Textbook of Pulmonary Diseases

Contents

Section VII. Environmental Lung Disease

Volume 2
Section VIII. Obstructive Lung Disease

Section IX. Respiratory Insufficiency

Section X. Pulmonary Manifestations of Systemic Diseases

Section XI. Pulmonary Vascular Diseases

Section XII. Neoplastic Diseases

Section XIII. Congenital, Developmental, and Genetic Diseases of the Lung

Section XIV. Pleural Diseases

Contributing Authors

Muzaffar Ahmad, M.D. *Professor of Medicine, Department of Medicine, Cleveland Clinic Foundation, 9500 Euclid Avenue Cleveland, Ohio 44195-5014*

Gerald L. Baum, B.S., M.D. *Professor Emeritus, Department of Medicine, Tel-Aviv University, Sackler School of Medicine, Tel-Aviv University, Ramat Aviv, Medical Director, Israel Lung Association, Tel-Aviv ISRAEL*

Maher A. Baz, M.D. *Assistant Professor of Medicine, Department of Medicine, Division of Pulmonary and Critical Care Medicine, University of Florida, 1600 SW Archer Road, Gainesville, Florida 32610*

William S. Beckett, M.D., M.P.H. *Occupational Medicine Division, Department of Environmental Medicine, University of Rochester School of Medicine, 601 Elmwood Avenue, Rochester, New York 14642*

Issahar Ben-Dov, M.D. *Senior Lecturer, The Pulmonary Institute, Chaim Sheba Medical Center, Tel-Aviv University, Sackler School of Medicine, Tel Hashomer 52621 ISRAEL*

Robert Bilenker, M.D. *Head, Comprehensive Care and Developmental Pediatrics, Case Western Reserve University School of Medicine; Pediatric Pulmonologist, MetroHealth Medical Center, 2500 MetroHealth Drive, Cleveland, Ohio 44109*

David J. Birnkrant, M.D. *Assistant Professor, Department of Pediatrics, Case Western Reserve University School of Medicine and Pediatric Pulmonologist, MetroHealth Medical Center, 2500 MetroHealth Drive, Cleveland, Ohio 44109-1998*

Richard J. Blinkhorn, Jr., M.D. *Assistant Professor of Medicine, Department of Internal Medicine, Case Western Reserve University School of Medicine; and MetroHealth Medical Center, 2500 MetroHealth Drive, Cleveland, Ohio 44109*

Hugh A. Cassiere, M.D. *Assistant Clinical Instructor in Medicine, Departments of Thoracic Cardiovascular Surgery and Pulmonary and Critical Care Medicine, Winthrop-University Hospital, 259 First Street, Mineola, New York 11501*

Bartolome R. Celli, M.D. *Professor of Medicine, Department of Medicine, Division of Pulmonary and Critical Care, Tufts University School of Medicine; and Chief, Division of Pulmonary and Critical Care, St. Elizabeth's Medical Center, 736 Cambridge Street, Boston, Massachusetts 02135-2997*

Shan C. Chu, M.D., F.A.C.P. *Senior Staff Fellow, Pulmonary-Critical Care Medicine Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, 10 Center Drive, MSC 1590, Bethesda, Maryland 20892-1590*

James D. Crapo, M.D. *Chairman, Department of Medicine, Executive Vice President of Academic Affairs, National Jewish Medical and Research Center, 1400 Jackson Street, Denver, Colorado 80206*

Robert O. Crapo, M.D. *Professor of Medicine, Department of Medicine, Pulmonary Division, University of Utah School of Medicine; and Medical Director, Pulmonary Lab, LDS Hospital, 8th Avenue and C Street, Salt Lake City, Utah 84143*

Jeffrey L. Curtis, M.D. *Associate Professor of Internal Medicine, Department of Internal Medicine, The University of Michigan Medical Center, 3916 Taubman center, Ann Arbor, Michigan 48109-0360*

Michael V. Cutaia, M.D. *Pulmonary Section, University of Pennsylvania, University and Woodland Avenues, Philadelphia, Pennsylvania 19104*

Stephen L. Demeter, M.D. M.P.H. *Professor of Medicine; and Head of Pulmonary Division, Northeastern Ohio Universities College of Medicine, 4209 State Route 44, Rootstown, Ohio 44272*

Thomas A. Dillard, M.D. *Associate Professor of Medicine, Department of Medicine and Uniformed Services University of the Health Sciences, Madigan Army Medical Center, MCHJ-MPU (COL.. Dillard), Tacoma, Washington 98431*

Jeffrey M. Drazen, M.D. *Parker B. Francis Professor of Medicine, Department of Pulmonary and Critical Care, Brigham and Women's Hospital, 75 Francis Street, Boston, Massachusetts 02115*

Raed A. Dweik, M.D. *Staff Physician, Department of Pulmonary and Critical Care Medicine, Cleveland Clinic Foundation, 9500 Euclid Avenue, Cleveland, Ohio 44195*

N. Tony Eissa, M.D. *Senior Staff Fellow, Pulmonary-Critical Care Medicine Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, 10 Center Drive, MSC 1590, Bethesda, Maryland 20892-1590*

Jack A. Elias, M.D. *Professor of Medicine, and, Chief, Section of Pulmonary and Critical Care Medicine, Department of Internal Medicine, Yale University School of Medicine, 333 Cedar Street-105 1CI, New Haven, Connecticut 06520-8057*

Patrick J. Fahey, M.D. *Professor of Medicine and Anesthesiology, Department of Medicine and Anesthesiology, Loyola University of Chicago, Stritch School of Medicine, 2160 South 1st Avenue, Maywood, Illinois 60153*

M. Elon Gale, M.D. *Associate Professor of Radiology, Department of Radiology, Boston Veterans Administration Medical Center, 150 South Huntington Avenue, Boston, Massachusetts 02130*

Daniel R. Gale, M.D. *Department of Radiology, Veterans Affairs Medical Center, 150 South Huntington Avenue, Boston, Massahcusetts 02130*

Introduction

The Sociopolitical Response to the Discovery of *Mycobacterium Tuberculosis*

François Haas · Sheila Sperber Haas

F. Haas: Department of Rehabilitation Medicine, New York University Medical Center, New York, New York 10016.
S.S. Haas: New York University Medical Center, New York, New York 10016.

> "'Children and others, who work in the large cotton factories, are particularly disposed to be affected by contagion of fever, and when such infection is received it is rapidly propagated, not only amongst those who are crowded together in the same departments, but in the families and neighborhoods to which they belong.' However, the warning went unheeded. The passion for financial gains made acquisitive men blind to the fact that they were part of the same social body as the unfortunates who operated their machines. Tuberculosis was, in effect, the social disease of the nineteenth century, perhaps the first penalty that capitalistic society had to pay for the ruthless exploitation of labor."
>
> Rene and Jean Dubos, *The White Plague*

> "To combat consumption successfully requires the combined action of a wise government, well-trained physicians, and an intelligent people."
>
> A. S. Knopf, *Tuberculosis as a Disease of the Masses, and How to Combat It*

In the previous edition of this book, we discussed the historical development of tuberculosis, from Fracastoro's critical formulation of the germ theory during the Renaissance to Robert Koch's landmark discovery of *Mycobacterium tuberculosis* in 1882. Discovery of the bacterium, confirming the contagious nature of this epidemic disease, had broad implications that demanded a response from both the medical/scientific community and society as a whole. Because space is limited here, and the developments in medical treatment are already reasonably well-known, this chapter focuses on the closely interwoven social and political reactions to tuberculosis.

We are doing this in a general textbook on pulmonary diseases because tuberculosis—which infects one third of the world's population—is still the leading infectious killer of adults. It is responsible for 26% of avoidable deaths in developing industrial countries, which face health problems similar to those that confronted countries undergoing industrialization during the 19th century. And it is resurgent now in these same industrialized countries, as past problems—homelessness, overcrowding, inadequate health infrastructure, and disenfranchisement—re-emerge and the pool of patients with drug-resistant tuberculosis, particularly among disenfranchised groups, increases. To these problems must be added the epidemic of HIV infection; tuberculosis is becoming the leading cause of death among affected individuals. Worldwide, tuberculosis will kill 30 million people in this decade, according to the World Health Organization.

Our hope is that this chapter will be "useful to those who want to understand clearly the events which happened in the past and which—human nature being what it is—will, at some time or other and in much the same ways, be repeated in the future."[1]

PERCEPTION OF THE DISEASE

> "...Cleanse the slums, limit the pubs, stop the smoke, clear the air,
> And the water, of all the foul things that they bear,
> Give food to the needy and good clothing to wear,
> Shut up the wild lads who turn night into day,
> And succor the women who lead them astray,
> When your race is again strong, healthy and fair,
> Rely on my word, you'll not find us there,
> When struma, syphilis, cancer and gout,
> By cleaner living have been driven out,
> When lechery's over, carousing and riot,
> We'll gladly return to our guinea-pig diet ..."
> James Hurd Keeling (1831–1909), *The Song of the Squirt*

While the industrializing northern Europeans were still relegating tuberculosis contagion to the closet, the Italians and Spanish were returning to strong anticontagion public health legislation—modeled on Lucca's 1699 laws—to protect their citizenry. In Florence, the 1754 edict included the admonition "to take care that the patient does not empty his sputum except into vessels of glass or glazed earthenware, and that these utensils be frequently cleansed and boiled..." Naples built a tuberculosis hospital and passed the stringent laws of July 19, 1782, stipulating both precautions during illness and measures to be taken after death.[2] Although these laws were eventually revoked because of the financial burdens they placed on both families and the community, the common people in these regions continued to fear contagion throughout the 19th century.

In contrast, northern Europe and North America had adopted the notion that tuberculosis reflected an inherited constitutional vulnerability and was a disease capable of bestowing genius—the *spes phthisica*—on its victims. The ubiquitous nature of the disease and the long, lingering death it entrained may well have fueled the romantic movement in the arts, making languid consumptive pallor—exemplified by Marie Duplessis, the mistress of Alexandre Dumas *fils* and the model for Marguerite of *The Lady of the Camellias*—highly attractive. Lord Byron, for example, was overheard saying while looking into a mirror, "I look pale. I should like to die of consumption." When asked why, he answered, "Because the ladies would all say, 'Look at that poor Byron, how interesting he looks dying'" (Dubos and Dubos, 1987).

Although the longstanding notion of inheritability persisted throughout the 19th century, a changing perspective on the source of vulnerability began to surface—particularly in North America and England—in the latter part of the century. Vulnerability was now attached to class and morality. Tuberculosis was becoming a social disease, a "...diathesis ...built up with equal certainty by impure air, drunkenness, and want among the poor, and by dissipation and enervating luxuries among the rich ..." (Dubos and Dubos, 1987). Since one could now, in that current view, avoid tuberculosis by leading a "good life," it followed that contracting and dying of the disease documented one's inner weakness and intrinsic moral unfitness. Discovery of the tuberculosis bacterium clearly accelerated this trend in both Europe and the United States. A typical example was Dr. S. Adolphus Knopf, an American whose prize-winning tract—*Tuberculosis as a Disease of the Masses, and How to Combat It,* published in 1907—identified those most susceptible to the disease as either the personally depraved, whose alcoholism had temporarily or permanently enfeebled them, or the innocent victims of poverty.

Fertile Conditions for the Spread of Tuberculosis

As the population in Europe moved from rural to urban centers and immigrants inundated the eastern cities of the United States, greedy landlords on both sides of the Atlantic Ocean built dark, cramped living quarters—lacking adequate water, sewage, and ventilation—in the open yards behind apartment buildings. These “back tenements” and “dark rooms” created virulent seedbeds of tuberculosis (Fig. 1 and Fig. 2). Ernest Poole, a member of the antituberculosis committee of New York City's Charity Organization Society, described this typical scene in the “lung block” (Fig. 3) in the most crowded part of the city:

FIG. 1. Tenement house yard. Photograph by Jacob Riis (reproduced with permission of the Museum of the City of New York).

FIG. 2. There were 361,000 such “dark rooms” in New York City. Photograph by Jacob Riis (reproduced with permission of the Museum of the City of New York).

FIG. 3. Ground-plan of the “lung block.” The shaded sections are courts and air shafts. Each letter represents a new case of tuberculosis reported to the Health Department between 1894 and 1903 (e.g., *a* represents 1 case in 1894 and *b* represents 1 case in 1895). Because the records do not indicate whether a given case resided in the front or rear tenement, all have been assembled in the front building except at 144 Cherry Street, as there was not enough room. (Huber JB. *Consumption: Its Relation to Man and His Civilization; Its Prevention and Cure.* Philadelphia: JB Lippincott; 1906:147.)

> “In a rear tenement a young Roumanian Jew lay dying of consumption.... In this room, 10 feet square, six people lay on the floor.... The other room was only a closet six feet by seven, with a grated window high up opening on an air shaft 18 inches wide. And in that closet four more people were sleeping” (Huber, 1906).

Another typical house, called the “ink pot,” had front and rear tenements five floors high, with a small court between them. One hundred forty-five people, including 23 babies, lived in this building.

> “Up on the third floor, looking down into the court, is a room with two little closets behind it. In one of these a blind Scotchman slept and took the plague in 1894.... He died in the hospital. Only a few months later the plague fastened ...(on) his little daughter.... At last she, too, died. Then one year later, in October, a Jew rented this same room. He was taken, and died in the summer. The room was rented ...in the autumn by a German and his wife. She had the plague already, and died. Then an Irish family came in. The father was a hard, steady worker, and loved his children.... But six months later he took the plague. He died in 1901.... In the rear house is another plague room.... Here, in 1896, lived an old Irish hat maker with his wife, small daughter, his two sons.... He took the plague, worked a year or more there on his hats, then died. The cough came on his wife soon after. She suffered long, weary months, only to see at the end her young daughter begin the same suffering. The mother died. The home was shattered. The girl was taken by her aunt, and soon followed her mother. The two sons died of the same disease, spreading it out into other tenements.... When the next housekeeper came to this same room with his wife, both were strong and well. The man took the plague in 1899. He still fought for life when all knew he was hopeless ...; he ...could ...only lie alone in one of these closed bed rooms. (There are no fewer than 20 such rooms in this rear house—windowless, six feet by eight.) That winter of 1900 brought the memorable blizzard. While it was raging, a settlement visitor came to his room and found the water pipe burst, the room flooded. The plucky little wife had carried her husband upstairs on her back. A few days later his struggle was ended. The wife is still there” (Huber, 1906).

Responding to the Threat

Although laws with codes setting minimum ventilation and window areas for individual rooms had been on the books since 1890, greed, indifference, political corruption, inventiveness of landlords, plus the sheer numbers of immigrants, overwhelmed any attempt at enforcement or further reform. During that decade, however, a death rate of 776/100,000 and the knowledge that the “white plague” was reaching out beyond these impoverished neighborhoods added to the urgency for action.

One response to this threat was zealous reform. Progressive reformers such as Jacob A. Riis,[3] the author and photographer of *How the Other Half Lives,* brought the plight of the tenement-dwelling poor in New York City to public notice. One of the most effective of the tenement house reformers in New York, he advocated broad welfare programs to eliminate both poverty and illness and urged programs for remodeling tenement houses, abolishing sweatshops, reducing work hours, outlawing child labor, purifying water, and building parks and playgrounds.

The alternate response was fueled by the conviction that those living in such abominable circumstances found themselves there because they were morally unfit. The designation of “unfit” was applied to those who made the power structure anxious. In the United States, one saw an escalating xenophobia among Americans who feared being outnumbered by aliens who did not share their language, heritage, or democratic institutions. Europeans feared the revolutionary zeal of the anarchists and socialists among the poor. Throughout the industrial world, the germ of tuberculosis spread by immigrants and the poor became intertwined with the “germs” of radical political reform.

