitonin inhibits bone resorption and decreases renal tubular resorption of calcium and phosphorus, but the precise role of calcitonin in normal human physiology is unknown. The highest concentration of calcitonin is found in the parafollicular cells of the thyroid gland, but calcitonin is produced by neuroendocrine cells in many tissues. Indeed, the lungs contain more calcitonin than the thyroid gland. Serum and urine calcitonin levels are increased in smokers and in chronic COPD, and calcitonin has been found in extracts of neoplasms of all types, particularly small-cell carcinoma of the lung. An increased serum calcitonin response to pentagastrin has been described in lung cancer patients whose basal calcitonin concentrations were normal. Both serum and urine calcitonin concentrations correlate positively with lack of tumor differentiation and increased disease activity. Calcitonin concentrations are decreased in patients who respond to therapy and are increased in association with relapse or tumor progression.

Alternative intranuclear splicing of calcitonin mRNA yields either calcitonin or calcitonin gene-related peptide (CGRP), which is a potent vasodilator and is found in pulmonary neuroendocrine cells. The CGRP messenger RNA has been detected in lung tumor cell lines by several groups but may not be produced by lung tumor cells *in vivo.*

No adverse clinical consequences of calcitonin or GCRP production by bronchogenic carcinoma are known. Patients do not develop diarrhea, and serum calcium, inorganic phosphate, and vitamin D concentrations remain normal.

Gonadotropins

Human chorionic gonadotropin (HCG) was once thought to be a specific marker for tumors derived from trophoblast tissue. However, HCG has been found in extracts

from a wide range of normal tissues, including the lung, and in extracts of all types of carcinomas. At least three different HCG-related molecules can be measured in lung cancer patients who have high immunoreactive serum HCG: intact HCG, free HCG b subunit, or HCG b core fragment (b-CF). Only 12% to 30% of lung cancer patients have high serum HCG, and the HCG concentration does not reflect the extent of disease. Because tumor HCG is poorly glycosylated, secreted HCG may be degraded too rapidly to be measured in most patients. Approximately 50% of patients with lung cancers of all types have elevated levels of b-CF in their urine whether or not serum values are high. The more advanced cases are more likely to have high urine b-CF, but even with stage IV cancers, urine b-CF was elevated only 72% of the time.

In one series of patients with lung cancer and high serum HCG, testosterone levels actually were lower in the cancer patients than in the control group. Estrogen concentrations were not measured in that study, although increased estradiol concentrations, which correlated with tumor mass and HCG concentration, were reported by another group. None of the male patients in the series had gynecomastia, although gynecomastia has been found in other patients with lung cancers producing HCG. Gynecomastia is very common in men over 50 years of age and is correlated with body weight. Because gynecomastia usually is not measured as part of the routine physical examination, it is difficult to determine whether the gynecomastia reported in lung cancer patients is of recent onset and whether its absence reflects weight loss secondary to disease. Tumor HCG is not suppressed by administration of androgens, estrogens, or progestins.

There is one case report of a step up in the arteriovenous gradient of FSH but not LH across a bronchogenic carcinoma capillary bed. Serum concentrations of both FSH and LH were elevated before tumor resection and decreased postoperatively. In all other cases in which lung tumors have been associated with gonadotropin production, either the gonadotropin proved to be HCG or the immunoassay was not sufficiently specific that cross-reactivity with HCG could be excluded.

Human Placental Lactogen and Prolactin

Increased serum levels of human placental lactogen (HPL) and prolactin have been found in a few patients with bronchogenic carcinoma, but no clinical concensequences of either HPL or prolactin have been reported.

Hormones Regulating Growth

Small amounts of human growth hormone (HGH) are found in all normal human tissues and in extracts of lung carcinomas of all histologic types. Growth hormone-releasing hormone (GHRH)-producing bronchial carcinoid tumors can produce classic acromegaly. The clinical features and the pattern of HGH secretion are the same whether the GHRH comes from the hypothalamus or the lung. Many patients with carcinoid tumor secretion of GHRH have an intrasellar mass. Clinical improvement of acromegalic features in soft tissues occurs after carcinoid tumor resection. Treatment with chemotherapy (CCNU and 5-fluorouracil), bromocriptine, or the somatostatin analog octreotide have been reported to decrease circulating GHRH, HGH, and somatomedin-C concentrations and to reduce symptoms and signs of acromegaly. These treatments may not affect the size of the tumor mass.

Somatostatin is a tetradecapeptide that inhibits release of many hormones, including growth hormone. Somatostatin is found in all bronchial carcinoid tumors and in 25% to 40% of small-cell carcinomas. Paracrine and autocrine effects of tumor somatostatin such as inhibition of local growth factors or bombesin-like peptides have been proposed. No clinical sequelae of tumor somatostatin production are known.

Initially somatostatin receptors were thought to be expressed only in bronchial carcinoid tumors and small-cell carcinomas, but non-small-cell carcinomas and their metastases also express somatostatin receptors, albeit fewer of them. Scintographic labeling of the somatostatin receptor by ^{111}In-pentetreotide cannot be used clinically to identify lung tumor type but has been used to locate small tumor masses.

Gastrointestinal Hormones

Bombesin-Like Peptides

Gastrin-releasing peptide (GRP) has considerable homology with bombesin (BN), a tetradecapeptide first found in amphibians, and also with the slightly smaller peptide neuromedin C. GRP does considerably more than regulate gastrin secretion, and all of these bombesin-like peptides have similar actions. They are modulators of CNS activity, especially in the hypothalamus, and also have a wide range of peripheral actions. They lower body temperature, increase the pain threshold, increase plasma glucose, cause satiety, increase GI motility, and affect respiration in addition to stimulating release of gastrin and glucagon. Peak levels in pulmonary neuroendocrine cells occur shortly after birth, indicating a role for bombesin-like peptides in fetal lung development.

Most small-cell carcinomas produce BN/GRP, although only 5% of patients with small-cell carcinoma have elevated serum levels; BN/GRP also is found in carcinoid tumors and adenocarcinomas. A role for BN/GRP as an autocrine stimulator of small-cell carcinoma growth has been proposed because BN/GRP stimulates clonal growth and DNA synthesis in small-cell carcinoma cell lines. An antibody directed against the BN/GRP binding site prevents growth of tumor cells. No clinical manifestations of BN/GRP produced by a bronchogenic carcinoma are known, but BN/GRP might contribute to cancer patients' anorexia. Gastrin is found in small-cell carcinomas and in bronchial carcinoid tumors, but no clinical consequences are known.

Vasoactive Intestinal Peptide

Vasoactive intestinal peptide (VIP) is another intestinal peptide that actually is a neuropeptide with a wide central and peripheral distribution, structural similarity to a many-peptide family, and multiple actions including regulation of blood flow, relaxation of smooth muscle, and stimulation of electrolyte and water secretion. Patients with small-cell carcinomas with VIP hypersecretion have developed the watery diarrhea–hypokalemia–achlorhydria syndrome usually associated with VIPomas. Stools do not contain blood, mucus, or excess fat. The hypokalemia can produce profound weakness. Acidosis results from loss of bicarbonate in the stool, and hyperglycemia results from the hypokalemia and from VIP-induced liver glycogenolysis. Treatment includes fluid and electrolyte replacement. Prednisone may reduce the volume of diarrhea. Octreotide inhibits VIP secretion and improves symptoms in most cases.

Renin

Most renin-secreting tumors are of renal origin. The renin usually is secreted in the form of a large, inactive precursor, which suggests that the tumor is unable to carry out normal posttranslational processing. However, occasional bronchial carcinoid and small-cell carcinomas of the lung secrete enough active renin to produce hypertension and hypokalemia. The hypertension may be severe, resulting in retinal hemorrhage, and is poorly responsive to treatment, including treatment with b blockers and angiotensin-converting enzyme inhibitors.

Hypoglycemic Factors

Most tumor-associated hypoglycemia occurs in patients with large retroperitoneal tumors, but hypoglycemia has been reported with intrathoracic tumors including bronchogenic carcinoma. Increased glucose utilization by the tumor mass cannot account for the hypoglycemia. In most cases circulating insulin concentrations are low. Insulin-like growth factors (IGF-I and IGF-II) and other peptides with insulin-like bioactivity not suppressible by antibodies directed against insulin are almost never associated with bronchogenic carcinoma. The mechanism responsible for most hypoglycemia associated with bronchogenic carcinoma is unknown. Hypoglycemia usually develops when patients are fasting. Food ingestion may not be sufficient to relieve symptoms in patients with very severe disease.

HORMONAL SYNDROMES ASSOCIATED WITH BRONCHIAL CARCINOID TUMORS

Carcinoid tumors are neuroendocrine tumors that arise from a heterogeneous population of enterochromaffin cells found mostly in the submucosa of the intestine and the bronchi. Carcinoids have been classified according to the part of the primitive gut from which they are derived and by whether or not they reduce silver salts and produce 5-hydroxytryptamine (5-HT). Carcinoid tumors arising in tissues derived from the primitive foregut usually produce 5-HT. They may produce a wide array of peptides and amines and have receptors for numerous peptide hormones and neurotransmitters. Both bronchial carcinoids and small-cell carcinomas contain secretory granules that are typical of polypeptide-secreting endocrine tissues. Carcinoid tumors arising from primitive midgut usually produce 5-hydroxytryptophan (5-HTP), which is converted to 5-HT in other tissues. Tumors arising from the hindgut secrete neither 5-HT nor 5-HTP.

The carcinoid syndrome refers to the clinical manifestations that occur if sufficient quantities of vasoactive substances from the carcinoid tumor reach the systemic circulation.The syndrome is characterized by episodic flushing, diarrhea, paroxysmal bronchospasm, and valvular disease of the right side of the heart. These are attributed to overproduction of serotonin and its metabolites and possibly to prostaglandins and substance P, an undecapeptide distributed in gut and brain. Severe tryptophan depletion may result from excessive diversion of tryptophan into 5-HT synthesis. The carcinoid syndrome occurs in £10% of bronchial carcinoid tumors even though most of them contain 5-HT.

Bronchial carcinoids are remarkable for the number of clinical syndromes resulting from the peptide hormones they secrete. Production of ACTH or corticotropin-releasing hormone or both results in Cushing's syndrome. ACTH and/or melanocyte-stimulating hormone can produce hyperpigmentation (Nelson's syndrome). Secretion of growth hormone or growth hormone-releasing hormone results in acromegaly. Bronchial carcinoid tumors can produce enough parathyroid hormone to cause hypercalcemia, enough ADH to cause hyponatremia, or enough insulin to cause hypoglycemia. Immunoperoxidase staining reveals additional hormones that are not accompanied by clinical syndromes: calcitonin, HCG and its a subunit, gonadotropin-releasing hormone, somatostatin, gastrin, VIP, and bombesin. As many as eight to ten hormones may be found within a single bronchial carcinoid tumor.

Bronchial carcinoid tumors have been classified either as typical carcinoids, which are centrally located, have classic morphologic features, numerous secretory granules, little pleomorphism, and have a benign course, or as atypical carcinoids, which may be peripherally located, are more pleomorphic, have fewer, smaller secretory granules, and are more likely to metastasize. Clinical syndromes resulting from hormone secretion are reported almost exclusively with the atypical tumors.

If the carcinoid tumor cannot be removed, treatment must be directed toward the systemic manifestations. Nicotinamide supplementation may be necessary to counteract tryptophan depletion. The somatostatin analog octreotide is the treatment of choice. It does not reduce tumor size but inhibits flushing, diarrhea, and bronchoconstriction. Flushing occasionally responds temporarily to phenoxybenzamine, and diarrhea may be ameliorated by serotonin antagonists such as cyproheptadine. Response rates are <25% for either single chemotherapeutic agents or combinations; remissions usually last only a few months. Anesthetics, surgery, and chemotherapy can precipitate a carcinoid crisis—severe flushing with hypotension. This can be treated with octreotide or methoxamine or angiotensin. Other pressors should be avoided.

ADDITIONAL PEPTIDE/PROTEIN PRODUCTS OF BRONCHOGENIC CARCINOMAS

Oncofetal Antigens

Several glycoproteins normally are found in high concentrations in the developing fetus but in low concentrations in tissues in adults. Increased carcinoembryonic antigen (CEA) has been found in patients with all types of lung tumors as well as in smokers and in patients with nonneoplastic pulmonary disease. Attempts to use scintographic localization of CEA for tumor location, to use serum CEA concentrations to follow tumor progression, to differentiate benign from malignant pleural effusions, and to differentiate adenocarcinomas from mesotheliomas have usually not been successful in individual patients.

a-Fetoprotein is seldom produced by lung tumors. Immunoreactivity against this antigen is found in less than 3%.

Neuron-Specific Enolase

Neuron-specific enolase (NSE) is found in normal neurons and in neuroendocrine cells, all of which contain secretory granules and store and secrete peptides and biogenic amines. Carcinoid tumors and small-cell carcinomas, which are derived from these cells, contain secretory granules and express NSE. Neuron-specific enolase is elevated in fewer than 15% of patients with other types of lung carcinoma. Trump and co-workers have proposed that NSE might be a useful marker for detection and monitoring of small-cell carcinoma and for separating atypical carcinoid tumors from epidermoid tumors, large-cell tumors, and adenocarcinomas. Levels of NSE have been reported to be correlated with the tumor burden in patients with small-cell carcinoma, and the transient rise in serum NSE following initial chemotherapy is thought to reflect tumor cell destruction.

Additional Proteins

High levels of creatine kinase BB are found in the serum of 25% to 62% of patients with small-cell cancer and correlate with patient survival. Alkaline phosphatase, amylase, thymidine kinase, ferritin, pancreatic oncofetal antigen, calmodulin, b-microglobulin, keratin and other cytoskeletal markers, and calmodulin all have been reported to be elevated in association with bronchogenic carcinoma. However, their presence and levels are too erratic and too nonspecific to allow their use as tumor markers.

NEUROLOGIC SYNDROMES

Denny-Brown first described a sensory neuropathy associated with bronchogenic carcinoma in 1948. Since then, neurologic syndromes accompanying lung cancer, primarily small-cell cancer, have been shown to be more common than previously thought and can involve any part of the central or peripheral nervous system. These disorders often are discovered before the tumor becomes evident, but, unfortunately, unlike the hormonal syndromes, most neurologic syndromes do not remit if the malignancy is removed. There is little correlation between the size of the tumor burden or the rate of progression of the tumor and the severity of the neurologic disease.

Some role for the immune system seems well established, based on a strong association between a neurologic syndrome and a specific antibody in cancer patients but not the controls. Kornguth has proposed that the immunologic response to the tumor initially protects the patient by slowing tumor growth. Paraneoplastic syndromes occur when antibodies to tumor tissue cross-react with neuronal antigens. It is not clear how the antibodies gain access to neuronal cells.

Most paraneoplastic neurologic syndromes do not respond to immunosuppression, plasmapheresis, cancer chemotherapy, or radiotherapy. Even if serum antibody titers are reduced, CSF titers remain elevated, and there is no clinical improvement. Occasional cases with milder syndromes remain stable for months.

Central Nervous System

Paraneoplastic Encephalomyelitis

The umbrella term paraneoplastic encephalomyelitis (PEM) covers limbic encephalitis, brainstem encephalitis, myoclonus-opsoclonus, and cerebellar degeneration. These disorders are characterized by perivascular inflammation as well as neuronal degeneration. Patients present with a variety of psychiatric disorders, memory loss, dementia, and seizures. Brainstem encephalitis may result in ophthalmoplegia, bulbar palsy, involuntary movements, evidence of bilateral pyramidal tract lesions, etc., depending on the location involved. Opsoclonus is characterized by involuntary, chaotic eye movements. Cerebellar disease presents with ataxia and may be mild or severe, localized or diffuse.

Paraneoplastic encephalomyelitis is one of the paraneoplastic syndromes that is associated with antineuronal nuclear antibodies, known as anti-ANNA-1 or anti-Hu antibodies, which bind selectively to neuronal tissue. These antibodies can be found in serum and cerebrospinal fluid in patients with small-cell carcinoma as well as in tumor extracts and tumor cell lines. Whether these are responsible for the development of the neuronal syndromes or are an epiphenomenon is not certain. Paraneoplastic encephalomyelitis is frequently associated with paraneoplastic subacute sensory neuropathy, which is described below.

Paraneoplastic Cerebellar Degeneration

Paraneoplastic cerebellar degeneration (PCD) occurs far more often in association with breast cancer than with small-cell lung cancer. It is associated with specific serum and CSF immunoglobulins that bind to Purkinje cell cytoplasm and proximal dendrites in a characteristic pattern. A group of cerebellar proteins that react with the anticerebellar antibodies has been identified. Neither the proteins or the antibodies have been found in patients with cerebellar degeneration who do not have a malignancy. The gene coding for one of the PCD target antigens has been cloned, and its mRNA identified in cerebellar and tumor tissue. These experiments support the concept that paraneoplastic neurologic syndromes are the end result of cross-reactivity of antibody with shared brain-tumor antigens.

The clinical presentation usually begins with ataxia, and nystagmus, dysmetria, tremor, or dysarthria may develop later. Degeneration of Purkinje cells is diffuse and is coupled with thinning of other molecular layers. In contrast to the cerebellar degeneration associated with anti-Hu antibodies and paraneoplastic encephalitis, in PCD few inflammatory lesions are found.

Cancer-Associated Retinopathy

Cancer associated retinopathy (CAR) is a syndrome characterized by the triad of scotomatous visual field loss, photosensitivity, and retinal arteriolar narrowing, all of which may precede discovery of the small-cell carcinoma. Patients produce circulating antibodies to components of retinal cells and optic nerve. Circulating antibodies primarily recognize the photoreceptor cell protein recoverin. Histologic examination reveals loss of the photoreceptor cell layer. Patients present with rapid visual loss,

color loss, and night blindness. Unlike the other paraneoplastic neurologic syndromes, CAR responds to immunosuppressive therapy, particularly with prednisone.

Necrotizing Myelopathy

Necrotizing myelopathy is a rare paraneoplastic syndrome associated with anti-ANNA-1 or anti-Hu antibodies. The syndrome presents with bilateral loss of motor, sensory, and sphincter function but little pain. Most patients deteriorate rapidly, with ascending paraplegia resulting in death.

Peripheral Nervous System

Subacute Sensory Neuropathy

Subacute sensory neuropathy (SSN), like paraneoplastic encephalitis, is associated with the anti-ANNA-1 or anti-Hu antibodies, and the two syndromes often occur together. Patients develop symmetric numbness and parasthesias, especially in the lower limbs. Painful dysesthesias develop later. Vibration and position sense are most often impaired, but all sensory modalities are involved. Later in the course, patients frequently are unable to walk because of pain and loss of proprioception. Pathologic findings include loss of sensory neurons of the dorsal root ganglia and degenerative changes in the remaining cells. Some investigators suggest serologic testing for anti-ANNA-1 in elderly smokers with a peripheral sensory neuropathy of unknown cause and screening for occult cancer if the antibody is present. However, there is no treatment advantage accompanying early diagnosis.

Peripheral Sensorimotor Neuropathy

A heterogeneous group of sensorimotor peripheral neuropathies may occur alone or in combination with other paraneoplastic neuropathies and may antedate the diagnosis of malignancy. An axonal form is seen most often in patients with small-cell carcinoma. Lower neuron symptoms and signs predominate and are symmetric; symptoms progress at a variable rate. The etiology is unknown.

Autonomic Neuropathy: Chronic Intestinal Pseudoobstruction

Pseudoobstruction is characterized by weight loss, early satiety, nausea and vomiting, gastroparesis, abdominal pain, small and large bowel dilation, and constipation. Some patients have other signs of abnormal autonomic nervous system function. This paraneoplastic syndrome may be present for months to years before the small-cell lung carcinoma is diagnosed. Pseudoobstruction results from degeneration of neurons in the myenteric plexus. Autopsy studies of the gut reveal axonal degeneration, infiltration of plasma cells and lymphocytes, and proliferation of Schwann cells of the myenteric plexus—findings similar to those in other paraneoplastic neurologic syndromes.

Pseudoobstruction is associated with high serum titers of the same antineuronal nuclear antibodies (anti-ANNA-1 or anti-Hu) that are associated with paraneoplastic encephalitis and paraneoplastic subacute sensory neuropathy. In one series very high titers of anti-ANNA-1 were found in four of five patients with small-cell lung cancer with chronic pseudoobstruction but were not found in 29 patients with small-cell cancer without pseudoobstruction or in patients with chronic idiopathic intestinal pseudoobstruction or in other control patients.

Because teatment of the tumor can halt progression of neuronal degeneration or at least its symptoms, the serum anti-ANNA-1 antibody titer seems to be a useful diagnostic tool in cases of unexplained chronic pseudoobstruction. Pharmacologic approaches to increase bowel motility usually fail, so total parenteral nutrition and supportive therapy are the primary treatments. A few patients regain bowel motility, but most do not, and their symptoms do not improve.

Paraneoplastic Vasculitic Neuropathy

Paraneoplastic vasculitic neuropathy (PVN) occurs with both small-cell carcinoma and adenocarcinoma. The syndrome is characterized by an asymmetric sensorimotor peripheral neuropathy. Nerve conduction studies reveal either no response or slowed conduction, indicating axonal disease. In most cases the sedimentation rate is high. In contrast to the other paraneoplastic neurologic syndromes, with which it often occurs, spinal fluid protein is high. The diagnosis is confirmed by nerve biopsy, which reveals microvasculitis and axonal degeneration. Improvement following cyclophosphamide treatment directed against the vasculitis has been reported in only one case.

Neuromuscular Junction Syndromes: Lambert–Eaton Syndrome

The Lambert–Eaton syndrome (LES) is the best understood of all of the paraneoplastic neurologic syndromes. It occurs in 2% to 5% of patients with small-cell lung carcinoma but also occurs with other cancers and is associated with many autoimmune disorders. Patients complain of easy fatigability and weakness, which affect the pelvic girdle and shoulder girdle muscles more than distal strength and bulbar function. Lambert–Eaton syndrome differs from myasthenia gravis because muscle strength improves with exercise, and the response to edrophonium chloride is poor.

A presynaptic defect in the calcium-dependent release of acetylcholine from nerve terminal storage vesicles is the underlying cause of LES. Acetylcholine release requires influx of calcium through voltage-gated channels. In patients with LES, these channels are the targets of IgG autoantibodies. The best evidence that antibodies are the actual cause of LES comes from passive transfer experiments in which the syndrome was transferred to mice by administration of purified IgG from the sera of LES patients with and without a malignancy. Investigators are exploring whether antibodies to specific calcium channel subtypes are the ones most involved.

Patients improve with corticosteroid or other immunosuppressive drug treatment or plasmapheresis.

CONNECTIVE TISSUE AND OSSEOUS SYNDROMES: HYPERTROPHIC OSTEOARTHROPATHY AND CLUBBING

Hypertrophic osteoarthropathy (HOA, Bamberg– Marie syndrome) is a combination of (1) proliferative subperiostitis, primarily along the shafts of long bones; (2) symmetric arthropathy; and (3) increased blood flow in the long bones, digits, nose, and, occasionally, periauricular tissues that is frequently associated with lung malignancies, especially squamous cell carcinoma. Patients develop bone pain and joint pain with swelling and effusions in the elbows, wrists, knees, and ankles. Bone scans show increased uptake in cortices of the affected bones. Radiographic changes occur most often in the tibia and fibula, femur, ulna, and the phalanges (Fig. 3).

FIG. 3. Roentgenogram of knees shows pulmonary hypertrophic osteoarthropathy. Note the periosteal thickening along the distal shaft of the femur and proximal shaft of the tibia and fibula.

This form of HOA often is referred to as secondary hypertrophic pulmonary osteoarthropathy to differentiate it from pachydermoperiostosis or primary HOA. The primary form, a rare familial disorder with the bone features of HOA but not the lung disease or pain, is accompanied by oily, thickened, deeply furrowed facial skin, broadening of the nose, and prominent nasolabial folds; this form is not associated with cancer.

Clubbing of the fingers and toes, which was described by Hippocrates, is a painless, symmetric uniform swelling of the soft tissues at the ends of the digits (Fig. 4). The

earliest changes occur at the base of the nail, where the skin becomes shiny and tense, and the nail rocks more easily on its bed. Later the nail becomes curved, and the angle between the nail and the soft tissues at the base increases to over 180°. At a more advanced stage, soft-tissue hypertrophy develops. The transverse diameter of the distal phalanx is increased (referred to as acropachy), and the digit resembles a drumstick. Histologic examination of the clubbed digits reveals dilated, engorged vessels in the nail bed, edema, and deposition of new collagen.

FIG. 4. A 64-year-old man presented with dyspnea, **(A)** gynecomastia, **(B)** clubbing of the fingers, and tender wrists. **(C)** Roentgenogram of the forearm and wrist shows hypertrophic osteoarthropathy. Note the periosteal thickening of the long bones. **(D)** Chest roentgenogram shows complete atelectasis of the left lung. A scalene node biopsy was positive for anaplastic carcinoma.

Both HOA and clubbing may develop long before the underlying tumor is apparent. Although clubbing almost always accompanies HOA, the reverse is not true. When clubbing does occur with HOA, the time of onset may be quite different, and the severity may not be proportional to the bone and joint changes. It is likely that clubbing results from a different process but one that usually occurs when HOA develops. Both HOA and clubbing respond to removal of the underlying tumor or to radiation or chemotherapy.

The mechanisms causing HOA and clubbing are uncertain. Tumor production of a vasodilator is considered unlikely because studies in dogs and humans have shown that vagotomy alone decreases peripheral blood flow and abolishes HOA. The increased blood flow is thought to be mediated through a reflex arc with afferents traveling via the vagus nerve, but the site and type of receptors mediating this pathway do not appear to involve any of the known chemoreceptor reflexes in the lung. The efferent pathway for the development of HOA is unknown. Vasodilators (i.e., nitric oxide) produced by vascular endothelium in response to nonadrenergic, noncholinergic neurotransmitters may be involved.

Increased estrogen, gonadotropin, and growth hormone secretion have been reported in some but not all patients, and the digital changes of acromegaly are different from those associated with clubbing and HOA.

The inflammatory changes resulting in damage to the microvasculature that have been seen with electron microscopy may be important and may explain the response of HOA symptoms to prostaglandin synthetase inhibitors such as indomethacin and aspirin and to glucocorticoid therapy.

VASCULAR SYNDROMES

Venous Thrombosis

The association of venous thrombosis and malignancy has been reported repeatedly since it was first described by Trousseau in 1868. Thrombosis is associated particularly with mucin-producing adenocarcinomas including those of the lung. Pulmonary embolism is a frequent complication of deep venous thrombosis (DVT); large thrombi also may cause gangrene or priapism. Possible mechanisms for thrombosis include release of procoagulants from tumor cells or monocytes and macrophages, hypercalcemia, dysfibrinogenemia, and decreased antithrombin III in addition to mechanical obstruction by the tumor, thrombocytosis, and increased platelet adhesiveness.

Pulmonary embolism with or without overt deep vein thrombosis may precede appearance of the neoplasm by months or years. One prospective study followed 153 acute DVT patients with no history of previous DVT, obvious risk factors, or cancer. Sixteen percent developed cancer within 2 years. Most of the cancers were detected in those who had a second DVT. Another study that screened patients with a first DVT more aggressively using tumor markers, CT scans, etc., found a 23% incidence of underlying malignancy. The positive predictive value of DVT for cancers of all types is approximately 20%, but only one patient in each series had unsuspected lung cancer. It is not clear what the impact of more aggressive screening and earlier diagnosis would be on survival.

Evaluation for an underlying malignancy probably is most useful if the location of the thrombosis is unusual (i.e., thrombosis migricans, Budd–Chiari syndrome) or recurrent. Treatment is difficult if the tumor cannot be removed. Anticoagulants may be effective in acute situations and can be used to prevent pulmonary emboli, but thromboses often recur despite apparently adequate anticoagulation.

Nonbacterial Endocarditis

Nonbacterial endocarditis is characterized by formation of sterile vegetations as a result of accumulation of fibrin on the mitral and aortic valves in patients with a variety of wasting illnesses, including bronchogenic carcinoma.

Fibrinogen Deficiency

Fibrinogen deficiency has been reported in patients with bronchogenic carcinoma, although this is seen more commonly with carcinoma of the prostate. Fibrinogen deficiency may be caused by widespread intravascular clotting, but elaboration of a circulating fibrinolysin by the tumor also has been suggested.

HEMATOLOGIC SYNDROMES

Anemia

Anemia in the absense of blood loss is common in malignancy. Most anemias result from nonparaneoplastic causes such as iron deficiency, impaired iron utilization and erythrocyte formation, chemotherapy and hemolysis, and bone marrow infiltration. However, hemolytic anemia does occur in response to tumor production of hemolysins.

Leukemoid and Leukoerythroblastic Reactions

Leukemoid and leukoerythroblastic reactions also are associated with bronchogenic carcinoma. Profound eosinophilia may occur, especially with tumor necrosis. Blood eosinophilia is not always associated with tumor eosinophilia. Several eosinophilopoietic and eosiniophil chemotactic peptides have been described.

CUTANEOUS SYNDROMES

Acanthosis Nigricans

Adult acanthosis is characterized by bilateral, soft, symmetric, darkly pigmented, verrucous lesions situated in the axillae, in flexural areas, in body folds, around the neck, around the umbilicus, and in the perianal region. Mucous membranes also may be involved. Histologic examination reveals thickened layers of the epidermis with an increase in the pigmented basal layers. If acanthosis nigricans is associated with malignancy, the tumor is usually intraabdominal, but about 5% of patients have adenocarcinoma of the lung. Although detection of acanthosis nigricans may precede detection of the underlying tumor, both the tumor and the skin disorder tend to

progress together. Removal of the tumor may lead to regression of the cutaneous changes.

Dermatomyositis

Approximately 15% of persons with dermatomyositis have an underlying malignancy. The percentage is higher in persons over 50, especially in men. Cutaneous manifestations often precede overt appearance of the tumor. Classical findings include a violaceous rash on the face, heliotrope eyelids, and proximal muscle weakness and atrophy. The mechanism underlying the development of this disorder is unknown. The skin changes may or may not resolve after the malignancy is treated.

Erythema Gyratum Repens

This is a rare condition usually found in association with cancer, especially lung cancers. Erythema gyratum repens is a slowly moving, erythematous, gyrate macular eruption that gives the skin a knotty-pine appearance. This condition is thought to develop in response to altered organ proteins produced by tumor necrosis. Immunoglobulin deposits are found at the basement membrane zone of the skin and in the lung tumor, and antibodies to basement membrane also appear in the circulation. The mechanism of the migration is unknown but has been compared to the movement of amebae in agar. Resection of the tumor results in disappearance of the cutaneous stigmata.

Additional Cutaneous Conditions Associated with Lung Cancers

A number of nonspecific dermatitides have been associated with lung cancers, including hyperpigmentation, erythema, bullous and eczematous rashes, ichthyosis, hypertrichosis, and pruritus. Tripe palms are thickened palms with hyperkeratosis and acanthosis and exaggerated skin markings that are associated with lung and gastric malignancies. The palm contours supposedly resemble the surface of tripe.

GASTROINTESTINAL SYNDROMES

Chronic Intestinal Pseudoobstruction

This condition has been discussed above; see the section on autonomic neuropathy under neurologic syndromes.

Biliary Tract Dilation

Three cases of biliary tract dilation associated with adenocarcinoma of the lung have been described. None of these patients had biliary symptoms, but they had high levels of alkaline phosphatase, modestly increased total and direct bilirubin, and increased g-glutamyltransferase. All had dilation of the entire biliary tree confirmed by CT scan and ERCP (endoscopic retrograde cholangiopancreatography). None of these patients had any other explanation for biliary tree dilation. There was no anatomic obstruction, no evidence of metastases to the liver, bile ducts, or bone, and no evidence of any other infiltrative process or gallstones. These patients had no evidence of hepatitis, no use of drugs or medications associated with liver disease, and no history of surgery or other systemic disease to explain the biliary tract dilation. Biliary mannometry and liver biopsies were not done.

RENAL SYNDROMES: NEPHROTIC SYNDROME

Nephrotic syndrome presenting in adult patients, especially older adult patients, is associated with bronchogenic carcinoma approximately 3% of the time. In most cases involving bronchogenic carcinoma, nephrotic syndrome is caused by membranous glomerulonephritis, with deposition of immune complexes including tumor antigen and IgG or IgA on the glomerular basement membrane. Nephrotic syndrome regresses in 75% of cases if the tumor responds to surgery or chemotherapy.

CHAPTER

72 Developmental Anomalies of the Respiratory System

INTRODUCTION

The larynx and trachea begin as a lengthwise groove in the floor of the embryonic gut. Furrows appear at the lateral edges of this groove and then fuse, separating the developing larynx and trachea from the esophagus. This structure is ridge-like, and its rounded caudal end forms the lung bud. The larynx develops from endoderm lining the cranial end of this laryngotracheal ridge. Supporting structures derive from the mesoderm of the fourth and fifth branchial arches. Arytenoid swellings then form laterally to the opening in the trachea or glottis. These swellings move cranially and forward to fuse into the primitive epiglottis. Proliferating epithelium obliterates the larynx before 10 weeks. After continuity is restored, the vocal folds appear below the lateral recesses of the ventricles. Innervation is provided by the vagus nerve, which supplies the structures derived from the fourth and fifth branchial arches.

The trachea develops from the midportion of the laryngotracheal tube and then elongates and descends into the thoracic cavity, as do the lungs. The muscles and cartilage-supporting structures derive from splanchnic mesoderm. Tracheal glands develop from the epithelial lining. The lung buds divide into right and left bronchopulmonary buds that later become the mainstem bronchi. These buds extend into the primitive pleural cavities. Secondary bronchi then form: two on the right, one on the left, which will develop into the three-lobed right lung and two-lobed left lung. By 7 weeks' gestation, third-order bronchi appear and then further develop into 18 bronchopulmonary segments, ten on the right and eight on the left. Twenty-four generations of bronchi and bronchioles develop by 16 weeks' gestation.

The following classification of the intrauterine development of the fetal lung is based on Boyden's description:

1. Pseudoglandular period (5 to 17 weeks). The lung appears as acinous glands, and elaborate branching of the airways and pulmonary vasculature dominates. Epithelium is cuboidal toward the periphery and pseudostratified near the hilum. By the end of this period, all prealveolar structures have developed.
2. Canalicular period (13 to 25 weeks). The bronchi and bronchiolar lumina enlarge during this period. At 24 to 25 weeks, each terminal bronchiole elongates and divides into two respiratory bronchioles. Vascularization rapidly proceeds, and proliferating vessels thin the cuboidal lining of these respiratory bronchioles. This process is necessary for subsequent terminal sac and alveolar development.
3. Terminal sac period (24 weeks to birth). During the final trimester, new respiratory bronchioles continue to develop within a thinned epithelium. Two types of epithelial lining pneumocytes can now be recognized. Surfactant, produced by type II pneumocytes, is first detected at this time. The developing pulmonary vasculature and thinned epithelial lining allow for extrauterine survival of increasing numbers of infants born preterm (38 weeks of gestation).
4. Alveolar period (late fetal period to 8 years). The number of alveoli reach adult levels by the age of 8 years. The newborn has one-sixth to one-eighth as many alveoli as does the adult.

DEVELOPMENTAL ANOMALIES INVOLVING THE LARYNX AND TRACHEA

Embryology of the Larynx and Trachea

The epiglottis develops anteriorly from the upper portion of the larynx, then broadens and grows upward toward the posterior pharynx. The arytenoid swellings form the lateral boundaries of the glottal opening. Proliferation of this epithelium temporarily occludes the larynx, which lengthens and reopens at 10 weeks of gestation. The laryngeal ventricles are lateral outpouchings found below the glottis opening. The vocal folds, which will eventually be lined with stratified squamous epithelium, are just caudal. From this point down, the lining will be pseudostratified columnar respiratory epithelium. The trachea lengthens considerably during development as the primary lung buds differentiate and move approximately eight segments downward into the pleural cavities. Developmental anomalies of the larynx and trachea result from aberrations in the pattern of normal differentiation.

Laryngomalacia

Sometimes called congenital stridor, laryngomalacia is caused by the flaccidity of a long epiglottis, short arytenoepiglottic folds, or bulky arytenoid swellings. These abnormal structures prolapse upward on inspiration, causing stridor. A soft expiratory stridorous component may be present as well. Stridor may present at birth or during an upper respiratory tract infection and may subsequently recur unrelated to any infectious episode. Stridor usually increases with quiet breathing and thus may be noted only during sleep. It can also be exacerbated by agitation or the supine position. Approximately half the affected infants have associated feeding difficulties, with vomiting or prolonged feeding time. The diagnosis is usually suspected clinically and must be confirmed by direct laryngoscopy, which is the procedure of choice. Severely affected infants manifest obstructive apneas and can develop cor pulmonale. The problem tends not to persist, with most symptoms resolving by the age of 1 to 2 years. Findings on indirect laryngoscopy in 19 children performed 7 to 12 years after the initial diagnosis were reported as normal. However, some children have persistent symptoms that occur during stress in later childhood. Current surgical therapy utilizes endoscopic CO_2 laser removal of redundant tissue performed unilaterally. Some individuals will require subsequent removal of tissue on the other side. There is a higher incidence of pectus excavatum in individuals with laryngomalacia.

Subglottic Stenosis

Congenital narrowing of the subglottic area may be caused by cricoid cartilage anomalies or by increased amount of soft tissue surrounding the subglottis. It is thought to result from external compression by the sixth branchial arches before 10 weeks of gestation. Affected infants present with stridor at birth, and the stridor is persistent.

Differentiation from laryngotracheobronchitis (croup) may be aided by roentgenographic findings. In both entities, the subglottic air column is narrowed on inspiration, and the hypopharynx is distended with air. On expiration, however, the narrowing associated with subglottic stenosis appears fixed, whereas it often widens in croup. Minimal findings of anterior or posterior indentations of the air column are unlikely to be related to croup. Infants with mild symptoms of subglottic stenosis may require no treatment; others require tracheostomy or other surgical interventions.

The extreme form of subglottic stenosis is subglottic atresia. Prolonged endotracheal intubation for respiratory support has caused an increase in acquired laryngotracheal stenosis. Laryngotracheal reconstruction has been performed in some patients.

Laryngotracheoesophageal Cleft

Laryngotracheoesophageal (LTE) cleft is a rare disorder associated with significant morbidity and mortality. The disorder may be separated into a mild form involving the posterior larynx but not extending through the cricoid cartilage, a form that extends through the cartilage into the cervical tracheal rings, and into a complete LTE cleft involving the thoracic trachea. A LTE cleft is usually caused by a lack of rostral extension or failure in formation of the tracheoesophageal septum. Failure in fusion of the dorsal portion of the developing cricoid cartilage plays a contributory role. These infants have increased oral secretions, cyanosis, and choking with all feedings. The presentation may simulate esophageal atresia (EA) or tracheoesophageal fistula (TEF). The LTE cleft and EA or TEF coexist in 20% of patients with LTE. The diagnosis may be suspected from the anterior position of a nasogastric tube on a lateral chest radiograph. On occasion, the diagnosis may be missed because of a physiological apposition of the edges of the cleft with inspiration. Cineesophagram reveals spillover of liquid into the larynx and trachea on swallowing. Laryngoscopy is the preferred method for diagnosis and repair of supraglottic clefts. Those LTE clefts extending to the carina or beyond to the mainstem bronchi present major challenges to successful surgical and postoperative management. Postoperative management may require prolonged nasotracheal intubation or tracheostomy.

Tracheal Agenesis

Floyd and associates divided tracheal agenesis into three types: type 1 (10%) consists of agenesis of the upper trachea with communication between the esophagus and the distal patent trachea; type 2 (59%) is agenesis of the entire trachea with a small fistulous connection between the esophagus and the carina where normal bronchi are fused; and type 3 (31%) is complete agenesis of the trachea with the bronchi arising from the esophagus. Polyhydramnios during pregnancy and prematurity are risk factors. There is very high incidence (70%) of major associated malformations in other organ systems, particularly in the cardiac, renal, and gastrointestinal systems. Of the embryologic explanations offered, Bremer's theory of a marked ventral location of the developing LTE system appears most tenable. Infants will present with respiratory distress and an inability to vocalize, and intubation will be impossible. The diagnosis can be made by immediate laryngoscopy, which will reveal a blind pouch, and esophagoscopy to look for a fistula. A temporary airway can be surgically created, and a tracheostomy can be done for type I agenesis if the pouch is long enough, but definitive therapy of the other types is not possible.

Complete Tracheal Rings

The posterior membranous portion of the tracheal rings may rarely be replaced by cartilage. The trachea is then poorly distensible, which causes respiratory distress that worsens markedly with infection. When the defect is limited, segmental resection may be attempted. However, the most common anomaly has not been successfully repaired thus far.

Laryngeal Web

This is a rare anomaly of the larynx, with an estimated incidence of one in 10,000 births. The web is caused by partial or complete failure of the larynx to reopen at 10 weeks of gestation. Seventy-five percent of laryngeal webs result from membranes extending across the anterior one-half to two-thirds of the true vocal cords. The remainder occur in supraglottic (1.5%), subglottic (7.5%), or combined locations. An absent or hoarse cry is usually present at birth. Respiratory distress may be a presenting sign. The diagnosis is made by direct laryngoscopy. The membrane may be quite dense, with muscle, fat, and/or cartilage present. Insertion of a Silastic or tantalum keel can prevent the incised edges from rejoining in such cases. Simple incision is insufficient for well-differentiated webs.

Laryngocele

This rare anomaly presents as an air-filled cystic outpouching of the laryngeal wall. It is most often palpated in the anterior triangle of the neck at the level of the thyrohyoid membrane. The cyst increases in size during a Valsalva maneuver and decreases in size with palpation. These lesions may become infected, increase in size, and obstruct the airway. Surgical intervention is necessary; an external approach is preferred.

Vascular Rings

Extrinsic compression of the trachea by anomalous vessels may cause respiratory difficulty during infancy. The anomalous vessels represent persistent branchial arch vessel(s), as in double aortic arch, the most common of the vascular compression syndromes. A lateral chest film may show tracheal compression. The diagnosis can be confirmed on esophagram, which will reveal narrowing of the esophagus.

ESOPHAGEAL ATRESIA AND TRACHEOSOPHAGEAL FISTULA

The anomalous development of the esophagus was first described by Gibson in 1696 in a report of a proximal EA with a distal TEF. The first feeding gastrostomy was done in 1888 by Steele, and the length of the blind distal segment was measured. In 1913, Richter first attempted transpleural ligation of the distal fistula with establishment of a feeding gastrostomy. In the late 1930s, adoption of an extrapleural approach plus establishment of cervical esophagostomy foreshadowed the subsequent primary repair independently developed by Leven and Ladd in 1939. Both patients underwent gastrostomy, ligation of the distal fistula, cervical esophagostomy, and eventual anastomotic repair of the proximal and distal esophagus.

Several different categorizations have been proposed for these anomalies. Esophageal atresia with distal TEF is by far the most common type (86.6%). Atresia without fistula (7.7%), TEF without EA or H-type TEF (4.2%), EA with proximal fistula (0.8%), and EA with proximal and distal fistulas (0.7%) are much rarer in occurrence. All these entities occur sporadically, with an incidence of one in 3000 live births. Only a few examples of more than one case in a family have been reported.

The prognosis is dependent on the severity of the esophageal pathology and the overall condition of the infant. Measurement of the length of the atresia (gap length) may be a useful predictor of outcome. Longer gaps have a worse prognosis. When the proximal esophagus ends in a blind pouch, aspiration pneumonitis is common. A proximal TEF results in direct flow of proximal esophageal contents into the tracheobronchial structures. A distal TEF results in regurgitation of stomach contents in a retrograde manner into the trachea. Crying causes acute gastric dilation followed by flow of gastric acid into the lungs. Attempts at feeding produce crying with resultant choking, regurgitation, and cyanosis. The capacity of the proximal segment may be limited to only a few milliliters.

Findings on anteroposterior and lateral chest radiographs may confirm the diagnosis (Fig. 1). Absence of air in the gastrointestinal system suggests no associated distal fistula, and a technically more difficult surgical repair can be anticipated. The morbidity and mortality associated with surgical repair depend on the presence of other anomalies, which are common (50%) in these patients (Table 1). Esophageal atresia also has been associated with pulmonary agenesis.

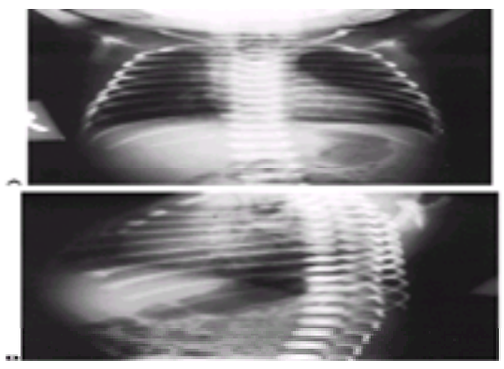

FIG. 1. Tracheoesophageal fistula. Note the curving nasogastric tube in the proximal esophagus. Presence of air throughout the remainder of the gastrointestinal tract results from the fistulous connection.

Patients with no associated anomalies (52%)	553
Patients with associated anomalies (48%)	505
Congenital heart disease	201
Gastrointestinal anomalies	134
Genitourinary anomalies	109
Imperforate anus	99
Musculoskeletal anomalies	91
Central nervous system anomalies	63
Facial anomalies	53
Other	99
Total number of anomalies	849

TABLE 1. *Incidence of additional anomalies in patients with respiratory anomalies*

Division of the TEF and primary anastomotic reconstruction of the esophagus are the procedures of choice in term infants. With sick, preterm, or small-for-gestational-age infants, a staged repair has been advocated to decrease morbidity and mortality. A gastrostomy is done, followed in a few days by retropleural division of the distal TEF. After aspiration pneumonitis has been controlled and nutrition provided via gastrostomy, an end-to-end anastomosis may be performed. Esophageal atresia without TEF (»7.7% of cases) and EA with proximal TEF (1% of cases) are associated with the widest gaps between the proximal and distal segments. When primary repair is not possible, colonic interposition using an isoperistaltic segment of transverse colon has been the procedure of choice. Postoperative complications have included stricture, leak at the anastomotic site, and pneumonia.

Long-term follow-up has shown an increased incidence of respiratory infection secondary to aspiration from reverse peristalsis and mild restrictive pulmonary deficits. Feeding should continue, and patients should sleep in a 60° upright position indefinitely.

CONGENITAL DIAPHRAGMATIC HERNIA

The diaphragm results from the embryonic fusion of four structures; the largest of these, the septum transversus, arises from the same cervical somites (C3 to C5) as the phrenic nerve. This septum extends inward from the ventral surface to separate the pericardial and peritoneal cavities. The bilateral pleuropericardial and pleuroperitoneal folds then arise from the body wall to surround and separate the embryonic lungs from the heart and abdominal viscera. The mediodorsal portion of the diaphragm is formed from the dorsal mesentery. The pleuroperitoneal folds join the septum transversus to form the diaphragm. Failure of this fusion allows herniation of abdominal contents to occur through the patent pleuroperitoneal canals and accounts for the posterolateral herniation through the foramen of Bochdalek in 80% of all cases of congenital diaphragmatic hernia (CDH). This usually occurs at gestational age of 10 to 12 weeks, when bronchi and bronchiolar differentiation is taking place. Retrosternal herniation through the foramen of Morgagni accounts for most of the remaining cases.

The incidence of congenital diaphragmatic hernia (CDH) is thought to be about one in 2200 births, based on the British Perinatal Mortality Survey. There is no significant correlation with increased parity, advanced maternal age, or socioeconomic status. Boys are affected twice as often as girls. Although CDH is almost always sporadic in occurrence, some families with near-total unilateral agenesis of the diaphragm inherited as an autosomal recessive trait have been described. Associated anomalies (cardiac, genitourinary, extralobar sequestration, neural tube defects, other chromosomal abnormalities) are commonly associated with CDH.

Infants with CDH through the foramen of Bochdalek present in the first day(s) of life with dyspnea, tachypnea, and cyanosis. There may be dullness to percussion and decreased breath sounds on the affected side, prominence of the affected hemithorax, and a scaphoid abdomen as a result of displacement of abdominal contents into the thorax. Herniated contents consist of stomach, small intestine, and the descending colon (Fig. 2), and the herniation occurs through the left hemidiaphragm approximately five times as often as through the right. Herniation of some but not all bowel would fail to produce a scaphoid abdomen. Accurate prenatal diagnosis can be made with ultrasonography: polyhydramnios, mediastinal shift, bowel herniation and malrotation, and absence of an intraabdominal stomach bubble suggest the diagnosis. The diagnosis can be confirmed at the time of birth by conventional chest radiography showing the herniated contents and mediastinal shift toward the opposite side. Contrast studies are rarely needed.

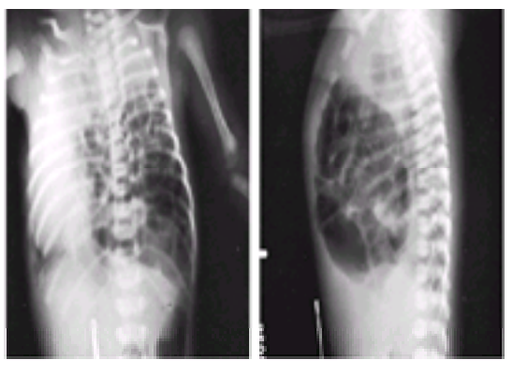

FIG. 2. Congenital diaphragmatic hernia. There is herniation of small intestine, large intestine, and stomach (or parts thereof) into the left hemithorax. Note the air in the descending colon.

Congenital herniation of abdominal contents into the thoracic cavity was rarely recognized during life before roentgenography became available. Successful surgical correction began in the 1930s, and the techniques were well described by Ladd and Gross in 1940. Survival rates have not improved since that time despite improved newborn care, anesthesia, and surgical management. Advances in care have allowed patients with more severe abnormalities to survive until operation. Mortality rates range from 30% to 80% and depend on (1) the severity of the defect, (2) persistent fetal circulation with associated pulmonary hypertension, and (3) associated pulmonary hypoplasia (ipsilateral, contralateral, and bilateral).

Antenatal correction is still experimental but has been successful in selected cases (22 to 30 weeks of gestation). It is now felt that neonatal surgical intervention should be delayed until the respiratory status has been stablized by mechanical ventilation. Several authors advocate an abdominal approach because of easier reduction by traction and the high incidence of associated malrotation (30%). A transthoracic approach also has been used, with comparable survival rates. Bowel reduction does not ensure survival. The associated pulmonary hypoplasia affects the ipsilateral and, in some cases, contralateral lung. The total number of airways and airway generation number are decreased. Even when herniation is unilateral, there are associated elevated pulmonary arterial pressure and vascular resistance. No abnormality in the nitric oxide system or in thromboxane levels has been found. There is an increase in endothelin-1. Increased pulmonary arterial muscle mass has been observed in children dying with CDH. In addition to pharmacologic management and instillation of artificial surfactants at the time of birth, partial liquid ventilation and extracorporeal membrane oxygenation (ECMO) have been employed; these modalities may be associated with improved survival rates. Comparisons in outcome among institutions are difficult to make but may be facilitated by using predictors of severity such as the best postductal PO_2. Values higher than 100 mm Hg were associated with survival in 41 (91%) of 45 patients, and only one (7%) of 14 patients with a best postductal PO_2 less than 100 mm Hg survived. At the present time, mortality rates for patients with CDH diagnosed in early gestation are still high despite optimal postnatal therapy including ECMO.

CONGENITAL CYSTIC DISEASES OF THE LUNG

This group of entities is characterized by cystic pulmonary tissue. Although the exact embryogenesis of various forms is disputed, all result in aberrant differentiation of bronchi, bronchioles, alveoli, and pulmonary vasculature. The major forms of congenital cystic lung disease include bronchogenic cyst, pulmonary sequestration, congenital cystic adenomatoid malformation, and congenital lobar emphysema.

Bronchogenic Cyst

Bronchogenic cysts originate in abnormal diverticuli of the lung bud in the third to sixth week of fetal life. They are usually located adherent to the left mainstem bronchus or carina and are extrapulmonary in location within the middle mediastinum. Abnormal budding in the distal tracheobronchial tree causes intraparenchymal cysts. The cyst wall contains all elements of the normal bronchus: columnar and mucus-secreting epithelium, smooth muscle, elastic tissue, and cartilage.

Most children with obstructing cysts who present in early infancy have moderate to severe respiratory distress and clinical signs of airway obstruction such as stridor, wheezing, and cyanosis. Cysts may be air filled, fluid filled, or exhibit air–fluid levels. Chest radiographs may not show a mass but may reveal signs consistent with obstruction by a cyst: postobstructive hyperlucencies or severe obstructive atelectasis with mediastinal shift; a lucent cystic area containing curvilinear shadows consistent with lobar hyperaeration may also be seen (Fig. 3). Subcarinal bronchogenic cysts have been demonstrated using real-time ultrasonography and a parasternal approach. The optimal modality for imaging cysts is computed tomography (CT). Cysts may also be visualized by magnetic resonance imaging and generate high signal intensities on T_2-weighted scans. T_1-weighted scans are of variable intensities depending on the contents of the cyst.

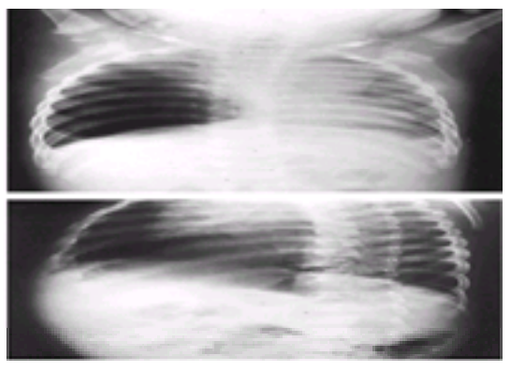

FIG. 3. Bronchogenic cyst. Hyperaeration with definable boundary within a lobe.

The diagnosis can usually be made by barium swallow, which reveals an esophagus typically deviating backward and to the right, with the trachea pushed forward and narrowed. A communication between the cyst and the tracheobronchial tree cannot always be demonstrated at operation. Bronchoscopy is generally not helpful, and bronchography is dangerous and not recommended.

Bronchogenic cysts generally range in size from 1.5 to 4.0 cm. All identified bronchogenic cysts should be surgically removed because they have a high likelihood of eventually becoming infected. After removal, prognosis is excellent; however, cysts have recurred. Imaged thoracoscopic surgery has been successful in removing mediastinal cysts without a thoracotomy. Two cases of embryonal rhabdomyosarcoma have been found within lung cysts.

Pulmonary Sequestration

Sequestrations are cysts that are not connected with the tracheobronchial tree. They are generally divided into intralobar sequestration, which is located within lobar tissue, and extralobar sequestration or accessory lobe, which has its own pleural covering. About two-thirds are located within the left lower lobe, and the remainder in the right lower lobe. Sequestrations arise from accessory bronchial buds located either inside (intralobar) or outside (extralobar) the developing lung, along with persistence of a pulmonary branch of the dorsal aorta secondary to failure of the pulmonary artery to vascularize the periphery of the lower lobe. Exposure of the pulmonary aortic branch to systemic pressure then causes cystic degeneration of the sequestered lobe. About 75% of sequestrations receive blood via a feeding artery from the thoracic/abdominal aorta. The remainder receive blood from many sources, including the subclavian, intercostal, pulmonary, pericardiophrenic, innominate, internal mammary, celiac, gastric, splenic, and renal arteries. Feeder vessels are usually solitary, but between 15% and 25% of sequestrations may be fed by multiple vessels. Venous drainage is most commonly via the pulmonary veins (intralobar) or bronchial or other (extralobar) vessels. One review of 42,000 pediatric autopsies questions the designation of intralobar sequestration as a congenital malformation.

The clinical presentation is variable (Table 2). Extralobar sequestration is associated with diaphragmatic hernia on the left in almost 60% of cases. Intralobar sequestration usually presents as an inflammatory mass in the posterobasal segments of the lower lobes (Fig. 4). There are several reports of pulmonary sequestration presenting with congestive heart failure rather than the far more common respiratory symptoms.

Distinguishing feature	Extralobar	Intralobar
Bronchopulmonary tissue	Found above or below the diaphragm	Confined to posterior basilar segments of lower lobe
Pleural covering	Separate from the rest of the lung	No pleural separation
Side affected	Left > 90%	Left 65%
Foregut communication present	Occasionally	Rarely
Associated anomalies	Frequent	Uncommon
Found in neonates	Often	Never
Age at diagnosis	<1 year in 60%	>20 years in 50%
Sex distribution	M:F = 4:1	M = F
Venous drainage	Systemic or portal	Pulmonary

TABLE 2. *Pulmonary sequestration*[a]

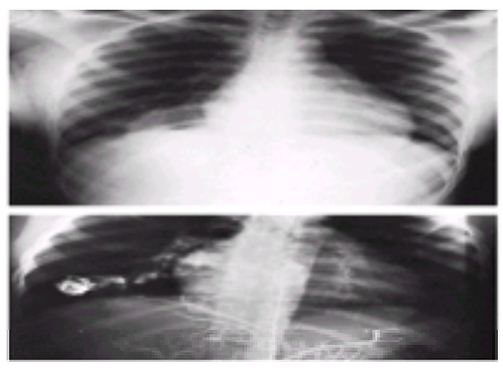

FIG. 4. Intralobar sequestration in the right lower lobe. Retrograde arteriogram shows that the blood supply is from the aorta below the level of the diaphragm. Opaque material remains from the previous bronchogram.

The diagnosis is generally made by CT imaging. Barium contrast studies may demonstrate the occasional extralobar sequestration that is associated with a fistulous connection to the esophagus. Magnetic resonance angiography and ultrasonography have been useful in demonstrating the aberrant systemic blood supply, but angiography remains the gold standard, as these other modalities do not detect small vessels. Surgical removal is curative.

Congenital Cystic Adenomatoid Malformation

Congenital cystic adenomatoid malformation (CCAM) is a rare form of congenital cystic disease of the lung, with fewer than 100 cases reported before 1978. The lesion is caused by an arrested alveolar development associated with a proliferation of terminal bronchioles in the affected lobe. These bronchioles are lined by columnar or cuboidal epithelium and have soft walls. Air enters and then is trapped, causing cystic dilation of the bronchioles. The entire malformation may cause a mediastinal shift to the opposite side and compressive atelectasis of otherwise normal adjacent lung tissue.

Three morphologic types have been described. Type I is characterized by large cysts 3 to 10 cm in diameter. Type II is characterized by numerous cysts, each between 0.5 and 3.0 cm in diameter. Type III is characterized by many small cysts, each less than 0.5 cm in diameter. The CCAM specimen shown in Fig. 5 demonstrates radiolucent areas with curvilinear densities associated with scattered coalescent soft-tissue density infiltrates, representing areas of atelectasis, that may also be seen with bronchogenic cysts.

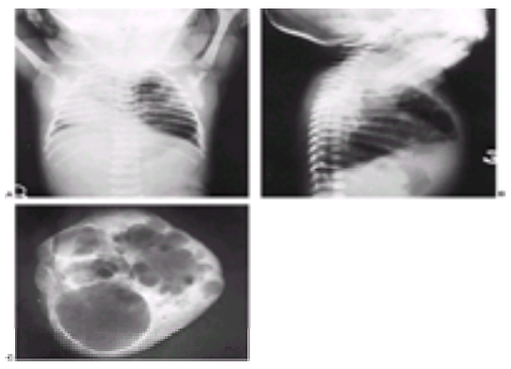

FIG. 5. (A and B) Congenital cystic adenomatoid malformation of the lung. **(C)** A roentgenogram of the surgically resected specimen.

CCAM has three distinct clinical presentations. About a third of patients present as stillborns with anasarca with or without a history of maternal polyhydramnios. Early detection of these patients by ultrasonography is possible, and an early clinical clue to the presence of CCAM is polyhydramnios. The CCAM in these cases is severe in that the involved lobe hampers cardiac function and obstructs venous return, causing anasarca. In type I lesions, intervention *in utero* with placement of a thoracoamniotic catheter may be done and allows resolution of hydrops and mediastinal shift. Resection of the CCAM may be done after delivery. The CCAM may also be removed during fetal life in selected cases.

The newborn infant may present with tachypnea, dyspnea, and cyanosis. Roentgenographic diagnosis of the mass may be difficult; it may be confused with congenital lobar emphysema (CLE). Lobectomy is the procedure of choice; on occasion, an anomalous vessel may be found. Preoperative bronchography or aortography is generally not necessary. Resected patients have a good prognosis. Less commonly, patients with CCAM present in childhood with a history of recurrent pulmonary infection or when the mass ruptures into the pleural space.

Congenital Lobar Emphysema

Congenital lobar emphysema is a surgically correctable cause of severe respiratory distress in infancy. Affected infants may present with respiratory distress that is mild or severe, precipitated by crying, feeding, or, on occasion, respiratory infection. Boys are somewhat more often affected than girls. The left upper lobe is most frequently involved, followed by the right middle lobe. Disease of the lower lobes and bilateral disease are rare (Fig. 6). Congenital lobar emphysema is almost always not of genetic origin, but two affected sisters and an affected mother and daughter have been reported.

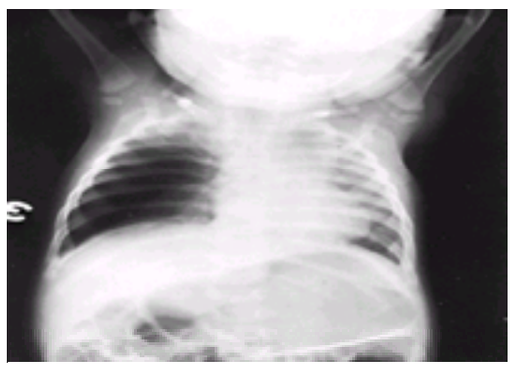

FIG. 6. Congenital lobar emphysema with hyperexpansion of the right middle lobe. The compressed lower lobe is visible as a triangular shadow in the cardiophrenic angle.

The pathology of CLE has been attributed to deficient bronchial cartilage in the affected main bronchus, which causes endobronchial proliferation of mucous membranes and subsequent obstruction. Deficient cartilage (25% of cases), endobronchial obstruction (13%), extrinsic compression of the bronchus by an anomalous vessel (1%), and diffuse lobar bronchial abnormalities (4%) have all been demonstrated; no cause has been found in 50% of cases. An alveolar wall defect in the quantity, quality, or distribution of collagen or elastin has been postulated to explain CLE of unknown cause.

Affected neonates or infants present with respiratory distress. Half the cases present in neonates, and three-fourths in infants under the age of 6 months. The thoracic wall may be prominent over the involved lung, with hyperresonance on percussion and decreased breath sounds over the involved lobe. The apical cardiac impulse may be shifted away from the involved side, and the diaphragm may be depressed on the affected side. Chest radiographs reveal a hyperinflated lobe with the mediastinum shifted away from the affected lobe. The emphysematous lobe may be herniated into the contralateral hemithorax. Retained fetal fluid may cause the cyst to have a more solid appearance. With clearing, the more typical radiolucent lobe is revealed. The differential diagnosis of CLE includes pneumothorax, pneumatocele, and congenital cyst of the lung. Congenital lobar emphysema may be distinguished from these entities by the persistence of lung markings in the affected lobe on chest radiographs. The other lesions cited have absent lung markings in involved areas. In CLE, the vessels may be attenuated and abnormally separated within the emphysematous lobe. Lung scanning has provided helpful information regarding ventilation and perfusion in the cystic areas. Pneumothorax is rarely associated with CLE. There are associated cardiac defects (ventricular septal defect, patent ductus arteriosus) in a much higher percentage of patients with CLE than with other congenital cystic diseases of the lungs. Some authors have speculated that dilation of the pulmonary artery is pathogenetically related to the evolution of CLE in some patients.

Congenital lobar emphysema may be treated surgically with excellent results. Lobectomy is generally advocated. High-frequency jet ventilation has been used intraoperatively to maintain oxygenation and provide a near-motionless lung. Segmental resection may be curative in some instances. Nonoperative management is almost never indicated. There have been some reports of nonsurgical treatment in individuals presenting with concurrent viral infection during infancy or when patients were older (7 and 10 years) at initial diagnosis.

DEVELOPMENTAL ANOMALIES OF MEDIASTINAL STRUCTURES

The mediastinum contains all the viscera of the thorax with the exception of the lungs and their surrounding pleura. Embryologically, pleuropericardial folds appear longitudinally against the lateral body wall in the fourth week of gestation. These grow together in the midline and separate the developing heart from the lungs as they grow downward into the pleural canals. When the primary lung buds appear in the fifth week, the heart is a large structure. Over the next 2 weeks, the lungs undergo two subsequent divisions, and the bronchopulmonary segments are established. The lung enlarges relative to the heart, and the pleural membranes form the lateral

boundaries of the mediastinum.

The mediastinum may be anatomically divided into superior and inferior compartments, with the inferior further subdivided into anterior, middle, and posterior portions. Alternatively, the entire mediastinum may be divided into anterior, middle, and posterior divisions.

The anterior mediastinum contains the thymus, the anterior portion of the pericardium, and the heart. A few anterior mediastinal lymph nodes and, rarely, a substernal extension of the thyroid may be present. The most common anterior mediastinal mass in infancy is a hyperplastic thymus gland (Fig. 7). Regardless of the size of the thymus, it does not cause tracheal compression or displacement. If compression of the anterior tracheal wall is noted, an esophagram is indicated. Findings positive for a mass exclude enlarged thymus from the differential diagnosis. Surgical intervention should not be required because the thymus undergoes involution with age. Thymomas rarely occur and are frequently associated with immunodeficiency. Thymomas presenting in adult life may be associated with myasthenia gravis, diabetes, chronic hepatitis, or arthritis.

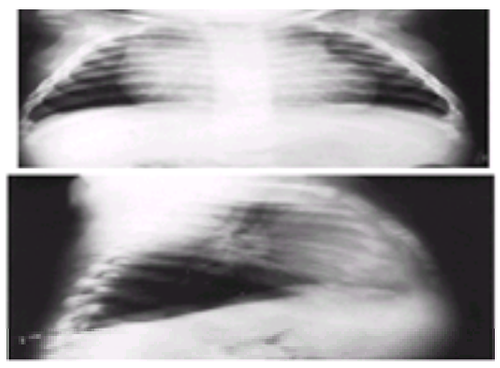

FIG. 7. Normal thymus. Note the absence of the retrosternal clear space and of tracheal compression.

Teratomas also occur in the anterior mediastinum. These lesions contain cells from all three germ layers (Fig. 8). Teratomas also may be intrapericardial in origin (Fig. 9). When symptomatic, mediastinal teratomas produce respiratory compromise, and newborns may present with signs of cardiac tamponade or hydrops fetalis. Teratomas may be benign or malignant. Pericardial cysts may also be found in the anterior mediastinum at the right cardiophrenic angle. They are neither symptomatic nor premalignant.

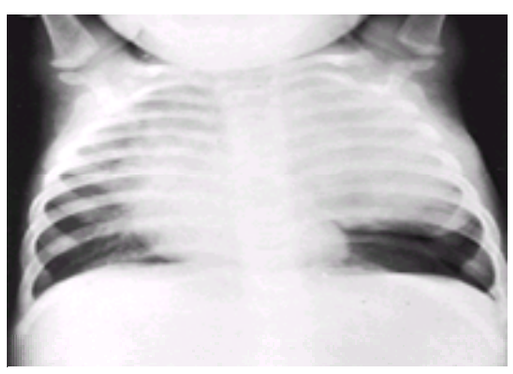

FIG. 8. Mediastinal teratoma. Air in the pleural space outlines the inferior margin of the teratoma. This particular lesion had no distinguishing characteristics such as teeth or bone. Obliteration of the upper portion of the heart border is a positive silhouette sign indicating anterior location of the mass.

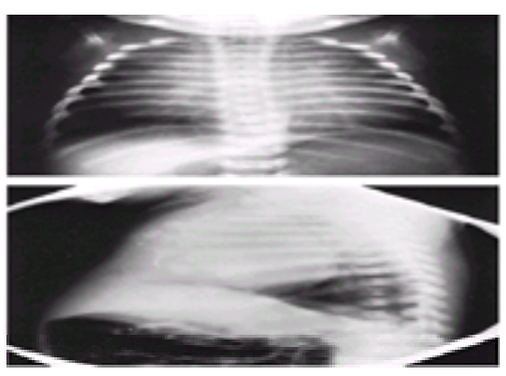

FIG. 9. Pericardial teratoma. Note the calcification within the pericardium on the lateral view.

Computed tomography of the chest is the imaging procedure of choice in the evaluation of suspected mediastinal masses. The CT differentiates cystic, solid, vascular, and fatty lesions. Diagnostic thoracotomy or mediastinoscopy may not be necessary in patients with benign fat deposition or asymptomatic cysts.