Governments attempted to meet both the social activists' reform agenda and the conservatives' demand for restraining the behavior of the poor, as the same means could be applied to satisfy both. The operative tenets were that the disease was preventable if patients could be removed from society, and that it was curable if patients could be persuaded (or helped) to live properly (or humanely). The first required a political reaction—the development of public health departments and policy, so that patients with tuberculosis could be identified and controlled. The second involved the development of treatment facilities, and accompanying efforts to return

these patients to society.

THE POLITICAL RESPONSE

The Local Department of Health

Politically, the results of the debate over the establishment of strong departments of health—which included compulsory identification of the tubercular patient—varied from place to place. But rather than present a superficial survey of these variations, we have opted to focus on New York City, where the establishment of a strong Department of Health and compulsory notification reflected the first clear victory for the group of physicians, politicians, and lay people who were convinced that only through strong administrative control could tuberculosis be contained.

In the United States, state health departments were first established in the mid-19th century. They employed sanitarians—engineers sent out to locate the causal elements in the transmission of disease (then believed to stem from foul-smelling or miasmic conditions). They were to establish uncontaminated water supply systems and uncontaminating sewage systems, and develop efficient and safe disposal for garbage and dead animals.

In the 1890s these sanitarians began to be replaced by public health physicians, whose mandate was broadened to the control of all transmittable diseases. For them, notification of contagious diseases was a necessary step in effective social policy to protect public health. Foremost among the proponents of this kind of social control was Hermann M. Biggs of New York (Fig. 4).

FIG. 4. Hermann M. Biggs, 1859–1923, established the New York City Board of Health Laboratory, set administrative controls for tuberculosis, and introduced diphtheria antitoxin and programs in child health.

Born in Trumansburg, a small village in the Finger Lakes region of New York State, Biggs took pride in the fact that he was descended from six American-born generations on his father's side and eight on his mother's. Convinced that one's station in life is partly a gift of inheritance, he grew up with a strong autocratic sense modulated by his father's passion for order. Early in his career, Biggs fastened onto the notion that cleanliness is next to godliness, turning his views on hygiene into a political credo in his baccalaureate thesis at Cornell in 1882 (coincidentally, the year of Koch's discovery of the tuberculosis bacillus): “Upon recognition and careful observance of hygienic laws depend the healthy physical condition, and so prosperity, not only of individuals and communities, but also of whole states and nations” (Winslow, 1929).

Biggs received his medical degree from the Bellevue Medical College in 1883, in the first medical class in the United States to take a formal pathology course, which was held in the country's first pathology laboratory.[4] William H. Welch, who founded the laboratory, remembered Biggs as the most active and interested student in the class, often staying late and working on special problems assigned him by Welch.

Biggs' choice of Bellevue was fortunate for other reasons as well. First, the faculty (including Edward Janeway and Francis Delafield as well as Welch), which had already begun to be involved in bacteriologic studies, espoused the highly unpopular hypothesis that all of tuberculosis was one disease, and readily accepted Koch's etiologic discovery of the tuberculosis bacterium. They countered the prevailing view of this microbe, as stated, for example, in the *Report of the Committee on Practical Medicine and Epidemics of the Illinois State Medical Society for 1882–83:* “...mere accompaniments of certain deteriorative changes in organic matter, and possessing no causative relations whatever.” Second, Bellevue's origin in 1816 as a prison, evolving into a hospital that embodied the notion of providing aid—sometimes forcibly—to the indigent population, provided an orientation that Biggs, probably because of his upbringing, supported unflinchingly. He clearly stated his position several years after entering medical practice, in an address to a meeting of the British Medical Association in Montreal:

> “The government of the United States is democratic, but the sanitary measures adopted are sometimes autocratic, and the functions performed by sanitary authorities paternal in character. We are prepared, when necessary, to introduce and enforce, and the people are ready to accept, measures which might seem radical and arbitrary, if they were not plainly designed for the public good, and evidently beneficent in their effect” (Winslow, 1929).

Biggs' first application of bacteriology to a Health Department problem occurred in 1887, when he and T. Mitchell Prudent (then professor of pathology at the College of Physicians and Surgeons, and Biggs' close friend) correctly identified the cholera spirillum in an Italian immigrant who had presented with a clinically doubtful case of cholera and died on board the steamship Britannia. The passengers had been quarantined on the ship, and Asiatic cholera later developed in a considerable number of them.

This incident helped convince Commissioner of Health Joseph D. Bryant of the need to establish a Division of Bacteriology and Disinfection within the Board of Health. In 1888, as a consequence of meetings on the cholera issue between the New York City Health Department and the New York Academy of Medicine, Biggs and Prudent, along with colleagues Drs. Janeway and Loomis, were appointed as consulting pathologists to the New York City Board of Health. In May 1889, Commissioner Bryant asked them to issue a position paper on tuberculosis for the Board.

This document asserted the validity of Koch's findings and declared that tuberculosis was preventable, was not directly inherited, and required direct transmission from sick to healthy individuals. As such, the position paper suggested the following measures: a system of rigid inspection of cattle to prevent public consumption of tainted meat and milk; public education regarding the dangers of pulmonary discharges from tubercular people; and disinfection of rooms and hospital wards occupied, or previously occupied, by tubercular patients. Their report was received coolly by the medical community, with the large majority indicating that no official action was called for.

The Push for Public Health Measures

Because Biggs, Prudden, Commissioner Bryant, and Board President Dr. C. C. Wilson were sufficiently politically astute to realize that any further legislative initiative would be fruitless without public support, they undertook a direct campaign of public education, handing out flyers—issued in several languages—prepared by the pathologists and signed by the Board of Health President and Secretary. (Cultivating a favorable political constituency by means of educational materials would become a hallmark of the campaign waged by Biggs and colleagues to control tuberculosis via a strong Board of Health and compulsory notification.) These flyers detailed the following preventive measures:

> “DO NOT—permit consumptive patients to spit on the floor; sleep in a room with a consumptive patient; fail to wash thoroughly the eating utensils of a consumptive patient as soon after eating as possible; mingle a patient's unwashed clothing with the clothing of others; fail to catch the bowel discharges of a consumptive patient with diarrhea in a vessel containing corrosive sublimates; fail to consult the family physician regarding the social relations (i.e., 'sexual relationships') of people suspected of having consumption; permit mothers suspected of having consumption to nurse; keep, but destroy, household pets suspected of having consumption; fail to cleanse thoroughly the floors, walls, and ceilings of the living and sleeping rooms of consumptive patients at least once in two weeks” (Winslow 1929).

On November 28, 1893, 41/2 years after the initial report, the Board again took up the cause of tuberculosis control by asking Dr. Biggs (now Chief Inspector of the Division of Pathology, Bacteriology, and Disinfection) for an updated recommendation. His report—curiously dated the same day as this request—presented seven measures:

> “(1) Educate the public via circulars and publications; (2) require notification by public institutions (e.g., asylums, social welfare facilities, hospitals) within 7 days of all persons suffering from pulmonary tuberculosis; (3) appoint special inspectors to ensure effective disinfection of contaminated premises; (4) separate tuberculosis patients from other patients; (5) establish a

> hospital exclusively for tuberculosis patients; (6) require the Board of Health Department to carry out a diagnostic bacteriologic sputum examination in every case of pulmonary disease of doubtful character; (7) insist that all physicians practicing in this city notify the Board of all pulmonary tuberculosis coming under their professional care (Winslow, 1929).”

This time around, the Board adopted Biggs' plan as “timely and well advised,” except for the notification clause addressed to individual physicians. They correctly sensed that the medical profession would not passively accept it. Biggs strategically retreated—temporarily—to “recommending” full notification and counterbalanced by recommending even more stringent treatment of infected dwellings. He required that “...the Medical Sanitary Inspectors visit all premises (vacated) ...by consumptive patients either by death or removal, and shall forward written recommendations as to the cleansing and renovation of the premises.... The Board (would) not allow the premises to be occupied by (new renters) ...until the (recommendations have) been complied with” (Winslow, 1929).

The Board found Biggs' slightly softened position acceptable. On February 15, 1894, the *Sun* newspaper wrote that “the Board of Health formally declared war upon consumption when it adopted Professor Hermann Biggs' plan of campaign.” However, the article, noting the parallel to the Naples law of 1792 (see footnote 2)—which had punished nonreporting physicians with 10 years of banishment and punished those who resisted the intervention of authority with 3 years in the galleys—stated that “...the Board *will not yet compel* (the authors' emphasis) physicians to report their consumptive patients. That will come later on” (Winslow, 1929).

Grumbling by the New York medical establishment—whose members saw the handwriting on the wall—was not yet followed by organized resistance. However, repercussions were felt elsewhere. Philadelphia's College of Physicians—over the objections of Dr. L. F. Flick, the compassionate pioneer of Pennsylvania's antituberculosis movement, and Dr. William Osler—met on January 12, 1894, and presented an antinotification edict to their municipal Board of Health, ostensibly because “the attempt to register consumptives and to treat them as the subjects of contagious disease would be ...stamping (these unfortunates) as the outcasts of society ...(and) not lead to any measures of real value not otherwise obtainable....” (Winslow, 1929).

Notification: Friends and Enemies

Overt hostility between the New York Board of Health and the medical establishment broke out in earnest the following year, but the Board held firm and eventually—on January 19, 1897—Biggs saw his vision become reality in an amendment to the sanitary code:

> “Section 225. That pulmonary tuberculosis is hereby declared to be an infectious and communicable disease, dangerous to the public health. It shall be the duty of every physician in this city to report to the Sanitary Bureau in writing the name, age, sex, occupation, and address of every person having such disease who has been attended or who has come under the observation of such physician for the first time within 1 week of such time....” (Winslow, 1929).

The medical profession's response to what they saw as a loss of authority and possible income was immediate. Dr. George Shrady's editorial in the influential *Medical Record* minced no words:

> “The real obnoxiousness of this amendment to the sanitary code is its offensively dictatorial and defiantly compulsory character.... The profession as a whole has watched with jealous eye the encroachments of the Board upon many of the previously well-recognized privileges of the medical attendant....” (Winslow, 1929).

And in a follow-up editorial he accused the Board of wanting “...to assume official control of the cases after they have been reported, thus not only ...directly interfering with the physician in the diagnosis and treatment of the patient, but ...possibly depriving him of one of the means of a legitimate livelihood” (Winslow, 1929). (Ironically, Shrady—as a consulting physician to the Board—had written an editorial in the 1983 *Medical Record* endorsing the original compulsory notification regulation for cases diagnosed in public institutions. Why he eventually changed sides is unclear, although he did voice the views of a considerable faction of physicians.)

This feared loss of income because of anticipated interference by the Board of Health was paramount in the resistance of the medical profession, both to the notification program and to the establishment of tuberculosis hospitals. Physicians felt that the eradication or limitation of this disease would dramatically shrink the income-producing population of tuberculosis patients, and that improved public health facilities would attract many of the remaining patients. They blamed elimination of the income assessment previously used to qualify patients for these facilities—now leaving it up to individual honesty—for “distributing the best care below market cost.”[5] The welfare cheat, who can afford to pay but pretends poverty (a recurrent image in the United States), was evoked: “Dispensary patients leave their carriages and servants around the nearby corner of a street” (Fox, 1974).

The issue came to a head in March 1897. The Medical Society of the County of New York unanimously protested the view of tuberculosis as infectious and communicable, and stated “that in the judgment of this society the recent edict of the Board of Health in relation to compulsory reporting of cases of tuberculosis is unnecessary, inexpedient and unwise” (Winslow, 1929).

The West Side German Dispensary resolved that the view of tuberculosis as a communicable disease “is not entirely correct, (and that) ...to grant the Health Board officials further powers ...in regard to the removal of those subjects of tuberculosis ...would be an interference that would be alike humiliating to the physician and intolerable to the patient and his family” (Winslow, 1929). The *Medical Record* asserted, “It would now appear that the time has come for the Health Board to rescind the obnoxious regulation, in order that it may, as formerly, work in harmony with the wishes of the profession.” Arthur M. Jacobus in his presidential address to the County Society accused the Health Department of “usurping the duties, rights, and privileges of the medical profession” (Fox, 1974).

Despite this bellicose posturing, Prudden described the opposition as the “little scattering of a gang of purps” [*sic*] who longed for the “good old times when a patient with tuberculosis could be lulled into a sense of security....” (Fox, 1974). Biggs attributed this medical opposition to “timidity, selfishness and ignorance.”

However, the local medical societies did not speak for all physicians in New York City. The Medical Association (the local branch of the American Medical Association, or AMA) was already competing for physician support in two other extremely sensitive areas: the right to consult with homeopaths, and the right to advertise and sell proprietary remedies. Both rights were favored by the local societies, but stringently opposed by the AMA's code of ethics. The split of the medical community on the notification issue fell along these predrawn organizational alliances.

The pro-notification group included members of the New York Academy of Medicine, the state's most prestigious group of physicians. The Academy contingent worked behind the scenes for a compromise. The Academy's Committee of Eight, with Biggs' friends Prudden and Janeway as spokesmen, suggested that the Board of Health “might wisely delay the enforcement of compulsory notification but should adopt more stringent measures for the care of all sputum.” The full Academy accepted this motion that the Board delay, but not rescind, enforcement of compulsory notification of tuberculosis patients. With Shrady leading the outraged physicians and Biggs leading the notification forces, an agreement was forged to leave the new but gently enforced regulation on the books in return for an official consulting board, chosen by the Academy, to advise the Board of Health. (This new board came into being in 1898.)

The medical societies, however, would not accept the Academy compromise. Both the New York County and Kings County Medical Societies tried to push bills through the state legislature calling to rescind that provision of the New York City charter empowering the municipal Board of Health to deal with tuberculosis as an infectious disease. They had gone to Albany believing that the Republican-dominated legislature would be eager to discredit the Board of Health as a means of diminishing the power of Tammany Hall.[6] But because the notification controversy had divided Republican physicians just as it had other physician subgroups, the legislators saw no clear gain in restricting New York City's Board of Health on this issue. Although a legislative committee was appointed for show, in actual fact the issue was quickly dropped. Thus, a strong, well-organized minority with access to sufficient patronage and publicity—like Biggs and his colleagues—was able to achieve its goals over the objections of a poorly organized majority.

The primacy of New York City's Board of Health in this realm can be attributed to public health innovators who—by need, inclination, or both—were intensely political and selectively partisan and had cultivated ties to the various power bases. Joseph Bryant had connections with the Democratic organization. Dr. Alvah H. Doty, Health Officer of the Port of New York, was close to the Republican organization. Prudden had ties to the anti-Tammany reformers, and Biggs himself had a warm relationship with C. F. Murphy, then Tammany district leader and subsequently county leader.

Once notification was finally the rule, Biggs, Prudden, and their allies were careful to develop a favorable constituency among their fellow physicians. This was done in part by increasing the Board's importance in the city's medical economy, which was particularly influential because of the economic depression afflicting the country during the century's final decade. The Board paid out approximately $250,000 yearly in part-time and full-time salaries. In 1897, for example, in a politically popular move, the Board hired 192 physicians as school inspectors, with each one receiving $30 per month to spend 40 minutes a day in neighborhood schools. (The move was practical as well as politically prudent. On the first day alone they examined 4225 children and found among them 14 cases of diphtheria, 3 of measles, and 55 of parasitic disease.)

The reformers also avoided antagonizing the general population. They separated the antidisease and antipoverty issues. Prudden, in an article in *Harper's Magazine* in March 1894 entitled “Tuberculosis and Its Prevention,” said that the tuberculosis bacilli lived in the “thick pile carpets” belonging to the rich and to those others who also accepted the “tyranny of things.” And they remained neutral in the controversy about society's responsibility to the poor, and in debates about heredity versus environment, self-help versus charity, fit versus unfit, and the movement against health abuses in the workplace.

They also gained the loyalty of that 80% of the New York City population who were either foreign-born or first-generation Americans by printing educational circulars in a variety of languages (initially German, Italian, and Yiddish, and eventually Bohemian, Finnish, Polish, Slovakian, Ruthenian, Swedish, Armenian, Spanish, and Chinese), and making sure that Board of Health personnel who visited the homes of tubercular patients either spoke their native language or were accompanied by an interpreter who did.