Enterogenous Cysts (Duplications)

Foregut duplications may present in the mediastinum. Occasionally, the presence of cervical vertebral anomalies such as hemivertebrae may suggest a foregut duplication. The endoderm of the foregut develops in close proximity to the notochord. A portion of endoderm may adhere to notochord as the latter is surrounded by paraxial mesoderm to form the vertebral bodies. Defects in these bodies are then formed. There may or may not be a fistulous connection to an enterogenous cyst, which forms at the cervical level and is then pulled into the thorax with the developing fetal lung. More commonly, duplications result from accessory foregut budding in early fetal life.

Enterogenous cysts present as rounded densities in a retropleural, paraesophageal position adherent to the esophageal wall (Fig. 10). They are lined by the columnar epithelium of the primitive esophagus. Other duplications may present in the mediastinum but are lined by gastric mucosa or other distal endodermal lining. In the latter cases, erosion with perforation into the right lower lobe may occur. These patients present with respiratory distress and hemoptysis from massive hemorrhage. Treatment is surgical when vertebral anomalies accompany the mediastinal cyst; a spinal cyst may be present as well. Computed tomographic scanning with myelography should be done even when the patient is asymptomatic.

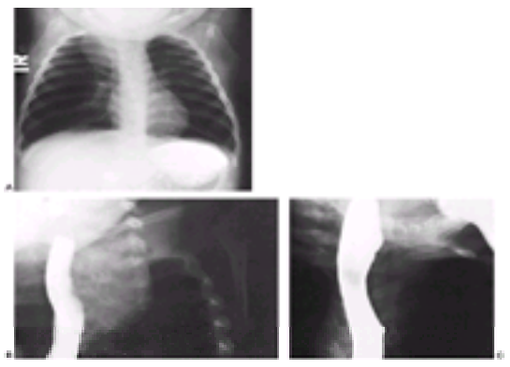

FIG. 10. Esophageal duplication. **(A)** Anteroposterior chest x-ray film shows a rounded soft-tissue density of mediastinal origin. **(B** and **C)** Spot films from esophagram show pressure on the esophageal wall from an extrinsic mass. The obtuse angle of the barium above and below the mass shows it to be submucosal in origin.

ANOMALIES OF THE PLEURAL FISSURES

The visceral pleura constitutes the most distal layer of the visceral mesothelial tissues enveloping the lung, and the fissures may be regarded as inward plications of the pleura, separating the pulmonary lobes. There are some anomalies of these fissures or pleural extensions that, though seldom of clinical importance, deserve brief mention.

Absence or Incomplete Development of Fissures

One or more of the major interlobar fissures may be absent or incomplete. Such a defect may be suspected when an expected fissure marking is not visible in the posteroanterior or lateral roentgenogram. Absence or incomplete fissure formation can be proved only at thoracotomy. These defects are significant because absence of a fissure may permit direct extension of lesions, notably tuberculous lesions, from one lobe to another and also because such defects may complicate operative procedures such as lobectomy.

Complete or Incomplete Accessory Fissures

Complete or incomplete accessory fissures are responsible for the formation of the following accessory lobes: (1) a dorsal lobe, set apart from the superior segment of one of the lower lobes; (2) a cardiac lobe, lung tissue cut off from the medial basal segment of one of the lower lobes; (3) an anterior basal lobe, a fragment separated from one of the anterior basal segments; and, at times, (4) a true left middle or lingula lobe, the lingula fully separated from the rest of the left upper lobe by an accessory fissure.

These accessory fissures may be recognized in roentgenograms as linear densities at the locations indicated. They are generally of no clinical significance.

AZYGOS LOBE

The azygos lobe is actually a portion of the right upper lobe. It is separated from the rest of that lobe by an abnormally laterally placed azygos vein, which is invaginated into the pleural covering of the lobe, producing a linear roentgenographic density that courses upward and outward from the upper pole of the right hilum to midclavicle or apex. This anomaly, of no practical significance, is said to occur in about 1% of individuals.

SUBCARDIAC LOBE

The so-called subcardiac lobe (lobus caval) is created when a part of the right lower lobe herniates into a pocket formed by the parietal pleura, in close relationship to the inferior vena cava. Like the azygos lobe, it has no clinical importance.

ANOMALIES OF THE THORACIC CAGE (PECTUS DEFORMITIES)

Pectus excavatum and pectus carinatum are congenital abnormalities of the anterior chest wall. They are probably caused by abnormal growth rates in costal cartilages causing retrusion (excavatum) or protrusion (carinatum) of the sternum. Excavatum is seen eight to 12 times as frequently as carinatum and occurs three times more often in boys than girls. Most cases are sporadic, although genetic transmission occurs.

The functional consequences of these deformities have been difficult to document. Some children complain of chest pain and reduced exercise tolerance. Studies of pulmonary function have shown mild restrictive deficits compared with normal controls, with decreases in vital capacity, total lung capacity, and maximal breathing capacity. These deformities may be corrected using a number of different techniques. Reviews of surgical series report good cosmetic and psychological results. Some patients have improved exercise tolerance after surgery. Cardiac function has been studied in some patients; results of complete right-sided heart catheterization were normal, as was the response to supine exercise. Upright treadmill exercise showed decreased cardiac output compared with that of normal controls. Cardiac output was improved after surgery, although neither value was in the abnormal range.

Many patients with pectus deformities require no surgical intervention. There is generally no progression of the deformity. Indications for correction include young age (4 to 6 years) to prevent compressive thoracic deformity and pulmonary and cardiac dysfunction and to improve cosmetic appearance. The current surgical technique for excavatum, described by Haller and colleagues, includes subperichondrial removal of all abnormal cartilages preserving the perichondrium. A sternal osteotomy is then done, and the sternum is elevated and fixed in place with nonabsorbable sutures. In older children and adults, the correction is supported by a metal strut placed anterior to the rib cage and beneath the sternum in a perpendicular position. In patients with carinatum deformity, the lateral depression on either side of the deformity is surgically corrected.

ACKNOWLEDGMENT

The author thanks Norman Glazer, M.D., late Clinical Professor of Radiology, Case Western Reserve University School of Medicine, who supplied and interpreted the roentgenograms accompanying this chapter.

INTRODUCTION

Many pulmonary diseases may be viewed as having both genetic and nongenetic components in their causation. In some conditions, inherited as Mendelian traits, the disease is primarily caused by the effects of a single mutant gene but is influenced to different degrees by environmental factors. These entities are relatively few and usually present as systemic diseases in which pulmonary manifestations are prominent. Cystic fibrosis is the prime example. At the opposite end of the spectrum are many common pulmonary disorders in which environmental factors predominate, but in which genetic factors may play some modulating role. The genetic component in this latter group may fit the model for polygenic or multifactorial inheritance, in which several genes, each with a small additive effect, place the individual at increased risk of developing disease when exposed to inciting environmental factors. The multifactorial inheritance model fits when applied to some congenital malformations, exemplified by spina bifida and cleft palate. Disorders with a significant polygenic component would be expected to show familial aggregation and perhaps exhibit differences among ethnic groups or races. The identification of the polygenic components of pulmonary disease would provide clinically useful data because individuals at increased risk could be counseled and the patients' environment modified to prevent the disease or ameliorate its course.

In the following sections, several diseases are described in which a genetic cause is either proved or implied. For some of these entities, detailed information is lacking on the mode of inheritance, the frequency of the mutant gene in populations, or on the basic biochemical defect producing the disease.

CYSTIC FIBROSIS

Cystic fibrosis (CF) is the most common lethal genetic disease in Caucasian populations and is the cause of much of the chronic progressive pulmonary disease encountered in children. With improving prognosis over the past several decades (the median survival age is now approximately 30 years), CF has also become a disease of young adults.

Cystic fibrosis is characterized by the clinical triad of excessive concentrations of sodium and chloride in exocrine sweat, chronic obstructive pulmonary disease (typically associated with chronic bacterial infection with *Staphylococcus aureus* and/or *Pseudomonas aeruginosa*), and exocrine pancreatic insufficiency. However, the severity of expression is variable, especially with regard to pancreatic function. Approximately 7% of patients have clinically sufficient pancreatic function; many of these have specific mutations in the CF gene that are associated with relatively mild pulmonary disease. Other patients have mutations in the gene associated with CF but do not exhibit typical clinical manifestations of disease; whether these individuals should be diagnosed as having CF is problematic. Congenital bilateral absence of the vas deferens (CBAVD) is the primary example of this phenomenon.

Genetics

It has long been known that CF is an autosomal recessive disorder involving approximately one in 2500 to one in 3500 newborns in North America. CF results from a mutation in a gene located on the long arm of chromosome 7 (7q31.3). The most common mutation involves a three-base pair deletion, which results in the absence of a phenylalanine residue at amino acid position 508 of the gene product. This mutation is referred to as the DF508 mutation. About two-thirds of all CF chromosomes examined to date carry this mutation. Several hundred other mutations, some of which are associated with relatively mild clinical disease, have been documented in this same gene.

Cystic fibrosis heterozygotes are clinically normal. It is estimated that approximately one in 25 to one in 35 white individuals in North America is a heterozygote. Various theories have been proposed to explain a putative heterozygote survival advantage given the high gene frequency. In view of the current understanding of the gene and its function, the most attractive such hypothesis is that heterozygotes are relatively protected against the effects of chloride-secreting diarrhea, especially infantile or epidemic diarrhea such as cholera.

The gene product, known as the cystic fibrosis transmembrane regulator (CFTR), is a large, glycosylated, 1480-amino-acid protein. CFTR functions as a chloride-selective ion channel located in the apical membrane of epithelial cells in the airways, sweat glands, and intestine or may be the entire channel. The function of CFTR is regulated in part by changes in intracellular cyclic adenosine monophosphate (cAMP). Different mutations lead to loss of chloride channel functions by a variety of mechanisms.

Incidence and Prevalence

The incidence of CF varies widely in different populations; it is most common in southern Europe and least common in Asian and black populations. Likewise, the incidence of specific mutations varies. The DF508 mutation is more common in northern than in southern European populations. Reported incidence figures range from 1:620 live births in individuals of Dutch descent in Southwest Africa to 1:90,000 live births in Orientals. The incidence in U.S. blacks has been estimated to be about 1:17,000. Cystic fibrosis is predominately a disease of Caucasians, in which the incidence of heterozygotes is estimated to be approximately 3% to 4%.

The total number of patients with CF is unknown. The Patient Registry of the Cystic Fibrosis Foundation (Bethesda, MD) records data on each patient followed by care centers in the United States. At the end of 1995, approximately 20,000 patients have reported to the Registry; of these, 24.6% were age 21 years or older; 96.2% were white, and 3.3% were black; 53.6% were male, and 46.4% were female. The total number of individuals with CF has been estimated to be twice as high as the number recorded in the Registry data base; but 25,000 may be a more reasonable estimate.

Pathophysiology

The most important clinical feature of CF is chronic obstructive pulmonary disease, which is characterized by accumulation of thick secretions in airways and chronic bacterial infection. Although ciliary structure and beat are apparently normal, mucociliary clearance is impaired, and mucous plugging of small airways can be detected in infants with no discernible pulmonary infection. The current (though incomplete) understanding of this phenomenon relates to the function of CFTR (and chloride permeability of respiratory epithelial cells) in the regulation of mucociliary transport and the composition and volume of the fluid lining the airway surfaces.

Because of the dysfunctional gene product, the apical membrane of the respiratory epithelial cells is impermeable to chloride, and the normal flux of chloride across the luminal surface is reduced. At the same time, there is excessive active sodium reabsorption. These phenomena are reflected in the bioelectric properties of the airway epithelium. The resting transepithelial electrical potential is elevated in CF individuals, from the normal range of 25 to 35 mV to 55 to 90 mV. Selective inhibition of the sodium pump (i.e., by a drug such as amiloride) reduces the transepithelial potential to nearly 0 mV. Amiloride does not reduce the potential nearly as much in normal subjects, as continued flux of chloride maintains a potential of 10 to 15 mV (lumen-negative). Furthermore, chloride flux is normally increased by b agonists such as isoproterenol, but this response is absent in CF individuals. These electrophysiological phenomena have been utilized to facilitate the diagnosis in patients with equivocal sweat test results or atypical clinical manifestations.

Although a full understanding of the mechanisms is lacking, it is widely assumed that failure of normal regulation of the volume and/or electrolyte composition of the periciliary fluid results in impaired clearance of pulmonary secretions, thus leading to obstructive pulmonary disease. Infants and young children may have evidence of airway obstruction such as bronchial casts recovered in bronchoalveolar lavage fluid. Infection may or may not be present. Failure of mucociliary function alone does not account for the entire pathogenesis, as patients with congenitally absent ciliary function (primary ciliary dyskinesia) do not have the same degree of viscous changes in their pulmonary secretions, nor are they characteristically infected with *Ps. aeruginosa.* The role of CFTR in other cellular membranes (such as the Golgi apparatus) is not yet understood, but it is possible that alterations in the function of such membranes could play a role in other CF-specific phenomena such as the marked susceptibility to infection with *Ps. aeruginosa* and the increased sulfation of mucus glycoproteins.

The hypothesis that the primary event in causing clinical disease is mucus hypersecretion or mucociliary clearance failure has been challenged. There is apparently a dysregulation of inflammation in the lungs of CF patients, with increased levels of proinflammatory mediators and decreased levels of antiinflammatory mediators such as IL-10. The relationship of this phenomenon to dysfunctional CFTR is unclear, but the two may be linked. Autopsy studies of young infants with CF suggested that in at least some patients, evidence of infection begins before there is evidence of airway obstruction. Other investigators have reported elevated levels of inflammatory mediators (IL-8) in BAL fluid from very young infants with CF even in the absence of a neutrophil response. Destruction of the bronchial epithelium by infection or impairment of mucociliary transport by abnormally viscous secretions also contributes to widespread airway obstruction. High concentrations of neutrophil elastase are found in the purulent airway secretions, which may overwhelm the indigenous antiprotease activity and destroy airway walls. Chronic inflammation and proteolysis may therefore contribute substantially to the progressive bronchiolectasis and bronchiectasis that are characteristic of CF. For this reason, there has been interest in the use of antiinflammatory and protease inhibitor therapy as part of the comprehensive management of CF patients.

Abnormalities of chloride permeability are also found in nonrespiratory epithelia, including the pancreatic and sweat ducts. In the pancreas, obstruction of small ducts as a result of decreased fluid secretion with subsequent release of pancreatic enzymes into the tissue leads to autodigestion of the exocrine pancreas. In the majority of patients, this process has progressed to the point of clinical pancreatic insufficiency by the time of birth and can be detected by elevations in circulating trypsinogen or pancreatic isoamylases. Ultimately, at least 90% of such patients require enzyme replacement therapy. Deficiency of pancreatic enzyme secretion and the consequent maldigestion in turn lead to a myriad of secondary problems, including protein–calorie malnutrition and fat-soluble vitamin deficiencies.

The primary secretory product of sweat glands is isotonic with plasma, and the composition of sweat at the skin surface is controlled by the relative reabsorption of water and electrolytes by the sweat duct. The volume of sweat is regulated by blood flow into the gland and thus by the total volume of ultrafiltrate in the primary secretory coil. Normally, sodium and chloride are actively reabsorbed, leaving a hypotonic fluid at the surface. The concentration of chloride in normal sweat is on the order of 10 to 20 mEq/liter; in CF, the ductal epithelial cells are relatively impermeable to chloride, so that the concentration of chloride in the sweat at the skin exceeds 60 mEq/liter. If the rate of sweat formation is very low, there may be enough reabsorption of chloride so that the concentration at the skin is in the normal range (<60 mEq/liter). Thus, for diagnostic purposes it is important to measure sweat chloride concentrations in secretions from maximally stimulated sweat glands (see below).

Diagnosis

The traditional diagnostic criteria for CF include a sweat chloride concentration exceeding 60 mEq/liter and at least one of the following: (1) chronic obstructive pulmonary disease (especially if associated with *Ps. aeruginosa* infection), (2) exocrine pancreatic insufficiency, and (3) confirmed family history of classic CF in a sibling, parent, child, or first cousin. DNA analysis, with demonstration of two mutations known to be associated with CF, is another diagnostic criterion. However, because of the possibility that yet another mutation could modify the effects of the CF mutation, some authorities do not accept a diagnosis of CF made solely on the basis of DNA analysis. At least one patient has been reported with typical pulmonary and gastrointestinal manifestations of CF but with a normal sweat chloride; this individual was homozygous for the DF508 mutation but also had the R553Q mutation. It is not practical to assay for every known mutation in the CF gene (several hundred have been reported), and therefore, a “negative” DNA analysis does not totally exclude the diagnosis of CF.

In practice, the most important diagnostic tool is the sweat test. This test, although simple in concept, is difficult to perform accurately. As mentioned, sweat must be collected from glands maximally stimulated by iontophoresis of pilocarpine. At least 100 mg of sweat should be collected to ensure an adequate sweat volume. The sweat should be collected with great care to avoid evaporation and analyzed titrimetrically for chloride. Alternative methods for sweat analysis involve quantification of chloride by ion-specific electrodes or by conductivity. These methods are unreliable, even for screening purposes. Sweat osmolality has been used instead of electrolyte measurements but may be less specific. The use of nonstandard sweat test methods is partly responsible for the high rate of false-negative and false-positive results commonly seen in patients referred to major CF centers after diagnostic studies elsewhere.

The normal value for sweat chloride is less than 60 mEq/liter and, in the majority of normal subjects, less than 40 mEq/liter. There may be a slight increase in normal values with age, with an occasional normal adult having a sweat chloride concentration as high as 70 mEq/liter. In patients with suggestive clinical presentations who consistently have sweat chloride values in the range of 50 to 60 mEq/liter, additional testing, including DNA studies, may be helpful. Physiological studies may help with the diagnosis if the genetics are uncertain. Studies would include measurement of the transepithelial bioelectric potential in the nasal epithelium and its response to amiloride and isoproterenol (the abnormal response is an elevated basal potential, with marked response to amiloride but none to isoproterenol), and the response of sweat glands to intracutaneous injection of atropine and isoproterenol (the abnormal response is a lack of secretion).

The most important and practical aspects of DNA-based diagnostic tests for CF involve prenatal diagnosis and the identification of family members who are heterozygous for the gene. Within families, even though the affected individuals may have an unusual or as-yet-undefined mutation, it may be possible to identify heterozygotes with reasonable accuracy. DNA-based population screening (i.e., universal newborn screening), however, is impractical with present technology.

Other methods have been advocated for population screening. Sweat testing would be extremely expensive and is therefore impractical. Screening for pancreatic insufficiency in newborns has been done by detecting increased amounts of albumin in the meconium or finding evidence of active pancreatic destruction (elevated serum levels of immunoreactive trypsin). These tests do not necessarily detect those patients with normal pancreatic function and are, therefore, of somewhat limited value. A positive result from any screening test must be confirmed by definitive testing.

Diagnosis in Adults

The majority of patients are diagnosed in the first year of life, but many will escape recognition until adolescence or even adulthood. Thirteen percent of patients reported to the Patient Registry of the Cystic Fibrosis Foundation in 1995 were diagnosed after the age of 10 years (and 5% after age 20 years). These patients may

have milder or atypical forms of the disease and thus escape clinical suspicion. It is a mistake to think that a patient looks too good to have CF or is too old. Well-characterized patients have been diagnosed in the sixth decade of life. Cystic fibrosis should be suspected in patients with early onset of chronic bronchitis, especially if accompanied by chronic gastrointestinal symptoms of nearly any kind. Chronic sinusitis, male (or female) infertility, nasal polyps, a history of rectal prolapse or heat prostration, and pulmonary colonization with *Pseudomonas* species (especially if a mucoid strain) are all potential indications for further investigation. Many adult patients will successfully deny their gastrointestinal problems (malabsorption) and may attempt to hide their chronic cough behind a cloud of tobacco smoke.

Pathology

Lung

The earliest manifestations of CF in the lung are dilation and hypertrophy of bronchial glands and goblet cell metaplasia. As obstruction proceeds, infection develops, and a vicious cycle is established, the result of which is bronchiectasis and decreased lung function. Early in the course of disease, the bronchioles are the principal location of obstruction and inflammation, and peribronchial abscess formation and fibrosis develop late. The alveolar spaces are relatively spared, although interstitial disease has been reported. Cystic bronchiectasis is common in end-stage disease.

Gastrointestinal Tract

Exocrine pancreatic insufficiency, which occurs in more than 90% of patients, results from inspissation of secretions in the pancreatic ducts. The consequent autolytic destruction of the exocrine portions of the organ gives the disorder its original name, cystic fibrosis of the pancreas. The islet tissue is relatively spared despite near-total fibrofatty replacement of the remainder of the organ.

Intestinal mucous glands are hypertrophied, with extensive ductal obstruction, and goblet cells are prominent. Similar changes in mucus-secreting elements may be seen in salivary glands. Fatty changes occur in the liver of as many as 30% of patients, and biliary cirrhosis, caused by inspissation of bile, may be found in 20% to 30% of older patients. Portal hypertension with esophageal varices occurs in 2% to 3% of patients.

Genitourinary Tract

Male infertility is almost universal and results from absence or atresia (perhaps from *in utero* obstruction) of the vas deferens. Testicular function and spermatogenesis are normal. There are no specific abnormalities of the female reproductive tract, although evidence of mucus hypersecretion and inspissation of gland ducts may be seen.

Sweat Glands

The sweat glands are anatomically normal despite their failure to reabsorb sodium and chloride.

Clinical Manifestations

The clinical manifestations of CF are variable and are influenced by treatment and by genetic and environmental variables. In the majority of patients, the pulmonary component predominates, but some patients have virtually no lung symptoms until the second or third decade of life. Patients with clinically normal pancreatic function tend to have milder pulmonary involvement.

Pulmonary

Cough is the earliest and most prominent clinical manifestation of pulmonary disease. It may begin as an infrequent and nonproductive cough but progresses inexorably (usually over years) to become productive of thick sputum. The chest often remains clear to auscultation until the airways disease is relatively advanced (the thick secretions do not generate noise). Radiographic and physiological (i.e., spirometric) evaluation is helpful in following the course of disease. Wheezing may be prominent during acute exacerbations in infants, but coarse crackles and rhonchi are more likely, especially in older patients. There is a distinct predilection for involvement of the right upper lobe, and many patients have worse disease in the right lung than the left. With progression, digital clubbing develops, the lungs become hyperinflated, physical findings become persistent, and the patient grows more symptomatic. Usually, however, patients do not exhibit cyanosis or marked decreases in exercise tolerance until relatively late in the course. In contrast with chronic obstructive lung disease in adults, the clinical course of CF is usually precipitous once overt respiratory failure develops.

The upper airway may also be involved. Pansinusitis is almost universal, and nasal polyps are present in 10% to 15% of patients. In 1995, 2.8% of patients reported to the CF Patient Registry required surgery for nasal polyps.

Chronic pulmonary infection is an almost constant finding in CF patients. Early in the course, *S. aureus, H. influenzae,* and a variety of other organisms may be found. Eventually, *Ps. aeruginosa* becomes the predominant or only organism in the majority of patients (two-thirds to three-quarters of patients between ages 11 and 24). Other gram-negative organisms such as *Stenotrophomonas maltophilia* may also be pathogens in CF patients. Viral agents are often responsible for symptomatic exacerbations and may be implicated in the initiation of lung damage early in life. Fungi, especially *Aspergillus* species, also may be isolated from sputum, although their clinical significance may be difficult to discern. Allergic bronchopulmonary aspergillosis is not rare in CF patients; a 1.8% incidence was reported in 1995. Recently, *Burkholderia cepacia* (formerly known as *Ps. cepacia*) has became a major pulmonary pathogen and was reported in 7.2% of patients aged 18 to 34 years. In about 20% of patients who become colonized with *B. cepacia,* a catastrophic downhill course ensues. For this reason, patients known to be colonized with *B. cepacia* should be isolated from other CF patients when hospitalized. Strains of atypical mycobacteria are also found in some patients and may be pathogenic.

Other pulmonary manifestations of CF include hemoptysis (which may be massive), atelectasis, pneumothorax, and cor pulmonale.

Gastrointestinal

Meconium ileus (neonatal intestinal obstruction) occurs in 15% to 20% of patients with CF. In addition to the usual clinical findings of obstruction, there may be radiographic evidence of *in utero* perforation, with sterile peritonitis resulting in peritoneal calcifications. Malrotation or volvulus may also occur in association with meconium ileus.

More than 90% of patients have clinically significant exocrine pancreatic insufficiency. In some, secretion of bicarbonate and enzymes may be reduced, but sufficient function may remain to prevent steatorrhea. Episodes of acute pancreatitis may occur in these patients. The effects of pancreatic insufficiency include fat and protein maldigestion with consequent malabsorption and production of bulky, greasy, foul-smelling stools. Secondary caloric, protein, and fat-soluble vitamin deficiencies may develop in untreated or inadequately treated patients. Rectal prolapse is common in younger, untreated patients and may be a presenting symptom.

Late intestinal obstruction (“meconium ileus equivalent”) may develop as a result of inspissation of bowel contents in the cecum or terminal ileum and occurs in 2% to 4% of patients annually. The colon tends to be distended because of the malabsorption, and intussusception (often relatively painless and sometimes without obstipation) is not uncommon. Patients taking very high doses of pancreatic enzyme supplements may develop a syndrome of fibrosing colonopathy with colonic strictures.

Genitourinary

Almost all men with CF are sterile, but a semen analysis is required to be certain, as some patients have normal sperm counts. Female fertility is reduced, both by chronic illness and by thick cervical mucus. However, a significant number of women with CF have conceived (151 pregnancies were reported in 1995). Those with moderate to advanced disease who become pregnant are at risk of worsening their clinical condition. Infants born to these women are obligate heterozygotes.

Sweat Glands

Failure to reabsorb salt from the sweat ducts is almost universal in patients with CF, with sweat electrolyte concentrations above 60 mEq/liter. With adequate replacement of salt in the diet, there are usually no significant clinical manifestations of the sweat defect. Excessive loss of salt can lead to heat prostration, and, in infants, metabolic alkalosis can develop, even in cold weather. Patients presenting with metabolic alkalosis unexplained by loss of gastric or intestinal fluid should be

carefully evaluated for CF.

Metabolic

Many patients develop glucose intolerance in the late second or third decade of life, with an incidence reaching 16% by age 35 to 44. This is presumably related to gradual loss of functioning pancreatic islet tissue. Although ketoacidosis is unusual, many patients require insulin to control their glucosuria.

Treatment

Recent advances in the understanding of the molecular basis of CF have been impressive. Improvements in therapy have been somewhat slower to evolve but are the subject of intensive development. Unfortunately, because the rate of progression of disease is slow, it is very difficult to discern meaningful benefit in clinical trials. Another difficulty of developing new therapy is compounded by the fact that the most benefit can be expected in infants and young children, in whom clinical research is more difficult. Definitive evidence of successful therapy may be difficult to obtain in a short-term study, and it is often necessary to utilize surrogate indicators for success.

New and Developing Therapy for CF

Pharmacologic manipulation of epithelial ion transport is an obvious target for therapy aimed at reversing defective CFTR function. Amiloride blocks the increased absorption of sodium from the airway lumen, thus (presumably) maintaining better hydration of the periciliary fluid and secretions. Results of pilot studies in adult patients were encouraging, but larger-scale clinical trials have not borne out the early enthusiasm. Nucleotide triphosphates (ATP, UTP) appear to open an alternative chloride channel in airway epithelial cells; clinical trials of UTP and amiloride in combination are under way.

Pharmacologic manipulation to reduce the viscoelastic properties of tracheobronchial secretions has long been a goal of therapy. The presence of high concentrations of DNA in purulent secretions may contribute substantially to viscosity. Human recombinant DNase has been reported to reduce the viscosity of airway secretions and, in clinical trials, has led to modest improvement in pulmonary function in some patients.

Modification of the inflammatory processes in the airways has been attempted by several approaches. Administration of alternate-day prednisone (1 mg/kg) resulted in improved pulmonary function in a multicenter trial, but there were unacceptable side effects. Aerosolized steroids are currently under investigation. Nonsteroidal antiinflammatory agents such as ibuprofen have also been shown to have moderating effects on the progression of pulmonary disease, at least in young patients, by reducing neutrophil migration into the airways. Ibuprofen must be given at very high doses, and there is evidence that low doses may actually enhance inflammation. Clinical trials of aerosolized protease inhibitors are under way.

Modification of the function of the defective gene product and modification of posttranslational processing of the gene product are additional potential therapeutic approaches under development.

Ultimately, CFTR gene transfer seems the best hope for a cure. Successful experiments with *in vitro* gene transfer have been reported from many laboratories. *In vivo* studies have also begun to show promise, and a number of different approaches are being developed. Transduction of the CFTR gene into epithelial cells via modified viral vectors, by encapsulation within cationic liposomes, and by receptor-mediated transfer are some strategies that have been used. At present, it can be said that gene therapy is exciting and promising but unlikely to be totally successful in the near term. It is clear that gene therapy will not be curative in patients with extensive bronchiectasis, so it is imperative that patients be treated aggressively today in hopes of preserving their lungs in preparation for curative therapy in the future.

Conventional Treatment

The empirical, conventional therapy for CF has not changed dramatically in the past two decades. There is considerable disagreement as to the most effective therapeutic regimen, and objective data in support of one or another method are scant. In general, however, it may be said that CF is a complex disorder that involves multiple organ systems, and treatment is best handled in specialized centers where concentrated expertise and experience are available. Continuity of care and a strong patient–physician relationship are important components of successful therapy.

Pulmonary Therapy

The main goal of pulmonary therapy is to prevent or reverse the progression of pulmonary disease. This is approached in two ways: by efforts to improve airway clearance and by efforts to reduce infection.

Physical measures to enhance clearance of pulmonary secretions include chest percussion, forced expiratory maneuvers, vigorous exercise, and cough. The flutter device is a useful adjunct to mobilization of secretions and can be used by patients without dependence on parents or other caregivers. Airway obstruction begins at a very early age, and chest physiotherapy should be initiated at the time of diagnosis, even in patients who are asymptomatic. At times of symptomatic exacerbation, the frequency or the intensity, or both, of such therapy should be increased. Dehydration should be avoided.

Various forms of aerosol therapy, including mucolytic agents, bronchodilators, and antibiotics, have been used. There is little evidence to support the use of mucolytic aerosols. b-Adrenergic agents have been shown to increase mucociliary transport in patients with CF, but the clinical efficacy of such therapy is unknown. Some patients exhibit increased airway obstruction following bronchodilator therapy, and the response is not necessarily consistent over time. Therefore, such treatment must be individualized. Aminoglycoside (or other antibiotic) aerosols may be effective, either alone or in combination with parenteral therapy. In general, aerosolized agents may be expected to be more effective in the earlier stages of the pulmonary disease because obstruction with thick secretions limits the penetration of aerosols.

Antibiotic therapy is important in reducing the pulmonary bacterial burden. The presence of large numbers of bacteria in the airways induces secondary inflammatory responses that may in themselves be harmful; reducing bacterial numbers is usually helpful. Early in the course of disease, patients may produce little or no sputum, and it may be difficult to define the bacterial flora of the lower respiratory tract. In young children, infection with organisms such as *H. influenzae* or *S. aureus* is more common than with *Ps. aeruginosa,* although this organism may also be seen in infants. Oral antibiotics may be efficacious for younger patients, but with *Ps. aeruginosa* infection, or in those with significant disease, parenteral therapy is usually necessary. The choice of antibiotics should be guided by cultures of respiratory secretions. If sputum is not available, swabs of the posterior pharynx (taken after vigorous coughing) or cultures of bronchoscopic specimens may be used; the latter are much more sensitive and specific but should be used selectively because of the associated cost and other factors. Bronchoscopic investigation at the time of initial diagnosis may be important, as the initial therapy may help determine the future course of disease.

Patients with CF require higher doses of virtually all antibiotics than do other patients because of the larger volume of distribution, more rapid renal clearance of most drugs, and more rapid metabolism of others. When drugs such as aminoglycosides are used, care must be taken to ensure that the doses are sufficient to produce effective levels while avoiding toxicity.

All reasonable measures should be taken to prevent infection. Children (and parents) should be taught good hygiene practices to reduce the incidence of viral respiratory infections, especially in infants. On the other hand, isolation of young patients with CF is not necessarily a good thing, even though it may reduce the frequency of viral infections. Immunization against respiratory infections such as influenza is important.

When the disease cannot be controlled by oral or aerosolized antibiotic therapy, or when only parenteral drugs can be effectively used, hospitalization may be required. Indications for intensified therapy or hospitalization include weight loss, increased cough and sputum production lasting more than 2 weeks, worsening pulmonary function, and the development of complications such as pneumothorax, significant hemoptysis, or cor pulmonale. In selected patients, parenteral therapy can be continued at home. In the hospital, intensive chest physiotherapy, nutritional support, psychosocial support, and other therapeutic modalities may be employed. In the majority of patients, clinical improvement will be evident after 5 to 7 days, but courses of therapy shorter than 2 weeks rarely result in a satisfactory clinical response. In many patients, longer (or even continuous) therapy is necessary. Monitoring of the patient for drug toxicity and for the development of resistant organisms is essential.

End-stage lung disease in CF patients is increasingly being managed by lung transplantation (135 transplants were reported in the United States in 1995). This procedure is expensive, is difficult for patient, family, and physician alike, and is not appropriate for all patients. Indications for transplantation are not yet clearly defined. The long-term prognosis of patients who have undergone lung transplantation is uncertain. Although many patients exhibit amazing improvement, others die within weeks or months from complications of the transplant or rejection. In 1995, 10% of deaths in CF patients in the United States were related to transplant complications.

Gastrointestinal Therapy

Nutrition plays a major role in the global well-being of CF patients. Because of inefficient digestion and absorption, as well as other factors, CF patients require 125% to 150% of the usual daily requirement of calories and other nutrients. High-fat diets are important to provide sufficient calories. In addition, fat-soluble vitamins should be given in water-miscible form.

Pancreatic insufficiency should be treated with pancreatic enzyme replacement. Enteric-coated preparations are most effective, and the dosage should be spread throughout the meal to achieve optimal mixing. The dosage is empirical and is adjusted according to the quantity and nature of the food ingested as well as by the patterns of growth and stool character. Steatorrhea is almost never totally eliminated despite adequate enzyme replacement.

Meconium ileus can sometimes be relieved nonoperatively by an enema of hygroscopic radiographic contrast material, but more often, surgery is necessary. Late intestinal obstruction can usually be relieved by enemas, as can intussusception, and such methods should be tried before surgery is resorted to. Cleansing of the bowel with oral electrolyte solutions can also be effective if the obstruction is not complete.

Liver disease with symptomatic portal hypertension develops in a small percentage of patients. Endoscopic sclerotherapy, vascular shunting, and even liver transplantation have been utilized for management. Somewhat surprisingly, despite the presence of chronic bacterial infection in the lungs, many CF patients do well after liver transplantation and the immunosuppressive regimens necessary to maintain the transplant. Hepatocellular damage short of portal hypertension may respond to treatment with ursodeoxycholic acid.

Treatment of the Sweat Defect

Patients should be encouraged to maintain a high salt intake, especially in hot weather. No other treatment is necessary unless salt depletion has occurred. Some years ago, when low-sodium infant foods and formulas were introduced, the incidence of hypochloremic alkalosis in infants with CF increased significantly.

Metabolic Therapy

Patients who develop glucose intolerance may require treatment with oral hypoglycemic agents or insulin. Ketoacidosis is rare, and the primary goal of therapy is symptomatic relief rather than tight control of blood sugar. Treatment is otherwise similar to that of adult-onset diabetes.

Psychosocial Therapy

Cystic fibrosis is a chronic, progressive, and ultimately fatal disease. Virtually no form of therapy yields dramatic, immediate results, and it is therefore difficult for patients and other caregivers to discern the benefit of day-to-day therapy. Compliance with therapy may thus be compromised, even in the most motivated and intelligent patients and families. The importance of a positive attitude on the part of the patient, family, and the physician and other caretakers cannot be overemphasized. A fatalistic attitude can literally be fatal. As more and more patients reach adulthood, problems with education, career planning, marriage and family, sterility, dependence–independence, fear of impending death or disability, and the cost of medical care assume major proportions and can be overwhelming. It is therefore important to pay as much attention to mental health as to physical health.

Prognosis

The outlook for patients with CF has improved dramatically over the past several decades. In 1966, the median survival age of patients reported to the Patient Registry of the Cystic Fibrosis Foundation was just over 10 years. By 1995, the median survival age had increased to 30.1 years, although the prognosis is slightly worse for female than male patients. The prognosis for any individual is difficult to predict.

The reasons for the improving prognosis are not fully understood. The mean age at diagnosis has not changed substantially over the past several decades, suggesting that neither earlier diagnosis nor diagnosis of older, more mildly affected patients is what has changed. Significant differences in survival patterns have been reported by various centers, suggesting that differences in treatment may be of importance. Centers in Europe and Australia have reported survival experiences similar to that of major North American centers.

What is clear is that further improvements in prognosis will depend on advances in therapy. Several large centers that have traditionally had very high survival rates have not seen increases in survival rates over the past two decades, while survival rates in other centers have been “catching up.” The rapid progress in the molecular biology of CF over the past several years promises dramatic changes in our approach to therapy and, we hope, improvements in prognosis. In anticipation of potentially curative therapy in the relatively near future, it is important to treat patients aggressively today.

PRIMARY CILIARY DYSKINESIA (IMMOTILE CILIA SYNDROME, KARTAGENER'S SYNDROME)

The clinical triad of situs inversus, bronchiectasis, and pansinusitis was recognized as a distinct entity in 1936 by Kartagener, who also noted the occurrence of the triad in siblings. Kartagener's syndrome remained a clinical oddity until Afzelius and colleagues reported that sperm from these patients were immotile and that their ciliary ultrastructure was abnormal. Subsequently, the generalized nature of the ciliary abnormality was recognized. Several kindreds have since been reported to have a variety of ultrastructural abnormalities and a common clinical picture of chronic sinus and bronchial disease, with or without situs inversus. Because many patients with similar clinical syndromes have abnormal cilia with disordered but not absent movement, the preferred term today is *primary ciliary dyskinesia* (PCD) rather than *immotile cilia syndrome.*

Genetics

The familial pattern of Kartagener's syndrome is consistent with an autosomal recessive mode of inheritance. The syndrome has been documented in siblings of both sexes but has rarely been seen in two consecutive generations. Other variants of PCD have been observed in siblings. At least one family has been reported with an X-linked inheritance pattern. From the estimated incidence figures above, it may be calculated that approximately one in 70 persons is heterozygous for one form or another of the disorder.

Incidence and Prevalence

Situs inversus occurs with an incidence of one in 8000 to one in 24,000 live births, and of these, only 12% to 25% have the complete triad of Kartagener's syndrome. It is not clear whether situs inversus occurs with a 50% (i.e., random) incidence in all patients with immotile cilia. However, with a few assumptions, it may be estimated that the incidence of PCD may be as high as one in 20,000 live births.

Pathophysiology

Mucociliary function depends on a number of factors, including the number, orientation, and beat frequency of cilia and the dimensions and viscoelastic properties of the mucus and the aqueous periciliary fluid layers. Virtually any structural abnormality of cilia that results in an abnormal ciliary beat can result in clinical abnormalities. The ultrastructure of cilia is quite constant, with two central microtubules surrounded by nine outer microtubule doublets. The microtubules are composed of tubulin, a protein with no intrinsic contractile activity. Radial spokes extending from the central doublet to the outer tubules and nexin links help maintain the structure. Other structures projecting from the outer doublets (dynein arms) have ATPase activity. Motion of the cilia is thought to occur by interaction of the dynein arms with adjacent microtubules via a sliding mechanism similar to that of muscle contraction.

Electron microscopy of cilia from sperm tails and from nasal and bronchial epithelium of patients with Kartagener's syndrome reveals the partial or complete absence of dynein arms. Other kindreds with absent radial spokes or with other ultrastructural patterns have also been reported. Familial clusters of patients with ciliary aplasia have also been reported; these patients have similar clinical manifestations to those with classical PCD.

Not all patients with chronic sinopulmonary disease have immotile cilia, yet many of these patients do demonstrate abnormal ciliary ultrastructure. Chronic infection or inflammation may itself produce abnormalities. Clinical and ultrastructural data must be interpreted with caution, and it is difficult to assign a genetic basis to a particular patient's problem unless the ultrastructure is classic (i.e., absence of dynein arms) or there is familial clustering. It also should be pointed out that fixation and staining

techniques may have a great impact on the ultrastructure visualized, and artifacts are common.

It has been postulated that ciliary beat is necessary for the normal embryonic rotation of the primitive foregut and that the situs inversus commonly associated with immotile cilia results from an essentially random rotation. Although this hypothesis is unproven, it is clear that siblings of patients with Kartagener's syndrome often have pansinusitis and bronchiectasis without situs inversus. Many other patients with immotile cilia who do not have situs inversus have been reported. In 65 patients with Polynesian bronchiectatic disease, there were none with situs inversus. These patients have been reported to have deficient dynein arms on their ciliary microtubules, but the relationship between the two syndromes remains unclear.

Patients with PCD develop bronchial disease much more slowly than do those with CF and do not usually have the extensive mucous hypersecretion and airway plugging so characteristic of CF. Also in striking contrast to CF, they do not have a high frequency of infection with *Ps. aeruginosa.* The very existence of the clinical syndrome emphasizes the physiological importance of cilia in the respiratory tract, but it is clear that other factors are of importance in the pathogenesis of severe bronchopulmonary disease.

Diagnosis

The diagnosis of PCD may be suspected on the basis of the clinical picture, and it must be emphasized that situs inversus is not a necessary finding. A simple screening test may be performed by microscopic examination of scrapings of nasal epithelium (obtained from the middle to posterior third of the nose and placed into tissue culture medium). If adequate specimens are obtained, and the patient does not have an acute infection, the absence of ciliary beat on repeated testing is presumptive evidence of immotile cilia. In adult men, sperm also may be examined. It is important to obtain sheets of ciliated epithelium rather than isolated cells for examination and to compare the ciliary motility of the specimen with that of control material. Most isolated cells will not be viable, and their cilia will not beat. Confirmation of the diagnosis depends on the demonstration of characteristic ciliary ultrastructural abnormalities. No other laboratory findings are diagnostic. Specimens for ultrastructural study may be obtained from the nose or a bronchus.

Patients may have defective mucociliary transport for reasons other than immotile cilia, and the demonstration of normal ciliary beat or normal ciliary ultrastructure does not mean that mucociliary function is normal.

Pathology

Primary ciliary dyskinesia affects all ciliated epithelia, including those of the middle ear, Eustachian tube, nose, paranasal sinuses, tracheobronchial tree, and perhaps other locations. However, there is no distinctive histologic picture, and these patients cannot be distinguished from those with other forms of bronchiectasis or sinusitis on the basis of light microscopy. Electron microscopy reveals characteristic ultrastructural abnormalities, including disorientation of the ciliary basal bodies. The classic finding is absence of inner or outer dynein arms (or both), but microtubular transposition, absence of radial spokes, and other abnormalities have been reported as well.

Clinical Manifestations

The clinical manifestations of PCD may begin early in life, or they may not become apparent until the second or third decades. In infants and children, cough and recurrent otitis media may be the primary signs. Patients are often suspected of having CF, but sweat testing will exclude this possibility. The usual signs and symptoms of sinusitis, bronchitis, and bronchiectasis are present in most patients; cough and sputum production, recurrent fevers, hemoptysis, digital clubbing, and eventually cyanosis may be present. Recurrent otitis media and conductive hearing loss are common. Although sperm counts may be normal, most men are infertile; some patients with well-documented PCD have fathered children.

Treatment

There is no specific treatment that will alter ciliary function in patients with PCD. The bronchopulmonary disease is treated by chest physiotherapy, antibiotics, and bronchodilators as needed. Sinusitis should be treated with antibiotics and surgical drainage if necessary. Attention to the management of upper respiratory tract infections and otitis media should help reduce the complications of conductive hearing loss. When bronchiectasis is localized and severe, excision of involved areas of the lung may be indicated if medical management is insufficient.

The ultimate therapy for PCD is correction of the genetic defect. Techniques being developed for gene transfer therapy of other diseases such as cystic fibrosis will have direct and immediate application to PCD once the defective gene has been identified. The Human Genome Project can be expected to result in the identification of the gene or genes involved in PCD, so that it is not unreasonable to anticipate successful gene transfer therapy in the foreseeable future.

Prognosis

The complete spectrum of PCD is not yet defined. What is clear is that the involvement and severity are quite variable. The classical patient develops severe bronchiectasis in the third to fourth decade and may succumb to pulmonary complications. Patients can reach advanced age, and many live a comparatively normal life. The majority of patients appear to develop bronchitis in childhood and to demonstrate findings of airway obstruction after two to three decades. Infections may be most severe in childhood and adolescence, with a partial clinical remission in adult life. Effective gene therapy would be expected to substantially impove prognosis.

ASTHMA

The familial disposition toward asthma has long been a part of conventional clinical wisdom, but no studies have succeeded in defining the precise role of genetic factors in its pathogenesis. The imprecise nature of the definition of asthma emphasizes the diversity of predisposing factors and the difficulty of defining a genetic role. A study of 7000 Swedish twin pairs found that although 4.8% of the dizygotic twin pairs were concordant for asthma, 19% of the monozygotic twin pairs were concordant. This is strong evidence for genetic factors in the causation of the asthmatic syndrome. In recent years, a number candidate genes for roles in asthma have been investigated, but no single gene has emerged as being responsible for even a small percentage of clinical cases of asthma. The genetic basis of asthma is almost certainly polygenic and involves a number of different, though related, mechanisms. Mutations in genes involving adrenergic receptors, inflammatory mediators, and immune responses are most likely involved. The role of environmental factors in the pathogenesis of asthma cannot be underestimated; identification of genetic factors that increase susceptibility to environmental stimuli could be helpful in patient counseling and possible prevention.

CYSTIC LUNG DISEASE (LOCALIZED SACCULAR BRONCHIECTASIS)

Cystic lung disease is a name given to a wide variety of conditions in which bronchiectasis is associated with fluid- or air-filled, sharply defined, round structures that have a definite wall. The cysts are usually discovered on chest roentgenograms or in anatomic specimens. In most patients, cysts found with the cylindrical variety of bronchiectasis have been related to the syndrome of infectious chronic bronchitis. Localized saccular bronchiectasis, which appears to be a distinct entity, has been described in Sephardic Jews emigrating to Israel and in the Maoris, Polynesian natives of New Zealand. Whether these are examples of genetic lung disease remains a somewhat open question. A recent report suggests that the Polynesian patients with bronchiectatic disease have deficient dynein arms on their ciliary microtubules. Thus, the disease in the Maoris may have the same basis as PCD. This observation lends further credence to the hypothesis that it is a genetic disorder. In the Jewish patients, the striking findings were cylindric dilations of the medium-sized and small bronchi with cyst-like cavities that were usually connected to the bronchi. The cylindric nature of the bronchiectatic changes suggests that these cases were not the classic, acquired forms of bronchiectasis. Perhaps the most compelling evidence to support a genetic component in this form of bronchiectasis was the ethnic clustering. In Israel, 92% of the patients were found among immigrants from Yemen, Iraq, and Morocco, groups that have been isolated and highly inbred for 2000 years. Jews who emigrated from central and western Europe made up only 8% of the patient population. Similar clustering was observed in the Maoris as compared with the Anglo-Saxon immigrant populations of New Zealand. Higher frequencies of a disease in specific population groups suggests a genetic component in its cause if environmental conditions are held constant. Thus far, multiple cases in a family or transmission in two consecutive generations has not been reported. The hypothesis that saccular bronchiectasis has a genetic basis needs to be confirmed by additional studies.

YELLOW NAIL SYNDROME

The association of primary lymphedema with yellow discoloration of the nails has been termed the yellow nail syndrome. A third manifestation is unexplained recurrent pleural effusion. Patients studied by lymphangiography show lymphatic abnormalities consisting mostly of lymphatic hypoplasia. Bronchiectasis is common (five of 12 patients in one report and four of four in another). Sinusitis has been reported in a high percentage of patients but is not felt to be caused by primary ciliary dyskinesia, as ciliary beat frequency is normal. The recurrent pleural effusions are most likely secondary to hypoplastic lymphatics. Chronic cough is present in all patients. Dyspnea may be present and is related to the extent of pleural effusion or to bronchiectasis. Lymphedema, pleural effusion, or bronchiectasis may not become evident for years after the nails become yellow. Lymphedema usually occurs before pleural effusions become manifest. The disorder has been reported in a mother and child

as well as in cousins, suggesting a genetic basis.

TRACHEOBRONCHOMEGALY

Mounier-Kuhn presented the first clinical description of tracheobronchomegaly, a unique syndrome characterized by striking dilation of the trachea and bronchi. The occurrence of two documented cases in a single family suggests a familial cause, but the genetic basis has not yet been firmly established. The incidence of tracheobronchomegaly in the general population is unknown but is undoubtedly low. Six cases were discovered in a series of 1200 adults undergoing bronchography for chronic pulmonary disease. Affected individuals show a distinctive clinical and roentgenographic picture consisting of marked dilation of the trachea and major bronchi associated with chronic respiratory infection. The symptoms of chronic respiratory disease in this condition do not differ from those of a great variety of other respiratory diseases. Patients may have cough, dyspnea, hoarseness, and copious production of purulent sputum. The course is often of long duration, with onset of symptoms in infancy or childhood.

The diagnosis is based on roentgenographic findings. Plain films of the chest may reveal the width of the tracheal air column to be equal to that of the vertebra. The major bronchi are also markedly enlarged, and there are large outpouchings between cartilage rings in which secretions may pool. Occasionally, cystic changes in the peripheral bronchi are noted. Computed tomography is a convenient method to confirm the diagnosis. The size of the trachea and bronchi in affected adults deviates by more than 3 standard deviations from that in normal adults. Normative data are now available for infants and young children. The dynamics of the trachea and bronchi are abnormal, with diffuse tracheobronchomalacia.

The pathogenesis of tracheobronchomegaly is not known, but it has been speculated that it is caused by a sparsity of elastic and muscular fibers in the airway walls. It is of interest that the syndrome has been reported in patients with connective tissue disorders, including the Ehlers–Danlos syndrome, Marfan's syndrome, and cutis laxa. Acquired forms of tracheobronchomegaly may be related to prolonged respiratory support with positive-pressure ventilation, especially in premature infants.

Treatment measures include chest physiotherapy to improve clearance of secretions and prompt treatment of infections. If pulmonary clearance of secretions can be maintained, the prognosis is relatively good, but if there are recurrent infections, the prognosis is poor. In selected patients, tracheobronchial stenting may be helpful.

OTHER FORMS OF AIRWAYS DISEASE WITH POSSIBLE GENETIC BASES

Williams and Campbell described a group of patients with bronchiectasis caused by a generalized deficiency of bronchial cartilage. The clinical picture is characterized by persistent cough and wheezing, digital clubbing, chest deformities, and short stature. In the original reports, no familial pattern was seen, but later, two siblings with this syndrome were reported. Recurrent respiratory infections are the rule in these patients, and pulmonary function studies reveal marked air trapping and airway obstruction on expiration. Bronchographic studies demonstrate ballooning of the bronchi during inspiration and collapse during exhalation. Approximately 25% of the reported patients died before age 5, and most of the remainder have chronic pulmonary disease with persistent symptoms. Treatment is the same as for other forms of bronchiectasis.

At least one sibship has been reported in which four or five siblings had symptomatic bronchiectasis of the right middle lobe.

Generalized bronchomalacia without bronchiectasis has been reported on a familial basis. Laryngomalacia also has been reported to have a familial pattern. One family has been reported in which two siblings had severe tracheal obstruction caused by an anomalous innominate artery, requiring emergency surgery. Two sets of siblings with nasal polyps in infancy, aplasia of the nasal sinuses, and bronchiectasis have been described. This condition has been termed Woake's syndrome.

There are a number of familial immunologic disorders that lead to sinopulmonary infection and bronchiectasis, including X-linked agammaglobulinemia, common variable immunodeficiency, and selective immune globulin deficiencies. Esophageal atresia with associated tracheoesophageal fistula has been reported to occur in families. Infants with bronchopulmonary dysplasia may have a higher proportion of first-degree relatives with asthma than infants with normal lungs. It is possible that infants with a genetic predisposition toward reactive airways may respond adversely to neonatal insults, with consequent development of permanent airways disease.

a_1-ANTITRYPSIN DEFICIENCY

a_1-Antitrypsin deficiency is an inherited disorder associated with emphysema, bronchiectasis, and hepatic cirrhosis. a_1-Protease inhibitor (a_1-antitrypsin, AAT) is the major protease inhibitor in human plasma. Its primary role is to neutralize neutrophil-derived elastase by tightly binding to it, forming a stable complex that can be catabolically metabolized. Any mutation that reduces the ability of AAT to tightly bind neutrophil elastase will reduce its activity and functionality.

Mechanisms causing functional a_1-antitrypsin deficiency include abnormalities in the transcription, translation, and intracellular processing of AAT. The resulting mutant proteins are characterized by their electrophoretic mobility and are referred to by their PI (“protease inhibitor”) types. Because each allele is codominant, both alleles must be identified in order to characterize the individual. The most common (normal) phenotype is PIMM; the most common abnormal variants are the S and Z alleles.

Genetics

a_1-Antitrypsin deficiency results from inheritance of two abnormal AAT alleles on chromosomal segment 14q32.1 in the AAT gene locus. This locus (PI) is situated in a cluster of genes that code for related proteins of the serpin superfamily including cortisol-binding globulin, a_1-antichymotrypsin, a_1-antitrypsin, a_1-antitrypsin pseudogene/protease inhibitor-like gene (AATP), and the protein C inhibitor. With the exception of the AAT pseudogene, all of these proteins have substantial amino acid and structural homologies. a_1-Antitrypsin is synthesized primarily by liver but also may be made by mononuclear cells, polymorphonuclear leukocytes, intestinal epithelium, and the kidney parenchyma. a_1-Antitrypsin is an acute-phase reactant, and concentrations in plasma may vary by as much as fourfold in response to acute infection or inflammation.

The AAT gene is composed of seven exons and six introns spanning more than 12 kb. The first three exons contain the promoters responsible for macrophage and hepatocyte transcription. The remaining four exons encompass 1434 bp. The start codon ATG and the 24-amino-acid signal peptide sequence are located on the fourth exon. The fifth exon contains the most common polymorphic site within the coding region, and the sixth exon contains the site of the most common mutation associated with a_1-antitrypsin deficiency. This exon also contains the stop codon and the polyadenylation site.

The AAT mRNA synthesized by hepatocytes is 1.6 kb in length, and three macrophage-derived a_1-antitrypsin mRNAs of 1.8, 1.8, and 2.0 kb have been identified. These differences result from alternative splicing of the first three exons. The promoter region is a 557-bp fragment that starts 20 nucleotides upstream from the transcription start site. This region contains a conventional TATA box and three additional elements (X, Y, and P elements) that are necessary for efficient transcription. The X and P elements are required for transcription in hepatocytes. Transcriptional factors that have been identified to play an important role include LFB-1/HNF-1, C/EBP, HNF-3, and HNF-1/LFA-1. Interleukin-6, the major cytokine associated with development of the acute-phase reaction, up-regulates AAT transcription.

Translation of AAT mRNA results in a 418-amino-acid protein with a 24-amino-acid leader signal peptide that directs the protein to the rough endoplasmic reticulum. Here, the signal peptide is cleaved, and glycosylation of the protein takes place. The glycosylated protein is then transported to the Golgi, where further processing occurs. After this, the completed 52-kDa globular glycoprotein is secreted into the serum. This entire process takes about 90 min.

Molecular Epidemiology, Incidence, and Prevalence

DNA sequencing has revealed the presence of at least 49 AAT allelic variations, and about 100 phenotypic (PI) variants of AAT may be detected by the isoelectric focusing technique. PI*M (with its several subtypes) is the most common allele associated with normal levels of activity. Evidence suggests that all PI*Z alleles have a single geographic origin.

Most mutations occur in the coding sequence for the AAT protein and are generally spread evenly throughout the sequence, with two exceptions. A higher concentration of mutations may be found in codons 51 to 53 and in codons 361 and 362. These areas may be sites of excessive deletions or insertions of one or more bases because they contain highly repetitive sequences on which the DNA polymerase may make mistakes.

The majority (95%) of individuals with severe AAT deficiency are homozygous with a PI type of ZZ. These individuals are most commonly white and of European extraction. The condition is not found in Asian and black populations. The frequency of this defect in Europe and North America is about 0.0122, which corresponds to

an incidence of about one in 5000 to 7000. Because of this frequency, it is thought that only a very small proportion of those with AAT deficiency have been diagnosed.

The remaining 5% of AAT-deficient persons who are not PI*ZZ exhibit about 20 other variants that are not identifiable by PI typing. These variants may be associated with substantially reduced levels of functional protein or with normal or reduced levels of nonfunctional AAT or with undetectable levels of the protein. Homozygous individuals with null alleles (PI*Q_0Q_0) have either zero or less than 1% of the normal amount of AAT. The frequency of this mutation is estimated to be about 1.7×10^{-4}, which is approximately 1/100th of the frequency of the PI*ZZ genotype.

Population studies suggest that the known number of AAT-deficient persons is much less than the actual number of those present in the population: 4.5% in the United Kingdom, 6% in Sweden, and about 5% in the United States. The reason for this is that physicians often do not diagnose the disease in young smokers. An average delay of 7.2 years between the first onset of symptoms and the initial diagnosis of AAT deficiency was found in 304 AAT-deficient individuals. Many of these patients had been seen by multiple physicians before the diagnosis was made. It is important to consider this diagnosis in all patients who present with emphysema at a young age, whether they smoke or not.

About one in 25 individuals of Northern European descent carry the Z mutation of AAT, which is the most common form of genetic abnormality. This particular mutation does not allow AAT to fold properly during synthesis so that it is more susceptible to intracellular breakdown. Individuals homozygous for the ZZ genotype synthesize normal amounts of the protein in the liver but secrete only 15% into the blood. The remaining 85% remains in the hepatocyte and is either degraded or accumulates as large intracellular inclusions. Two other mutations are associated with the deletion of most of the coding region of a_1-antitrypsin. Other mutants are associated with abnormalities in mRNA splicing or stability or abnormal retention in the rough endoplasmic reticulum or Golgi with subsequent degradation.

Clinical Manifestations

The clinical manifestations of AAT deficiency involve primarily the lung, although some young patients have hepatic involvement.

Chronic Obstructive Pulmonary Disease

The most common syndrome associated with AAT deficiency is chronic obstructive pulmonary disease (COPD), usually of the emphysematous type, and is usually panacinar and basilar in location. Clinical findings are similar to those of patients with other forms of COPD (see Chapter 43). The primary symptom is dyspnea, but many patients also have chronic cough and sputum production. Physical findings include an increased anteroposterior diameter of the chest, hyperresonance, and decreased breath sounds. Digital clubbing is not usually present unless there is also bronchiectasis. Radiographic abnormalities include marked hyperinflation with bilateral hyperlucency, predominantly in the lower lobes. Physiological studies reveal marked increases in lung volumes and decreases in expiratory flows (reflecting air trapping as a result of loss of tissue elastic recoil with airway collapse on expiration) as well as decreased diffusing capacity (reflecting loss of alveolar tissue). Hypoxemia is common in patients with advanced disease, who may also have signs of congestive heart failure. Chronic bronchitis is seen in 20% to 35% of patients, and as many as 45% of patients may develop bronchiectasis.

Liver Disease

Hepatic disease is the second most frequent clinical manifestation of AAT deficiency and usually presents in the postnatal period as cholestatic jaundice. Only patients with the PI*ZZ variant develop hepatic disease, which is caused by intracellular accumulation of AAT in the hepatocytes. Liver disease in most AAT-deficient children is mild, with only 10% having clinically significant disease. Abnormal liver chemistries often disappear as the child develops. AAT-deficient children with severe hepatic disease may require liver transplantation.

Dermatologic Manifestations

Panniculitis is the least common manifestation of AAT deficiency and is found in individuals with a variety of phenotypes, including PI*ZZ, PI*MZ, PI*SS, and PI*MS. It is characterized by inflammatory and necrotizing lesions of the skin.

Pathophysiology

The panacinar emphysema in AAT-deficient individuals is produced by elastolysis of lung elastin, which occurs by several mechanisms. Generally, these individuals have a relative deficiency of anti-neutrophil-elastase activity in lung tissue at all times, resulting in a relative imbalance between elastase and antielastase activity. In addition, smoking causes a large influx of neutrophils and macrophages to the lung, thus increasing the elastase burden in lung tissue. Oxidant components of cigarette smoke also inactivate any AAT that is present in lung by oxidizing a crucial methionine (position 358) at the center of the active site of the molecule and thus potentiate the effects of neutrophil elastase. Thus, individuals with reduced levels of AAT are at greatly increased risk of elastolysis with loss of normal alveolar structure, especially if they smoke. Macrophages also secrete an elastase; cells in contact with elastic fibers have the potential of degrading elastin. Bronchiolar pathology (cellular infiltration, goblet-cell metaplasia, fibrosis, luminal secretion, increased airway smooth muscle) is not always present with the emphysema.

Smoking is clearly the most important associated risk factor for the development of chronic obstructive pulmonary disease. Individuals who do not smoke do not necessarily develop disease, and if they do, it usually begins by the third decade and becomes evident in the fifth or sixth decade of life, when reductions in expiratory flow may be noted. However, the emphysema may be very severe, even in individuals who have never smoked. Usually, ZZ homozygous patients will develop moderate airflow reduction between the ages of 45 and 55.

Little is known about the deleterious effects of environmental air pollution on the development or severity of lung disease in individuals with AAT deficiency. It is likely that breathing ozone, sulfur dioxide (SO_2), oxides of nitrogen, and other such pollutants will increase the rate of worsening of lung disease occurring in the AAT-deficient setting. Individuals with AAT deficiency should make every attempt to limit their exposures to these materials.

Respiratory infections in early childhood seem to be a risk factor for the early development of emphysema in individuals with severe AAT deficiency. Chronic bronchitis with repeated acute bacterial exacerbations by the usual offending organisms in AAT-deficient adults also seems to be a risk factor. Other genetic factors may promote the early development of COPD because the risk of an AAT-deficient individual developing COPD is increased if a parent has emphysema, bronchitis, or asthma.

Chronic liver disease is not a sequela of AAT deficiency, although cirrhosis and carcinoma of the liver are found in about 5% to 15% of AAT-deficient adults older than 50. The presence of hepatitis B is an additional risk factor for disease. The development of hepatocellular carcinoma in these individuals is not related to alcohol abuse. The relation to previous viral hepatitis, especially hepatitis C, is unclear.

Diagnosis

When a diagnosis of AAT deficiency has been established by low serum levels, the PI phenotype should be determined. It may be necessary to determine the genotype in the case of patients with unusual clinical phenotypes. Genotyping can give a more precise diagnosis and enable prognostic statements to be made with more confidence.

Screening

The overwhelming majority of patients with emphysema are not AAT deficient, so that screening for this condition is both costly and not generally effective. About 3% of this population will have AAT levels below the normal range. Screening of siblings of known AAT-deficient individuals is useful because the positive yield will be 25%. These individuals can be counseled to stop smoking and can be evaluated for therapy, although it is unclear whether currently available therapy alters the course of the disease.

Historically, screening for AAT deficiency has been done in three ways. The first is general screening of adults, usually done in the blood donor population. This has been useful for estimating the prevalence of undiagnosed AAT deficiency in the community, but it is not cost effective because of its low yield.

Directed screening of adults who have a higher-than-average risk of having AAT deficiency is useful. Such screening has been offered by the AAT Deficiency Detection Center in Salt Lake City since 1991 to individuals with chronic bronchitis, emphysema, and asthma, who have a family history of AAT deficiency. In the five years ending February 29, 1996, 16,748 samples were received for testing; 514 PI*ZZ individuals were found with levels of immunoreactive AAT <11 M. It is estimated that the center has diagnosed ~15% of the known individuals with AAT deficiency in the U.S.A. during its 5 years of operation.

Last, several neonatal screening programs have provided knowledge about the prevalence of the disease and eventually will provide information about the natural history of the disease in children and adults. Over 300,000 neonates have been screened in past years.

Therapy

Treatment of AAT deficiency may be divided into measures directed at the primary defect (low levels of AAT) and those directed at the secondary effects of the disease (i.e., emphysema, bronchitis, bronchiectasis). The latter measures are similar to those in other patients with COPD (Chapter 43). Smoking cessation should play a prominent role in any therapy program for AAT deficiency, as smoking is the most important single risk factor for development of lung disease in AAT-deficient individuals.

Intravenous AAT Augmentation

A serum AAT level exceeding 80 mg/dl (11 µM) is thought to protect against the development of emphysema. Repeated weekly infusions of partially purified, plasma-derived AAT at a dose of 60 mg/kg body weight was found to result in a mean nadir AAT level of 126 mg/dl in 21 patients whose pretreatment level was 30 mg/dl. Antibodies were not produced in response to the AAT, and the infusion was shown to result in increases in serum and bronchoalveolar lavage fluid anti-neutrophil elastase activity, suggesting that the infused AAT was active in the lung and might afford some protection against continued elastolysis and alveolar wall destruction and reduce the progression of emphysema. The half life of the infused AAT was between 4–5 days. At this time, about 2000 individuals with AAT deficiency are being treated worldwide with pooled plasma concentrate (Prolastin) on a weekly basis.

In a few patients given Prolastin at a dose of 250 mg/kg once every 28 days for 1 year, serum AAT levels of 70 to 80 mg/dl were maintained for 20 days. Even at 28 days, the BAL AAT levels and anti-neutrophil-elastase capacities were above threshold, suggesting that alveoli were protected over the whole cycle. These results are controversial at this time, and a once-a-month dosing regimen is not currently recommended.

Recombinant AAT is a 45,000-kDa nonglycosylated protein produced by yeast. This protein does not contain the terminal methionine and three carbohydrate chains of the native molecule. Recombinant AAT has a half-life of hours because of rapid renal clearance, and its clinical use is not appropriate.

Studies evaluating whether augmentation therapy prevents worsening of emphysema are not feasible because of the long intervals needed for study, the lack of a noninvasive, objective marker of emphysema, the large numbers of patients needed, and expense. A random, double-blinded study would require at least 250 patients in each arm of a placebo-versus-AAT augmentation trial followed for 3 years. Although preliminary data have suggested that the annual change in FEV_1 in 235 patients treated for 2 to 6 years with Prolastin was less than for 161 untreated patients, the difference was small and not statistically significant.

Side effects of Prolastin are few and include headache, myalgias, arthralgias, and low back pain. Some patients with pulmonary hypertension related to their disease develop worsening dyspnea during or shortly after the infusion. This may be secondary to the protein load and water retention. All patients slated to receive Prolastin should be vaccinated against hepatitis B, although no cases have been reported. Acute allergic or anaphylactic reactions have been few. Rare patients with severe AAT deficiency may also be IgA deficient; because they may receive some IgA with the Prolastin infusion, acute anaphylactic reactions have been noted in these individuals.

Patient selection for i.v. AAT augmentation therapy is somewhat controversial. The American Thoracic Society has published guidelines for therapy, but they are not universally accepted, given the uncertainty of therapeutic efficacy and the cost involved. In general, only patients with clearly deficient AAT levels (PI*ZZ, PI*Null-Null, PI*Z-Null, PI*S-Null, and a few PI*SZ) should be treated. The age at which therapy should be begun is unclear; although *a priori* reasoning would suggest initiation of therapy at a young age, there are no data on which to base judgment on this issue. The ATS recommends that patients who continue to smoke not be treated, as they are unlikely to benefit from the treatment.

Aerosol delivery of AAT is currently under investigation. This could potentially offer effective enhancement of AAT levels in the airway surface liquid while utilizing much less protein (and thus be more cost effective).

Lung Transplantation

More than 4300 patients, about 30% with COPD, have undergone lung transplantation (LT) worldwide. Approximately 12% of these transplants were performed for emphysema caused by AAT deficiency. Although the 6-year actuarial survival for all LT recipients is approximately 40%, patients with emphysema have a 4-year survival rate of 54%, the best survival among all groups. Recipients who are AAT-deficient have an actuarial survival of 45% at 5 years. Most LT survivors have reported functional improvement. Because of the shortage of suitable lung donors, most patients now receive single lung transplantation.

Liver Transplantation

Liver transplantation is associated with normal circulating levels of AAT and, thus, presumably with a normal pulmonary prognosis. Liver transplantation is not a viable form of therapy for lung disease, but in those few (mostly pediatric) patients with end-stage liver disease, liver transplantation is also an effective form of pulmonary therapy.

Lung Volume Reduction Surgery

Lung volume reduction (LVR) is a surgical technique that attempts to reduce hyperinflation and improve lung function by removing multiple emphysematous areas of lung identified by computed tomography. Physiological function has been shown to improve in selected individuals through partial restoration of the normal domed shape of the diaphragm and its mechanical advantage. In addition, elastic recoil of the lung may increase after reduction pneumoplasty, thereby increasing compliance and improving function.