Furthermore, so as not to exacerbate the alienation of opposing physicians, the Board of Health's eventual enforcement was, as promised, cautious, selective, and politically wise. During the first decade of compulsory notification, only six “recalcitrant” physicians were fined.

In retrospect, the Board of Health's compulsory notification directive was successful. Reported cases of tuberculosis increased from 8559 in 1898 to 32,065 in 1910, and sputum examinations increased from 2920 to 40,000 during this same period.

The forum in which the antituberculosis public health crusaders had fought for compulsory notification was the political arena. As such, it required the resolution of political conflicts and use of the bargaining process to transform positions into legislated public policy and workable administrative arrangements. Although similar battles were fought in most industrialized communities, the successful achievement of compulsory notification in New York was unique. (For example, although Sir Robert Philip first pressed for compulsory notification in Britain as early as 1890, it took 20 years to be enacted into law.)

The medical profession in New York City could take pride in the international recognition they received for their success in identifying tubercular patients. In 1901 Robert Koch told Biggs, “I wish to cite the example of the American people, who of their own free will accepted the limitation of their liberties in the interest of public health,” and recommended the New York model to the “study and imitation of all municipal sanitary authorities” (Fox, 1974). This model, in fact, dominated medical and public debate so thoroughly that it helped bring about an international medical and public consensus about the communicability of tuberculosis and the importance of notification.

THE CRUSADE

National Organizations

The world's first international medical congress, which met in Paris in 1867, included presentations on tuberculosis, among them Jean-Antoine Villemin's classic work on its specificity and communicability. Afterward, international congresses devoted specifically to tuberculosis were held at regular intervals until the end of the century.

This latter period also saw the emergence of national organizations—made up of medical, lay, and government personnel—to battle the disease. The first of these national organizations, called “A Society for the Establishment of Sanatoria for the Consumptive Poor,” was established in Austria in 1890. Organizations in Denmark (“National League for the Campaign Against Tuberculosis”) and France (“French League Against Tuberculosis”) were established in 1891, and then Germany, Belgium, England, Portugal, Italy, and Canada rapidly followed suit.

A large, variegated country like the United States initially produced local antituberculosis organizations, with Philadelphia in the lead. On April 22, 1892, Dr. Lawrence F. Flick gathered 25 people, mostly lay persons, in his office, carefully excluding everyone who was inimical to the contagious theory of tuberculosis, to form the first American organization dedicated to combatting tuberculosis. With Flick as president, it became incorporated in 1895 as the Pennsylvania Society for the Prevention of Tuberculosis and set itself the following objectives: (1) to spread the gospel of contagiousness (still far from universally accepted) through public education; (2) to provide the poor with hospital treatment; (3) to visit poor patients and supply the necessary materials for protecting those they lived with; (4) to cooperate with the Board of Health's preventive measures; and (5) to lobby for appropriate public health laws. After the establishment of this unique antituberculosis group, another one finally followed in Ohio in 1901; then in quick succession associations were incorporated in six more states, including New York, and 11 local societies were formed.

The initial impetus to form a national association came not from the medical establishment, but from the Medico-Legal Society of the City of New York, a group of lawyers, scientists, and physicians who had organized a national meeting in 1900 to discuss state laws relating to the disease and its treatment. This meeting had heralded a shift in emphasis from treating individual patients to controlling the disease in society, a point of view that had been accepted a decade earlier in Canada and several European countries.

Between 1900 and 1903, Clark Bell (nonmedical president of the Medico-Legal Society) led an abortive attempt to parlay this meeting into a permanent, all-inclusive national organization. However, it failed because of territorial squabbles between physicians and lay persons. These often bitter conflicts arose between the AMA-supported organizations—representing practicing physicians' predominant emphasis (motivated by self-interest) on what they felt should be a purely medical approach to the disease—and organizations supported by public health officials and social workers dedicated to educational and legislative weapons for controlling the disease.

One of these conflicts erupted over an AMA-supported International Congress on Tuberculosis planned to be held Paris in 1904. On December 5, 1903, the *Journal of the American Medical Association* published a letter calling attention to the impropriety of proposed American congresses by “certain groups of little-known people who independently had been soliciting support, lay and political, for conflicting congresses.” The AMA called for the formation of the following:

> “...a committee with power to act to consider the conditions existing with regard to the proposed Tuberculosis Congress and other National Antituberculosis Associations in the United States; also to consider the formation of a National Committee to represent this country at the International Congress at Paris, and that the members of this conference will abide by the action of the Committee; also that the Committee had power to add to its membership ...” (Knopf, 1922).

The formative meeting took place, fittingly, in Philadelphia on March 28, 1904. Present on the medical side were the profession's foremost luminaries in the fight against tuberculosis: Edward Livingston Trudeau, S. A. Knopf, Henry Bowditch's son Vincent (founder of the first sanatorium in Massachusetts), Lawrence Flick, Sir William Osler, William Welch, and Hermann Biggs. Although physicians were heavily in the majority, all parties present resolved to coalesce into a national organization. Thus, the committee that was initially formed to head off anti-AMA competition became a stepping stone to the formation of an inclusive national organization. On June 6th, in Atlantic City, New Jersey, the United States Society for the Study and Prevention of Tuberculosis[7]—with Trudeau as its first president in recognition of his past achievements—was born; it comprised a broad alliance of health care workers, politicians, clergy, employers, and philanthropists.

The International Movement

At this same time, the international movement was materializing. The first step had been taken at the 1899 International Congress, held in Berlin, with the granting of official recognition to lay government and voluntary organizations as part of the expanding drive against tuberculosis. The Congress of 1902, again in Berlin, formalized acceptance of these organizations by creating the Central Bureau for the Prevention of Tuberculosis (soon renamed the International Antituberculosis Association). Headquartered in Berlin and composed of representatives appointed by national organizations and governments, the Association's work was interrupted by World War I, then resumed with 24 member nations. Renamed the International Union Against Tuberculosis (IUAT) and based in Paris, the IUAT—currently with 114 member countries—continues to organize international meetings and publishes the *Bulletin of the International Union Against Tuberculosis.* Its expanded mission eventually called for the following:

> “All countries wishing to eradicate tuberculosis to decide among themselves on the methods, to agree on the most effective weapons, and to forge and implement them jointly against the common enemy.... Antituberculosis measures must some day be standardized ..., but first it is necessary for the research workers to make a thorough investigation of the problem in order to provide governments with the necessary information. It is in this spirit and for these ends that we wish to create an International Union Against Tuberculosis” (Rouillon, 1982).

It was also at this meeting that the double red cross, as suggested by Dr. Gilbert Sersiron of the French national association, became the unofficial—and in 1928 the official—international symbol[8] of the voluntary movement to control tuberculosis. The cross, associated with the Christian Crusades, was the ideal symbol for what was viewed as an international “crusade” against this killer disease. Eradication was the common goal, although individual eradication campaigns reflected their national gestalt.

The Crusade in America

Because Americans typically viewed tuberculosis as a disease of the poor, the unfit, and the ethnically inferior, the campaign here took on an evangelical aura fed by the melding of three judgmental philosophies that stemmed, respectively, from the following: (1) the ascetic Protestant-capitalist tradition based on the Calvinistic doctrine of predestination[9]; (2) the converse view that individuals are responsible for their actions; and (3) a newly emerging corollary of Darwinian evolution whose precept was survival of the morally and physically fittest for the good of the human race—the biologic equivalent of the Calvinistic doctrine of predestination. Despite the obvious differences between these three social views, they all identified a subclass—the *same* subclass—as needing help.

Central to ascetic Protestantism (and those sects, such as Puritanism and Methodism, that derive from Calvinism) is the two-point doctrine of predestination: (1) God chooses before birth those to be saved and those destined for eternal damnation. (2) God's choice can only be guessed at by looking for signs of His grace. Although ascetic Protestants professed to disdain the pursuit of wealth as an end in itself, when it was attained as the fruit of one's labor, it was surely a sign of God's blessing. So the rich were confident that their wealth documented their place among the chosen, and they found the damned equally recognizable simply because of their poverty. Tuberculosis was easily woven into this fabric; the chosen did not fall ill, while those afflicted with tuberculosis were clearly among the damned.

A group opposing this deterministic view held that individuals could control where and how they lived. People who chose to live in filth, or were too unambitious or lazy to find work outside the crowded tenement districts, bore full responsibility if they contracted tuberculosis.

The third version—of the “defective” patient, the “Darwinian” point of view in relation to tuberculosis—was expressed in an article in the *Atlantic Monthly* by the noted Boston physician Henry Bowditch:

> “We must confess the sad and unwelcome truth that (some children) are doomed to an early death ...by the diseased condition of the parents, sometimes ...alas! due to their own or their ancestors' previous excesses.... 'For the sins of the fathers are visited upon the children unto the third and fourth generation.' Such children die early; **and this is exactly right. The race would constantly deteriorate were it otherwise** (*authors' emphasis*).... Only to strength and perfect health belongs the highest life, which alone has as its birthright the will and the power to contribute to the continuance of the human race” (Bowditch, 1869).

As all three viewpoints regarded the tubercular patient as inferior—whether damned by God, by his ancestors, or by his own actions—the National Association for the Study and Prevention of Tuberculosis found it easy to integrate them. The organization embarked on a campaign of propaganda, education, and aid dedicated not only to controlling tuberculosis, but also to developing a power base to control what was becoming a major industry. (By 1950, for example, the antituberculosis program in the United States approached $500 million.)

The *Confidential Bulletin,* the organization's internal newsletter, urged a concerted effort to recruit employers into the antituberculosis crusade because of their influence over their workers. Employers, selfishly motivated, were easily persuaded to join. On the one hand, the need to keep a healthy work force led these “captains of industry” to confront the “captain of all these men of death.” Some large corporations built “cure” facilities for their workers. The Standard Oil Company of New Jersey, for example, built such a pavilion at the Loomis Sanatorium in the Catskill Mountains of New York. (Ironically, during and after the industrial revolution it had been the blind drive for wealth—and thus evidence of God's grace—with its exclusive focus on profits and consequent disregard for humane working conditions, that had created an environment so favoring the spread of the disease.) And on the other hand, at a time when labor was becoming more restive and militant, this health crusade taught that passive obedience to employers was in the worker's best interest. Because the National Association viewed the city-dwelling poor as morally inadequate and thus in need of society's vigilance, they offered hygiene and morals in one basket. Lectures on tuberculosis, housing, and working conditions went hand in hand with such lectures as “The Amusement Problem: Snares of Amusements, Saloons, Dance Halls and Burlesque Theaters.” And the urban masses themselves were given the following admonitions:

Don't spit on the floor of your shop.
When you spit, spit in the gutters or spittoon.
Don't cough without holding a handkerchief or your hand over your mouth.
Don't drink whiskey, beer, or other intoxicating drinks.
Whatever thou take in hand, remember the end and thou shall never do amiss.
Whatever is worth doing is worth doing well.

Because health and personal conduct were now intertwined, coming down with tuberculosis became plainly unpatriotic: “Community health is essential to national preparedness. Now is the time to show that wasteful sickness can be prevented.”

Consistent with the prevailing capitalistic mentality, public participation in the fight against tuberculosis took the concrete form of donations to finance the different programs. The very first appeal for public funds was a small-scale effort mounted in Denmark, based on Einar Holboell's idea of selling special stamps or seals to raise money. In 1907, one of these seals reached the notice of photographer and social reformer Jacob A. Riis, whose ensuing article in an American magazine sparked the idea here. Emily P. Bissell of Wilmington, Delaware, who had read the article, commissioned the artist Howard Pyle to design a seal that she sold to raise $3000, financing construction of an eight-bed tuberculosis cabin. She then persuaded the American Red Cross to apply the idea nationwide, and they raised $135,000 in 1907 and $200,000 in 1908. For the next decade, the seal campaign was a joint Red Cross and National Tuberculosis Association effort. Then in 1919 the Red Cross gave full proprietorship and responsibility to the National Tuberculosis Association, which used the seal to raise $4 million that year. By 1950, the Christmas Seal program, as it came to be known, raised $20 million a year.

MEDICAL CARE

Compulsory notification and the social welfare movement were necessary, but not sufficient, weapons in the fight against tuberculosis. Once identified, tubercular patients needed treatment—whether they wanted it or not. The form that treatment took was tied to economic level, and patients were segregated by race. The wealthy were often treated at home by a private physician, to whom they paid a standard fee. Private funds were also required for sanatorium treatment, which promised a cure in return for subservient obedience. The majority of poor patients relied on public dispensaries combined with some sort of home care. The municipal hospitals cared for patients who were either terminally ill, noncompliant, or indigent.

The Sanatorium Movement

The history of the sanatorium movement has been well documented, if somewhat idealized, and the reader is referred to the ample literature on this subject for a detailed review. The summary here provides the outlines.

Sanatoria had sprung up in central Europe during the last half of the 19th century, then spread to coastal and riverside areas of Great Britain; after 1882 they crossed the Atlantic to America. Philosophically, sanatoria fell into two groups. One adhered to the motto of the Hotel/Sanatorium at Davos, Switzerland—*mox sani* (“the merry are soon well”)—illustrated in Thomas Mann's *The Magic Mountain.* The other upheld the motto of Brehmer's Sanatorium at Gobersdorf—*die Patienten kommen nicht um zich zu amusiren sondern um geheilt zu werden* (“patients do not come here to amuse themselves but to be cured”)—agonizingly portrayed in A. E. Ellis's *The Rack.*

The latter approach, incorporating the same Puritan ethic that permeated the National Association, better suited the American psyche. Patients entering sanatoria here implicitly agreed to a bargain: medical advice, treatment, and nursing care in exchange for complete submission to a rigorously demanding institutional authority. Although the sanatorium life was often romanticized in European literature, in reality it meant sacrificing dignity for the uncertain prospect of a cure. Patients typically entered an Orwellian society in which they became a number, divested of all sense of individuality via a combination of ideologic and psychologic assaults.

The experience was unchanged decades later when Marshall McClintock, who became a long-term resident of the Adirondack Cottage Sanatorium, described his arrival. On entering he was handed a rule book inscribed with his number (8027), which he was required to read and sign. He noted, “I felt worse than ever. Like a prisoner. And the book was full of rules, lots of rules” (McClintock, 1931).

Some patients viewed sanatoria as oases because they provided a refuge from sweat shops and squalid tenements. But the rigidly regimented life (not by accident reminiscent of monastic routine) often quickly became untenable, especially when it came to segregation of the sexes. Sex was believed to be both a major factor in the development of tuberculosis (“...girls with the tuberculosis diathesis do not have the same moral stamina that girls in robust health have.... This explains ...why so many prostitutes are tubercular” [Peters, 1909]), and a result of tuberculosis “toxemia,” which was regarded as “...effective in the direction of causing sexual irritability” (Fishberg, 1919). The harshness of sanatorium rules caused between 10% and 30% of these patients to leave within their first month.

Society replicated its inequalities and prejudices in the health care system in general, and in the sanatoria in particular. Blacks, for example, whose death rate from tuberculosis was twice that of whites, were completely barred from sanatorium treatment. When Lawrence F. Flick defended the initial nonsegregation policy at White Haven Sanatorium in Pennsylvania, the white patients there threatened to leave:

> “As there is nothing in your advertising literature sent to patients ...that they would be expected to associate with Negroes; we think it is an injustice to live in daily contact with them ...(and) we do not think it desirable for the White and Black Races to mix” (Bates, 1992).

Flick, to his credit, pitted his principles against the economic survival of the institution he had helped found. But the sanatorium board voted against him and issued a

new rule: “No Negroes will be admitted to the sanatorium.” In response, Flick resigned as medical director.