Patients with end-stage emphysema, i.e., those with generalized severe disease associated with pulmonary hypertension (mean pulmonary artery pressure > 35 mm Hg), severe hypercapnia (P_aCO_2 > 55 mmHg), low FEV_1 (<20% of predicted), and barrel chests, are not good candidates for resection. Persistent air leaks and inability to wean from mechanical ventilation are major problems in these individuals.

Inclusion and exclusion criteria for this procedure are not yet well defined. Reported mortality is about 5%. Functional improvement with increased FEV_1 is variable, although many patients report lessened dyspnea and an increase in exercise tolerance. Long-term benefits more than 1 year after surgery have not yet been reported. Very few patients with AAT deficiency have had LVR, and results are not clear.

Gene Therapy

Although AAT deficiency may be treated with weekly infusions of AAT, this treatment is expensive and inconvenient. Investigations are currently ongoing regarding transfection of the complete a_1-antitrypsin cDNA to the respiratory tract of deficient individuals. Expression of the protein in the airway and alveolar space would theoretically provide levels of AAT sufficient to prevent reductions in pulmonary function.

Similar to what has been used for genetic therapy of cystic fibrosis, modified nonreplicating retroviruses and adenoviruses and nonviral vectors have been used to deliver AAT cDNA to the lung or other tissues. Retroviral delivery systems are effective in placing the AAT cDNA into cells, and AAT protein has been produced by cells not normally synthesizing the protein. However, serum therapeutic levels are not achieved. Transfection efficiency is low, and the transfections are not always stable. The modified viruses are incapable of replication. One study administered modified transfected fibroblasts intraperitoneally to mice and demonstrated AAT production. Another study utilized transfected hepatocytes that were returned to animals and demonstrated effective AAT production and systemic levels for more than 6 months. Exogenously transfected T lymphocytes have also been used.

Unlike retroviruses, adenoviruses function in the cytoplasm of the cell. They have also been shown to be effective in transfecting respiratory epithelium of rats with human AAT cDNA and producing AAT protein that can be detected in cells and bronchoalveolar lavage fluid. Administration of the modified vector must be repeated on a periodic basis because the transfection is not stable. This form of therapy is undergoing active investigation at this time; clinical application of this approach may be limited by the recipient's immune response to the viral vector.

Plasmids containing AAT cDNA and a cytomegalovirus promoter contained within cationic liposomes have been given to rabbits by the aerosol or intravenous route.

Respiratory tract epithelial cells take up the liposomes and express and release AAT protein into bronchoalveolar lavage fluid.

Prognosis

The natural history of lung dysfunction in AAT deficiency is one of progressive decline. Although lung function is relatively normal during the first two decades of life, it declines thereafter at a variable rate ranging from about 40 to 300 ml of FEV_1 lost per year. Death among homozygotes is usually from respiratory failure, although some may be ascribed to complications of hepatic disease. Only about 16% of ZZ homozygotes survive to age 60 as compared to 85% of normal age-matched individuals, so that severe AAT deficiency leads to reduced survival.

AAT Deficiency Registries

The natural history and the efficacy of intravenous augmentation therapy with human AAT in patients with severe AAT deficiency and pulmonary emphysema is currently being studied in three large multicenter registries including a U.S. NHLBI Registry, a Danish–Dutch registry (European Randomized Placebo-Controlled Trial of a_1-Protease Inhibitor Replacement Therapy), and a German registry (the Westdeutsche Arbeitsgemeinschaft zur Therapie von Lungenerkrankungen, WATL; Multicenter Trial of a_1-PI Augmentation Therapy in Patients with a_1-PI Deficiency). These studies are all of different designs. Because of limited patient numbers and slow disease progression, it is unlikely that results will demonstrate statistically significant reductions in the rate of decline of pulmonary function.

Patients with AAT deficiency are often severely depressed. The a_1 National Association (A1NA) is the main source of information for AAT-deficient patients regarding new developments and support groups. Free screenings, an informational CD-ROM for patients and health professionals (AlphaMedia), and information about patient infusion services (AlphaNet) are available. The a_1 *News* is produced by the association, as is an information hotline (*AlphaLine,* 1-800-4ALPHA1).

PULMONARY ARTERIOVENOUS MALFORMATIONS

Pulmonary arteriovenous malformations (PAVMs) are abnormal vascular connections that cause intrapulmonary right-to-left shunting of unoxygenated blood. They can be congenital or (rarely) acquired and occur as single or multiple lesions. A PAVM is frequently a manifestation of hereditary hemorrhagic telangiectasia (HHT; Osler–Weber–Rendu syndrome). The latter is characterized by multiple arteriovenous communications in any organ system of the body, such as telangiectasia of the skin, mucous membranes, and viscera and AVMs of the brain and lung. Hereditary hemorrhagic telangiectasia is an autosomal dominant disorder with an estimated incidence of one in 50,000. Genetic linkage for some HHT families has been found on chromosome 9 (gene locus at 9q3.41), but the syndrome is genetically heterogeneous. The gene may code for endoglin, a binding glycoprotein of vascular endothelium. Pulmonary AVMs occur in approximately 30% of patients with HHT and tend to be multiple, whereas single pulmonary lesions are more common in sporadic, nonfamilial cases. Hereditary hemorrhagic telangiectasia is often unrecognized in patients with PAVM; examination of family members for telangiectasias can be helpful. In most large series, 60% or more of all patients with PAVMs have HHT.

Over 500 cases of PAVM have been described in patients of all ages. Although there are reports of symptomatic infants and children, most patients present in the second decade of life or later. Typical symptoms include dyspnea on exertion, palpitations, cough, and chest pain. Hemoptysis is not uncommon, and pulmonary hemorrhage is a major cause of mortality. Mortality or morbidity may also result from stroke or brain abscess from emboli arising from PAVMs. In HHT, epistaxis, gastrointestinal bleeding, and neurologic symptoms may occur. Physical and laboratory signs of PAVM include digital clubbing, cyanosis and polycythemia as a result of right-to-left intrapulmonary shunting of blood, with hypoxemia refractory to supplemental oxygen therapy. The chest radiograph often shows a smooth, noncalcified pulmonary nodule or mass in the lower lobes (Fig. 1 and Fig. 2). Diagnostic sensitivity can be improved by the use of contrast-enhanced chest computed tomography (CT); helical CT with three-dimensional surface reconstruction; chest fluoroscopy; magnetic resonance imaging; contrast echocardiography; and/or pulmonary angiography/cardiac catheterization (the latter being the “gold standard”).

FIG. 1. An irregular density in the right lower lobe of a patient with arterial hypoxemia, a continuous murmur, dyspnea, and palpitations.

FIG. 2. Angiographic demonstration of a single pulmonary arteriovenous fistula in the patient shown in Fig. 1.

Treatment options for PAVMs include embolotherapy and operative resection. Transcatheter embolization using detachable balloons and/or stainless steel coils has been successful. These procedures are especially effective in patients with multiple PAVMs (e.g., in association with HHT) or patients who are poor surgical candidates. Occluding all arteries supplying a PAVM that are 3 mm or larger in diameter has been reported to optimize results. Surgical resection of PAVMs can be curative and is generally associated with minimal postoperative morbidity or mortality. Lung-conserving resection (such as segmentectomy or local excision) should be performed when possible to preserve lung function. In cases of multiple PAVMs or recanalization of PAVMs, combined staged surgical/embolization therapy has been successful. The role of observation alone for PAVMs is unclear. Further study is necessary to better define the optimal timing of PAVM therapy, especially for asymptomatic cases. Stricter therapeutic guidelines will be difficult as long as the natural history of PAVMs remains unknown.

FAMILIAL PRIMARY PULMONARY HYPERTENSION

Primary pulmonary hypertension (PPH) is characterized by elevated mean pulmonary artery pressure (>25 mm Hg at rest or >30 mm Hg during exercise) in the

absence of secondary causes such as chronic cardiopulmonary diseases or chronic pulmonary venous hypertension. The condition is rare (194 patients in the 1981 NIH registry). The familial form of PPH is thought to account for only 7% of cases. Primary pulmonary hypertension affects women more often than men with typical onset in the 20- to 50-year age range.

Familial PPH has been documented in at least 19 families. Inheritance varies: in some families, more than one generation is affected, suggesting autosomal dominant inheritance. In other families, only members of the same generation are affected, suggesting autosomal recessive inheritance. There is some evidence that PPH demonstrates “genetic anticipation”; i.e., the severity worsens and age of onset decreases with successive generations. In any event, for both sporadic and familial PPH, the prognosis is almost always poor. The median life expectancy after diagnosis is approximately 2 to 5 years but varies with clinical status and is inversely related to the degree of elevation of mean pulmonary artery pressure.

All PPH is characterized by obliteration of the small pulmonary arteries. Diagnosis is made on the basis of clinical symptoms, laboratory/imaging studies and, if available, tissue pathology. Pathologic subtypes include “isolated” medial hypertrophy (IMH), plexogenic pulmonary arteriopathy (PPA), thrombotic pulmonary arteriopathy (TPA), and pulmonary venoocclusive disease. As in sporadic PPH, pathologic heterogeneity is evident in familial PPH, and pathologic subtypes may coexist among individuals in the same family and within blood vessels from the same individual. The clinical symptoms of PPH include dyspnea, fatigue, chest pain, syncope, and palpitations. Physical findings include a loud pulmonic component of the second heart sound, a murmur of tricuspid regurgitation, and a right-sided third or fourth heart sound. The typical chest roentgenogram shows dilation of the main and/or hilar pulmonary arteries, occasionally with pruning of the peripheral vessels. The ECG shows right axis deviation and right ventricular hypertrophy. Pulmonary function testing may show a mild restrictive pulmonary defect with decreased D_LCO.

The cause of PPH is unknown. Recent theories have focused on inflammatory or immunologic abnormalities associated with endothelial dysfunction. There is likely an imbalance of vasodilator and vasoconstrictor factors and abnormal platelet aggregation and thrombosis. No treatment strategy has proven very effective. Some patients have better survival when treated with chronic anticoagulation. Digoxin, diuretics, and oxygen therapy are used in some clinical trials but are usually of limited benefit. Vasodilators benefit some patients, especially those who demonstrate “pulmonary vascular reactivity” (i.e., >20% reduction in pulmonary vascular resistance with the study drug). A trial of calcium channel blockers, especially in high doses, may reduce pulmonary artery pressure. Prostacyclin or epoprostenol has recently been approved by the FDA for continuous intravenous administration for PPH. It has a very short half-life (about 6 min) and is theoretically a more selective, safer pulmonary vasodilator when delivered through a central venous catheter. Patients can be treated long-term with a portable pump; a recent study showed improved survival. Recently, inhaled nitric oxide has been used with short-term success. The limitations of vasodilators include negative inotropic effects and systemic hypotension. Nitric oxide may circumvent these potential side effects by providing selective pulmonary vasodilation; however, long-term studies are lacking. Heart-lung or single lung transplantation is another possible treatment. Four-year survival of approximately 49% has been reported, with serious complications outside the perioperative period most often related to bronchiolitis obliterans or infection. Although transplantation appears to be the current treatment of choice, the supply of transplant organs is limited, and mean waiting time for lung transplantation is 1 to 2 years.

Because the genetics of familial PPH are not well defined, and clinical symptoms are not apparent until the disease is advanced, patients with PPH require a thorough family investigation. Whenever possible, autopsy reports and death records should be examined for clues to familial PPH. In established familial PPH, serial examinations and laboratory testing (such as estimation of pulmonary artery pressure by echocardiography) are recommended for early diagnosis of family members.

SCIMITAR SYNDROME

Over 95 cases of the scimitar syndrome have been described. It is a rare disorder of partial anomalous pulmonary venous connection (PAPVC), accounting for approximately 3% to 5% of all PAPVC. The basic features of the disorder include hypoplasia of the right lung associated with dextroposition of the heart, systemic arterial supply to the right lung, and anomalous right pulmonary venous drainage to the inferior vena cava. The most constant feature is the anomalous venous drainage. The entire right lung is usually drained by a single vein that runs parallel to the right border of the heart to join the inferior vena cava between the right atrium and the hepatic veins. The site of junction is usually below the diaphragm. The arterial supply to the right lung is variable and can arise from the pulmonary, bronchial, or systemic arterial systems. Typically, arteries arise from the aorta, often below the diaphragm. Hypoplasia or absence of the right upper lung segment is frequent; cardiac malformations (especially atrial septal defects) are common. Extracardiac malformations may include vertebral anomalies, scoliosis, or an abnormal right hemidiaphragm.

The cause of the syndrome is undefined, but it probably arises early in right lung bud development secondary to the persistence of embryonic connections of the pulmonary plexus with the cardinal veins. The syndrome can show familial clustering. An affected father and daughter have been reported, which suggests autosomal dominant inheritance. The majority of cases appear to be sporadic; however, the fact that affected individuals may be asymptomatic and are discovered accidentally by routine chest roentgenogram complicates genetic assessment. A systematic study of first- and second-degree relatives of affected individuals could clarify the genetic component of this syndrome.

In the infantile form of the disorder, symptoms are severe and occur in the first year of life. Congestive heart failure, pulmonary artery hypertension, substantial left-to-right shunts, and respiratory failure are common. Older children and adults may present with milder symptoms, including recurrent pneumonia, mild exertional dyspnea, or, rarely, hemoptysis. Not uncommonly, the disorder is diagnosed in asymptomatic individuals.

The chest roentgenogram may suggest the diagnosis when the anomalous vein that courses downward parallel to the right atrium to the inferior vena cava produces an arc-like shadow that resembles the blade of a Turkish sword or scimitar (Fig. 3). Hypoplasia of the right lung and dextrocardia are common radiographic findings. Contrast-enhanced CT of the chest may be helpful. Definitive diagnosis and anatomic characterization of the arterial and venous supply to the right lung require angiocardiography. In addition, cardiac catheterization is useful to evaluate pulmonary artery pressure and left-to-right shunt.

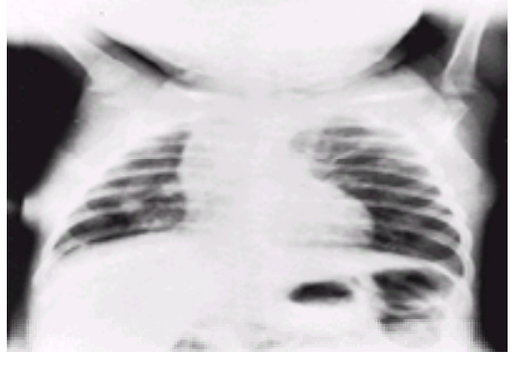

FIG. 3. Scimitar syndrome in a child. The pulmonary vein on the right runs parallel to the right atrium to its connection with the inferior vena cava below the diaphragm.

The optimal therapeutic strategy is not known. For infants and older patients who present with severe symptoms associated with pulmonary artery hypertension and large left-to-right shunts, surgical repair is indicated. In some patients with large shunts, redirection of the anomalous pulmonary venous return has been successful. However, thrombosis of the anastomosis of the anomalous vein to the left atrium has been reported and is a severe potential complication. Pneumonectomy may improve hemodynamic abnormalities; more often, it is reserved for cases of severe recurrent lung infection. The prognosis of older children and adults without pulmonary hypertension is very good. For these patients, medical therapy with aggressive management of pulmonary infections appears to be at least as effective as surgical management. Long-term complications, however, may include bronchiectasis. Conservative management is also indicated if infradiaphragmatic drainage is diagnosed, as surgical risk in these cases is substantial.

DEFECTS IN IMMUNITY

Inherited defects in immunity are very rare. Most inherited defects can be conveniently divided into antibody (B-cell) immunodeficiencies, cellular (T-cell) immunodeficiency, combined antibody and cellular deficiencies, phagocytic dysfunction, and complement deficiency. Recurrent pulmonary infections characterize most of these disorders. A complete review of immunodeficiency is outside the scope of this chapter. We focus on selected immunodeficiency states that affect the lungs.

Antibody Deficiency

Antibody deficiency disorders include X-linked agammaglobulinemia, selective IgA deficiency, common variable immunodeficiency, IgG subclass deficiency, and

immunodeficiency with elevated serum IgM. These diseases are caused by a disorder in B cells resulting in a functional deficiency in antibody. Screening for antibody deficiency can be accomplished with immunoglobulin quantification, from isoagglutinin titers (anti-A, anti-B), and by assaying functional immunity with antibody titers before and after immunization to pneumococcus, *H. influenzae,* and tetanus. The frequency of primary inherited antibody deficiencies varies from about one in 50,000 for X-linked agammaglobulinemia to approximately one in 500 people for selective IgA deficiency. It has been estimated that antibody deficiencies account for 46% of all primary immunodeficiencies.

In X-linked agammaglobulinemia, symptoms generally occur after loss of maternal antibody (after 6 months of age). There is susceptibility to infection with pyogenic organisms, such as pneumococcus and *H. influenzae,* and to enterovirus. In contrast, infection with viral, fungal, and parasitic pathogens is more common with combined cellular and antibody deficiencies or isolated cellular deficiencies.

The level of cellular defect in X-linked agammaglobulinemia is at the pre-B-cell stage of lymphocyte maturation. T-cell number and function are usually normal; serum concentrations of IgG, IgA, IgM, and IgE are markedly decreased or absent. The current therapy of choice is intravenous replacement g-globulin (IVIG). Potential for anaphylaxis from anti-IgA antibodies is a risk when IVIG that contains IgA is used. Transmission of hepatitis B and, more recently, hepatitis C by IVIG has also been described. Despite IVIG, chronic bronchiectasis is common, and the prognosis is guarded.

In contrast to X-linked agammaglobulinemia, common variable immunodeficiency (CVID) is characterized by a later age of onset, approximately equal sex distribution, and generally milder severity of immunoglobulin deficiency and clinical symptoms. It is associated with an arrest of B-cell maturation into plasma cells. T-cell function is usually intact, but some patients have moderate helper T-cell depletion. The disorder is clinically and genetically diverse; a recessive mode of inheritance is present in some families. The diagnosis is associated with a high incidence of autoimmune disease and malignancies (e.g., lymphomas, especially in female patients).

Isolated IgG subclass deficiency is a somewhat controversial clinical entity. Most investigators agree that some IgG subclass deficiencies (especially of IgG_2) are associated with an absence of functional immunity. Reduced antibody response to vaccines (e.g., *H. influenzae, S. pneumoniae* polysaccharides) may aid in the diagnosis of functional immunodeficiency. Patients without IgG subclass deficiency but who lack functional immunity may also be susceptible to recurrent infections. There is also literature associating IgG subclass deficiency with clinical asthma, and a few studies suggest clinical improvement in asthmatics treated with replacement immunoglobulin. This therapeutic approach remains extremely controversial, however, and there are several reports of individuals lacking various IgG subclasses who are entirely asymptomatic.

Cellular and Combined Immunodeficiency

Severe primary T-cell immunodeficiency is rare, with an estimated incidence of one in 100,000 births in Europe. Individuals with T-cell immunodeficiency are susceptible to opportunistic infections, including *Pneumocystis carinii,* fungi, and parasites. Infection with herpes viruses is especially common, including herpes simplex, cytomegalovirus (CMV), varicella-zoster, and enteroviruses. Severe combined immunodeficiency (SCID) affects both B- and T-cell function; most affected individuals become ill in the first few months of life. Clinical findings include profound lymphopenia and cutaneous anergy. Failure to thrive, thrush, anemia, and chronic diarrhea (e.g., from adenovirus or rotavirus) are common. Interstitial pneumonia caused by *Pneumocystis carinii* or CMV infection can be fatal, and many affected individuals die in the first year of life. Vaccination with live, attenuated viruses (e.g., polio, measles) can cause severe, even fatal infection. Blood transfusions are often necessary because of anemia of chronic illness; care should be taken to obtain CMV-negative, irradiated blood products. Without irradiation, blood transfusions include donor white cells that can induce fatal graft-versus-host disease in individuals with SCID. Most patients with SCID are treated with replacement immunoglobulin, which may help protect against vaccine complications. Bone marrow transplantation has been successful in a limited number of patients with SCID.

Severe combined immunodeficiency can be inherited in an X-linked or autosomal recessive manner. In approximately 40% of patients with autosomal recessive SCID, absence of the enzyme adenosine deaminase (ADA) is observed. Gene therapy is especially promising in ADA-SCID.

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is a rare inherited disorder of immunity, affecting one in 500,000 to 1,000,000 persons. Both X-linked and autosomal recessive inheritance has been described. This is a genetically diverse disease; approximately 60% of affected individuals have X-linked CGD. It is characterized by recurrent pyogenic infections caused by bacteria and fungi. Pulmonary involvement may include bronchopneumonia, empyema, or lung abscess. Serious infections of the gastrointestinal tract, skin, and draining lymph nodes are common. The liver, bone, or kidney can be infected by contiguous or hematogenous spread. Most patients are symptomatic by the first year of life. Clinical findings include lymphadenopathy, hepatosplenomegaly, anemia, failure to thrive, short stature, hypergammaglobulinemia, and granulomatous obstruction of the gastrointestinal tract.

Phagocytes from people with CGD ingest but cannot kill pathogenic microorganisms because of an inability to generate a “respiratory burst.” This functional deficiency, the result of an inherited defect in the enzyme NADPH oxidase, leads to prolonged retention of material in leukocytes and to a chronic granulomatous inflammatory response. The major components of the NADPH oxidase system are a membrane-bound cytochrome b and at least two cytosolic factors. X-linked CGD is most commonly caused by a defect in the gp^{91}-phox subunit of the cytochrome b system (designation $X91^0$, i.e., complete deficiency of the 91-kDa glyprotein subunit). Defects in the other cytochrome subunit (p^{22}-phox) or one of the cytosolic factors (especially p^{47}-phox) are found in most cases of autosomal recessive inheritance.

When the NADPH oxidase system malfunctions, superoxide (O_2^-), hydrogen peroxide (H_2O_2), and hypochlorous acid (HOCl) are lacking, resulting in severe impairment of microbial killing. Patients with CGD are especially susceptible to organisms that contain catalase because catalase prevents the CGD phagocyte from using the H_2O_2 generated by microbials. Common pathogens in CGD include *Staphylococcus aureus, Aspergillus* and *Nocardia* species, and gram-negative bacilli including *Pseudomonas cepacia.*

The prognosis of CGD is poor. Although the clinical course is variable, death in young adulthood is common. Approximately 50% of patients have been reported to survive to age 20 years because of improvements in antibiotic therapy. It has been reported that more than 80% of CGD patients present with life-threatening infections of the lung and that 50% of childhood CGD mortality is attributed to lung infections. The use of prophylactic antibiotics (e.g., trimethoprim–sulfamethoxazole) appears to be effective in reducing the frequency of serious infections. Recombinant human interferon-g also appears to reduce the frequency of serious infections and is generally well tolerated. Potentially curative therapies for CGD include bone marrow transplantation (BMT) and somatic gene therapy. Thus far, however, BMT has been successful in only a limited number of patients, and gene therapy remains in the preclinical stages of development.

CHROMOSOME ABNORMALITIES

The chromosome disorders discussed in this section were selected because they have been associated with defects in immunologic function. In none of these disorders is the pulmonary lesion diagnostic. Problems related to the lung reflect primary systemic defects in host resistance.

Down's Syndrome

Trisomy of chromosome 21 was the first chromosomal abnormality described in humans and is the most frequent autosomal anomaly. The clinical phenotype is well known and is usually recognized at birth. Early diagnosis is important because mental retardation is a consistent feature. The dysmorphoses observed include a small, round head with a flat occiput, palpebral fissures that slant upward and outward with the inner angle marked by epicanthal folds, and irises that show a ring of small, round, irregular whitish spots (Brushfield's spots). The ears are usually small. The nape of the neck is short, flat, and broad with redundant skin folds. Infants always show marked muscle hypotonia. The fifth finger is short and incurved, and the hands may show a single palmar crease (simian crease). Associated structural defects are found in the heart in 40% of patients. Malformations of the gastrointestinal tract include duodenal stenosis or atresia, annular pancreas, and anal atresia. Infection, leukemia, other cancers, and thyroid disease occur with increased frequency.

These clinical observations may be related to the qualitative and quantitative defects in the immune response described in affected individuals. Abnormalities of T-cell and B-cell function and numbers have been described in Down's syndrome, but the observations are not consistent. The lung in Down's syndrome may show pulmonary hypoplasia because of a diminished number of alveoli in relation to acini. The resultant decrease in alveolar surface area may account for the severe pulmonary hypertension observed in some Down's syndrome patients. The obstructive sleep apnea (OSA) syndrome is another factor that produces pulmonary hypertension unassociated with, and out of proportion to, the presence of congenital heart disease. Oropharyngeal muscle hypotonia, small airways, large tongue (relative to mouth size), and adenotonsillar hypertrophy may contribute to OSA. Adenoidectomy and/or tonsillectomy may be helpful but is rarely curative. There are reports of tracheal stenosis and segmental “ring” tracheal cartilages (absence of the pars membranacea) in Down's syndrome. In addition to OSA and pulmonary infections, cystic pulmonary disease has been associated with Down's syndrome. There is a high frequency of wheezing and gastroesophageal reflux disease in young patients. There is also an association with tracheoesophageal fistula and recurrent aspirations. Thus, the causes of wheezing/recurrent pulmonary infiltrates in an infant or child with Down's syndrome are likely multifactorial, and their respiratory management can be challenging and complex.

The clinical diagnosis of Down's syndrome should be confirmed by cytogenetic analysis, which is indispensable for genetic counseling. The majority of cases (90%) show trisomy of chromosome 21 resulting from nondisjunction at the time of the first (73%) or second (23%) meiotic division. The patients have 47 chromosomes instead of the normal number of 46. Trisomy 21 can be considered an isolated accident, with the risk of recurrence related to parental age. In women at age 20, the frequency of trisomy 21 is on the order of one in 2000 births, but the frequency increases exponentially to one in 50 births after 45 years of age. Approximately 5% of Down's syndrome patients show a chromosome number of 46, with the extra 21 chromosome attached to another autosome, usually one of the D group. This translocation is a sporadic event in half the cases. In the remaining translocation patients, a balanced translocation is demonstrated in one of the parents, who is phenotypically normal. In these families, the risk of recurrence is high, ranging from 1% or 2% if the father is the carrier to 10% to 15% if the mother is the carrier. Down's syndrome can be diagnosed before birth by amniocentesis and chromosome analysis of fetal cells. This option may be considered by families with the translocation form of Down's syndrome or in women over age 35 because of the statistical increase of nondisjunction.

CHROMOSOME INSTABILITY

Ataxia-Telangiectasia

Ataxia-telangiectasia is a recessively inherited disease characterized by ataxia, telangiectasia of the bulbar conjunctiva, and sinopulmonary infections as the result of variable cellular and/or humoral immunodeficiency. Susceptibility to both bacterial and viral infections is increased, and there is an increased risk of malignancy. Cerebellar ataxia becomes evident when the child begins to walk. Oculocutaneous telangiectasia may be delayed until 2 to 6 years. Neurologic dysfunction is often progressive, with complete incapacitation by 12 years of age. However, the prognosis is variable, with death commonly occurring from pulmonary infection or lymphoreticular malignancy. The most frequent immunologic abnormality is IgA deficiency. However, IgG/IgG subclass levels may also be low; specific antibody titers may be depressed; and lymphopenia is often present, with moderately decreased T-cell function and absent responses to delayed hypersensitivity skin tests. Cell-mediated immune deficiency is also evidenced by delayed skin allograft rejection and inhibition of *in vitro* lymphocyte responses to mitogens. Pathologically, there is depletion of lymphocytes in lymphoid tissues with a predominance of reticular epithelial cells. Between 10% and 30% of patients develop lymphoreticular malignancies or other neoplasms. The syndrome appears to be causally related to a basic repair defect in the DNA of ataxia-telangiectasia cells. Cultured cells from patients show increased numbers of breaks, gaps, and rearrangements, especially involving chromosomes 7 and 14. There is an increased susceptibility to radiation with defective DNA repair. Chromosomal breaks are clustered at chromosome 14q12 with translocations to chromosomes 6, 7, and X. Ring formation of chromosome 14 also has been noted. There are no definitive tests to detect carriers of the mutant gene, although family members may show some degree of anergy, delayed hypersensitivity responses, or IgE deficiency. The abnormal gene has been mapped to the long arm of chromosome 11 (11q22.3) and was recently identified by positional cloning.

Treatment is supportive and consists of antibiotics to control respiratory infections, aggressive pulmonary toilet, immunization with killed vaccines only, and physical therapy for the neurologic dysfunction. Replacement of immunoglobulins may be considered if IgG and other specific antibody levels are significantly depressed, but care must be taken to minimize the risk of anaphylaxis in IgA-absent individuals.

Bloom's Syndrome

The major clinical features of Bloom's syndrome are dwarfism with normal body proportions, a narrow face with nasal prominence, dolichocephaly, and sun-sensitive telangiectatic erythema of the face, usually in a butterfly distribution. Affected children are small at birth, and body size remains small. This disorder is inherited as an autosomal recessive trait, predominantly among Ashkenazic Jews. During the first decade of life, infections of the upper and lower respiratory tracts are frequent. The increased incidence of infection is associated with immune dysfunction, which may include a poor lymphoproliferative response to pokeweed mitogen and variable changes in serum immunoglobulin levels (especially IgM deficiency). The significant predisposition to cancer shown by these patients is probably related to the tendency to excessive spontaneous mutations. The characteristic cytogenetic abnormality consists of a marked increase of sister chromatid exchange in cultured cells. This finding is consistent and is of diagnostic value. Chromosome-transfer studies have shown the locus for Bloom's syndrome mapping to chromosome 15q26.1. The diagnosis is suggested in dwarfed children with normal body proportions who show facial dysmorphism and sun-sensitive telangiectatic skin lesions of the face. The prognosis is poor, with death occurring from cancer or infection. Treatment of pulmonary complications consists of aggressive use of antibiotics and possibly replacement immunoglobulin.

HERITABLE DISORDERS OF CONNECTIVE TISSUE

Connective-tissue proteins are complex and interdependent in their anatomic arrangement and physical properties. The major proteins of connective tissue are collagen, elastin, and proteoglycans. A large number of enzymes participate in the biosynthesis and degradation of these proteins. Genetic mutations affecting biosynthetic enzymes at the level of transcription or translation may alter the primary structure of the protein. Mutations also could alter the function of enzymes involved in the posttranslational modification of the protein, thereby affecting its secondary or tertiary structure. A change in protein structure could be expected to alter the normal organization and function of connective tissue and produce disease. Genetic mutations affecting enzymes involved in the degradation of connective tissue proteins are well documented, as they produce diseases through the accumulation of material in lysosomes.

Several reviews relate the biochemistry of collagen, elastin, and proteoglycans to connective-tissue disease. The disorders selected for discussion in this section illustrate the progress made in defining the biochemical basis for certain connective-tissue disorders that affect the lungs. The heritable disorders of connective tissue provide models that define the functions of specific connective-tissue proteins in normal pulmonary function.

Marfan's Syndrome

Marfan's syndrome (MFS) is an inherited multisystem disorder of connective tissue—specifically, fibrillin, a component of elastic fibers, one of the components of extracellular matrix. Marfan's syndrome affects the eyes, skeletal system, heart, skin, and blood vessels. The Marfinoid habitus is a result of overgrowth of arms and legs, resulting in an unusually tall, thin body with long extremities (dolichostenomelia) and long fingers and toes (arachnodactyly). Spontaneous pneumothorax, bullous emphysema, sleep-disordered breathing (obstructions), airways defects or hyperreactive airways, scoliosis, and pectus excavatum can all contribute to pulmonary morbidity. Inheritance is autosomal dominant. As in all autosomal dominant genetic diseases, spontaneous mutations are common. There is a broad range of clinical expression of the gene, and genetic testing is not perfected.

The salient criteria to diagnose MFS include a family history, ocular findings, cardiovascular abnormalities, and the skeletal features described previously. At least two features should be present to make the diagnosis. In the absence of positive family history, there must be skeletal and either cardiovascular or ocular defects present. In classic cases, three or four features are usually evident. Because each of the clinical features of the syndrome occurs with variable frequency in the general population, it is to be expected that several can occur by chance alone in some individuals. For example, individuals with isolated pectus excavatum may also have mitral regurgitation and/or mitral valve prolapse. Determining whether such individuals are affected with Marfan's syndrome will tax the acumen of the best clinician.

The basic genetic defect that produced Marfan's syndrome has now been identified. The syndrome is caused by mutations in the gene encoding fibrillin-1 (FBN-1), localized to the long arm of chromosome 15. The fibrillin monomer is a 350-kDa glycoprotein that is associated with microfibrillar fibers. These fibers are integral components of elastic elements and are also present in a variety of other cells and tissues. A decreased content of fibrillin has been documented in the microfibrils of tissues from patients with Marfan's syndrome and in cultured Marfan's fibroblasts using monoclonal antibodies to fibrillin. In addition, there appears to be a direct relationship between the decreased content of fibrillin and the presence of symptoms.

Life expectancy in MFS has improved substantially with aggressive medical and surgical management of the cardiovascular complications. Specific surgical interventions include aortic root replacement and aortic aneurysm repair. Medical therapy includes use of b-adrenergic receptor blocking agents, which may decrease the rate of aortic dilation in MFS. A recent study of 417 MFS patients showed a 25% increase in mean age at death, from 32 years in 1972 to 41 years in 1993.

Ehlers–Danlos Syndrome

The classic clinical features of the Ehlers–Danlos syndrome include hyperelastic skin, hyperextensible joints, fragile tissues, and bleeding diatheses; however, the clinical phenotype is variable. At least nine variants are recognized on the basis of clinical, genetic, and biochemical criteria. The biochemical defect is not known for several types. Types I, II, and III are almost always inherited as dominant traits. They are classified by the severity of the clinical features described above. Type I patients have gross skin extensibility, severe joint hypermobility, fragile skin, poor wound healing, and moderate bleeding diatheses. They are frequently born prematurely with rupture of fetal membranes before the mother goes into labor, because these tissues are derived from the fetus and share the same connective-tissue defect. Musculoskeletal deformities are common. Patients with the type II variants are less severely affected, whereas type III patients may show only hypermobile joints.

The ecchymotic form or type IV variant is characterized by bleeding diatheses, arterial rupture, and intestinal perforation. Autosomal dominant and recessively inherited

kindreds have been described. In all type IV patients studied, the unifying biochemical abnormality is a defect in the synthesis, structure, or secretion of type III collagen with a resultant deficiency in mature type III collagen. The gene for type III collagen (COL3A1) has been localized to chromosome 2q31-32. Analyses of lung tissue from a patient with type IV Ehlers–Danlos who developed recurrent pneumothoraces and whose apical bullae were resected, showed that the relative proportion of type III collagen in the lungs was markedly decreased. These data suggested that the structural abnormalities in the lung that led to pneumothorax were consequences of a deficiency of type III collagen.

A case of fatal hemoptysis has been described in an individual with type IV Ehlers–Danlos, most likely because of vascular fragility with recurrent pulmonary hemorrhage. Respiratory pathology may occur from kyphoscoliosis, rupture of the lung, mediastinal emphysema, and pneumothorax. In patients who died from rupture of an artery, large emphysematous subpleural bullae have been described. Pulmonary function has not been extensively studied in affected individuals; no consistent spirometric or lung volume abnormalities have been detected.

THE LUNG IN LYSOSOMAL STORAGE DISEASE

Lysosomes are pleomorphic cellular organelles that contain a variety of hydrolytic enzymes with an acid pH optimum. These acid hydrolases are synthesized in the endoplasmic reticulum, transported through the Golgi apparatus, and finally packaged in lysosomes, where they degrade biological macromolecules. The sequence by which macromolecules are degraded is complex, involving several enzymes acting in a coordinated sequential fashion. The deficiency of a single degradative enzyme leads to the accumulation of the macromolecule or its partially degraded metabolite within the lysosome; such accumulation produces disease. The best-characterized groups of lysosomal storage disorders are the mucopolysaccharidoses and the glycosphingolipidoses. Almost all lysomal storage diseases show phenotypic heterogeneity ranging from severe infantile to mild adult forms.

In the mucopolysaccharidoses (MPS), glycosaminoglycans are abnormally accumulated in lysosomes. Hurler's syndrome is the prototype MPS in which at least 13 variants are known. This disorder is inherited as a recessive trait. The gene has been isolated and mapped to cytogenetic band 4p16.3. The biochemical basis for the disease is a deficiency of the enzyme a-L-iduronidase. As a result of the enzyme deficiency, dermatan sulfate and heparin sulfate are stored in cells throughout the body, which produces multiple organ dysfunction and mental retardation.

Pulmonary problems develop secondary to kyphoscoliosis and deformities of the ribs. Storage of mucopolysaccharides in bone decreases the size of the chest cavity and limits chest excursions. Hepatosplenomegaly compresses the diaphragm from below. Upper airway obstruction is frequent as a result of storage of polysaccharides in lymphoid tissue and deformity of respiratory cartilage. The tongue is large and thick, and the mandible is small and immobile. Chronic rhinorrhea is common. Tracheal and bronchial airways may be abnormally shaped and collapsible. Airway problems dominate the clinical course of many severely affected individuals. Obstructive sleep apnea is common, and endotracheal intubation is very difficult. Perioperative mortality has been reported to be as high as 20% in patients with MPS. As the disease progresses, recurrent respiratory infections, upper airway obstruction, and aspirations may lead to chronic hypoxemia and cor pulmonale. Intercurrent infections can produce respiratory decompensation. Bronchopneumonia is a frequent cause of death.

The pulmonary problems in the mucopolysaccharidoses are but one component of a systemic metabolic disorder. The clinical appearance of the patient with Hurler's syndrome suggests the diagnosis, which can be confirmed by appropriate biochemical studies. The other variants may show similar pulmonary problems to those described for Hurler's syndrome, especially as the patients enter the second decade of life. All variants are inherited as autosomal recessive traits except for type II (Hunter's syndrome), which shows X-linked inheritance. The clinical phenotype, biochemical defects, and genetics of the other established disorders of mucopolysaccharide metabolism are detailed in various reviews. The disease phenotypes are secondary to gene mutations that result in the synthesis of dysfunctional degradation enzymes. All mutant genes have been mapped to specific chromosomes, and many have been defined. Bone marrow transplantation has partially reversed upper airway and CNS symptoms in some patients but is available only in specialized centers.

Two disorders of glycosphingolipid metabolism may present with pulmonary symptoms. The chronic nonneuronopathic form of Gaucher's disease (type 1) may produce respiratory difficulties because of diffuse interstitial pulmonary involvement (Fig. 4) or because of capillary plugging with Gaucher cells. The primary clinical findings are bone abnormalities, hematologic abnormalities (including anemia and thrombocytopenia), hepatosplenomegaly, and metabolic dysfunction with variable pulmonary and kidney involvement. In some patients, the pulmonary process is severe enough to produce cor pulmonale. Gaucher's disease is inherited as a recessive trait. The biochemical basis for the storage of glucosylceramide in lysosomes is a deficiency of the enzyme glucocerebrosidase, which is required for the hydrolysis of glucocerebroside to ceramide and glucose. Enzyme replacement therapy improves the clinical course of type 1 Gaucher's disease and may improve oxygenation and diffusing capacity of the lung in some patients. Potential disadvantages include the high cost of the replacement enzyme and the production of antienzyme IgG antibodies. Gene therapy holds promise: the defect has been localized to chromosome 1q21, and its nucleotide sequence has been ascertained.

FIG. 4. Chronic nonneuropathic Gaucher's disease in a child showing diffuse pulmonary infiltrates.

The second group of lysosomal storage diseases involving glycosphingolipids that may present with pulmonary symptoms comprises the nonneuronopathic forms of Niemann–Pick disease. Radiographically, the lungs show diffuse reticular infiltrates. Histologic examination at autopsy frequently shows foam cells in the alveoli, lymphatic vessels, and branches of the pulmonary artery. This disorder is also inherited as an autosomal recessive trait. The biochemical basis for the lysosomal storage of sphingomyelin is a deficiency of the enzyme sphingomyelinase, which is required for the hydrolysis of sphingomyelin to ceramide and phosphocholine. The gene has been defined and mapped to chromosome 11p15.1.

In both Gaucher's and Niemann–Pick disease, patients usually show hepatosplenomegaly in addition to pulmonary infiltrates, which should suggest these diagnostic possibilities. Aspiration pneumonia may cause death in these and the other glycosphingolipidoses; the pulmonary problems in neuronopathic glycosphingolipidoses are secondary to involvement of the central nervous system with attendant difficulties in handling secretions and swallowing.

CHAPTER

75 Diseases of the Pleura and Pleural Space

Steven A. Sahn

S.A. Sahn: Division of Pulmonary and Critical Care Medicine, Medical University of South Carolina, Charleston, South Carolina 29425.

PLEURAL EFFUSIONS

The clinical recognition of a pleural effusion signifies that an abnormal physiological state exists whereby there is a dysequilibrium between the formation and removal of pleural fluid. The pleural fluid usually is the sequela of primary pulmonary disease but can also result from disease in an extrapulmonic focus such as the heart (congestive heart failure), kidneys (nephrotic syndrome), liver (cirrhosis), and pancreas (acute pancreatitis). Pleural fluid can also result from systemic diseases, such as systemic lupus erythematosus, metastatic malignancy, and iatrogenic causes such as drug therapy (nitrofurantoin) and extravascular migration of central venous catheters. Thus, patients with pleural effusions may present not only to the pulmonologist but to the internist, family physician, medical specialist, and surgeon.

The clinical presentation, chest radiographic findings, pleural fluid analysis, treatment, and outcome of the most common causes of transudates and exudates are discussed (see Chapter 12).

Transudates

Congestive Heart Failure

Congestive heart failure is the most common cause of a transudative effusion and probably is the most common cause of all pleural effusions, certainly in those over the age of 60 years. The precise incidence of pleural effusion with congestive heart failure is difficult to ascertain, as there is variance in the study populations, the techniques of detecting the effusions, and the stage and degree of heart failure at the time of evaluation. Clinically, about 40% of patients with congestive heart failure have pleural effusions; however, if a more sensitive technique such as ultrasonography is used to evaluate such patients, the incidence would be substantially higher. Pleural effusions in the presence of congestive heart failure are related to elevated pulmonary venous pressures, and most patients with congestive heart failure effusions have pulmonary capillary wedge pressures ^{3}24 mmHg. Interestingly, this is the pulmonary venous pressure associated with visualization of Kerley B-lines on a chest radiograph. It appears that pleural effusions result when high pulmonary venous pressures cause increased filtration of fluid from the microvessels into the lung interstitium, and this interstitial fluid moves along a pressure gradient between mesothelial cells into the pleural space.

If pleural fluid formation exceeds pleural space lymphatic drainage, then fluid will accumulate in the pleural space. Patients with an isolated increase in right atrial pressures or patients with primary pulmonary hypertension do not develop pleural effusions, thus supporting the association of elevated pulmonary venous pressures and the development of pleural effusions. For example, patients with COPD and cor pulmonale rarely have pleural effusions. Patients with pleural effusions from congestive heart failure always have left ventricular failure and frequently associated right ventricular failure.

Most patients with pleural effusions secondary to congestive heart failure have the classic symptoms and signs. The chest radiograph shows cardiomegaly and bilateral small to moderate-size pleural effusions of relatively equal size, with the right being slightly greater than the left. There is usually evidence of pulmonary congestion on chest radiograph, and the severity of pulmonary edema appears to correlate with the presence of pleural effusions.

The pleural fluid is a transudate with mesothelial cells and lymphocytes accounting for the majority of the cells; it is unusual for the neutrophil count to exceed 10%. Acute diuresis over several days can transform the congestive heart failure transudate into a pseudoexudate.

In the patient with clinical congestive heart failure, bilateral pleural effusions, and an enlarged cardiac silhouette, finding a transudative effusion makes a presumptive diagnosis. Treatment consists of decreasing pulmonary venous hypertension and improving cardiac output with diuretics, digitalis, and afterload reduction. When heart failure is managed successfully, the effusions resolve over days to weeks. In patients with refractory heart failure and symptomatic pleural effusions, unilateral chemical pleurodesis should be considered.

Hepatic Hydrothorax

Pleural effusions occur in approximately 6% of patients with cirrhosis of the liver and clinical ascites. However, in rare cases, hepatic hydrothorax can occur without clinical ascites. Pleural fluid results from movement of ascitic fluid through diaphragmatic defects. When enough ascitic fluid is present, peritoneal pressure exceeds pleural pressure, and fluid moves through the diaphragmatic defects into the pleural space.

The patient usually has the physical stigmata of cirrhosis and clinically apparent ascites. With a large to massive pleural effusion, the patient may present with acute dyspnea, but with a smaller effusion, dyspnea may be present only with exertion, or the effusion may be detected on a routine chest radiograph.

The typical chest radiograph shows a normal cardiac silhouette and a right-sided pleural effusion (70%) that can vary from small to massive (<10%); effusions are sometimes isolated to the left pleural space (15%) or are bilateral (15%). Thoracentesis shows a serous transudate with a low nucleated cell count and a predominance of mononuclear cells, a pH > 7.40, a glucose similar to that in serum, and a low amylase concentration. Fluid can be hemorrhagic in the presence of an underlying coagulopathy.

A transudative right pleural effusion in the setting of cirrhosis with ascites provides a presumptive diagnosis. To be more certain, the clinician can compare pleural and ascitic fluid protein and LDH values, which should be similar. On occasion, the protein and LDH may be slightly higher in the pleural fluid than in ascitic fluid; this occurs when the increased portal pressure prevents reabsorption of non-protein-containing fluid by the peritoneum. To absolutely confirm the diagnosis, injection of a radiolabeled tracer into the ascitic fluid with detection on chest imaging within 1 to 2 hrs supports pleural–peritoneal communication through a diaphragmatic defect. Spontaneous bacterial empyema has been noted and occurs by hematogenous seeding or transfer of infected ascites through a diaphragmatic defect.

The treatment of hepatic hydrothorax is directed at the ascites with sodium restriction and diuresis. A pleural effusion frequently persists unchanged until all the ascites have been mobilized clinically. Patients refractory to therapy who remain symptomatic from a large pleural effusion can best be treated by thoracoscopy with repair of the diaphragmatic defect and pleural abrasion/talc pondrase. These patients should not undergo chest tube drainage because it can lead to hypovolemia, protein depletion, and immunosuppression. Patients with spontaneous bacterial empyema usually can be treated with antibiotics without chest tube drainage.

Nephrotic Syndrome

Pleural effusions are frequent in nephrotic syndrome (21% in one series), with the incidence varying with the degree of hypoalbuminemia. The mechanism responsible for pleural fluid accumulation is decreased oncotic pressure in the pleural microvascular circulation as a result of hypoalbuminemia; increased hydrostatic pressure from salt and water overload may also be contributory.

Patients with pleural effusions from nephrotic syndrome usually have anasarca by the time pleural effusions develop. In the evaluation of a pleural effusion in a patient

with nephrotic syndrome, pulmonary thromboembolism needs to be considered, as this complication occurs in approximately a third of patients. The chest radiograph in patients with nephrotic syndrome usually shows small to moderate bilateral pleural effusions without evidence of pulmonary edema.

Thoracentesis reveals a serous transudate with a small number of mononuclear cells, a normal glucose concentration, and a pH > 7.40. The presence of hemorrhagic fluid, an increased protein concentration, or neutrophil predominance suggests thromboembolic disease or another diagnosis. Treatment should be directed at arresting the protein-losing nephropathy. A therapeutic thoracentesis should be done only for increasing dyspnea. If medical therapy is ineffective for the symptomatic pleural effusion, chemical pleurodesis should be considered.

Hypoalbuminemia from any cause is associated with bilateral pleural effusions. When the albumin concentration is £1.8 g/dl, pleural effusions may develop. It is unusual for patients with hypoalbuminemia to have edema fluid isolated only to the pleural space, as the pleural lymphatics are effective in clearance of a moderate amount of increased pleural fluid formation. Therefore, by the time patients with hypoalbuminemia develop pleural effusions, they have anasarca. Other causes of hypoalbuminemia that result in pleural effusions include severe malnutrition, which is commonly seen in patients admitted to the ICU and in end-stage AIDS, and in patients with protein-losing enteropathy.

Atelectasis

Atelectasis is a common cause of small pleural effusions in the postoperative patient, especially following upper abdominal surgery, and in patients in medical intensive care units. Atelectasis was the cause of pleural effusions in 23% of patients admitted to a medical intensive care unit. Atelectatic effusions also occur with major bronchial occlusion from lung cancer, a mucus plug, or foreign body. The mechanism producing atelectatic effusions is decreased pleural pressure. With alveolar collapse, the lung and chest wall separate further, creating local areas of increased negative pressure. This decrease in pleural pressure favors the movement of fluid into the pleural space, presumably from the parietal pleural surface. Fluid accumulates until the parietal pleural interstitium/pleural space pressure gradient returns to normal. The chest radiograph typically shows small unilateral or bilateral pleural effusions with normal heart size and absence of parenchymal infiltrates. Pleural fluid in acute atelectasis has not been studied in detail; however, in patients with mainstem bronchial obstruction and a chronic effusion, the fluid is a serous transudate with a small number of mononuclear cells, a normal glucose concentration, and a pH > 7.40. It is not known whether effusions from atelectasis remain transudates or transform into exudates over time. If the stoma remain patent and there is no preferential removal of liquid over protein, the fluid should remain a transudate. The diagnosis is presumptive in the proper clinical setting. Treatment should be directed at reversing the cause of the atelectasis. If it is successful, the pleural effusion resolves over several days.

Peritoneal Dialysis

Although peritoneal dialysis frequently is associated with small, transient pleural effusions, massive right pleural effusions are occasionally seen. These large effusions usually occur within 48 hr after the initiation of peritoneal dialysis and presumably result from opening of a congenital diaphragmatic defect from the increased peritoneal pressure, causing a rapid transfer of fluid from the peritoneal to the pleural cavity. Patients generally present with the acute onset of dyspnea. The chest radiograph shows a large to massive right pleural effusion with contralateral mediastinal shift. Thoracentesis shows pleural fluid resembling the dialysate. The total protein is usually <1 g/dl with a nucleated cell count of <100/ml and a glucose concentration in the 300 to 400 mg/dl range. The combination of a protein concentration <1 g/dl and a markedly elevated glucose concentration virtually confirms the diagnosis. Rapid movement of a radiolabeled tracer from the peritoneal to the pleural cavity confirms the diaphragmatic defect if there is doubt about the diagnosis. Continued drainage from the peritoneal catheter should be allowed to occur and will result in pleural space drainage as well. If the patient has severe dyspnea or cardiovascular instability, a therapeutic thoracentesis should be performed promptly. The most effective long-term treatment is to change to hemodialysis. The effusion will resolve completely with discontinuation of peritoneal dialysis, but success also has been reported after switching from continuous ambulatory peritoneal dialysis to intermittent dialysis in the semierect position.

Urinothorax

Urinothorax, a pleural effusion secondary to obstructive uropathy, has been associated with carcinoma of the genitourinary system, nephrolithiasis, trauma, surgical stent manipulation, and following renal transplantation. With urinary tract obstruction and hydronephrosis, perirenal and retroperitoneal fluid collections can occur. Pleural fluid moves from the retroperitoneal space through diaphragmatic defects into the pleural space. Patients present with evidence of urinary tract obstruction; the pleural effusion is suspected because of acute dyspnea or is discovered on a routine chest radiograph. The pleural effusion is always ipsilateral to the obstructed kidney; the chest radiograph shows a small to moderate pleural effusion without other abnormalities. Thoracentesis shows a straw-colored transudate with the odor of urine. The nucleated cell count is low, with a predominance of mononuclear cells. Pleural fluid glucose is similar to blood glucose; pleural fluid pH has been reported from 7.00 to 8.00. The pleural fluid pH depends on the urinary pH and on how rapidly the fluid moves from the perirenal area into the pleural space. The pH of a urinothorax is probably determined by the rate of hydrogen ion back-diffusion into the blood from extravasated acidic urine during passage from the retroperitoneal to the pleural space. As the hydrogen ion gradient is dissipated during the movement of fluid, the fluid pH approaches blood pH. Thus, the pH of urinothorax should lie intermediate between that of urine and blood, generally acidic, but can be alkaline if the urine pH is high. Urinothorax is the only cause of pleural fluid acidosis in the setting of a transudative effusion.

The diagnosis of urinothorax can be established by finding a pleural fluid/serum creatinine ratio >1.0. Early thoracentesis may be an important factor for diagnostic sensitivity, as the longer the fluid remains in the pleural space, the more likely equilibration between pleural fluid and serum will occur. In a patient with urinary tract obstruction, a low-pH transudate with a pleural fluid/serum creatinine ratio >1.0 establishes the diagnosis of urinothorax. Relief of the urinary tract obstruction results in prompt resolution of the effusion.

Trapped Lung

A trapped lung is the result of pleural inflammation that causes a pleural peel to develop over a portion of the lung surface. It is most commonly observed after empyema but can be seen with rheumatoid pleurisy, uremic pleuritis, benign asbestos pleural effusion (BAPE), malignancy and any other inflammatory pleural process. The trapped lung cannot expand to the chest wall, creating increased negative pleural pressure and increasing the parietal pleura/pleural space pressure gradient, leading to increased formation of pleural fluid. The formation of pleural fluid continues until a new steady state is reached. The patient may be asymptomatic if the effusion is small or complain of dyspnea if the area of trapped lung is large. The chest radiograph generally will show a small to moderate unilateral pleural effusion without other chest radiographic abnormalities. Thoracentesis usually shows fluid that is borderline between a transudate and exudate and has a small number of mononuclear cells with a normal pH and glucose. Diagnosis can be confirmed by finding a pleural liquid pressure of more negative than –7 cm H_2O at the initial entry of the needle into the pleural space and a rapid decrement in pleural liquid pressure when a small volume of fluid is removed. Therapeutic thoracentesis usually results in rapid reaccumulation of a similar volume of pleural fluid. In the asymptomatic patient with a small effusion, no treatment is indicated; if the patient has a large symptomatic effusion, decortication is the treatment of choice. Decortication can be done years after the initial event with an excellent result as long as the underlying lung parenchyma is normal.

Constrictive Pericarditis

It is common knowledge that pleural effusions are associated with constrictive pericarditis, but it is not generally appreciated that a pleural effusion may be the presenting manifestation of constrictive pericarditis. Pleural effusion was the presenting feature in 60% of patients in one series of 30 patients, with some presenting as a pleural effusion of unknown origin. The most common cause of constrictive pericarditis today is cardiac surgery. Other causes include uremia, radiation therapy, tuberculous pericarditis, bacterial pericarditis, connective tissue diseases, malignancy, or fibrosing mediastinitis.

Constrictive pericarditis is an uncommon disorder with a varied presentation. It is misdiagnosed frequently as chronic liver disease, abdominal carcinomatosis, malignant pleural effusions, tuberculous pleurisy, and restrictive cardiomyopathy. The presenting symptoms include exertional dyspnea, peripheral edema, and increased abdominal girth. Jugular venous distention is the cardinal physical finding, with pleural effusions occurring in 50% to 60% of cases. Pedal edema and ascites are commonly present. The pleural effusions are caused by a combination of pulmonary and systemic venous hypertension, low oncotic pressure, and possibly inflammatory pericardial disease. The chest radiograph is abnormal in most patients, with the majority showing nonspecific findings such as pleural effusion and increased cardiac silhouette. Pericardial calcification, if present, is a specific finding in association with a typical presentation. The pleural fluid is serous and may be an exudate or a transudate, with the total protein concentration being <4 g/dl. Nucleated cell count is modest, usually being <5000/ml with a lymphocyte predominance. The pleural fluid glucose is equal to the serum glucose, and the pH is >7.30. When the diagnosis is suspected clinically, it can be confirmed by echocardiography, CT scan, or cardiac catheterization. Treatment is pericardiectomy.

Exudates

Parapneumonic Effusions

Parapneumonic effusion, pleural fluid associated with bacterial pneumonia, is the most common cause of an exudative effusion. Parapneumonic effusions occur in 36%

to 57% of patients with pneumonia, resulting in an estimated 1,000,000 people per year in the United States developing these effusions. Parapneumonic effusions may be uncomplicated (free-flowing effusions that resolve spontaneously with antibiotic therapy) or complicated (effusions that require pleural space drainage for resolution of pleural sepsis). The natural course of a complicated parapneumonic effusion is to develop a single loculus or multiple loculations and to progress to an empyema cavity. Empyema, from the Greek meaning accumulation of pus in a body cavity, represents the end stage of a complicated parapneumonic effusion.

After the aspiration of microorganisms into subpleural alveoli, neutrophils migrate and adhere to the adjacent endothelium. Oxygen metabolites, granule constituents, and products of membrane phospholipases released by activated neutrophils result in endothelial injury of the pulmonary, subpleural, and pleural vessels, causing increased capillary permeability. The resultant extravascular fluid increases the interstitial–pleural pressure gradient and drives more fluid from the interstitium between mesothelial cells into the pleural space if the rate of fluid production exceeds lung lymphatic clearance. Pleural fluid accumulation occurs only when fluid entering into the pleural space exceeds the absorptive capacity of the parietal pleural lymphatics.

The parapneumonic effusion that occurs in the first 48 to 72 hr is a small, sterile, neutrophil-predominant exudate (capillary leak/exudative stage). The pleural fluid pH is >7.30, the glucose is >60 mg/dl, and the LDH is <500 IU/liter. If the pneumonia remains untreated, after several days there is further endothelial injury with increased permeability edema and the formation of a greater volume of pleural fluid. Bacterial multiplication in the lung continues, and bacteria invade the pleural space and become persistent. The pleural fluid in the bacterial invasion/fibrinopurulent stage is characterized by an increased number of neutrophils, a fall in pleural fluid pH and glucose, and an increase in pleural fluid LDH. Interleukin-8 is a major chemotactic factor from neutrophils in empyema, and TNF-a may play a role in the local production of IL-8. The absolute glucose concentration is usually <40 mg/dl because of increased glycolysis from neutrophil phagocytosis and bacterial metabolism. As the end products of glucose metabolism, CO_2 and lactic acid, accumulate in the pleural space, the pH falls, usually to <7.10. The LDH increases to >1000 IU/liter because of cell lysis. Also during this stage, pleural fluid becomes clottable because of the movement of large concentrations of plasma proteins into the pleural space in conjunction with a loss of pleural space fibrinolytic activity by the inflammatory injury. These processes result in a deposition of a dense layer of fibrin on both pleural surfaces, and metabolically active fibroblasts move into the pleural space unimpeded by the injured mesothelium to begin to secrete glycosaminoglycans and collagen into clottable pleural fluid. Both fibrin and collagen compartmentalize the pleural fluid into loculations by bridging the two pleural surfaces in addition to limiting lung expansion. Pleural fluid volume may increase further because of blockage of the parietal pleura stoma by fibrin, collagen, and mesothelial swelling.

Without treatment, the organization/empyema stage ensues over the next few weeks, resulting in a single cavity or multiple loculations that are formed as fibroblast migration and growth continue in the fibrin–pleural fluid matrix. This process results in an inelastic pleural peel that inhibits pleural fluid drainage as well as lung expansion. Empyema fluid (pus) is a thick purulent coagulum not adequately drained by tube thoracostomy, assuming its specific character because of the coagulability of pleural fluid, the abundance of cellular debris, and increased fibrin and collagen deposition. Untreated empyema rarely resolves spontaneously. It may drain through the chest wall (empyema necessitatis) or into the lung (bronchopleural fistula).

The rapid identification of patients who are likely to develop complicated parapneumonic effusions would improve clinical outcome by allowing early pleural space drainage (Fig. 1). Unfortunately, it is not possible to differentiate clinically those patients with complicated parapneumonic effusions from those with uncomplicated parapneumonic effusions. Pleural fluid analysis remains the most useful diagnostic test in identifying the stage of a parapneumonic effusion and guiding therapy. If pus is aspirated at thoracentesis, diagnosing an empyema, pleural space drainage should be accomplished without delay. Empyema fluid is usually diagnostic for specific pathogens if the specimen is handled expeditiously, appropriate microbiological technique is applied, the patient has not received antimicrobial therapy, and the pleural space is not multiloculated. The pleural fluid protein concentration, nucleated cell count, or percentage of neutrophils cannot differentiate a complicated from an uncomplicated effusion; however, pleural fluid biochemistry can help do so. If the pleural fluid pH is <7.10, the glucose <40 mg/dl, and the LDH >1000 IU/liter, the fluid is a complicated parapneumonic effusion that requires pleural space drainage. If, however, the pH is >7.30, the glucose >60 mg/dl, and the LDH <1000 IU/liter, the fluid is almost always an uncomplicated effusion and will resolve spontaneously on appropriate antibiotic therapy directed at the pneumonia.

FIG. 1. Algorithm for management of parapneumonic effusions. Management of these patients has not been subjected to randomized clinical trials and, therefore, represents a rational approach based on current data.

Complicated parapneumonic effusions should be assessed by CT scan to determine the number and position of pleural fluid loculations. A single loculus with minimal pleural enhancement can be drained by a chest tube or radiologically guided catheter. Multiple locules will require either empyemectomy and decortication or tube drainage with the use of fibrinolytic agents, either urokinase or streptokinase. Many thoracic surgeons today are using thoracoscopy in the initial management of complicated parapneumonic effusions with debridement, pleural irrigation, and decortication. Open drainage should be reserved for the debilitated patient who is too ill to tolerate a major thoracotomy.

Malignant Pleural Effusions

Malignant pleural effusions are the most common cause of exudative effusions in patients over the age of 60. They are frequently the first manifestation and diagnostic source of malignancy, signal incurability, and often represent the first manifestation of recurrent disease. The diagnosis is established by finding malignant cells in pleural fluid or pleural tissue. Some patients, however, will have a pleural effusion associated with malignancy, but malignant cells cannot be demonstrated in pleural fluid or pleural tissue and actually are not present at the time of the diagnostic procedure. These effusions are termed paramalignant effusions and are caused by the malignancy but do not result from direct pleural involvement. Causes of paramalignant effusions include (1) direct local effect of the tumor (lymphatic obstruction, bronchial obstruction with pneumonia or atelectasis), (2) systemic effects of the tumor (pulmonary embolism, hypoalbuminemia), and (3) results of therapy (radiation pleuritis and fibrosis and drug reactions). Lymphatic obstruction, the predominant mechanism of pleural fluid formation in malignancy, can occur with blockage of the lymphatic system at any point from the stoma of the parietal pleura to the mediastinal lymph nodes.

In lung cancer, pleural metastasis occurs when cancer invades the pulmonary vasculature and embolizes to the visceral pleural surface. Once the visceral pleural surface is seeded with tumor, malignant cells migrate across the pleural space along preformed or tumor-induced adhesions. Alternatively, free tumor cells shed from the visceral pleura may adhere to the parietal pleura and multiply. Adenocarcinoma is the most common cell type to involve the pleura because of its peripheral location and propensity for contiguous spread.

Carcinoma from any organ can metastasize to the pleura; however, lung cancer is the most common tumor to result in malignant and paramalignant effusions. Carcinoma of the breast is second in incidence and, in some series, exceeds lung cancer as the cause of malignant effusions, depending on the study population. Ovarian and gastric carcinoma represent about 5% of malignant effusions. Approximately 7% to 10% of patients with malignant pleural effusions have an unknown primary site at the time of the initial diagnosis.

The most common presentation of patients with carcinomatous pleural effusion is dyspnea on exertion. The mechanism of dyspnea from a large pleural effusion is multifactorial and is related to decreased chest wall compliance, contralateral mediastinal shift, loss of ipsilateral lung volume, and neurogenic factors of the lung parenchyma.

The chest radiograph in lung cancer most commonly shows a pleural effusion ipsilateral to the primary lesion. If the primary site is other than lung, with the possible exception of breast cancer, there appears to be no ipsilateral predilection, and bilateral effusions are common. Most patients with carcinoma of the pleura will have a moderate to large pleural effusion, usually 500 to 2000 ml. Ten percent will have an effusion less than 500 ml, and a similar number will show a massive pleural effusion. Seventy percent of patients who present with a massive pleural effusion (occupying the entire hemithorax) will have a malignancy.

Malignant pleural effusions may be serous, serosanguinous, or grossly bloody. A grossly bloody effusion suggests direct pleural involvement with tumor; a serous effusion can result from either lymphatic obstruction or an endobronchial lesion with atelectasis. A majority of the nucleated cells are lymphocytes, macrophages, and

mesothelial cells, with lymphocytes representing more than 50% of the cell population half the time. The percentage of neutrophils is usually <25%. Pleural fluid eosinophilia is inexplicably rare, approximately 5%, in malignant effusions.

The pleural fluid associated with carcinoma of the pleura usually is exudative, but approximately 5% of patients have transudates. Transudative malignant effusions result from early stages of lymphatic obstruction, atelectasis from bronchial obstruction, or congestive heart failure with concomitant shedding of malignant cells into the pleural fluid.

A third of patients with malignant effusions on presentation will have pH < 7.30, which usually is associated with a glucose < 60 mg/dl. Low-pH/low-glucose malignant effusions usually have been present for several months and are associated with a large tumor burden and fibrosis of the pleura. These patients have a poor prognosis (average survival from time of thoracentesis of 2 months), a high yield (95%) of positive cytology on initial evaluation, and a poor (25% to 40%) response to chemical pleurodesis.

The most effective and minimally invasive treatment for patients with recurrent, symptomatic malignant pleural effusions is chest tube drainage with instillation of a chemical agent. Talc, either by poudrage or slurry, results in the best success rate (93%).

Malignant Mesothelioma

Malignant pleural mesothelioma is the signal neoplasm of asbestos exposure. Pleural mesotheliomas are more common in men in the sixth to seventh decade of life. The age occurrence is related to the long latency period of 20 to 40 years following initial exposure. The onset is usually insidious, with localized chest pain being the most common manifestation. A unilateral pleural effusion, more frequently on the right, is the most common radiographic finding. Early in the course, the effusion may be large or massive and cause contralateral mediastinal shift. As the tumor progresses, it encases the lung, grows along the mediastinum, and inhibits mediastinal shift, a radiographic sign suggestive of mesothelioma in the absence of an endobronchial lesion. The pleura may show marked thickening or nodularity, which is first noted near the diaphragm. Other signs of asbestos pleuropulmonary disease may be noted in the contralateral hemithorax.

At thoracentesis, there is marked resistance to the needle entering the pleural space. The pleural fluid may be serous, serosanguinous, or frankly bloody. The fluid is an exudate with nucleated cell counts <5000/ml. At diagnosis, 60% of patients with malignant mesothelioma have a low pleural fluid pH (<7.30) because of the large tumor bulk covering the pleural surface.

The diagnosis is suggested by the chest radiograph or chest CT scan and can be confirmed when a large amount of tissue can be obtained by thoracoscopy or thoracotomy for examination by special stains, electron microscopy, and immunologic studies.

Some patients with large pleural effusions may obtain relief with chest tube drainage and chemical pleurodesis. Chemotherapy, radiation therapy, and debulking surgery have not been shown to improve survival. Gene transfer therapy has shown promise in experimental animals.

Tuberculous Pleurisy

Tuberculous pleurisy is common in both the AIDS and non-AIDS population. Pleural effusion in tuberculosis occurs on an immunologic basis when a subpleural focus of *Mycobacterium tuberculosis* grows and ruptures into the pleural space. Tuberculin protein or the live bacillus interacts with sensitized T lymphocytes with liberation of lymphokines, which may alter the permeability of the pulmonary vasculature and affect activity of the mononuclear phagocyte and pleural fibroblast. Pleural effusions may also result from hematogenous dissemination of mycobacteria. Tuberculous pleurisy commonly occurs 3 to 7 months following the primary infection but can result from reactivation at any time.

The clinical presentation covers the spectrum from an acute illness simulating bacterial pneumonia to an indolent disease first suspected on a chest radiograph in a patient with minor constitutional symptoms. A nonproductive cough and chest pain, usually pleuritic, are the two most common symptoms at presentation. The patient is usually febrile, but peripheral leukocytosis is unusual.

The chest radiograph shows a unilateral, small to moderate pleural effusion, although massive effusions have been noted. Parenchymal disease can be detected radiographically in about a third of patients and can be seen on CT scan in most patients. The effusion is almost always ipsilateral to the infiltrate and is a marker of active parenchymal disease. The PPD will be negative in 30% of patients at presentation; most will convert their skin tests to positive in 6 to 8 weeks. A negative skin test with tuberculous pleurisy in the acute phase of the disease probably results from circulating mononuclear cells that suppress the sensitized T lymphocyte in the peripheral blood and skin but not in the pleural space.

The pleural fluid is a serous (serosanguinous in <10%) exudate with a total protein concentration almost always >4.0 g/dl. The nucleated cell count is generally <5000/ml with a predominance of lymphocytes (usually 90% to 95%). Neutrophil predominance occurs in the first few days following entry of the tubercle bacillus into the pleural space; neutrophils are rapidly replaced by mononuclear phagocytes and then by lymphocytes. A paucity of mesothelial cells is characteristic of tuberculous pleurisy, and pleural fluid eosinophilia is rarely observed. Low pleural fluid pH and glucose are found in 20% of patients. A pleural fluid pH >7.40 is rarely found in tuberculous pleurisy.