Patients who were poor and/or addicted to alcohol were also looked down on. These elitist attitudes are illustrated by the Otisville Sanatorium in New York, which had been built at Hermann Biggs' urging and embodied his autocratic notions. It was the first municipal sanatorium in the United States and, unlike most sanatoria, had a “work cure” to prevent “the cultivation of habits of idleness.” Biggs objected to the rest cure enforced at various other sanatoria on the grounds that their successful cases often consisted of “converting a sick tuberculosis individual into a fairly healthy loafer” (Winslow, 1929). (There was also a practical aspect, because inmates who were earning their keep to some degree reduced operating costs.)

Alcoholics were the most “worthless” patients of all. The rather terse notice sent to patients newly accepted at the Otisville Sanatorium included the following: “If under the influence of liquor, or smelling of the same, you will be rejected.” The antituberculosis movement was obsessed with alcohol, which in the United States was viewed as the prime nonbacterial factor contributing to the disease. (One can speculate as to the role of the antituberculosis movement in the development of Prohibition.)

Whether or not sanatorium treatment was effective in curing tuberculosis—it was never scientifically evaluated—in reality, the great majority of patients never had the opportunity to experience it. (By 1954, for example, when the incidence of tuberculosis was well on the wane, the 130,000 existing sanatorium beds could accommodate only half of the patients with active disease. Some of those unable to find space, or unwilling to submit to the demeaning regimen, went to the Colorado mountains or the southwestern desert, where large and desolate tent colonies—known as “bugsvilles” or “lunger's camps”—had been set up beyond town limits. The colony at Tucson, Arizona, for example, located 1 mile beyond the last bus stop and with no running water and only primitive sewage conditions, was a place of “lost souls and lingering death.” Those remaining in the city most often sought help via dispensaries and home care, and as a last resort entered a local municipal hospital.

The Dispensary

Antituberculosis dispensaries first appeared in Europe several years after the discovery, if not universal acceptance, of the communicability of the disease. The initial one was established in Edinburgh, Scotland, by Sir Robert Philip. In 1900, Ernest Malvov established the second dispensary in Liége, Belgium, with Albert Calmette doing the same in Lille, France, in 1901. The first American dispensary, the Henry Phipps Institute in Philadelphia, opened in 1903, and was followed soon after by Gouverneur and Bellevue Hospitals in New York City. The 1904 Bellevue Report described the dispensary as providing the following: (1) careful and thorough medical attention; (2) systematic investigation and supervision of the patient's home conditions; (3) education of both patient and family; and (4) evaluation of the social and economic conditions affecting the medical aspects of each case (Miller, 1904). Figure 5 shows the Bellevue Dispensary's first 5 months of activity.

FIG. 5. Expenses incurred by the Bellevue Hospital outpatient tuberculosis clinic during its first 5 months. (Miller JA. The tuberculosis clinic of the Bellevue Hospital outpatient department. In: Lambert A, Draper WK, Curtis BF, Woolsey G. *Medical and Surgical Report of Bellevue and Allied Hospitals in the City of New York,* 1904;1:204–205.)

Although all dispensaries shared these same basic aims, each institution had its individual perspective. At Bellevue, for example, “careful and thorough medical attention” involved collecting sputum for analysis by the Department of Health, making a probable diagnosis, and instructing the patient—both orally, and with written instructions for home use—as to nature of the disease and the needed precautions. Patient and family education was an ongoing responsibility of the physicians and nurses, and was supported with printed circulars. The 1904 Bellevue Report observed that each patient “is now a center of information in regard to the general principles of healthful living” (Miller, 1904). In contrast, the 1904 Gouverneur Report noted, “We have distributed very little literature. It has seemed to us that what patients know they will talk about, and that those with whom we work are usually more confused than helped by printed information” (Bradford and Seymour, 1904).

Both dispensaries prescribed a daily diet that started with a minimum of 2 quarts of milk and 4 raw eggs and increased to 3 quarts of milk and 10 eggs. (Very few patients were thought to benefit from more.) Patients were given a cuspidor and pocket sputum pouches free of charge. However, medication played a very minor role at Bellevue, whereas Gouverneur regularly used therapeutic agents such as strychnine, cod-liver oil, and ichthyol, and heroin was touted to control cough.

Patients at Bellevue were seen weekly, and their weight, temperature, pulse, and general condition were recorded. If needed, patients could be admitted to Bellevue's tent cottage (Fig. 6). The dispensary could also refer patients to an appropriate sanatorium and/or charitable organization. Investigation and supervision of the patient's home situation was done by home visits. In France, Calmette trained former tuberculosis patients for these visits, whereas the Phipps Institute and the New York City hospitals used visiting nurses. The year that the Phipps Institute dispensary opened, Dr. Lawrence L. Flick, soul of Philadelphia's antituberculosis movement, wrote, “Tactful, kind supervision by a well-trained woman soon brings the most ignorant consumptive under control” (Bates, 1992).

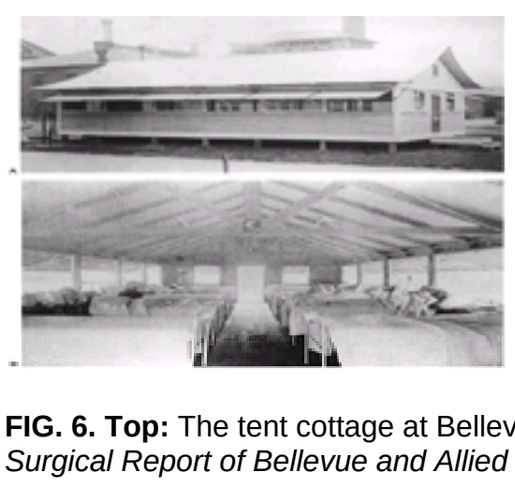

FIG. 6. Top: The tent cottage at Bellevue Hospital. **Bottom:** A tent interior, with gas light and steam heat. (Lambert A, Draper WK, Curtis BF, Woolsey G. *Medical and Surgical Report of Bellevue and Allied Hospitals in the City of New York,* 1904;1:204–205.)

As stated in the Bellevue Report, the aim of the visit was “to arrange the whole domestic economy to the best interest of the patient, and to provide against dangers of infection to his household and associates” (Miller, 1904). This included instructions for room ventilation, disinfection, expectoration, and general hygiene. Plans for taking the “rest cure” outdoors were made and, where possible, outdoor sleeping accommodations were constructed (Fig. 7 and Fig. 8). If a home was found to be completely unsuitable, the visiting nurse could insist that the patient be moved to a more healthful location.

FIG. 7. Fighting tuberculosis on the fire escape. (Lambert A, Draper WK, Curtis BF, Woolsey G. *Medical and Surgical Report of Bellevue and Allied Hospitals in the City of New York,* 1904;1:204–205.)

FIG. 8. Fighting tuberculosis on the roof. Photograph by Jacob Riis (reproduced with permission of the Museum of the City of New York).

As well-meaning as these health efforts were, patients did not always welcome them, as the following letter to Dr. Flick at the Phipps Institute indicates:

> “And doc, I now right to you to tell you, that you sent 2 nearses here to see Katie MiCarty and I would like to know, if you can tell who sent you a letter about my doarter.... I would like to tell your's nearses to pleas not bother a bout my business, for there is only one cure for my child and that is in heven” (Bates, 1992).

Just as it is today, patient compliance was of great concern to these public health pioneers. The 1904 Gouverneur Hospital Report notes the following:

> “The intelligence of these patients varies greatly.... Some at once sense the situation and work with us.... Among our most intelligent are the schoolchildren, who take kindly to the idea that they are in training as important as any athlete. On the other hand, there are those who come when they feel the need, and stay away at the slightest improvement.”

In the Phipps Institute's second annual report, Dr. Flick's earlier optimism that patients could easily be swayed to lead a “proper” life style with “tactful and kind supervision” had been replaced: “Considerable pressure is brought to bear on patients to induce them to practice preventive measures when they seem reluctant to do so.... When, ultimately, they are found to be intractable, they are discharged from the institute” (Bates, 1992).

The Municipal Hospital

For these disobedient patients, only the municipal institutions remained. As early as 1896, the AMA was urged to promote a network of state hospitals where “indigent consumptives who were careless in their hygienic habits could forcibly be confined.” The Rhode Island Commission, charged in 1911 with building such an institution there, listed “confinable” offenses as follows: being found a public nuisance; noncompliance; homelessness; friendlessness; dependency; dissolute behavior; dissipated and vicious behavior; residence in a lodging house or public institution with refusal to enter one's assigned hospital; living at home in unfavorable sanitary conditions, thus posing a danger to the family; and insisting on being discharged from a hospital against medical advice.

The New York Department of Health designated Riverside Hospital on North Island as the facility for involuntary confinement of all tubercular patients whose dissipated and vicious habits presented a danger to the community. But it failed both as a prison and as a hospital, as was typical of municipal efforts in the early 20th century. Riverside was often short of sputum cups, at the time a staple in the fight against contagion. It failed to give instruction in, or enforce, hygienic measures. Discipline was lax, bed rest was not enforced, and patients spent their days playing cards and wandering about.

In 1913, a report on 25 municipal facilities in five major cities (issued by the Committee on Hospitals for Advanced Cases of Tuberculosis of the National Association for the Study and Prevention of Tuberculosis) observed that, as in almshouses, patients would admit themselves as the weather grew cold and leave as soon as temperatures improved.[10] These institutions made no attempt to provide even rudimentary treatment or enforce the rules designed to prevent contagion. They were also cited for permitting patients to leave to visit friends and relatives. These municipal facilities, the Association concluded, served as “a place of last resort to the narrow group of cases in the extreme stages of physical and economic helplessness” (Rothman, 1993).

HOW EFFECTIVE WAS THE PUBLIC HEALTH INITIATIVE?

The death rate from tuberculosis between 1880 and 1920 decreased throughout the industrial world. In New York State, for example, it declined from almost 400/100,000 to just over 100/100,000, and in Wales and England from 200/100,000 to 100/100,000. The respective public health movements and national associations regarded this decline with pride and attributed it to their public health measures—that is, the education and isolation of an increasing proportion of patients.

This self-congratulatory attitude has been challenged on the grounds that these measures simply happened to coincide with a decline in tuberculosis deaths that reflected the larger cycles of the disease, a decline that was in reality not even accelerated by the public initiative. And a closer examination of death rates between 1800 (the start of reasonably accurate data) and 1950 (when effective antibacterial agents were first used) indicates that a constant decline in tuberculosis mortality had begun well before the interventions described above, and continued to fall at the same constant rate even after the health initiatives were put in place. Thomas McKeown and R. G. Record, among others, attribute this constant decline in tubercular deaths to a general improvement in social conditions during the period (improved housing, sanitation, and nutrition). Their position is based on two negative-inference arguments.

The first is that the slope of the mortality line did not grow steeper with each new public health initiative (Fig. 9, *top*), indicating that these initiatives apparently had no significant effect. The second argument is that the slope of the death rate remained nearly constant despite the increasing proportion of patients receiving treatment. Throughout most of this period, in any given decade the incidence of tuberculosis continuously decreased, while the number of patients isolated and treated remained fairly constant. (In New York, for example, it held steady at about 15,000 per decade.) Because this meant an increasingly greater proportion of patients were being treated, the death rate should have decreased more and more rapidly if the treatments were successful. But again the slope of the line appears constant, suggesting that these medical and social interventions were not having a significant impact.

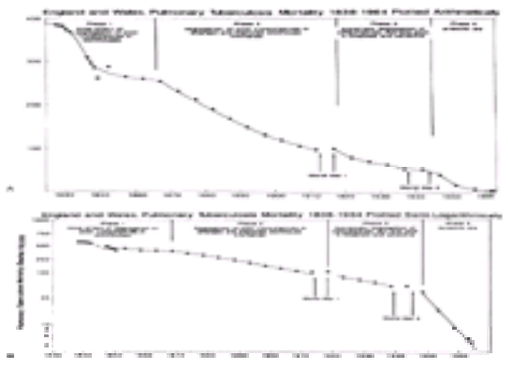

FIG. 9. Top: Arithmetic graph of tuberculosis mortality in England and Wales. **Bottom:** Semilogarithmic graph of the same data. (Wilson LG. The historical decline of tuberculosis in Europe and America: its causes and significance. *J Hist Med Allied Sci* 1990;45:390.)

In contrast, the public health and medical interventionists argue that their policies *did* accelerate the decrease in tuberculosis deaths. Leonard Wilson provides mathematical support for this view using the same data from England and Wales (Fig. 9, *bottom*). He argues that the decreasing mortality was not constant, but rather declined exponentially. And when the mortality data are plotted semilogarithmically, four distinct segments of increasing slope emerge. The discontinuity in the lines corresponds to the World Wars. The accelerated decrease in death rate, indicated by the steeper slope of each segment, coincides with better isolation of tubercular patients from the healthy population. A similar plot can be obtained from New York City data (Fig. 10), in which the steepest drop (1918–1922) immediately followed the opening of three large tuberculosis hospitals. Subsequently, the decline in deaths returned to approximately its previous steady exponential rate. (Those hypothesizing that the continued drop in tuberculosis deaths was a consequence of continuously improving social conditions could also view the two World Wars—during which the death rate soared in response to dramatically deteriorating social conditions—as perverse retrospective experiments favoring their hypothesis.)

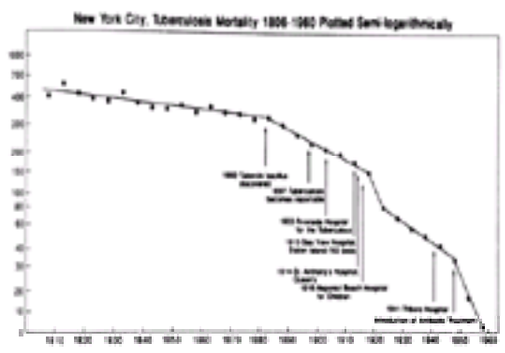

FIG. 10. Mortality in New York City between 1806 and 1960 plotted semilogarithmically. (Wilson LG. The historical decline of tuberculosis in Europe and America: its causes and significance. *J Hist Med Allied Sci* 1990;45:393.)

In our opinion, these conflicting observations actually illustrate two coincidental and superimposed mechanisms, one reflecting human interventions and the other reflecting the innate rhythms of the disease. On the one hand, a slow steady decline representing the effects of social improvements was interspersed with periods of accelerated decline consistent with the introduction of new antituberculosis initiatives. Disease epidemics, however, have their own natural and characteristic ebb and flow. For tuberculosis, these dynamics are dictated by the three types of postinfectious responses (Fig. 11). In most people who are infected, the disease does not develop further. Those remaining in the infectious pool separate into the relatively small group of “fast” (primary progressive) tuberculosis, and the larger group of “slow” (reactivation) tuberculosis. The early phase of an epidemic obviously represents the fast cases, and thus the death rate is high. As the epidemic progresses, the “slow” component becomes dominant and dictates a time unit of many decades, with the typical tuberculosis epidemic operating on a protracted time scale of 100 years or more. During this long-term phase, the death rate flattens substantially.

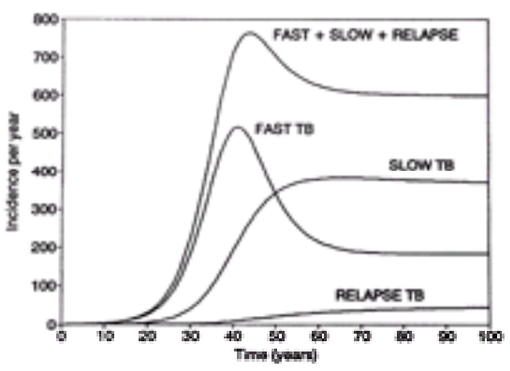

FIG. 11. A numerical simulation of a tuberculosis epidemic initiated by one infectious case at time zero in a disease-free, susceptible population of 200,000. The simulation illustrates the relative contributions of the three categories of tuberculosis (fast, slow, and relapse) to the incidence rate of this disease. A decline occurs in the absence of change in any parameter, and is simply the consequence of the intrinsic dynamics of transmission. (Blower SM, McLean AR, Porco TC, Small PM, et al. The intrinsic transmission dynamics of tuberculosis epidemics. *Nat Med* 1995;1:820.)