AFB (Acid-fast bacillus) smear of pleural fluid is positive in fewer than 10% of patients, whereas pleural fluid culture is positive in 25% to 70%. Pleural biopsy is the best single test for establishing the diagnosis. A granuloma can be demonstrated in the parietal pleura in 50% to 80% of patients and provides a presumptive diagnosis. Culture of the pleural biopsy specimen will grow *M. tuberculosis* 55% to 80% of the time. If pleural fluid and pleural tissue studies and sputum analysis are combined, the diagnosis can be confirmed in 90% to 95% of cases. Clinical presentation, pleural fluid findings, and diagnostic yield are similar with both AIDS and non-AIDS patients with tuberculous pleurisy.

Patients with tuberculous pleurisy can be treated with the same regimen used for pulmonary tuberculosis (three or four drugs for 2 months and INH and rifampin for 4 months). Some investigators have shown that because of the low organism load, INH and rifampin for 6 months is adequate therapy.

With treatment, the patient usually becomes afebrile within 2 weeks; however, fever may persist for as long as 6 to 8 weeks. The pleural effusion usually resolves by 6 weeks but can persist for 3 to 4 months.

Rheumatoid Pleurisy

Pleural involvement is the most common thoracic manifestation of rheumatoid disease and occurs in approximately 5% of patients. The typical patient is a man in the sixth decade who develops a pleural effusion within 5 years after the onset of rheumatoid disease. Effusions, however, can develop before or 20 years after the onset of articular disease. These patients usually have moderate to severe arthritis and subcutaneous nodules. The patient can present with pleuritic chest pain or dyspnea, or the disease may be discovered on a routine chest radiograph. Fever is not a frequent manifestation, in contrast to lupus pleuritis.

The chest radiograph shows a small to moderate unilateral effusion without other manifestations of rheumatoid lung disease. The effusion may appear turbid with a yellow-green tint. Occasionally it is milky (because of cholesterol) or appears to contain debris. These exudative effusions have high protein values and have the characteristic triad of glucose < 30 mg/dl, pH 7.00, and LDH > 1000 IU/liter. Pleural fluid nucleated cell counts vary from a few hundred up to 15,000/ml, with the cellular predominance depending on the timing of thoracentesis in relation to the active pleural process.

Rheumatoid pleural effusions have low total hemolytic complement and complement components and a rheumatoid factor usually ^{3}1:320 along with high levels of immune complexes. A characteristic cytologic picture consisting of a background of orange or red granular material, large elongated cells, and giant round or oval multinucleated cells is specific for rheumatoid pleurisy. The exudate appears to be derived from palisading histiocytes and their breakdown products, which occur in the inflamed rheumatoid pleura. Pleural biopsy generally shows nonspecific pleuritis and fibrosis. Because the majority of the rheumatoid nodules are found on the visceral pleural surface, the yield from pleural biopsy is low.

The course of rheumatoid pleurisy is variable. It is uncommon, however, for resolution to occur in less than 3 to 4 weeks; in the usual case, the effusion will resolve over several months. Some patients, however, have a prolonged course that lasts years and occasionally progresses to marked pleural thickening requiring decortication. The efficacy of corticosteroids in the long-term outcome of patients with rheumatoid pleurisy is unknown.

Lupus Pleuritis

Involvement of the pleura occurs during the course of systemic lupus erythematosus (SLE) in 50% to 75% of patients and can be the presenting manifestation in 5%.

Chest pain, the most common presenting symptom, is found in 90% of patients. Cough, dyspnea, pleural friction rub, and fever are also frequent findings. An episode of lupus pleuritis usually is associated with an exacerbation of SLE. The most common radiographic presentation of lupus pleuritis is small to moderate bilateral pleural effusions. Other abnormalities include alveolar infiltrates, atelectasis, and enlarged cardiac silhouette, which may result from pericardial effusion or congestive heart failure.

The pleural fluid may be serous, turbid, or bloody. Nucleated cell counts range from several hundred to 20,000/ml. Cellular predominance can be either neutrophil or mononuclear, depending on the time of thoracentesis in relation to the acute injury. In 20% of patients, the pH can be <7.30 and the glucose <60 mg/dl. Finding LE cells in pleural fluid is diagnostic of lupus pleuritis. These patients also frequently have low pleural fluid total hemolytic complement or complement components and can have immune complexes in the pleural fluid. If the pleural fluid ANA exceeds the serum ANA, the diagnosis of lupus pleuritis is suggested.

Patients with active lupus pleuritis usually have a dramatic response to corticosteroids with abatement of symptoms over several days and disappearance of the pleural effusion within 2 weeks.

Post-Cardiac-Injury Syndrome

Post-cardiac-injury syndrome (PCIS) is characterized by the onset of fever, pleuropericarditis, and parenchymal infiltrates 3 weeks (range 2 to 86 days) following injury to the myocardium or pericardium. The incidence following myocardial infarction has been reported from <1% to 15% and, following cardiac surgery, up to 30%.

The pathogenesis has not been clearly elucidated, but the syndrome appears to be an immunologic reaction in the lung, pleura, and pericardium associated with antimyocardial antibodies. It has recently been shown that a patient with PCIS had higher levels of antimyocardial antibodies in pleural fluid than in serum. However, at present the diagnosis remains one of exclusion.

The most common presenting symptom is pleuritic chest pain, which occurs in over 90% of patients. Fever, pericardial rub, dyspnea, and rales occur in approximately half the patients. Fifty percent of patients will have a leukocytosis, and almost all will have an elevated erythrocyte sedimentation rate in the range of 60 mm/hr.

The chest radiograph is usually abnormal, with the most common finding being a pleural effusion. In most instances the effusion is left-sided or bilateral. Pulmonary infiltrates are usually present, most commonly in the left lower lobe. A large cardiac silhouette has been noted in half of the patients.

The pleural fluid is a serosanguinous or bloody exudate with grossly bloody effusions occurring early in the course of the illness. The nucleated cell count ranges from 500 to 40,000/ml with a neutrophil predominance early and a mononuclear predominance late. Pleural fluid glucose and pH are normal.

Post-cardiac-injury syndrome is usually self-limited and may not require therapy if symptoms are trivial. The patient usually responds to aspirin or nonsteroidal antiinflammatory agents, but some patients require corticosteroid therapy for resolution. Recurrences may be related to withdrawal of corticosteroid therapy or reduction of the dose to below a critical level. In responders, the pleural effusion resolves within 1 to 3 weeks.

Pulmonary Embolism

Pleural effusions occur in up to 50% of patients with pulmonary embolism. Pleural effusions result from (1) increased pleural capillary permeability, (2) an imbalance in microvascular and pleural space hydrostatic pressures, and (3) pleuropulmonary hemorrhage. Ischemia from pulmonary vascular obstruction, in addition to evoking release of inflammatory mediators from platelet-rich thrombi, can cause capillary leak into the lung and subsequent pleural space, explaining the usual finding of an exudative pleural effusion. Transudates have been described in approximately 20% of patients and result from atelectasis.

With pulmonary infarction, necrosis and hemorrhage into the lung and pleural space may result. If infarction is present, more than 80% of the patients have bloody pleural effusions, but over 35% of patients with pulmonary embolism without radiographic infarction will also have hemorrhagic fluid.

Chest pain, usually pleuritic, occurs in almost all patients with pleural effusions complicating pulmonary embolism and is invariably ipsilateral despite the fact that lung scans or angiograms indicate that the emboli are bilateral. This suggests that pleural effusions from pulmonary embolism are unusual in the absence of ipsilateral chest pain.

The chest radiograph typically shows a small (less than a third of the hemithorax), unilateral pleural effusion. An associated pulmonary infiltrate is seen in 50% of patients. With radiographic infiltrates, effusions tend to be larger and resolution time longer, presumably because the infiltrate represents a pulmonary infarction.

Pleural fluid analysis is variable and nondiagnostic; however, the fluid is bloody in two-thirds of patients, and the number of red blood cells exceeds 100,000/ml in fewer than 20% of patients. Nucleated cell counts range from <100/ml in atelectatic transudates to >50,000/ml with pulmonary infarction. Neutrophil predominance occurs when thoracentesis is performed near the time of the acute embolus; a lymphocyte predominance occurs later. Pleural fluid eosinophilia may be a feature of the bloody pleural effusion. The pleural effusion usually is apparent on the admission chest radiograph and reaches maximum volume during the first 72 hrs. Patients with pleural effusion that progress with therapy should be evaluated for recurrent embolism, hemothorax secondary to anticoagulation, an infected infarction, or an alternate diagnosis. When consolidation is absent on chest radiograph, effusions resolve in less than a week. With consolidation, there is a longer resolution time.

The association of pleural effusion with pulmonary embolism does not alter therapy. The presence of a bloody effusion is not a contraindication to full-dose anticoagulation because hemothorax is a rare complication of heparin therapy. An enlarging pleural effusion on therapy necessitates thoracentesis to exclude hemothorax, empyema, or another etiology. Active pleural space hemorrhage necessitates discontinuation of anticoagulation, tube thoracostomy, and consideration of vena caval interruption.

Pancreatic Pleural Effusions

Pleural effusion has been described in 3% to 17% of patients with pancreatitis. Effusions can occur with either acute or chronic pancreatitis, with different clinical presentations, management, and prognosis. Several mechanisms are involved in the pathogenesis of pancreatic pleural effusion. These include direct contact of pancreatic enzymes with the diaphragm, transfer of ascitic fluid via a diaphragmatic defect, communication of a fistulous tract between a pseudocyst and the pleural space, and retroperitoneal movement of fluid into the mediastinum with mediastinitis or rupture into the pleural space. A probable explanation for the pleural fluid amylase being higher than the concomitant serum amylase is impaired lymphatic drainage from the pleural space and increased amylase clearance by the kidneys.

The pleural effusion associated with acute pancreatitis is usually small and left-sided; however, an effusion may be right-sided or bilateral. The patient usually presents with abdominal symptoms of acute pancreatitis. The diagnosis is confirmed by finding a pleural fluid amylase concentration that is greater than the serum amylase. Pleural fluid amylase has been found initially normal in acute pancreatitis but increases on serial measurement. The fluid is a neutrophil-predominant exudate with glucose values approximating those of serum. Nucleated cell counts may reach 50,000 cells/ml. The pleural fluid pH is usually between 7.30 and 7.35.

Patients with effusions from chronic pancreatitis usually present with dyspnea, chest pain, or cough from a large or massive pleural effusion. Effusions tend to recur rapidly following thoracentesis. Pleural effusions are slightly more common on the left, and bilateral effusions can occur. Patients with massive pancreatic pleural effusions frequently do not relate a history of pancreatic disease, although the majority are alcoholics. In contrast to acute pancreatitis, the amylase concentration in chronic effusions is always elevated and may reach levels >100,000 U/liter. Serum amylase may be elevated as a result of back-effusion or may be normal. The diagnosis of chronic pancreatic pleural effusion is suggested by an amylase-rich exudate that rapidly reaccumulates following thoracentesis in a patient with respiratory symptoms only. Ultrasound and CT scan are useful in confirming the diagnosis by demonstrating the pseudocyst and fistulous tract.

No specific treatment is necessary for the pleural effusion of acute pancreatitis—the effusion resolves as the pancreatic inflammation subsides. Approximately 50% of patients with chronic pancreatic pleural effusion respond to conservative management while the other half require surgery for resolution.

Benign Asbestos Pleural Effusion

Pleural effusion resulting from asbestos exposure is the most common manifestation of asbestos pleuropulmonary disease in the first 20 years following asbestos exposure. The latency period from time of initial asbestos exposure until the development of pleural effusions can be very short, occurring in the first year, or can be lengthy, occurring after 50 years.

The majority of patients are asymptomatic at the time the pleural effusion is discovered, usually by routine chest radiograph. The most common symptom is chest pain, which is noted in about a third of cases. The chest radiograph typically shows a small, unilateral pleural effusion. Pleural plaques may be seen in 20% of patients, and

moderate to severe asbestosis in fewer than 10% of patients.

The pleural fluid is usually a serosanguinous exudate, although the fluid may be serous or bloody on occasion. The cell count is usually <6000/ml with either mononuclear or neutrophil predominance. Pleural fluid eosinophilia (up to 50% eosinophils) occurs frequently. These effusions do not have high levels of hyaluronic acid, as seen in some patients with mesothelioma, and pleural plaques are usually not seen.

The diagnosis of benign asbestos pleural effusion (BAPE) is presumptive in a patient with known asbestos exposure. The effusion can remain from under a month to a year or more, with an average duration of 3 to 4 months. Resolution usually results in a blunted costophrenic angle (>90%) and diffuse pleural thickening in about 50% of patients. Recurrence is common, either ipsilateral, bilateral, or contralateral. Diffuse pleural thickening, with or without progression, may occur years after the initial asbestos effusion. A short latency period and absence of symptoms suggests BAPE, whereas a long latency period and symptoms suggest mesothelioma.

Chylothorax

Chylothorax is a pleural effusion that contains chyle. Chyle, the lymph found in the thoracic duct, is characterized by the presence of chylomicrons. When the thoracic duct ruptures, its contents can spill into the pleural space. Chylothorax can also result from movement of chylous ascites into the pleural space. The thoracic duct has its origin in the cisterna chyli, which are midline structures just anterior to the first or second lumbar vertebrae. The course moves cephalad through the aortic hiatus into the posterior mediastinum to the right of the midline between the aorta and azygous vein. The thoracic duct ascends between the T_{12} and T_8 thoracic vertebrae, crosses the midline between T_6 and T_4 posterior to the esophagus, and enters the left posterior mediastinum. It courses behind the aortic arch and left subclavian artery into the superior mediastinum and then descends and enters near the junction of the left internal jugular and subclavian veins. This anatomic course explains why thoracic duct injury below T_5 to T_6 produces a right chylothorax and injury above this level a left chylothorax. However, there is marked variability in thoracic duct anatomy. Because of the elaborate collateral lymphatic network, with distal obstruction, collaterals and anastomoses become functional, permitting ligation at any point of the thoracic duct. Within the lymphatic system, numerous valves insure unidirectional flow of 1500 to 2400 ml of lymph per day into the venous system.

Approximately 30% of chylothoraces are the result of trauma, mostly related to thoracic surgery. Seventy percent of chylothoraces are nontraumatic, with lymphoma representing 50%. Metastatic cancer from any organ of the body can result in a chylothorax. Idiopathic chylothoraces represent about 15% of all cases. Other nonmalignant, nontraumatic chylothoraces include lymphangiomyomatosis, cirrhosis, and lupus.

Several misconceptions concerning chylothorax have been perpetuated and often confuse the clinician in establishing the diagnosis. First, not all milky pleural fluid represents chylothorax; it also could be a cholesterol effusion or an effusion with a large number of leukocytes. Second, a milky effusion can stain negative for fat and still be chylous; the total fat content of chyle can be low, particularly in the malnourished patient. Third, chylous effusions can be bloody, turbid, or serous. Chyle is composed largely of proteins such as albumin and globulins, lymphocytes, electrolytes, and lymph from the lower extremities. Chylomicrons and lipoproteins compose only a small percentage of thoracic duct lymph.

The presentation of a patient with chylothorax will depend on the underlying cause. The most common presenting symptom is dyspnea on exertion as a result of a large pleural effusion. The chest radiograph characteristically shows a unilateral pleural effusion without parenchymal disease; mediastinal adenopathy may be present. The pleural fluid typically is milky in appearance but can be bloody, turbid, or serous. A chylothorax is an odorless exudate with a predominance of lymphocytes. Pleural fluid glucose is similar to serum glucose, and the pH is >7.40. Although chylous effusions tend to have a cholesterol/triglyceride ratio of <1.0, and nonchylous effusions have ratios >1.0, overlap exists. Cholesterol concentrations are not different in chylous and nonchylous pleural effusions; however, there is a striking difference in the triglyceride concentrations. If the pleural effusion has a triglyceride concentration >110 mg/dl, it has less than a 1% chance of not being chylous. Pleural fluid with a triglyceride concentration of <50 mg/dl has less than a 5% chance of being chylous. Values between 50 and 110 mg/dl require lipoprotein electrophoresis to diagnose or exclude a chylous effusion, which would contain chylomicrons. Patients with chylous effusions with triglyceride concentrations between 50 and 110 mg/dl are either severely malnourished or have concomitant bleeding into the pleural space causing a dilutional effect.

The major complications of chylothorax are malnutrition and immunologic compromises as protein, fat, and lymphocytes are depleted from the body with repeated thoracenteses or prolonged chest tube drainage. Initial treatment consists of pleural space drainage to relieve dyspnea, diminution in the rate of chyle formation, and maintenance of adequate nutrition. Tube thoracostomy is the most efficient method for pleural space drainage; because chyle is relatively bacteriostatic, the incidence of chest-tube-related empyema is low. Chyle formation is minimized by intravenous hyperalimentation, discontinuation of oral feedings, the use of gastric suction, and bed rest. Medium-chain triglycerides, which are absorbed into the portal vein and into the circulation directly, may be used as an oral source of fats. Most traumatic chylothoraces respond with either cessation or slowing of chyle flow within 7 to 10 days. If chylous drainage persists or is progressive, pleurodesis or thoracic duct ligation should be considered.

The basic management of nontraumatic chylothorax is similar to that of traumatic chylothorax, but a cause needs to be established in the former. If lymphoma is diagnosed, mediastinal radiation should be given because it controls the chylothorax in the majority of patients. If this is unsuccessful, chemical pleurodesis or pleuroperitoneal shunt should be considered for palliation.

Esophageal Perforation

Endoscopy or dilation is the most common cause of esophageal perforation today. Spontaneous esophageal rupture, Boerhaave's syndrome, is a potential life-threatening event requiring immediate diagnosis and therapy.

Patient presentation, radiologic evaluation, and outcome vary depending on the cause, location, and extent of the perforation. Most patients eventually have chest pain, which is universally present in those with cervical perforation. Dyspnea and dysphagia appear to be more frequent following mid- and distal esophageal perforation. Almost all patients will have a febrile response to perforation, and about half will demonstrate subcutaneous emphysema.

The history in spontaneous rupture usually is severe retching or vomiting or a conscious effort to resist vomiting. Early recognition of spontaneous rupture depends on interpretation of the chest radiograph. Several factors can influence chest radiographic findings: (1) the time between perforation and the chest radiograph; (2) the site of perforation; and (3) mediastinal pleural integrity. Mediastinal emphysema probably takes at least 1 to 2 hr to be demonstrated radiographically and is present in fewer than half of patients. Mediastinal emphysema tends to occur early with perforations of the intrathoracic esophagus. Pneumothorax, present in 75% of patients with spontaneous esophageal rupture, indicates violation of the mediastinal pleura and occurs with a 70% incidence on the left, 20% on the right, and is bilateral in 10%. Mediastinal air is seen early if pleural integrity is maintained, and pleural effusion secondary to mediastinitis tends to occur later. Pleural fluid, with or without associated pneumothorax, occurs in 75% of perforations.

The diagnosis is usually more obvious in iatrogenic than spontaneous rupture, as the symptoms are easily related to the recently performed procedure. With minor perforations, the mediastinal pleura usually remains intact, and the pleural fluid produces a sterile, neutrophil-predominant exudate with normal pH and amylase levels.

In spontaneous esophageal rupture, the acuteness of the pressure rise, rather than the absolute pressure, is critical in causing perforation. The tear almost always occurs in the distal half of the esophagus because that portion of the esophagus is devoid of striated muscle and is deficient in extramural support.

Radiographic confirmation of a presumptive diagnosis needs to be accomplished immediately. Esophagrams are positive in about 90% of patients. The contrast study should be done with the patient in the appropriate lateral decubitus position.

The pleural fluid findings in spontaneous esophageal rupture will depend on the degree of perforation and the timing of thoracentesis from the acute injury. Early thoracentesis without mediastinal perforation will show a serous, sterile exudate with a predominance of neutrophils and normal pleural fluid amylase and pH. Once the mediastinal pleura tears, amylase of salivary origin will appear in the fluid in high concentration. As the pleural space is seeded with anaerobic organisms from the mouth, the pH will rapidly fall to approach 6.00. Experimentally, it has been shown that pleural fluid leukocyte metabolism, not gastric acid reflux, is the major contributor to the low pH of esophageal rupture effusions. Other findings in pleural fluid suggestive of esophageal rupture include the presence of squamous epithelial cells and food particles.

The diagnosis of spontaneous esophageal rupture dictates immediate operative intervention. If it is diagnosed and treated with primary closure within the first 24 hr, survival exceeds 90%. In addition to primary closure, antibiotics covering mouth anaerobes, parenteral nutrition, and mediastinal and pleural space drainage constitute the therapeutic regimen. For iatrogenic rupture in patients with minimal symptoms and without signs of clinical sepsis, antibiotics, gastrointestinal tract drainage, and hyperalimentation usually are effective.

Uremic Pleural Effusions

At autopsy, approximately 20% of patients with uremia have a fibrinous pleuritis. Clinically, the incidence of uremic pleural effusions varies from 3% to 16%. Patients who develop uremic pleural effusions have usually been on chronic hemodialysis for more than 1 year. Half of the patients present with fever and chest pain, and cough is seen in about a third. Most patients do not complain of dyspnea. A friction rub is heard in one of three patients and usually lasts 2 to 3 days.

The chest radiograph typically shows a unilateral, moderate pleural effusion, although massive and bilateral effusions have been described. The pleural fluid can be serous, serosanguinous, or bloody. This exudate usually has fewer than 1500 nucleated cells per microliter, with a predominance of lymphocytes. Neutrophil predominance and pleural fluid eosinophilia have not been noted. The creatinine concentration is high, reflecting the blood creatinine, but the ratio of pleural fluid to serum creatinine is less than 1.0.

The differential diagnosis of the patient developing a pleural effusion on hemodialysis includes, most commonly, congestive heart failure, uremic pleural effusion, tuberculous pleurisy, and parapneumonic effusion. Pleural effusions usually resolve with continued dialysis over several weeks but may recur. Reports of fibrothorax following uremic pleurisy have been described with a successful result following decortication. Despite the coagulopathy that these patients have, this procedure has been carried out successfully.

Hemothorax

Hemothorax is defined as blood in the pleural space and connotes substantial pleural space bleeding. However, it is often problematic clinically to assess the degree of pleural space hemorrhage from visualization of the pleural fluid. Therefore, a hematocrit should be measured on all grossly bloody effusions. A hemothorax is arbitrarily diagnosed when the hematocrit of the pleural fluid is at least 50% of the peripheral blood hematocrit. Establishing the diagnosis of a hemothorax directs a more aggressive course of treatment that is different from that used for the patient with a hemorrhagic effusion.

Bleeding into the pleural space can originate in the chest wall, diaphragm, lung, or mediastinum. When blood enters the pleural space, it coagulates rapidly, although there is the potential of the mesothelial cell, through its fibrinolytic activity, to convert the clot to liquid hemothorax. However, transient clotting or lack of fibrinolysis may occur because of mesothelial cell injury. The clotted blood cannot be drained by tube thoracostomy.

Blunt or penetrating chest trauma is the major cause of hemothorax. Virtually every vessel within the chest can bleed into the pleural space following injury. Bleeding most commonly arises from laceration of the pulmonary vessels or intercostal veins. Blunt chest trauma often causes hemothorax from rib fracture, the risk increasing with the number of ribs fractured; delayed hemothorax following rib fracture has been noted. Life-threatening pleural-space hemorrhage can occur from the pulmonary, internal mammary, or subclavian artery as well as from cardiac lacerations. Bleeding from organs below the diaphragm, such as the liver, spleen, and kidneys, can also present as a hemothorax. A traumatic hemothorax is usually suspected when a unilateral pleural effusion is found on the initial chest radiograph. However, the diagnosis may be delayed, as the subtle, unilateral haziness is not noted on the supine radiograph. Pneumothorax is a frequent accompaniment of both blunt and penetrating chest injury.

Iatrogenic hemothoraces are common, seen mostly with laceration of the large arteries or veins of the thorax after central venous catheterization.

Other causes of iatrogenic hemothorax include leaking from the aorta after translumbar aortography and as a complication of thoracentesis or pleural biopsy.

Nontraumatic or spontaneous hemothoraces are uncommon. The two most common causes of nontraumatic hemothorax are metastatic pleural malignancy and anticoagulation for pulmonary embolism. Sarcomas of the lung and pleura are the most common malignancy to result in hemothorax. There have been only a few reports of lung cancer causing hemothorax despite the large number of patients and the high incidence of hemorrhagic effusions. Spontaneous hemothorax in patients receiving anticoagulant therapy (either heparin, warfarin, or both) has been described within the first week of treatment and after several months of therapy. The coagulation parameters are usually within the therapeutic range, and the hemothorax is usually on the side of the pulmonary embolus.

Other causes of spontaneous hemothorax include arteriovenous malformations, bleeding diathesis, dissecting aortic aneurysm, pneumothorax, neurofibromatosis, pulmonary sequestration, splenic artery rupture, thoracic endometriosis, and the blue rubber bleb nevus syndrome.

In the management of traumatic hemothorax, a large-bore chest tube (36 to 40 French) should be inserted to drain the pleural space, reexpand the lung, and monitor the rate of bleeding. Lung reexpansion often stops the bleeding by a tamponade effect. Although no study has quantified the amount of chest tube bleeding as an absolute indication for thoracotomy, if bleeding persists at 200 to 300 ml/hr or is not decreasing, exploratory thoracotomy should be performed to locate the bleeding site and achieve hemostasis.

The complications of hemothorax include retention of clotted blood in the pleural space, empyema, pleural effusion, and fibrothorax. Controversy exists whether residual clotted blood should routinely be removed from the pleural space. However, recent studies have shown that there is no difference in the incidence of empyema or residual pleural abnormalities in patients with or without residual hemothorax. Therefore, not all patients with residual hemothorax need a thoracotomy; thoracotomy should be reserved for patients who have >30% of the hemothorax occupied by clotted blood. There are no controlled studies evaluating the use of thrombolytic agents in management of clotted hemothorax.

Empyema occurs following hemothorax in 1% to 4% of patients. Risk factors for development of empyema include shock, gross contamination of the pleural space at the time of the original injury, associated abdominal injuries, and prolonged chest tube drainage. Treatment of hemothorax-related empyema is similar to that for pneumonic empyema. Empyemectomy and decortication should be accomplished without delay if tube thoracostomy drainage is unsuccessful in resolving pleural sepsis.

Pleural effusions are common following removal of the chest tube for hemothorax. A diagnostic thoracentesis should be done to exclude empyema. If thoracentesis is negative, observation is warranted as the effusion resolves over several weeks without pleural space sequela.

In fewer than 1% of patients following hemothorax, a fibrothorax develops. The risk of fibrothorax is increased when there is concomitant empyema or pneumothorax. If the patient has a persistent restrictive ventilatory defect several months following the hemothorax, decortication should be considered.

Pleural Effusions in AIDS

Pleural effusions are common in hospitalized AIDS patients, having been found in 27% of a large series. The cause was infectious in two-thirds of patients. Pleural effusions were most commonly caused by bacterial pneumonia and represented a third of all patients with pleural effusions. Half of the patients with parapneumonic effusions had pneumococcal pneumonia. Other infectious causes of pleural effusions in AIDS patients included, *Pneumocystis carinii* pneumonia, *Mycobacterium tuberculosis,* septic embolism, *Nocardia asteroides, Cryptococcus neoformans,* and *Mycobacterium avium intracellulare.* Among the noninfectious causes, hypoalbuminemia was the most common, occurring in 19% of all patients with effusions. Other noninfectious causes included congestive heart failure, atelectasis, Kaposi's sarcoma, uremic pleurisy, and the acute respiratory distress syndrome. Patients with AIDS who had pleural effusions had lower serum albumin levels and lower CD4 counts than those AIDS patients without pleural effusions. Most pleural effusions in hospitalized AIDS patients are small and asymptomatic and do not require pleural space drainage. Large pleural effusions in AIDS patients are most commonly caused by lymphoma, Kaposi's sarcoma, and tuberculosis.

PNEUMOTHORAX

Classification

Pneumothorax (air in the pleural space) can be classified as spontaneous, traumatic, or iatrogenic. Primary spontaneous pneumothorax (PSP) occurs in individuals without clinical lung disease, whereas secondary spontaneous pneumothorax (SSP) results as a complication of preexisting lung disease. A traumatic pneumothorax occurs from either direct or indirect chest trauma and iatrogenic pneumothorax results as a complication of a diagnostic or therapeutic procedure.

Primary Spontaneous Pneumothorax

Primary spontaneous pneumothorax is most commonly seen in tall, thin men when an apical subpleural bleb ruptures. Subpleural blebs can result from congenital abnormalities, small airway inflammation, and disturbances of collateral ventilation. Over 90% of patients with PSP are smokers or ex-smokers. Chest pain and dyspnea are the two prominent symptoms and usually occur while the patient is at rest. Physical examination may be unremarkable with a small pneumothorax. With a large pneumothorax, there may be decreased chest movement, decreased fremitus, hyperresonance to percussion, and diminished or absent breath sounds on the

ipsilateral side. A marked tachycardia (>135 beats/min) should alert the clinician to the possibility of a tension pneumothorax.

The physiological consequences of pneumothorax are a decrease in vital capacity and a fall in arterial oxygen tension; hypocapnia is usually present as a consequence of hyperventilation in response to hypoxemia and to chest pain. Hypercapnia is unusual with normal underlying lungs. The increased alveolar–arterial oxygen difference results from low-*V/Q* areas and shunts.

The diagnosis depends on demonstration of the visceral pleural line on an upright chest radiograph. In problematic cases, an expiratory or lateral decubitus radiograph with the suspected side up should be obtained. An expiratory film results in the pneumothorax gas occupying a larger portion of the hemithorax, and, therefore, the visceral pleural line may be more easily visualized.

The major treatment decision in PSP is whether or not to remove the air from the pleural space. Because these patients do not have clinical lung disease, a more conservative approach can be taken if the pneumothorax is small and the air leak has ceased. In general, if the patient's symptoms have resolved, and the pneumothorax is thought to be <15%, observation is warranted, as the pneumothorax gas would be resorbed in about 2 weeks; it is estimated that about 1.25% of the volume of the pneumothorax is absorbed daily.

Treatment options for PSP >15% include supplemental oxygen, catheter aspiration, tube thoracostomy, or tube thoracotomy with instillation of a chemical pleurodesis agent. Pleural air is absorbed more rapidly when patients are given oxygen supplementation, as the net gradient for gas absorption from the pleural space to blood will increase. Catheter aspiration will be successful if the air leak has stopped; its only advantage is in decreasing the resolution time of the pneumothorax. Standard chest tube drainage results in rapid resolution of the pneumothorax; small catheters may be equally successful if the air leak is not large. The chest tube or catheter can be removed 24 to 48 hr after the lung is fully expanded and the air leak has ceased. Chest tube drainage does not appear to decrease the rate of recurrence. Because approximately half of the patients with PSP will have a recurrence, chemical agents have been instilled intrapleurally through a chest tube, and talc has been administered as a poudrage through a thoracoscope in an attempt to diminish the recurrence rate. A recent VA cooperative study showed a decreased rate of recurrence of both PSP and SSP in patients receiving 1500 mg of intrapleural tetracycline compared to placebo. However, many clinicians are cautious concerning the use of chemical pleurodesis in young individuals with PSP because of the possibility of developing significant pleural fibrosis. Some prefer thoracoscopy with pleural abrasion and partial pleurectomy instead of the use of chemical agents. Laser therapy at thoracoscopy has also been advocated in the initial treatment of recurrence of PSP.

Secondary Spontaneous Pneumothorax

In contrast to the benign nature of PSP, SSP may be life-threatening, as these patients have significant underlying lung disease. There are multiple causes of SSP; however, the most common cause is chronic obstructive pulmonary disease (COPD). Other common causes include cystic fibrosis and interstitial lung disease, especially pulmonary histiocytosis and stage IV sarcoidosis. Malignancies, necrotizing pneumonias, tuberculosis, *Pneumocystis carinii,* and lymphangiomyomatosis are also causes of SSP (Table 1).

Diseases	Comments
Disease of the airways	
Chronic obstructive pulmonary disease	Most common cause of secondary spontaneous pneumothorax (SSP)
Cystic fibrosis	Usually in adolescents and adults
Asthma	Associated with status asthmaticus
Interstitial Lung disease	
Pulmonary histiocytosis X	Pneumothorax may be presenting problem; often recurrent
Sarcoidosis	Usually stage IV sarcoidosis
Idiopathic pulmonary fibrosis	Pneumothorax less common than in pulmonary histiocytosis
Tuberous sclerosis	Usually found in women
Other types	Risk of pneumothorax increases with advanced stage of disease
Infection	
Necrotizing pneumonia	Gram-negative aerobes, anaerobes
Tuberculosis	Usually active
Atypical mycobacteria	Usually active
Pneumocystis pneumonia	Pneumothorax associated with aerosolized pentamidine when *Pneumocystis carinii* infection develops
Malignancy	
Sarcomas	The most common tumors presenting as pneumothorax; incidence of pneumothorax from metastatic malignancy <1% of all SSPs
Lung cancer	
Others	
Lymphangiomyomatosis	Pneumothorax occurs in 66% of patients during course of disease
Endometriosis	Catamenial pneumothorax most common form of thoracic endometriosis
Marfan's syndrome	Incidence of pneumothorax 4% to 17%; with recurrence common
Pulmonary infarction	Rare complication of infected infarction

TABLE 1. *Diseases associated with secondary spontaneous pneumothorax*

Secondary spontaneous pneumothorax occurs when there is hyperexpansion of the distal air spaces because of inflammation or obstruction of the airways. When alveolar pressure exceeds interstitial pressure, air enters the interstitium and dissects retrogradely along the bronchovascular sheath to the hilum, causing pneumomediastinum. If the visceral pleura ruptures, then pneumothorax will occur. Necrotizing pneumonia causes pneumothorax from a distal visceral pleural tear.

The two major symptoms of SSP, dyspnea and chest pain, are the same as with PSP; however, the presentation may be more dramatic. Shortness of breath is universal, and some patients may have cardiovascular compromise. The finding of hypercapnia with pneumothorax signifies underlying lung disease, usually COPD. Occasionally it is difficult to differentiate between a pneumothorax and a bullous lesion. The visceral pleural line with pneumothorax usually follows the configuration of the chest wall, whereas a bullous lesion may have a concave relationship to the chest wall. Chest CT scan may help to differentiate problematic cases.