Current thought suggests that the rising phase of the ongoing epidemic in Europe and North America started when population densities exceeded transmission threshold levels. This coincided with the development of industrialization and the consequent vast migration from rural to industrial areas in both Europe and North America, and the inundation of North America by massive numbers of immigrants looking for a better life. After peaking in the early 19th century, deaths would have been expected to decrease as a consequence of the unique dynamics of a tuberculosis epidemic. Because the medical innovations and improved social conditions outlined here (with respect to hygiene and nutrition) happened to coincide with this declining phase, they were constrained to operate within—and thus appear muted by—the slow response time dictated by the intrinsic dynamics of the epidemic.

CONCLUSION

The discovery of *Mycobacterium tuberculosis* was essential for the development of an antituberculosis technology. The accumulation of new knowledge that followed precipitated an atmosphere of optimism, with the expectation that the means for detection and elimination of this single agent would ultimately achieve elimination of a feared and widespread disease. The irony is that altruism and charity played only a minor role in society's eventual attempts at controlling the tuberculosis epidemic. It was the often greedy fear of economic loss, combined with the anxiety of self-protection, that drove the campaign against this disease.

The leading edge of the current tuberculosis epidemic coincided with the initial phase of the Industrial Revolution, and its crest coincided with the subsequent apotheosis of unrestrained capitalism. The initial stimulus for the development of a societal antituberculosis initiative, therefore, came from the need to protect the investment and profits of the owning class. In the early phase, when large numbers of laborers migrated from farms to industrialized centers and the jobs there required little special training, workers were cheap and easily replaceable. In this kind of labor market, the health of individual workers was of little concern to employers. Eventually, however, the reserve of potential workers from rural areas shrank while the demand for skilled labor increased, so that employers had to spend significantly more to retain their workers. It became financially meaningful not to lose employees. (This cycle of an epidemic of tuberculosis coinciding with rapid industrialization, dense migration from rural to urban slum districts, and the exploitation of laborers, which characterized the Industrial Revolution in Western Europe and North America,

is recurring now in Latin America, Asia, and Africa.)

The second catalyst in the antituberculosis movement came from the gradual realization by physicians that the untreated and unsupervised poor were a real threat, not only to their fellow poor living alongside them in squalor, but to the middle and upper classes as well:

> “Then the poor servants of the well-to-do, if there be consumption in their own homes, are likely to bring infection into the families of their masters; as are also poor consumptive workmen who are employed upon repairs in the homes of the rich. There is in fact, no limit to the extent to which the disease may be disseminated from its primal base—the home of poor sufferers” (Huber, 1906).

The foot soldiers of the antituberculosis crusade—the compassionate nurses and physicians who dealt directly with patients—often participated for altruistic reasons, but the development of effective public health programs often had little to do with compassion and altruism and were, in fact, determined by hard economic concerns and fears. The antituberculosis program was enabled by scientific progress, brought to fruition through the deft amalgamation of public fears and self-interest, and facilitated by the skillful political manipulations of ambitious men to overcome what Castiglioni, in his 1933 *History of Tuberculosis,* called “...the short-sighted interests of a few who, in all times and every land, tried to sacrifice the public good to the selfish motive of the minority.”

The crusade achieved its success by playing on society's fears and bigotry. Because the poor were a ready target, the antituberculosis campaign purposefully emphasized and perpetuated the stereotype of the poor tenement dweller as an immoral drunkard who was sexually promiscuous and lazy, and reinforced the general notion that the tubercular patient was the cause, rather than the victim, of disease. This stereotype was a critical element in galvanizing and financing the public health campaign to eliminate tuberculosis. The dynamics of this campaign aptly illustrated Hermann Biggs' conviction: “Public health is purchasable and within natural limitations, any community can determine its own death rate” (Winslow, 1929).

---

[1]Thucydides (circa 460–400 BC), *The History of the Peloponnesian War.*

[2]The law of July 19, 1782, from the Kingdom of Naples:

I. The physician shall report a consumptive patient, under penalty of 300 ducats for the first offense and 10 years' banishment for repetition of it.

II. The authorities ...shall inventory ...the clothing in the patient's room to be identified after his death...if any opposition ...be made, (if) the person doing so ...belongs to the lower class, (he) shall have 3 years in the galleys or in prison, and if of the nobility, 3 years in the castle and a penalty of 300 ducats.

III. Household goods not susceptible of contamination shall immediately be cleansed and that which are susceptible shall at once be burned and destroyed.

IV. The authorities ...shall tear out and replaster the house from cellar to garret, carry away and burn the wooden doors and windows and put in new ones.

V. Newly built houses shall not be inhabited for 1 year after ...completion or 6 months after plastering has been done and everything (else) ...has been finished.

VI. The poor sick shall at once be removed to a hospital.

VII. Hospital superintendents must keep clothing and linens for the use of consumptives in separate places.

[3]Ironically, although Jacob A. Riis is known as a social reformer who was instrumental in improving living conditions for poor tenement dwellers in New York City, his outrage over these living conditions was reserved for victims of German or Bohemian descent. Virulently anti-Semitic, he castigated Jews for their industriousness even though fully aware that this was exactly what would lift them out of their poverty. He also admonished the Italians, Irish, and Chinese for various perceived sins.

[4]The College of Physicians and Surgeons had offered W. H. Welch a faculty position, but refused to build a laboratory in which he could implement the histology and microbiology techniques he had learned in Germany. Bellevue Hospital gave him this laboratory, and he joined the faculty there as Professor of Pathological Anatomy and General Pathology. The College of Physicians and Surgeons, soon realizing its mistake, built a pathology laboratory under T. Mitchell Prudent.

[5]Feared loss of income by physicians was a recurrent concern. A 1904 report from the tuberculosis clinic at Gouverneur Hospital, in an attempt to counter this apprehension, noted: “We are sure that the medical profession is not being impoverished because people are treated free. Occasionally we have a well-dressed child, but the appearance of some other member of the family outweighs the first impression of competence.”

[6]Tammany Hall, led at that time by Richard Cocker, was the political oligarchy—associated with corruption and governmental mismanagement—that ruled New York City at the turn of the 20th century. The Board of Health evolved mainly during Tammany's control of City Hall.

[7]This organization was renamed the National Tuberculosis Association in 1904 and is with us still as the American Lung Association.

[8]This double cross symbolized Christian Jerusalem in the second century AD. Eventually appearing in Byzantium as a “Greek cross,” it entered the Hungarian coat of arms in 1074 when the Byzantine Emperor gave it to Hungary's King Geasa I. Then, in 1099, Godefroy de Bouillon, Prince of Lorraine, added it to his banner to commemorate his Crusaders' capture of Jerusalem. Almost a millennium later, this cross was adopted as an emblem by the Free French in World War II. Since it has become associated with the antituberculosis movement, some countries have replaced it with a culturally more meaningful symbol (double red crescent or red lion and sun).

[9]Even a cursory discussion is beyond the scope of this chapter. The interested reader is referred to Erich Fromm, *Escape From Freedom* (New York: Avon Books; 1965) and Max Weber, *The Protestant Ethic and the Spirit of Capitalism* (New York: Charles Scribner's Sons; 1958).

[10]I (F.H.) remember a spring day in my childhood (in the early 1950s) when I accompanied my father to his job as Director of the Pulmonary Rehabilitation Program at Bellevue Hospital. A panhandler approaching our car suddenly recognized my father and apologized. That winter I saw him again, this time in Bellevue. My father explained that every year, he would check into the hospital when the weather turned cold, stay for the winter, then leave in the spring.

Introduction

Udaya B.S. Prakash

U.B.S. Prakash: Pulmonary and Critical Care Medicine, Mayo Medical School, Mayo Clinic, Rochester, Minnesota 55905.

The respiratory system, perhaps more often than any other organ system, frequently bears the brunt of injury initiated by diseases that are primarily nonpulmonary in origin. Indeed, in many of these diseases, pulmonary manifestations are the first indication of a multisystem disease. Furthermore, the respiratory features or complications may persist as the most significant clinical aspects of the nonpulmonary diseases. The mechanisms by which such involvement occurs are almost as diverse as the diseases themselves.

The most common and best-documented mechanism of lung injury is the inhalation of pathogenetic substances including dusts, gases, smoke, microorganisms, and various types of antigens and chemicals. Injuries arising from these usually appear in the conducting airways or pulmonary parenchyma as infections, bronchitis, emphysema, asthma, bronchogenic carcinoma, malignant mesothelioma, or pneumoconioses. These entities are appropriately covered in other sections of this textbook.

Changes in the lung vasculature may accompany widespread disease of the systemic blood vessels or be caused by various pulmonary or extrapulmonary conditions. Leakage of protein or red blood cells from capillaries into the extravascular and alveolar spaces can occur by mechanisms that are not well understood. This is exemplified by the intraalveolar hemorrhage of Goodpasture's syndrome, in which circulating anti-basement-membrane antibody is present, and the alveolar bleeding is a dramatic indication of underlying glomerulonephritis. A second example is the nonhydrostatic pulmonary edema of the respiratory distress syndrome, which may result from a wide variety of insults ranging from the hypoperfusion of the shock state to amniotic fluid embolism and pancreatitis. In contrast, the intraalveolar hemorrhage of Wegener's granulomatosis, systemic lupus erythematosus, and hypersensitivity angiitis results from the necrotizing vasculitis of small vessels, which occurs in these diseases as part of the damage caused by deposition of circulating immune complexes. Auscultatory and roentgenographic changes caused by pulmonary arteriovenous fistulas may be early indications of hereditary hemorrhagic telangiectasia, and bleeding from the lesions can be severe enough to threaten life. Chemical mediators produced at a nonpulmonary site may enter the pulmonary circulation and cause respiratory problems, as exemplified by the bronchospasm noted in patients with extrapulmonary carcinoid that produces serotonin.

The lung interstitium is involved in a number of heritable diseases. Defective collagen synthesis is believed to be a significant factor in the abnormalities of the Marfan and Ehlers–Danlos syndromes, and in both disorders tissue fragility may predispose to spontaneous pneumothorax. In some cases of tuberous sclerosis, smooth muscle replaces normal alveolar interstitial tissue to such an extent that gas exchange is rendered ineffective, and irreversible respiratory failure is produced. Interstitial fibrosis observed in collagen disorders such as rheumatoid arthritis, scleroderma, and polymyositis may have underlying autoimmune mechanisms.

More commonly, the lung parenchyma is a site of pathologic changes that represent infiltration by acquired disease processes. Prominent among these are the lymphoproliferative disorders, characterized by multiplication and aberration of lymphocytes and histiocytes and their precursors and derivatives. Similar mechanisms are responsible for lung involvement in uncommon diseases such as Langerhans cell granuloma (histiocytosis X or eosinophilic granuloma) of the lung, Gaucher's disease, and plasma cell dyscrasia. Diffuse infiltrative changes, both microscopic and roentgenographic, occur in acute and chronic leukemias, whether lymphocytic or nonlymphocytic. More nodular changes are seen in the tumor masses of Hodgkin's and non-Hodgkin's lymphomas, but pulmonary involvement by myeloma or Waldenström's macroglobulinemia is distinctly rare. These conditions and Langerhans cell granuloma of the lung, whose generic designation covers several patterns of histiocytosis, lack specific roentgenographic features that would permit ready diagnosis in the absence of microscopic proof. In all of them, pulmonary involvement may be an early or late feature. These statements are also true of the noncaseous granulomas of sarcoidosis, which may be recognized first in lung parenchyma without the presence of the characteristic hilar and paratracheal adenopathy. In both of these diseases, deposition of collagen often follows the inflammatory changes in the lungs, which are themselves only one part of a more generalized process. A similar progression can occur from a hypersensitivity or dose-related lung reaction to certain drugs.

The respiratory system is the most common site of infection in immunosuppressed patients. Frequently, unusual or recurrent pulmonary infections alert the clinician to the possibility of immunosuppression. For instance, *Pneumocystis carinii* pneumonia, in patients with undiagnosed acquired immunodeficiency syndrome, may alert the clinician to the possibility of underlying disease. It is not uncommon, however, for a patient with an immune deficiency problem such as common-variable immunodeficiency syndrome (hypo- or agammaglobulinemia) to experience recurrent lung infections and develop disabling pulmonary disease from bronchiectasis before the diagnosis is entertained and treated. Another example of frequent respiratory infections from an underlying systemic disease is in patients with sickle-cell anemia, who exhibit a very high incidence of pulmonary infection by streptococci.

The lungs may be affected in an unusual manner, as exemplified by the neurogenic pulmonary edema following damage to the brain, aspiration pneumonia as a result of incompetent lower esophageal sphincter, respiratory distress syndrome following acute pancreatitis, pulmonary calcification noted in patients on long-term hemodialysis, pneumothorax associated with menses, or pulmonary hypertension in patients with acquired immunodeficiency syndrome.

Even in a single disease entity, there can be a multitude of intrathoracic manifestations. In rheumatoid arthritis, for example, the pulmonary system may demonstrate any or many of the following: pleural effusion, pulmonary nodules, interstitial pneumonitis and fibrosis, laryngeal nodules, bronchiolitis obliterans, or pulmonary vasculitis. The examples provided in the following chapters are not exhaustive but are sufficient to illustrate that the respiratory system provides a valuable indication of the presence and progress of many important systemic diseases.

The diseases and chapters in this section are arranged on the basis of subspecialty orientation in the practice of internal medicine. It is, however, difficult to pigeonhole certain disease entities into a specific organ system because many diseases overlap subspecialty or organ-system boundaries. Nevertheless, the discussions on diseases or disorders are included under the subspecialty area where they are commonly handled in clinical practice. Several topics have been shifted from their location in the previous edition so that now they appear under more appropriate chapters and subject titles. The discussion of noninfectious pulmonary complications in patients with acquired immunodeficiency syndrome has been deleted from this section and moved to Chapter 26. The readers may observe commission of an occasional redundancy. This, however, is unavoidable in a book of this magnitude and format and is preferable to total omission of a topic.

I am very grateful to my colleague and friend Thomas V. Colby, M.D., for contributing many of the photomicrographs that greatly strengthen the educational objectives of this section.

Preface

The need to publish a new edition of this book has been dictated by an increased understanding of the basic science and clinical aspects of pulmonary diseases.

Many chapters from the previous edition have been continued albeit some of them with new authors. A chapter on Molecular Biology of Pulmonary Disease has been added, reflecting the current emphasis on the genetic basis for an increasing number of abnormalities. Two chapters on Differential Diagnosis have been added to emphasize the clinical aspects and the roentgenologic aspects of common pulmonary syndromes. The chapters dealing with aerosols, theophylline, and surfactant reflect an increasing emphasis on Pulmonary Pharmacology.

The broader world view of tuberculosis is presented in the chapters dealing with mycobacterial disease, which have been written in this edition by the group from the New Jersey Medical School National Tuberculosis Center.

The selection of new authors reflects the trend towards the combination of youth and excellence that characterize the best in recent medical literature. Thus, it is our opinion that this edition of the Textbook is written by the very best clinician/scientists in the world of pulmonary medicine.

Two other circumstances deserve mention. Dr. Wolinsky retired as an editor after the last edition, and Drs. Celli, Crapo, and Karlinsky have joined Dr. Baum in producing what we all hope is a textbook worthy of our readers. And Lippincott-Raven has taken on the responsibility of publishing the book. Thus continuity of the technical excellence of the book is assured.

We all sincerely believe that this edition of the *Textbook of Pulmonary Diseases* maintains the high standard achieved in previous editions and will be of value to students, both undergraduate and those highly experienced in the field of pulmonary medicine.

Preface to the First Edition

Why another textbook? A few years ago when this work began, I approached the prospective contributors and found that they felt, as I did, that the available compilations and texts were weak in one or another of the major areas in the field of chest diseases. It seemed that by using specialists whose major interests were in these areas and allowing them to be responsible for covering all that they felt belonged in their area, a more complete and current textbook would result. Thus, the authors were assembled with an overall plan to cover the field completely and in a coordinated way with current material being woven into concepts by each author.

The difficulties of such a project are apparent. As part of internal medicine, the study of pulmonary diseases involves a wide variety of disciplines. Anatomy, physiology, immunology, bacteriology, mycology, biochemistry, epidemiology, and pathology, among the basic sciences, must be blended with physical diagnosis, therapeutics, radiology, clinical pathology, physiatry, and psychiatry to present a complete picture of this field of medicine. In addition, emphasis must be placed on the more important problems in public health as they bear on each area. Putting this material into an orderly and readable form is crucial to the value of the book, and providing a complete but selective bibliography is essential to making this a true textbook and not just a review.

In many areas, such as allergic disease and interstitial diseases, extensive background discussions precede the actual clinical presentations. This was done in order to provide sound physiologic basis for the clinical expressions of pathology that direct the activities of the clinician. In addition, embryology of the lung is discussed within the areas of congenital, developmental, and hereditary diseases and in continuity with this material rather than in a remote part of the book where its application would not be directly apparent. For the same reason, details of bronchial and parenchymal anatomy are followed by well-illustrated chapters on emphysema and pulmonary insufficiency.

At the clinical level, the approach to the various infectious diseases is consistent, and it makes use of principles proven reliable in the field of clinical bacteriology as the basis of the approach to viral, rickettsial, and fungal diseases. The mycobacterioses are described in a fresh way which clearly integrates new knowledge of chemotherapy and rehabilitation with established pathogenetic and clinical principles. It is in this historically prime subject in the field of pulmonary diseases that this book offers something that has not been available before. The established treatises dealing with tuberculosis have merely modified and appended the old format to include the subjects of drug therapy, drug resistance, resectional therapy, and rehabilitation based on physical activity early rather than late in the course of treatment. No continuity of approach was projected in such an exposition. By contrast, in this textbook, Drs. Jenkins and Wolinsky have synthesized a discussion that deals with broad principles in light of current information on one hand and provide orderly presentation of details on the other.

Diagnosis is the first subject dealt with in this book, and this is appropriate. Drs. Smith and Kory have developed a unique set of tables at the end of their chapters which should be extremely useful to the student and to the practitioner alike. It is no coincidence that Drs. Amberson, Middleton, and Schwarz have each repeatedly stressed the primacy of accurate diagnosis to many generations of students.

The authors and I have attempted to make this book detailed and current enough to appeal to the sophisticated specialist and clinical researcher and orderly, clearly organized, and well indexed to be of use to the beginning student. Because this book deals with pulmonary diseases primarily, specific discussions of mediastinal diseases other than tumors or gastrointestinal diseases with thoracic manifestations have not been included. Finally, I have written nothing myself, but have devoted my efforts to organization of material and exhortation of the authors.

This textbook is only a beginning, since new work will make much of what is written here obsolete; possibly obsolescence will have set in before publication. Nevertheless, the soundness of the physiologic approach allows for the addition of current knowledge to that discussed here without loss of continuity.

I sincerely hope that this book will, through the authority of the authors' material, stimulate the most important ingredient of any textbook in any field: the curiosity of the student.

G.L.B.
Cincinnati

Acknowledgment

Of the many people involved in the production of this edition of the *Textbook of Pulmonary Diseases* who deserve our heartfelt thanks, none is in the league of Laurie Anello. This highly professional medical editor has worked with Dr. Wolinsky and Dr. Baum for two editions of the book and gave the sendoff to Drs. Celli, Crapo, Karlinsky, and Baum for this one.

We wish to express our gratitude to the editing staff at Little, Brown, especially Jo-Ann Strangis, who continued in their active and efficient efforts prior to the change in publishers. And since the changeover formally took place, the energetic approach taken by Joyce-Rachel John and Michelle LaPlante of Lippincott-Raven Publishers has been very impressive, and undoubtedly, responsible for this edition appearing on schedule and in the fine shape that it is in. Their help has been consistent, and the results impressive.

A word about Dr. Wolinsky must be said. As the previous editor of the Textbook, Dr. Wolinsky continued to help in the preliminary planning of this edition despite his formal retirement from editorship. His no-nonsense approach and his good sense is expressed in the best of this current edition.

And finally, all four editors wish to express their sincerest gratitude to our authors, new and veteran.

CHAPTER

1 Normal Anatomy and Defense Mechanisms of the Lung

Robert R. Mercer · James D. Crapo

R. R. Mercer: Pathology and Physiology Branch, National Institute of Occupational Safety and Health, Morgantown, West Virginia 26505.
J. D. Crapo: Department of Medicine, National Jewish Medical and Research Center, Denver, Colorado 80206.

INTRODUCTION

Inhalation of approximately 10,000 L of air is necessary to meet the daily gas exchange requirements of the adult human lung. The normal lung has an extraordinary respiratory reserve. Arterial oxygenation commonly improves with exercise, and even under heavy work conditions, pulmonary gas exchange in a normal adult is rarely a cause of limitation to aerobic performance. To accomplish the efficient extraction of oxygen and exchange of carbon dioxide, the lung has an internal surface area approximately equal to that of a tennis court. The upper and lower respiratory tracts act to condition the inhaled air, and the lung has developed unique defense pathways to allow it to maintain its fine, delicate gas exchange surface while being continuously exposed to potentially injurious reactive or infectious agents in inhaled air. This chapter reviews the normal anatomy of the human lung and focuses on the unique structural characteristics that allow the lung to maintain normal function while being continuously exposed to inhaled reactive gases and particles.

THE NORMAL RESPIRATORY TRACT

Two normal adult lungs at maximal capacity contain 5 to 6 L of air and weigh an average of 850 g in men and 750 g in women. Blood makes up a substantial fraction of the lung weight, and *in vivo* the lungs have been estimated to contain as much as 360 mL of blood. Lung weight is approximately 1% of total body weight in a normal adult. Ninety percent of the volume of the lungs is made up of gas exchange regions or lung parenchyma, whereas lung weight is approximately equally divided between the parenchyma and structures other than parenchyma (airways and large vessels).

The right lung is commonly slightly larger than the left, comprising about 53% of the volume of both lungs on average. Each lung is completely covered by a visceral pleura. The visceral pleura subdivides each lung, although incompletely, into lobes. The right lung has three lobes, and the left is divided into two lobes. Incomplete fissures between the lobes commonly allow for some collateral ventilation between lobes. The bronchopulmonary segments are defined by the primary segmental bronchi that branch off the lobar bronchi. Lobar segments are not commonly subdivided by pleura. There are 10 segments in the right lung (Fig. 1) and eight in the left. Common terminology identifies 10 segments in each lung, with the first and second (apical posterior) segments of the left upper lobe being a combined segment and the anterior basal and medial basal segments being combined in the left lower lobe. The left lingula is anatomically part of the left upper lobe and is not commonly separated by a pleura-containing fissure. The fissure separating the right middle lobe from the right upper lobe is termed the *horizontal fissure* and can occasionally be recognized as a horizontal line on an anterior-posterior chest radiograph. The oblique or major fissures separating the upper and lower lobes of both the left and right lungs can be identified on lateral chest radiographs. The left major fissure commonly lies slightly apically and anteriorly to the right major fissure (Fig. 2). However, this apparent position can be easily altered by small variations in the orientation of a left lateral chest radiograph.

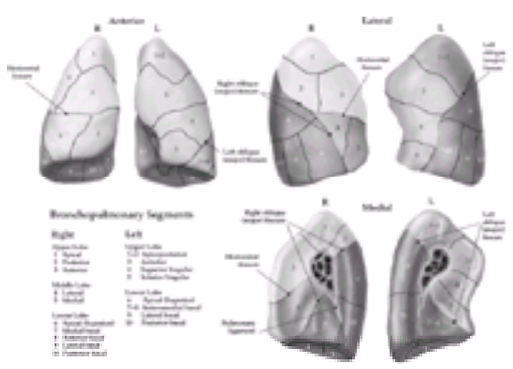

FIG. 1. Location of bronchopulmonary segments from anterior, lateral, and medial views. *See color plate 1.*

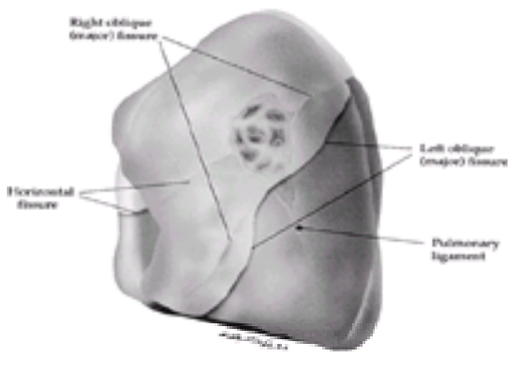

FIG. 2. Left lateral view of the lungs. Partially translucent image of the left lung allows the right lung to be seen. The location of the major fissures and the horizontal fissure of the right lung are illustrated in the positions in which they would appear on a left lateral chest radiograph. Note that the major fissure on the right side lies

slightly anterior and apical to the major fissure on the left side. *See color plate 2.*

A common variant in the lobation of the lung is the presence of a horizontal fissure partially demarcating the superior segment of either the right or left lower lobes. Another variant occurs when during development the azygos vein moves into the apical portion of the right pleural cavity. This displaces parietal pleura into the lung, producing a fissure in the apex of the upper lobe of the right lung. This partially separated lung lobe, known as an *azygos lobe,* occurs in slightly less than 1% of the population. The lingula of the left lung may also be demarcated by an anomalous fissure.

Contours along the lung surfaces for the heart, mediastinal structures, and major vessels are illustrated in Fig. 1. A fold of tissue containing connecting tissue and vessels that extends inferiorly from the hilum on both sides is termed the *pulmonary ligament.*

Pleura

The normal visceral pleura is a thin translucent sheet of mesothelial tissue. It is contiguous with the parietal pleura at the hilum, the parietal pleura being the surface covering of the chest wall. Pleural spaces are filled with a minimal amount of fluid ranging from 1 to 20 mL. The movement of fluid into and out of the pleural space depends on the combined effects of hydrostatic, colloid osmotic, and tissue pressures in the parietal and visceral pleura. The parietal pleura contains lymphatics that drain into the internal mammary artery, periaortic arteries, and diaphragmatic lymph nodes. Pleural fluid is thought to arise primarily from the capillaries lining the parietal pleura. This fluid circulates back across the parietal pleura, where it is cleared by lymphatics. Tracer studies have suggested that the parietal pleura accounts for most fluid movement into and out of the pleural spaces under normal conditions. Visceral pleural capillaries and visceral pleural lymphatics do not normally play a major role in fluid fluxes through the pleural space.

In total, the driving force withdrawing fluid from pleural spaces is greater than the net force moving fluid out of the pleural capillaries and into the pleural spaces. This results in the pleural space remaining relatively dry. Fluid does not normally accumulate in the pleural space unless hydrostatic pressure is elevated in the pulmonary capillary bed or an inflammatory condition of the pleura causes protein leakage into perivascular and pleural spaces, decreasing the oncotic pressure gradient and thereby the major force favoring extraction of fluid from the pleural spaces.

Anatomically, the pleura is made up of mesothelium. Mesothelial cells are characterized by their long microvilli, up to 2 μm in length. These cells contain desmosomal intracellular attachments (macular adherens) and also intermediate filaments in their cytoplasm (cytokeratin). Mesothelial cells have a well-developed endoplasmic reticulum, which suggests that they are metabolically active. Beneath the mesothelial cells is a thin, loose connective tissue structure containing both capillaries and lymphatics. There is also a deeper layer of elastic fibers between the relatively thin visceral pleura and the immediately subjacent alveolar septal tissues. The parietal pleura has a similar architecture, except that the underlying connective tissue layer is substantially thicker and overlies intercostal muscle, fat, and vascular structures.

Lung Lymphatics

Tissue fluids in the lung move centrally toward the hilum. In alveolar tissue, alveolar septal junctions create spaces through which fluid is thought to move until it reaches the walls of an airway or vascular structure in which lymphatic structures are present. These intrapulmonary lymphatics, termed *deep lymphatics,* drain the bronchovascular bundles toward the lung hilum. The superficial pleural lymphatics carry fluid along the pleural surfaces to the point at the hilum where the visceral pleura reflects into the parietal pleura. These superficial lymphatics also follow interlobular septa and thereby interconnect with the deep pulmonary lymphatic system. The deep pulmonary lymphatic system can be clearly identified anatomically beginning at about the level of respiratory bronchioles.

Lymph nodes are abundant in the pulmonary hilum and along the trachea and extrapulmonary bronchi. Lymphatic fluid drains through anastomosing channels that connect these lymph nodes and moves upward along the trachea. The lymphatics on the right side re-enter the systemic circulation through the subclavian vein near its junction with the jugular vein. Pulmonary lymphatics on the left side return to the systemic circulation through the thoracic duct or by directly emptying into the left subclavian vein.

Four major groups of lymph nodes exist in the lung. These include intrapulmonary nodes adjacent to lobar, segmental, and smaller bronchi and small nodes (1 to 3 mm) located in subpleural regions, often at junctions with interlobular septa. Extrapulmonary nodes are situated in the subcarinal region near the bifurcation of the main bronchi. They are also found along the walls of the trachea and main bronchi. The intrapulmonary nodes, which are part of either the pleura or small intrapulmonary airways, are termed *N1 nodes.* Extrapulmonary nodes along the main bronchi may also be termed *N1.* Subcarinal and ipsilateral tracheal nodes are termed *N2,* whereas contralateral hilar, tracheal, or bronchial nodes are termed *N3.*

The lung also can contain aggregates of lymphoid tissue along all levels of large and small airways. This tissue is called *bronchus-associated lymphoid tissue* (*BALT*). BALT contains lymphoid follicles with germinal centers but does not have the fibrous capsule and capsular sinus characteristic of lymph nodes. The question has been raised as to whether BALT occurs normally in humans or rather develops only after stimulation. Its specific role in immune regulation is not yet well defined.

Upper Respiratory Tract

The upper respiratory tract plays a critical role in conditioning air entering the lungs. Most of the air moving through the nasal cavity has turbulent flow characteristics. In addition, air moving downward into the trachea encounters a right-angle turn at the posterior nasopharynx (Fig. 3). Because of these characteristics of nasopharyngeal anatomy and air flow dynamics, most airborne particulate matter and highly reactive gases impact or are absorbed along the mucosal surfaces and so are removed in the upper airways. Aggregates of lymphoid tissue in the posterior pharynx (pharyngeal tonsils) also play a role in clearing the large amounts of airborne material deposited in the nose and other regions of the upper respiratory tract. Most airborne materials deposited in the upper airway tract are moved posteriorly along the nasal mucous coat to the posterior pharynx, where the secretions are eventually swallowed. The upper respiratory tract also plays a role in warming and humidifying the air. This process is continued in the large airways. For gases of low reactivity and particles of 1 μm in size, upper respiratory tract clearance is less efficient. A significant fraction of these airborne pollutants is deposited in the small airways and alveolar regions.

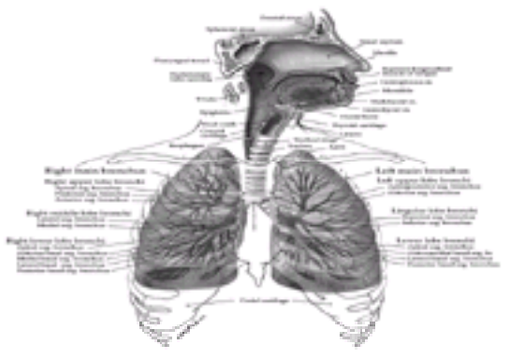

FIG. 3. Anatomy of the upper and lower respiratory tracts.