Because recurrence rates with SSP are similar to that of PSP, and, in the setting of lung disease, pneumothorax may be life-threatening, preventing recurrence is the primary concern. Virtually all patients with SSP should be treated with chest tube drainage. Even with tube thoracostomy, lung expansion takes longer, and the air leak persists longer, than in PSP. Options to prevent recurrence include instillation of chemical agents (talc slurry, doxycycline, or minocycline) through a chest tube, talc poudrage through a thoracoscope, laser therapy, and pleural abrasion/pleurectomy with thoracoscopy or thoracotomy.

CHAPTER

76 Surgery and Pleural Space: Fibrothorax, Thoracoscopy, and Pleurectomy

Scott J. Swanson · David J. Sugarbaker

S.J. Swanson and D.J. Sugarbaker: Division of Thoracic Surgery, Brigham & Women's Hospital and Harvard Medical School, Boston, Massachusetts 02115.

INTRODUCTION

The pleura is a thin membrane made up of mesothelial cells and connective tissue that envelopes the lung (visceral pleura) and reflects back over the mediastinum, diaphragm, and chest wall (parietal pleura) to create a potential space. It allows smooth movement of the lung during respiration and recirculates the pleural fluid via the lymphatics situated within both of the pleural leaves.

Surgery for disorders of the pleural space has a long and storied history dating back to the early therapy for tuberculosis and involves the first use of thoracoscopy. Tuberculosis helped define the field of thoracic surgery. Anesthetic techniques matured at a time when tuberculosis became widespread. Treatment strategies, before the development of antituberculous medication, centered around therapeutic pneumothoraces. The first use of thoracoscopy was carried out by Jacobaeus, a Scandinavian internist, in 1910 using a cystoscope to examine the pleural space and divide adhesions with a primitive cautery device to allow lung collapse in the treatment of tuberculosis.

PRESENTATION AND DIAGNOSTIC WORKUP

Many disease processes affect the pleura, the most common and notable being empyema and various malignancies such as lung cancer. Because of the intimate association with the underlying lung, diaphragm, and mediastinum and overlying chest wall, these problems lead to severe symptoms and physiological impairment requiring aggressive treatment. Manifestations typically include dyspnea and localized pain that worsens with respiration. Therapeutic interventions require a precise understanding of the etiology of the disorder. The diagnostic workup inevitably involves a chest x-ray, which typically displays thickening of the pleura or fluid within the pleural space. The differentiation between these possibilities traditionally requires positional x-rays (decubitus views) or, more commonly in the current era, a chest computed tomographic (CT) scan.

Once the abnormality is identified, a sample of the fluid or a biopsy of the abnormal pleura will make the diagnosis and direct treatment. Usually this is accomplished by thoracentesis, with or without radiologic guidance, depending on whether the fluid is loculated, or by a closed pleural biopsy. If the needle drainage or biopsy is deemed too dangerous or proves to be inadequate, then a surgical procedure can provide a diagnosis and often treatment. In particular, to differentiate an adenocarcinoma from a mesothelioma, a surgical biopsy is critical in providing enough tissue to make this sometimes subtle distinction. With the recent advent in fiberoptic and instrumentation technology, this can be accomplished using minimally invasive techniques, which, with respect to the chest, are referred to as thoracoscopy (see below). Thoracoscopic surgical biopsy is associated with minimal morbidity and close to 100% sensitivity and specificity. In many cases a simultaneous therapeutic procedure can be carried out (for example, drainage and decortication of an empyema).

FIBROTHORAX

Fibrothorax occurs when the lung becomes “trapped” in an incompletely expanded position because of the presence of fibrous tissue in the pleural space as the result of a prior infection (empyema) or hemothorax. The same mechanical problem can occur with a neoplastic process such as a malignant mesothelioma or pleural dissemination of a lung or other cancer. Both situations lead to physiological impairment of gas exchange and alterations in the mechanics of breathing secondary to shunting and restriction.

The treatment of fibrothorax depends on the magnitude of the functional impairment, the underlying etiology (malignant versus nonmalignant, including infection), and the presence of any medical comorbidities. The goal is to provide symptomatic relief and salvage lung function by removing the pleural peel (decortication) that is responsible for the collapsed lung. Achieving complete reexpansion of the lung will not only relieve the symptoms of the associated dyspnea but also, in the case of an empyema, eliminate a space in which a recurrent infection could develop. In the case of a malignant process, the goals are similar except for certain cases, such as malignant mesothelioma, in which complete eradication is the aim.

The goal of surgery, then, where there is a symptomatic pleural process, is the eradication of this process by completely removing the parietal pleura (pleurectomy) and associated fibrinous peel (inflammatory or neoplastic) to allow the lung to regain its full capacity and therefore function. Exceptions to this include mesothelioma with no other signs of dissemination, where radical surgery with a more curative intent may be warranted. At our institution, the treatment of malignant mesothelioma would entail an extrapleural pneumonectomy, which removes the parietal pleura, the underlying lung with its intimately associated visceral pleura, and the diaphragm and pericardium (Fig. 1).

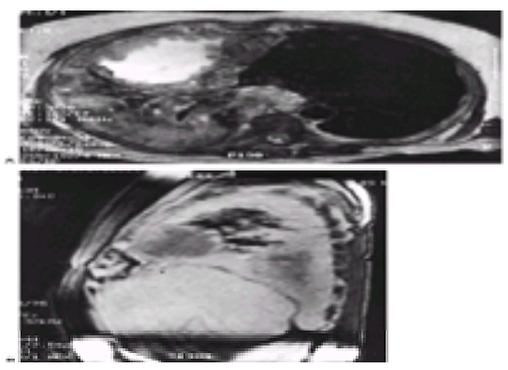

FIG. 1. Magnetic resonance imaging scan of the chest of a patient with malignant mesothelioma. **(A)** A cross-sectional image just above the diaphragm demonstrates the bulky pleural tumor compressing the lung. **(B)** A sagittal view of the same patient illustrates that even with bulky disease, the diaphragm is rarely transgressed.

In most situations where there is malignant involvement of the pleura leading to a fibrothorax, the cause is related to either disseminated (small-cell or non-small-cell) lung cancer or to metastases from another primary site, such as the breast. In these cases, palliation is clearly the goal, and the patient's life expectancy and ability to undergo an operation would determine the possible treatment. Ideally, a decortication would be performed.

SURGERY FOR PLEURAL DISEASE

In surgically treating pleural lesions, the aim of the surgery (palliative or curative) and the extent of the process determine the approach, either thoracoscopic or via a

thoracotomy.

Thoracoscopic surgery, as alluded to above, is surgery that involves a fiberoptic camera to provide visualization for the manipulations that are to be carried out using videoscopic surgical instruments. Typically, a true thoracoscopic procedure utilizes two to four small (2-cm) incisions in the thorax, which are made large enough to allow placement of the ports through which the camera or instruments will be placed. These ports are generally between 10 and 12 mm in diameter. They are positioned to triangulate the lesion that lies within the chest and, in the cases discussed here, are associated with the pleura (Fig. 2). The lung on the side of the surgery is collapsed by the anesthesiologist, who disconnects or clamps the lumen of the double-lumen endotracheal tube providing airflow to the lung of interest. Therefore, to undergo this type of surgery, the patient must be able to tolerate one-lung ventilation. Alternatively, under certain special circumstances, the procedures can be carried out using intermittent apnea and its associated passive atelectasis.

FIG. 2. Typical operating room setup for thoracoscopic surgery. (Reprinted with permission from Axford TC, Clair DG, Bertagnoli MM, Mentzer SJ, Sugarbaker DJ. Staged antrectomy and thoracoscopic truncal vagotomy for perforated peptic ulcer disease. *Ann Thorac Surg* 1993;55:1571–1573.)

Once the lung is collapsed, a videoscopic camera is placed through one of the ports and connected to the VCR monitor. Using the access provided by the other one to three ports, instruments for retracting the lung and sampling the pleural lesion or fluid are placed into the thorax under videoscopic visualization. Once an adequate sample has been obtained, it can be analyzed immediately by pathologic examination (“frozen section”) to assure that tissue from the lesion has in fact been isolated. Also, this may allow the surgeon to carry out simultaneous therapeutic intervention based on the pathologic information obtained. In addition, the remainder of the hemithorax, including the diaphragm, lung, and mediastinum, can be inspected carefully to look for and sample any other associated pathology. When the surgery is completed, hemostasis is obtained, usually with electrocautery or surgical clips, and a chest drain is typically placed through one of the ports and optimally positioned with the help of videoscopic visualization. It is secured to the skin with a suture. The pleural space is gently irrigated with saline, and then the other port incisions are closed with absorbable subcuticular sutures. A local anesthetic such as 0.5% bupivacaine with epinephrine is used to carry out a rib block to the five ribs surrounding the region of the incisions as well as a local field block to the area of the incisions themselves. This will provide 6 to 8 hr of excellent analgesia following the surgery. Where the thoracoscopic surgical procedure requires one of the port incisions to be enlarged to create a utility incision (of approximately 6 cm) to allow a larger portion of tissue to be removed or to provide direct visualization of some areas within the hemithorax where there are difficulties with videoscopic visualization—for example, areas of adhesions—then this is referred to as video-assisted thoracic surgery (VATS). In either case, limiting the incisions used for thoracic surgery appears to lead to less pain, earlier discharge from the hospital, and, in general, a shorter recovery period.

When drainage of fluid is the most important aspect of the procedure, and the pleural lesion is less extensive, a thoracoscopic technique utilizing two or three thoracoscopic ports will be sufficient to remove the fluid and strip the limited pleural disease. In most cases, however, the pleura is quite thickened, and the hemithorax is frozen by the tumor or the fibrotic process to some degree, necessitating a limited thoracotomy with guidance from the videoscopic camera (VATS) (Fig. 3). The procedure begins with the placement of the camera port in a position that will afford visibility of the involved area. Typically this is in the seventh interspace in the posterior axillary line because this gives the broadest view of the hemithorax and usually is also close to the most commonly involved area, which is in the base of the chest. After the lesion is identified via the camera, the next two ports are placed directly over the involved area. The goal is to set up the placement of the ports so that the area of interest is centered by the ports and at least one of the ports affords the possibility of direct digital palpation as part of the assessment. After any associated fluid has been removed, thoracoscopic scissors and forceps are employed to completely strip the peel from the lung using both sharp and blunt dissection. Typically, this requires the complete removal of the parietal and visceral pleura in the area of interest. Depending on the amount of inflammation that is present, this is quite often a bloody process, and an expeditious operation is important. Direct, gentle compression with a sponge mounted on a forceps or packing the area will control the bleeding until the lung is reinflated, at which time the majority of the bleeding ceases.

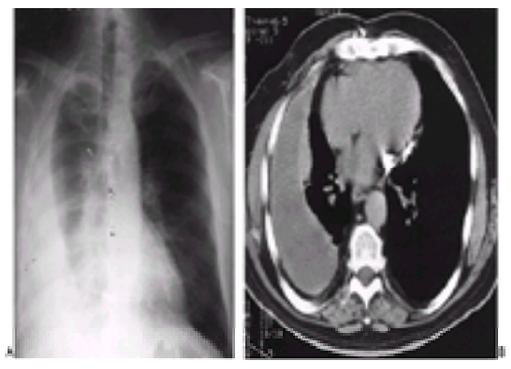

FIG. 3. Images of the radiologic examination of a patient with a fibrothorax on the basis of chronic empyema. **(A)** Posteroanterior view of the chest radiograph demonstrating the extensive nature of the pleural involvement. Linear calcification can be seen on the right at the base of the pericardium. **(B)** The chest CT scan at the level of the heart again demonstrates the extensive pleural disease, and pericardial calcification can be seen.

Because a visceral pleurectomy is often part of the procedure, a moderate air leak will occur when the lung is reinflated. As it is quite peripheral in its location, the leak will always stop over time if the lung completely reexpands. If there appears to be a deeper rent in the parenchyma, the edges can be reopposed with an endoscopic stapler or with an interlocking suture. This must be done very carefully because the lung is usually quite friable and will not hold either sutures or staples well. If the air leak is deemed sizable, it may be prudent to leave the patient on positive-pressure ventilation for 12 to 24 hr to allow the lung to adhere to the chest wall without excessively fatiguing the patient. If the lung will not reexpand to fill the space despite a maximal decortication, then recurrence of an empyema in the setting of infection or a prolonged air leak and probable secondary infection in other cases is likely to result. The ideal solution is to fill the resulting space with vascularized tissue such as an intercostal muscle pedicle or pericardial fat pad when the space is small or with a transposed muscle or omentum if the space is sizable.

Where the pleural process involves the majority of the hemithorax, the peel is quite thickened, or the adhesions are too great, then a standard posterolateral thoracotomy is required. Often in these cases, the chest is frozen as a result of the extent of the process, and thus the removal of a rib is helpful to obtain adequate exposure. The goal remains to remove the entire abnormal pleura and associated inflammatory or neoplastic rind. This, too, is accomplished in an open technique using sharp and blunt dissection. In the case where the process is extensive, it may be helpful to perform the dissection on an inflated lung because inflation makes the demarcation of the underlying normal lung more obvious. In the open technique, the failure of complete reexpansion of the lung is even more critical because the resulting space is potentially larger.

RESULTS

The results of surgical intervention for pleural space disease are variable and depend on the etiology. A recent study by Martella and colleagues revealed a 96% success rate for decortication for chronic postpneumonic empyema. They reported a 4% mortality. Pothula and colleagues reported a series of 90 patients in which 71 (79%) had a formal thoracotomy and 19 (21%) a limited operative approach. There was a 10% mortality in the former group and no deaths in the latter group. However, 10% of the patients in the limited group required a second operation for prolonged drainage or nonhealing. In a more acute or fibrinopurulent phase of empyema, surgical management can be accomplished using a thoracoscopic approach. Results for the surgical treatment of malignant pleural processes are more variable and depend to a large extent on the stage and type of the cancer and the overall health of the patient. In a recent series from the Brigham and Women's Hospital, certain

groups of patients with mesothelioma enjoyed a significant long-term survival (39% at 5 years) when treated with an extrapleural pneumonectomy in conjunction with adjuvant radiotherapy and chemotherapy. Last, the results of surgery for metastatic malignant pleural processes are dependent on the status of the underlying primary.

SUMMARY

In the current era, thoracoscopic techniques provide diagnosis of pleural diseases with a high degree of sensitivity and specificity and minimal morbidity. In early or limited diseases such as early empyema, or for palliation of malignant processes, the minimally invasive technique is an excellent therapeutic strategy. For more extensive or chronic fibrotic processes or for curative purposes for malignant disease, a traditional thoracotomy is the best approach.

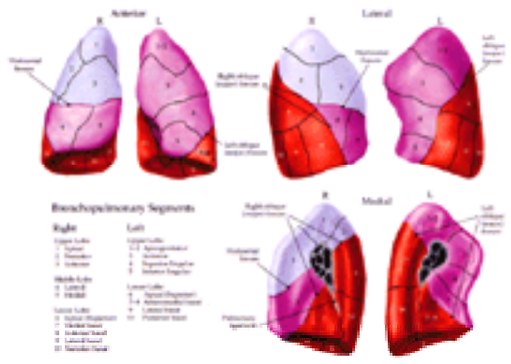
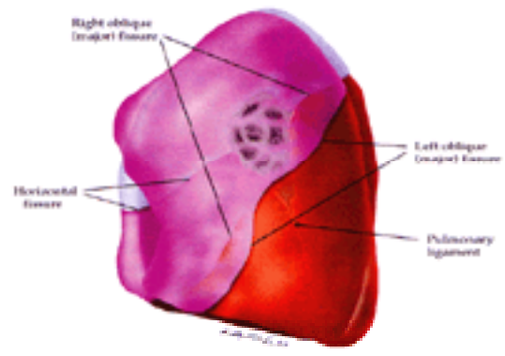
Extrapleural pneumonectomy in the multimodality therapy of malignant pleural mesothelioma: results in 120 consecutive patients. *Ann Surg* 1996;224:288–296. *This state-of-the-art paper presents striking results in treatment for a disease with a heretofore dismal prognosis. The treatment utilizes a trimodality approach involving extrapleural pneumonectomy followed by adjuvant radiotherapy and chemotherapy. The paper further validates a new staging system for this disease, which is based on local extent of the tumor and nodal involvement.*

Color Plates for Volume 1

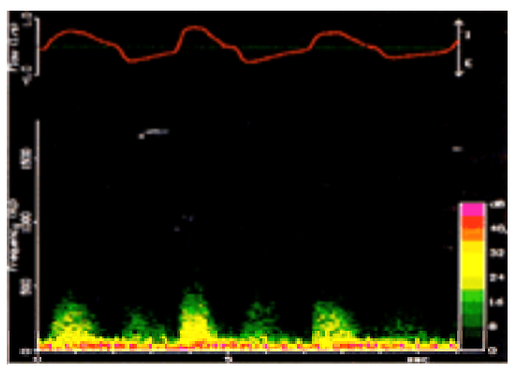


COLOR PLATE 1. Location of bronchopulmonary segments from anterior, lateral, and medial views. (See Fig. 1 in Chapter 1)

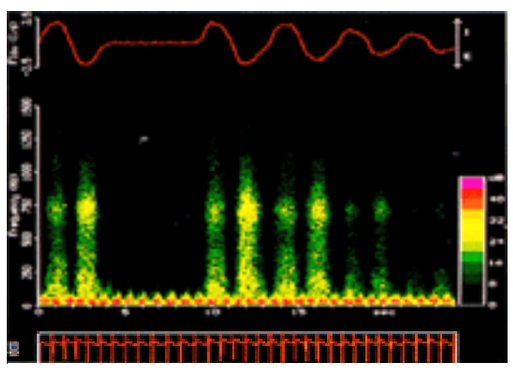


COLOR PLATE 2. Left lateral view of the lungs. Partially translucent image of the left lung allows the right lung to be seen. The location of the major fissures and the horizontal fissure of the right lung are illustrated in the positions in which they would appear on a left lateral chest radiograph. Note that the major fissure on the right side lies slightly anterior and apical to the major fissure on the left side. (See Fig. 2 in Chapter 1)

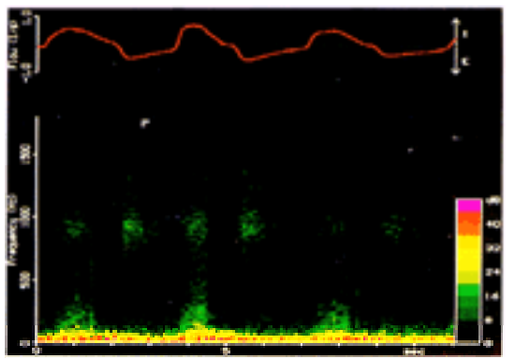
COLOR PLATE 3. Airway anatomy of the human tracheobronchial tree. This figure illustrates typical branching along one of the longer paths to a right lower lobe segment. In the normal human lung, there are approximately five to 15 branch points from a segmental bronchus to a terminal bronchiole. In a completely binary, symmetric branching system, 14 to 15 branch points from the trachea would be required to create the 43,000 terminal bronchioles in a human lung. Because many paths are shorter, there are also path lengths with >15 branch points from the trachea. Segmental bronchi are characterized by the presence of cartilaginous plates in their walls, whereas bronchioles contain smooth muscle in their walls but no cartilage. (See Fig. 8 in Chapter 1)



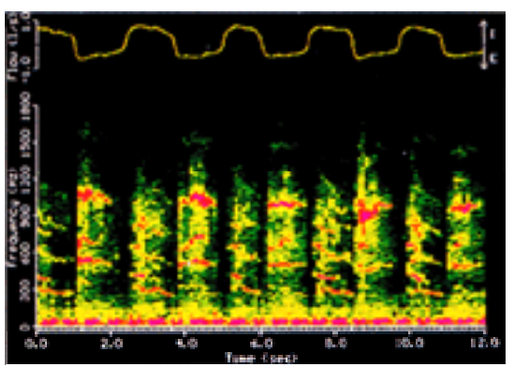
COLOR PLATE 4. Normal vesicular breath sounds. Sound spectrogram with simultaneous pneumotachogram (*top*); sound frequency in hertz (Hz) is represented on the ordinate, time (s) on the abscissa; colors designate sound intensity in decibels (dB) on the scale (*lower right*). Recorded over the left posterior lung base in a 13-year-old boy with cystic fibrosis. Note that inspiratory breath sounds are louder than expiratory sounds and that there is no pause between the respiratory phases. The frequencies are virtually all below 500 Hz and are most intense below 250 Hz. Contributions of low-frequency muscle and cardiovascular sound are visible. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) (See Fig. 17 in Chapter 14)



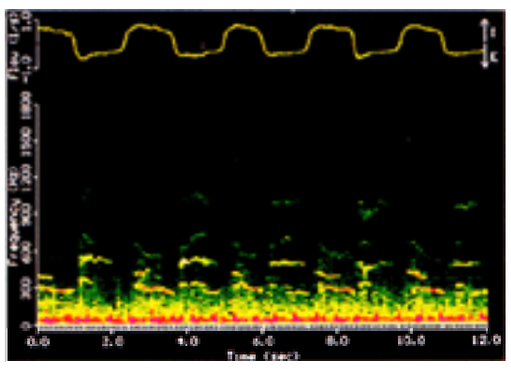
COLOR PLATE 5. Bronchial breath sounds. Sound spectrogram as described in Color Plate 4, simultaneously recorded over the corresponding site on the right posterior lung base in the same patient as in Color Plate 4. Pneumonia and consolidation of the right lower lobe were present, and bronchial breathing is evident. In comparison with the left side (Color Plate 4), there is a decrease in intensity of breath sounds but an increase in high-frequency components extending above 1000 Hz. This is most evident during expiration; in contrast to the normal left side (Color Plate 4), expiratory breath sounds are louder than inspiratory breath sounds. Contributions of low-frequency muscle and cardiovascular sound are visible. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) (See Fig. 19 in Chapter 14)



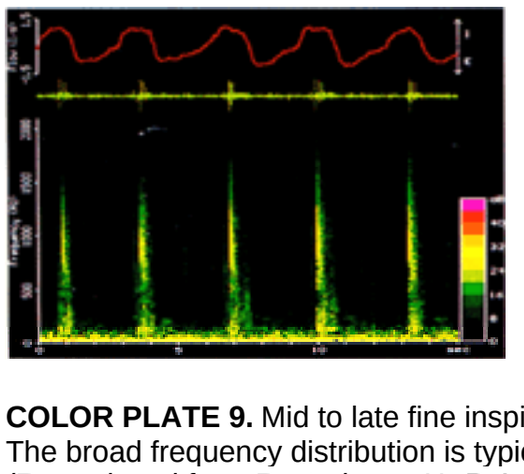
COLOR PLATE 6. Normal tracheal breath sounds. Sound spectrogram as described in Color Plate 4, but with simultaneously recorded electrocardiogram (*bottom*). Recorded over the trachea at the suprasternal notch in a healthy, 26-year-old, male nonsmoker. The typical features of normal tracheal sounds are evident, with a broad frequency distribution, extending close to 1500 Hz during both inspiration and expiration, a slightly louder expiration, and a clear break (absence of respiratory sound) between the respiratory phases. During 5 seconds of breath holding and zero air flow, the contribution of low-frequency cardiovascular sounds becomes evident. The electrocardiogram helps to identify the high-intensity, low-frequency heart sounds. The dependence of sound intensity on air flow is obvious during the latter parts of this observation, when the subject was breathing more shallowly. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) (See Fig. 18 in Chapter 14)



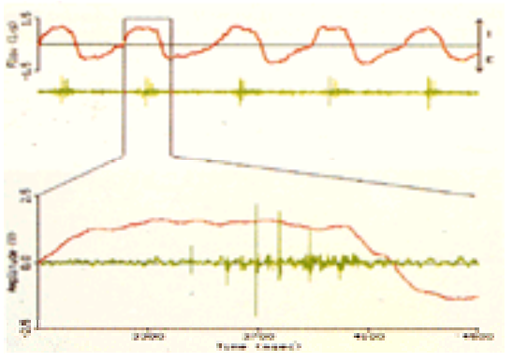
COLOR PLATE 7. Tracheal breath sounds in a patient with exercise-induced asthma. Sound spectrogram as described in Color Plate 4. Polyphonic wheezing is present during both inspiration and expiration, seen as broad bands of intense sound with a narrow distribution of frequencies. Contributions of low-frequency muscle and cardiovascular sound are visible. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) (See Fig. 20 in Chapter 14)



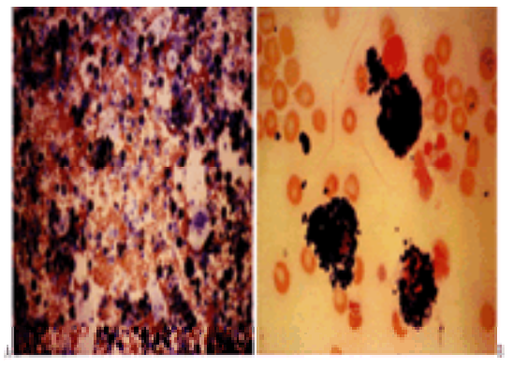
COLOR PLATE 8. Pulmonary breath sounds with wheezes. Sound spectrogram as described in Color Plate 4. Sounds recorded over the right infraclavicular region in the same patient as in Color Plate 7. Inspiratory and expiratory wheezes are seen as broad bands of intense sound with a narrow distribution of frequencies. The intensity of sound is less than in Color Plate 7. No sounds have frequencies higher than 900 Hz. (Reproduced from Pasterkamp H, et al. Digital respirosonography. *Chest* 1989;96:1405.) (See Fig. 21 in Chapter 14)



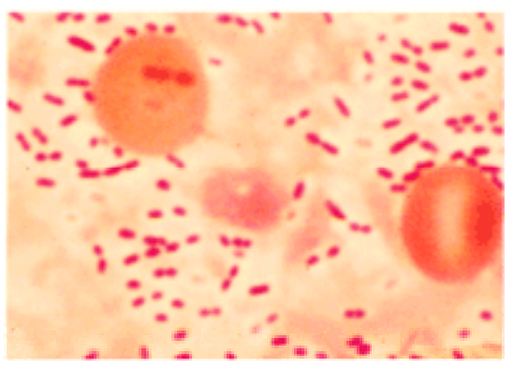
COLOR PLATE 9. Mid to late fine inspiratory crackles in a 60-year-old man with interstitial pulmonary fibrosis. These were recorded over the right posterior lung base. The broad frequency distribution is typical for fine crackles (coarse crackles would be contained largely below 1000 Hz). There are a few expiratory crackles as well. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) (See Fig. 22 in Chapter 14)



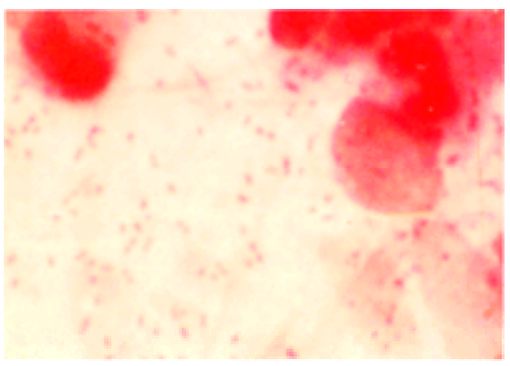
COLOR PLATE 10. The upper two records are the same as in Color Plate 9. One expiration and a small part of the adjacent inspiration are shown on an expanded time-based display. The mid to late crackles are well shown. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) (See Fig. 23 in Chapter 14)



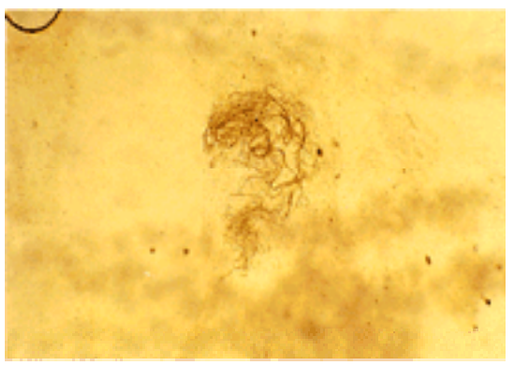
COLOR PLATE 11. A: Hemosiderin-laden macrophages. Photomicrograph of BAL fluid demonstrating numerous hemosiderin-laden macrophages with adjacent red blood cells indicating alveolar hemorrhage. Wright stain, low power. **B:** Photomicrograph of BAL fluid showing hemosiderin-laden alveolar macrophages stained blue by iron stain. Prussian blue stain, high power. (See Fig. 10 in Chapter 21)



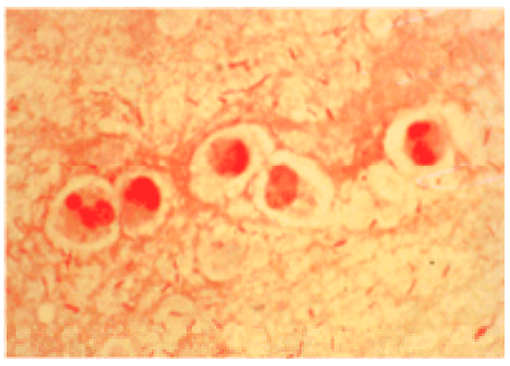
COLOR PLATE 12. *Streptococcus pneumoniae* in Gram's stain of sputum. x900. (See Plate 1 in Chapter 24)



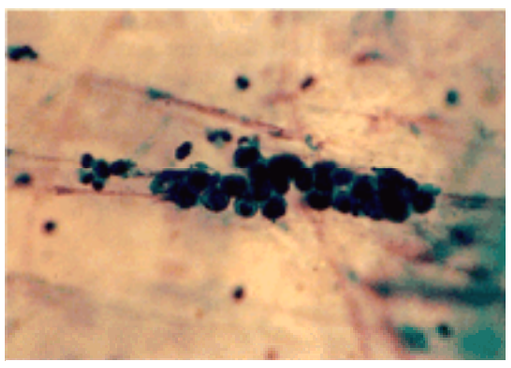
COLOR PLATE 13. *Haemophilus influenzae* in Gram's stain of sputum. X900. (See Plate 2 in Chapter 24)



COLOR PLATE 14. Elastin fibers in a potassium hydroxide preparation of sputum. (See Plate 1 in Chapter 25)

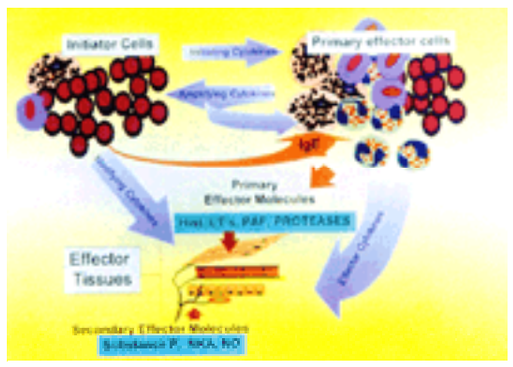


COLOR PLATE 15. *Pseudomonas* in sputum of a neutropenic patient. ×900. (See Plate 2 in Chapter 25)

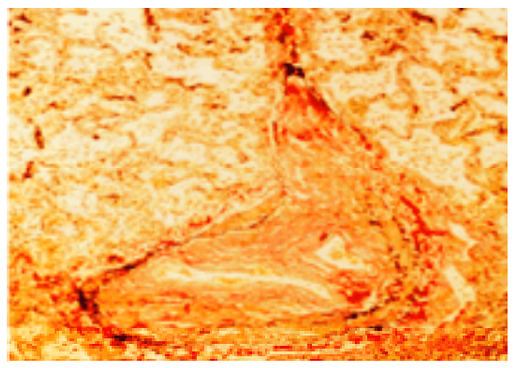


COLOR PLATE 16. Giemsa stain of endotracheal secretions showing intranuclear inclusions of HSV. Fever and diffuse interstitial pneumonia developed in this patient after coronary bypass surgery. (See Plate 3 in Chapter 25)

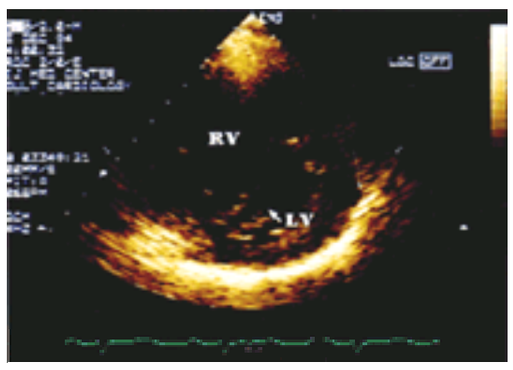
Color Plates for Volume 2



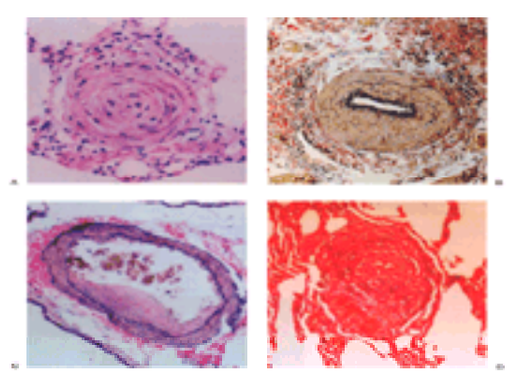
COLOR PLATE 17. Schema relating airway inflammation, shown in the top half of the figure, to airway obstruction, shown in the bottom half of the figure. See text for details. (See Fig. 1 in Chapter 40)



COLOR PLATE 18. Medium-sized pulmonary vein in a case of venoocclusive disease demonstrating intraluminal fibrosis and variably sized intravascular channels, suggesting recanalization of prior thrombosis. (Courtesy of Dr. D. Dantzker.) (See Plate 2 in Chapter 65)



COLOR PLATE 19. Ventricular pressure–volume diagram. EDP, end-diastolic pressure; PADP, pulmonary arterial end-diastolic pressure; ESP, end-systolic pressure; SV, stroke volume. See text for explanation. (See Fig. 5 in Chapter 67)



COLOR PLATE 20. (A) Small muscular pulmonary artery showing almost complete occlusion by myointimal hyperplasia and fibrosis. This is also termed concentric laminar intimal fibrosis or an onionskin lesion (H&E). (Courtesy of Dr. G. Pietra.) **(B)** Medium-sized pulmonary artery showing medial muscular hypertrophy between the external muscular coat and the internal elastic lamina (elastic stain). (Courtesy of Dr. D. Dantzker.) **(C)** Muscular pulmonary artery demonstrating eccentric intimal fibrosis, which is suggestive of remote thromboembolism (H&E). (Courtesy of Dr. G. Pietra.) **(D)** Plexiform lesion. (See Plate 1 in Chapter 65)

Image available in print only.

COLOR PLATE 21. Standard nasal CPAP mask connected to a “bilevel” type of portable pressure-limited ventilator (BiPAP S/T, Respironics, Inc., Murrysville, PA). (See Fig. 1 in Chapter 50)