Trachea and Bronchi

The trachea and main bronchi contain U-shaped rings of hyaline cartilage. The dorsal wall of the trachea is made up of a smooth muscle coat (the trachealis muscle). The main bronchi are fully encircled with cartilage for only four to six generations. Thereafter, the cartilaginous rings of intrapulmonary bronchi contain islands of cartilage that are not contiguous. The number and size of these cartilaginous islands diminish as the airways become smaller and more peripheral. This organizational pattern of cartilage has the advantage of assisting in an effective cough mechanism. The cough is initiated when intrapulmonary pressure is raised against a closed glottis, causing the smaller bronchi to narrow in size. The abrupt opening of the glottis with the onset of cough leads to high pressure and rapid flow through narrow airways, which can facilitate removal of obstructing secretions. Under normal breathing conditions, the intrapulmonary bronchi do not collapse because they are tethered to surrounding alveolar tissue with elastic and cartilaginous interconnections. The incomplete cartilage rings provide support for the intrapulmonary airways

while still permitting them to narrow.

Intrapulmonary bronchi contain a subepithelial elastic layer. Outside this, smooth muscle bundles form a narrow spiral around the airways, with the smooth muscle extending to the level of the respiratory bronchiole. The tight spiral organization of the smooth muscle causes airway narrowing when the smooth muscle contracts. A loose connective tissue layer surrounds the muscular coat, and bronchial glands and cartilage plates lie in this space.

The bronchial epithelium is a stratified epithelium that includes a number of cell types. Predominant among these are secretory cells, which in the large airways are primarily mucus-secreting cells. Ciliated epithelial cells and nonciliated basal cells make up the other two major airway epithelial cell types. The bronchial epithelium also contains neurosecretory cells, termed *Kultschitsky cells* or *K cells.* They are similar to the Kultschitsky cells found in the gastrointestinal tract. These cells, which occur singly or in clusters of four to 10 cells termed *neuroepithelial bodies,* are thought to have a neuroendocrine secretory function. These endocrine cells are found in both bronchi and bronchioles. Kultschitsky cells are most distinctively recognized by their large numbers of fine, dense core granules aggregated in the basal part of the cells. The granules are secreted basally into the peribronchial connective tissue and surrounding smooth muscle. Various products identified with the neuroendocrine cells influence smooth muscle contraction, secretion of mucus, and ciliary beat.

Cilia are the principal means for clearing inhaled toxicants deposited in the mucous lining layers of the nasal passages and airways. Dysfunction in cilia is known to predispose individuals to respiratory infections and bronchiectasis. Ciliated cells are densely distributed in the airways, and the cilia greatly increase their apical surface area. The plasma membrane surface of the cilia accounts for approximately 80% of the plasma membrane surface in airways. Thus, the cilia themselves are a primary filter and/or target for inhaled toxicants that react with cell membranes. In the serous fluid layer in which they beat, the cilia make up 40%–50% of the volume. Each ciliated cell contains approximately 200 cilia; these beat in a biphasic stroke consisting of a fast forward flick and a slower recovery motion. Coordinated strokes by adjacent ciliated cells produce a proximally directed wave of motion in the mucous lining layer. The beating cilia produce mucociliary transport rates that vary from approximately 20 mm/min in the large bronchi to a distinctly slower rate of approximately 1 mm/min in the bronchioles. This gradient in transport rates has been assumed to be the result of a corresponding gradient in ciliary density, with fewer cilia in the small airways and greater numbers in the larger airways, to prevent piling up of mucus on the relatively small surface area of the larger airways. However, direct measurements of the density of ciliated cells and their cilia do not support this hypothesis. The mechanism or mechanisms responsible for the higher transport rate of mucus in larger airways remain to be determined.

Ciliated cells not only mechanically move mucus but also have a secretory function. These epithelial cells contain ion pumps that move sodium away from the bronchial lumen and chloride toward it. This allows water to follow the resulting osmotic gradient and thereby control the thickness and viscosity of the serous fluid layer. Proteins controlling this ion flux are encoded by the cystic fibrosis transmembrane conductance regulator (CFTR) gene. This gene is a highly regulated chloride channel in the apical membrane of ciliated epithelial cells. Mutations in this gene cause cystic fibrosis.

Mucous cells (goblet cells) and mucous glands both produce mucus, but the volume coming from glands is substantially greater than that derived from mucous cells under normal conditions. The mucous glands are compound tubular glands lining the submucosa of the bronchi between cartilage plates. The glands are connected by a secretory tubule to the airway lumen. Plasma cells are often found around these secretory tubules. The plasma cells contain both IgA and IgG, although the primary immunoglobulin in mucus is 11S secretory IgA. Two IgA molecules, both of which are produced by plasma cells, are joined by the J protein. These molecules are then complexed with a secretory piece by epithelial cells lining the secretory tubules, and the complex is transported into the tubular lumen and into the mucous layer.

Examples of airway epithelium and mucous layer architecture from human bronchi are shown in the electron micrographs of Fig. 4. Characteristic profiles of ciliated and goblet cells are illustrated in Fig. 4A. In Fig. 4B, a goblet cell is in the process of secreting into the mucous lining layer. The mucous lining layer in this micrograph has a well-defined electron-dense surface film at the top of the sol layer. Examples of other secretory and basal cells in human airways are shown in Fig. 5. Secretory cells other than goblet cells are typically found in highly clustered groups, as illustrated in Fig. 5A, showing a group of secretory cells containing electron-dense granules. A basal cell with numerous desmosomes (*d*) and keratin filaments (*f*) appears in Fig. 5B. An intermediate cell (*I*) with the same features as a basal cell (i.e., desmosomes, keratin filaments, and a high nucleus-to-cytoplasm ratio) but no basement membrane contact is shown in Fig. 5C. The layered arrangement of cells in human bronchi is principally attributable to the basal cell layer, which accounts for approximately 90% of the cell surfaces making contact with the basement membrane. In the pseudostratified epithelium of human bronchi, the average basement membrane contact of a ciliated, goblet, or other secretory cell is significantly smaller than that of basal cells. The large concentration of keratin filaments and hemidesmosomes found in basal cells suggests that these cells play a primary role in the attachment of columnar cells to the basal lamina.

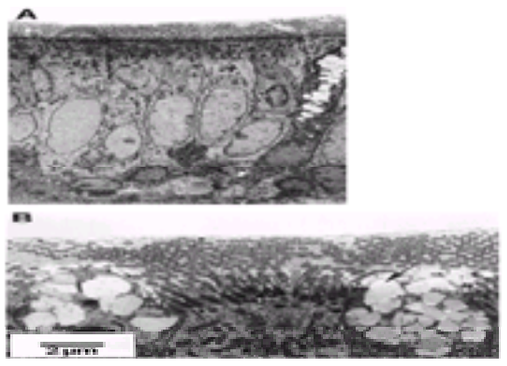

FIG. 4. Electron micrographs of the airway epithelium and mucous lining layers from human bronchi. **A:** Ciliated cells showing mitochondria concentrated in the apical portion of the cell and cilia extending into the mucous lining layer. One goblet cell is shown with its secretory granules distributed across the upper half of the cell. **B:** Two goblet cells in the process of releasing electron-lucent secretory granules from their apical surface into the mucous lining (*arrow*). This micrograph also illustrates a region in which the gel (or electron-dense) layer above the cilia is absent. (Reproduced with permission from Mercer RR, Russell ML, Roggli VL, Crapo JD. *Am J Respir Cell Mol Biol* 1994;10:613–624.)

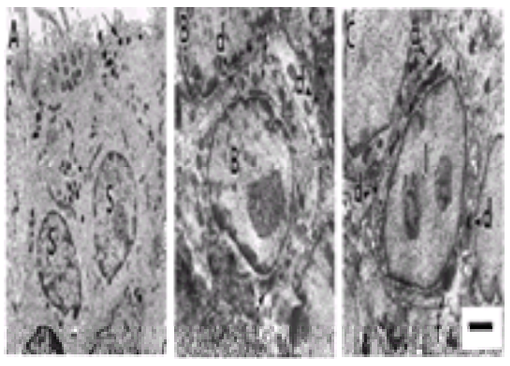

FIG. 5. Electron micrographs of secretory, basal, and intermediate cells from human bronchi. **A:** Secretory cells (*S*) containing electron-dense granules (*arrows*). **B:** Several desmosomes (*d*) and keratin filaments (*f*) of a basal cell (*B*). **C:** An intermediate cell (*I*) with the same features as a basal cell (i.e., desmosomes, keratin filaments, and a high nucleus-to-cytoplasm ratio) but no basement membrane contact. Whereas a prominent nucleolus is typically found in basal cell nuclei, two nucleoli, as illustrated in the intermediate cell in C, were noted only in intermediate cells. *Bar* at the bottom right represents 2 µm. (Reproduced with permission from Mercer RR, Russell ML, Roggli VL, Crapo JD. *Am J Respir Cell Mol Biol* 1994;10:613–624.)

Mucous Lining Layers

It has long been known that the lung clears or removes inhaled particulate matter by means of a mucociliary escalator mechanism. The mucous lining of the lung airways is composed of at least two physically and morphologically distinct layers: an underlying serous layer, in which the cilia beat (sol layer), is blanketed by a viscous layer (gel layer). Whether a continuous gel layer exists throughout the airways is a matter of debate. In general, studies focusing on the nasal epithelium and upper airways have found a continuous blanket, whereas studies focusing on more distal airways and bronchioles have not. More recent studies have demonstrated

that the mucous lining layer of the airways contains a surface-active film at the air-fluid interface in addition to the two layers originally described.

The bronchial epithelium plays a critical role in both producing and moving mucus out of the lung. The rate of movement of mucus is slowest in the small airways and fastest in the large bronchi and trachea. The normal adult produces substantial quantities of lung secretions daily, virtually all of which are transported by ciliary clearance to the posterior pharynx, where they are unconsciously swallowed. The outer layer of the mucous coat is a highly viscous gel containing glycoproteins with molecular weights of several million daltons. In addition to mucous glycoproteins, the airways secretions contain immunoglobulins (primarily IgA), proteinase inhibitors, and antibacterial proteins (lysozyme and lactoferrin). Sixty to eighty percent of the cells in the airway epithelium are ciliated cells; the remaining cells are either basal or secretory cells.

Methods for preserving the mucous lining layer have included direct visual observation on dissected airway specimens, fixation by immersion, vascular perfusion fixation, quick freezing, and osmium tetroxide vapor fixation. Of these different methods of preservation, vascular perfusion fixation is the most generally applicable, as mechanical disruption from immersion or airway instillation of fixative is eliminated. Because the extensive capillary bed of the lungs is used to place the fixative in the immediate vicinity of the fluid lining layers, this method has been shown to improve significantly the preservation of mucous lining layers in the airways and the surface-active film of the alveolar region. Figure 6 demonstrates the changes in the mucous lining layer along the respiratory tract of a lung fixed by a combination of osmium vapor and vascular perfusion fixation. The gel layer is present in the airways from the trachea to the bronchi. In the distal and terminal bronchioles, the gel layer is attenuated and not always present. Tubular myelin and other surfactant debris are commonly found in both the gel layer of the upper airways (trachea to bronchi) and near the surface of the sol layer of the more distal airways, where the gel layer may be absent.

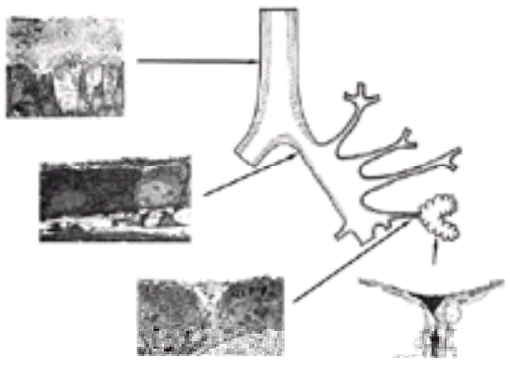

FIG. 6. Changes in the mucous lining layer along one airway path from trachea to alveolar surface. The thickness decreases from 10 to 20 μm in the trachea to 0.1 μm on the alveolar surface.

Bronchioles

Bronchioles are defined by the absence of cartilaginous structures in the bronchial wall. Smooth muscle continues along bronchiolar walls and reaches the terminal bronchioles. The bronchial smooth muscle spirals around the airways and does not form a continuous coat in the bronchial wall. Thus, there is no true muscular mucosa in bronchi. The connective tissue surrounding bronchial walls is termed the *lamina propria.* The lamina propria includes vascular structures, lymphatics, loose fibrous tissue, and modest numbers of inflammatory cells. Adipose tissue may also be found in the walls of bronchi, particularly in older individuals.

The airway epithelium of bronchioles is simple columnar and is made up of two primary types of cells, ciliated cells and nonciliated secretory cells. The latter cell type commonly is termed a *Clara cell.* Unlike the arrangement in the bronchial epithelium, ciliated cells and Clara cells in the bronchioles have extensive contact with both the luminal and basement membrane surfaces. Mucus-secreting cells are not found in bronchioles under normal conditions. Chronic exposure to tobacco smoke can cause proliferation of mucous cells, which are then found in bronchioles and likely account for the higher density of viscous small-airway secretions in smokers. The production of mucus in small airways in response to chronic irritation is an adaptive response that would have the effect of absorbing or reacting with inhaled pollutants, thereby providing better protection of the underlying bronchiolar epithelium. The function of Clara cells is still being defined. These cells are thought to be involved in production of the thin serous fluid that normally lines small airways, in the detoxification of chemicals depositing in small airways, and in regulating the immune or inflammatory responses in airways. Their products include surfactant apoproteins A, B, and D, antileukoproteinase, and a unique 10-kD protein that has been found to bind to environmental pollutants. Clara cells are also thought to be a stem cell involved in the regeneration or repair of epithelial injury in bronchioles.

The number of cells per unit area of epithelial basement membrane for human airways is shown in Fig. 7. The cells populating the airway epithelium change significantly as the airways narrow and a transition occurs from a pseudostratified epithelium (with an extensive population of basal and goblet cells) to a simple columnar epithelium in bronchioles. The pseudostratified arrangement of cells in the epithelium of human bronchi creates a total epithelial cell density almost twice that of the more distal bronchioles. In addition, the cell composition changes, from larger numbers of goblet and basal cells in bronchi to larger numbers of Clara cells in bronchioles.

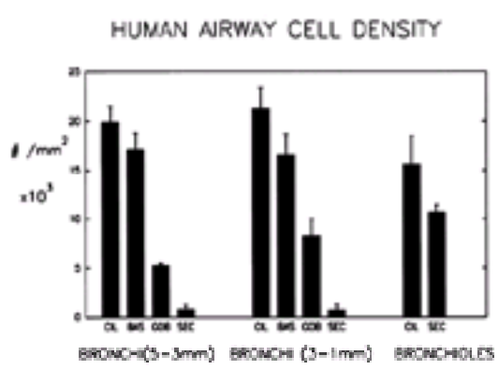

FIG. 7. The number of cells per unit area of epithelial basement membrane for human airways. Human airway cell populations change dramatically from the pseudostratified epithelium of bronchi, which have a large proportion of basal (*bas*) and goblet (*gob*) cells, to the simple columnar epithelium of bronchioles, composed primarily of ciliated (*cil*) and secretory (*sec*) cells.

Bronchial Branching

A terminal bronchiole represents, on average, 16 generations or branchings from the trachea. Most of the path lengths are shorter and can consist of as few as six to eight generations. The longest path length is the axial path to the posterior caudal tip of the right lower lobe, with 20 to 25 generations. Human lung airways are characterized by an asymmetric, dichotomous branching pattern in which the two (or three) daughter branches at most junctions are not of the same diameter and do not form a consistent, symmetric branching angle with the parent airway (Fig. 8). Pulmonary arteries follow the airways, whereas pulmonary veins lie in the boundaries between gas exchange units. This position allows the veins to accept blood from multiple adjacent gas exchange units (Fig. 9). An important result of the vascular supply following the airways is that each segmental bronchus with its pulmonary segment has its own vascular supply. Thus, a pulmonary segment can be resected as an anatomically discrete subdivision. Resection of one or more pulmonary segments does not compromise the blood flow to adjacent lung segments.

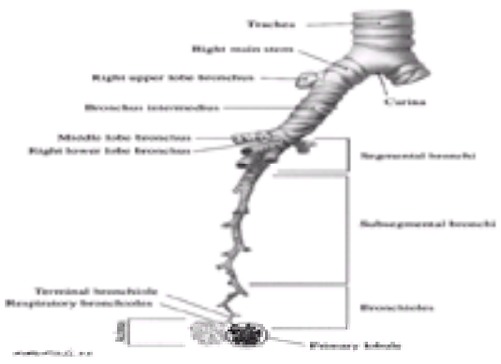

FIG. 8. Airway anatomy of the human tracheobronchial tree. This figure illustrates typical branching along one of the longer paths to a right lower lobe segment. In the normal human lung, there are approximately five to 15 branch points from a segmental bronchus to a terminal bronchiole. In a completely binary, symmetric branching system, 14 to 15 branch points from the trachea would be required to create the 40,000 terminal bronchioles in a human lung. Because many paths are shorter, there are also path lengths with greater than 15 branch points from the trachea. Segmental bronchi are characterized by the presence of cartilaginous plates in their walls, whereas bronchioles contain smooth muscle in their walls but no cartilage. *See color plate 3.*

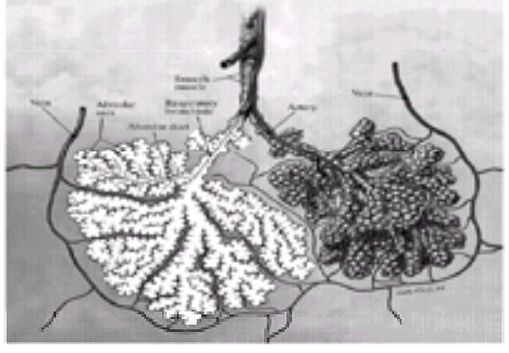

FIG. 9. Vascular supply and branching anatomy of the human acinus. Respiratory bronchioles typically show up to three branch points, whereas alveolar ducts have up to nine branches. Pulmonary arterioles travel with the respiratory bronchioles and alveolar ducts into the center of the acinus. The capillary network radiates outward from the arterioles to form anastomoses with the venous system, for which the major channels lie on the surface of the acinus.

Acini

All the gas exchange structures distal to a single terminal bronchiole represent an acinus. Thus, an acinus is a parenchymal lung unit in which all structures participate in gas exchange. The human lung fairly consistently has three generations of respiratory bronchioles that are followed by a number of divisions of alveolar ducts. Rats have from three to 13 divisions of alveolar ducts, and the human lung has a similar alveolar ductal architecture, with approximately nine generations of alveolar ducts.

A typical normal human lung contains approximately 30,000 to 40,000 terminal bronchioles and, by definition, the same number of acini. Each acinus is approximately 6 mm in diameter and has a volume of approximately 0.50 mm^3. Acini vary substantially in size and typically contain 10,000 to 12,000 alveoli (Table 1).

Volumes (gas)	
Upper respiratory tract	20 cm^3
Airways	
Bronchi	88 cm^3
Bronchioles	23 cm^3
Alveolar region	5018 cm^3
Numbers	
Terminal bronchioles	30–40,000
Acini	30–40,000
Alveoli	500×10^6
Cells (alveolar region)	20×10^9
Epithelial cells	
Upper respiratory tract	560×10^6
Bronchi	7200×10^6
Bronchioles	3300×10^6
Alveolar region	$52,000 \times 10^6$
Surface areas	
Upper respiratory tract	104 cm^2
Bronchi	1300 cm^2
Bronchioles	1100 cm^2
Alveolar epithelium	1,022,000 cm^2
Alveolar capillaries	720,000 cm^2
One alveolus	121,000 μm^2

TABLE 1. *Structural characteristicsof the normal human lung*

In older literature, divisions of the lung into primary and secondary lobules is described. The primary lobule refers to all respiratory tissue distal to a final respiratory bronchiole, and thus contains only alveolar ducts and alveolar sacs. Some animal species, such as the rat, have only rudimentary respiratory bronchioles, and in this situation a primary lobule is a useful concept to define aspects of ventilation and gas distribution in specific lung units. In the human, the primary lobule is not a very useful concept, because the acinus divides into multiple respiratory bronchioles and a high degree of collateral ventilation occurs between these subunits. Secondary lobules are lung units delineated by connective tissue septa; they are about 1 cm^3 in size. They form structures that are clearly visible on the pleural or cut surface of the lung. The secondary lobule is supplied by a bronchiole with a diameter of about 1 mm that divides into five to 12 terminal bronchioles, and thus into a similar number of acini.

Alveoli

The gas exchange region of the lung is made up of approximately 500,000,000 alveoli having a total surface area of approximately 100 m^2. These alveoli are highly vascularized, with the alveolar septal capillary bed having a vascular surface area of approximately 70 m^2. The normal alveolar septa are approximately 10 µm thick. The alveolar air-capillary barrier is made up of variable thin and thick segments. The thin segment is composed of an alveolar epithelium, a fused epithelial and endothelial basement membrane, and a capillary endothelium. Because both type I epithelial cells and capillary endothelial cells are highly attenuated, the combined thickness of this air-blood barrier can be as little as 0.5 µm. The alveolar walls contain connective tissue, primarily collagen, which weaves through the capillary mesh. This and other cellular and acellular components of the interstitium create the thicker portions of the alveolar septal walls. Three-dimensional reconstructions of alveolar septal walls from rats have demonstrated that the alveolar entrance rings are particularly rich in both collagen and elastin. Alveolar mouths form the boundary of alveolar ducts (Fig. 10), and their entrance rings are linked together into a connective tissue structure that spirals down alveolar ducts, providing a connection between the openings or mouths of individual alveoli. Elastic tissue is most prominent along the alveolar duct openings. Collagen strands or fibers interlace across the alveolar walls and connect adjacent alveoli along a single alveolar duct as well as connect alveoli between two adjacent alveolar ducts.

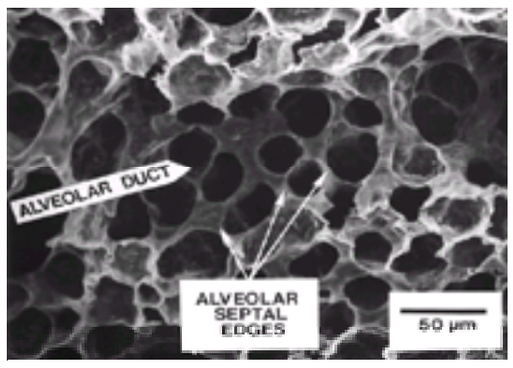

FIG. 10. Scanning electron micrograph of the alveolar duct region from a rat lung. The alveolar duct walls are made up of alveolar mouth openings surrounded by flattened alveolar septal edges forming the entrance rings around the alveolar openings. The primary collagen and elastin network lining the alveolar ducts is under tension in this fully expanded lung.

Based on morphologic evidence of collagen and elastin distributions and the effects of surfactant depletion on the structure of alveoli and alveolar ducts, Wilson and Bachofen developed a model of lung micromechanics comparing the contributions of alveoli and alveolar ducts to lung elasticity. This model suggests that elastic components abundant in the walls of alveolar ducts are primarily responsible for the function of alveolar ducts, whereas surface tension effects are primarily responsible for the tension in alveoli. Three-dimensional reconstructions of alveoli and alveolar ducts as transpulmonary pressure is raised from 0 to 30 cm H_2O demonstrate that at low lung volumes alveoli make up 80% of the parenchymal lung volume and dominate the gas volume changes. As pulmonary pressure increases, the contributions to changes in volume by both alveoli and alveolar ducts converge (Fig. 11). This suggests that at high lung volumes connective tissue elements, both between and within the alveolar ducts, come under tension and act to equalize further changes in volume between alveoli and alveolar ducts. This both limits overextension of alveoli and enhances lung stability by distributing stress among all contributing units of an alveolar duct interconnected by elastic and collagenous structures.

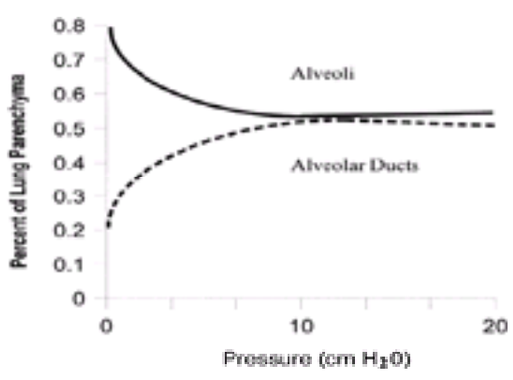

FIG. 11. Volume ratios of alveoli and alveolar ducts as a function of the transpulmonary extending pressure. These pressure-volume relationships were determined using morphometric point-counting procedures to estimate the relative contributions of alveoli and alveolar ducts during lung expansion. At low lung volumes, alveoli make up the majority (80%) of the lung parenchyma. As lung volume increases, alveolar ducts initially show the greatest change in volume, and they increase from 20% to almost 50% of the volume of the lung parenchyma. At about 10 cm of water pressure, the two curves converge, showing that changes in volume of these two compartments are proportionally similar from intermediate to high lung volumes or pressures. The convergence of these two curves at higher pressures suggests that the connective tissue elements within and between the alveolar ducts are under tension and help stabilize the lung by equally distributing further increases in lung volume.

The alveolar epithelium is covered primarily by type I and type II epithelial cells. The characteristics of the alveolar septal wall in normal human lung is shown in Fig. 12. Type I epithelial cells are thin squamous epithelial cells having an average surface area of approximately 7000 μm^2 (Table 2). Their highly attenuated cytoplasm has an average thickness of only 0.36 µm. The alveolar epithelium contains approximately equal numbers of type I and type II cells. The type II cell is cuboidal in shape and is commonly found at junctions of alveolar septa and along the alveolar surfaces surrounding intrapulmonary vascular and airway structures. Alveolar type II epithelial cells have conspicuous mitochondria and an extensive Golgi apparatus, indicating a high synthetic role for these cells. They are characterized chiefly by the presence of large numbers of small microvilli on the apical surface (Fig. 13) and of unique secretory granules, known as *lamellar bodies.* Each type II cell contains 100 to 200 lamellar bodies. These are composed of tightly packed whirls of surfactant, which give these bodies their lamellar appearance on cross-section. The continued secretion of lamellar contents replenishes surfactant at the alveolar air-liquid interface. Alveolar type II cells are connected to adjacent type I cells with a relatively impermeable tight junction. These junctions contain three to five junctional strands on electron microscopy of freeze-fracture replicas. Type II cells have four known primary functions: (1) They secrete surfactant. (2) They act as an ion pump, moving fluid from the alveolar spaces into the subjacent interstitial spaces. Type II cells move sodium from the alveolar lumen to the interstitium via an apical sodium channel regulated by cyclic AMP. Water passively follows the sodium movement. (3) They repair alveolar injury. These cells are the progenitor cells for alveolar epithelium and can regenerate alveolar type I epithelium. (4) They control alveolar inflammation. Type II alveolar epithelial cells secrete antiinflammatory cytokines. They also secrete antioxidants, including the extracellular superoxide dismutase enzyme. Type II cells have been shown to secrete nitric oxide by the activation of nitric oxide synthase. The secretion of both antioxidant enzymes and nitric oxide by type II cells is induced by the proinflammatory cytokines interferon-g and tumor necrosis factor-a, suggesting a role for these cells in the control of inflammatory functions.

FIG. 12. Transmission electron micrograph showing the alveolar septum from a normal human lung. An efficient exchange of O_2 and CO_2 between inspired air and red blood cells is promoted by the large gas exchange surface with minimal distances (*arrow*) across the epithelial, interstitial, and endothelial components of the alveolar septa. *I,* type I alveolar epithelial cell; *II*, type II alveolar epithelial cell; *c*, capillary endothelial cell. Bar = 1 µm. (Reproduced with permission from Crapo et al. *Am Rev Respir Dis* 1982; 125:740–745.)

	No. in both lungs	Average cell surface area	Average cell volume
Alveolar epithelial cells			
Type I	19×10^9	6900 μm^2	2400 μm^3
Type II	32×10^9	250 μm^2	800 μm^3
Capillary endothelial cells	73×10^9	1000 μm^2	600 μm^3

TABLE 2. *Characteristics of alveolar septal cells in normal human lung*

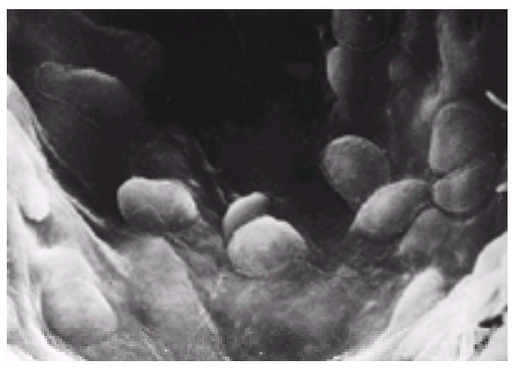

FIG. 13. Scanning electron micrograph of the alveolar septal surface showing several type II alveolar epithelial cells surrounded by type I epithelium. Type II cells are identified by their distinctive microvilli. In this micrograph, the overlying surfactant layer was removed by fixatives.

The shape of alveoli *in vivo* approximates a smooth partial circle. Smoothing of the folds on the alveolar surface is accomplished by folding of alveolar septal membranes into the capillaries and by filling of tissue depressions with alveolar lining fluid containing surfactant at its surface. Changes in alveolar size are thought to occur primarily by folding and unfolding of the alveolar pleats, and this process minimizes stress tension on alveolar septal cells.

Stability of alveoli with their small radius of curvature requires a highly surface-active material at the air-liquid interface. La Place's Law describes the relationship of the alveolar pressure (P) required to keep an alveolus open with alveolar surface tension (t) and radius of curvature (r):

$$P = 2\ \tau/r$$

According to this principle, as the radius falls during exhalation, the surface tension must also fall, or the required pressure to maintain open alveoli would rise. As alveolar pressure falls during exhalation, this scenario would result in alveolar collapse with each breath. Surfactant prevents alveolar collapse. As the radius of alveoli decreases, the surfactant phospholipids are packed more tightly and surface tension is reduced. Thus, alveolar surface tension and the radius of alveoli *in vivo* fall synchronously, and alveolar stability is maintained.

Surfactant is a complex mixture of lipids and proteins synthesized by alveolar type II epithelial cells. The primary lipids include saturated phosphatidylcholine and phosphatidylglycerol. Surfactant also contains a number of proteins, three of them identified as surfactant proteins A, B, and C. Each of these facilitates the spreading and recycling of surfactant. A fourth surfactant protein, SP-D, is produced and secreted by type II cells but is not known to be a part of surfactant. It is thought to play a role in antibacterial defense.

The proportion of the alveolar septum of the human lung that is interstitium is substantially greater than in many other species, as shown in Fig. 14. The alveolar interstitium increases as a function of age in both rodents and humans. The high amount of interstitium in the human lung likely reflects the substantially longer life span of the human and exposure to environmental air pollutants. The lungs of children have substantially less interstitial connective tissue and interstitial matrix elements than do adult human lungs (Fig. 14.) The alveolar macrophages on the alveolar surfaces in a normal nonsmoking human make up only about 3% of total alveolar cells. The number of alveolar macrophages is substantially elevated in smokers and can be 10% of the alveolar septal cells. The normal human alveolus has a diameter of about 225 µm and a surface area of 120,000 μm^2; it is made up of 148 endothelial cells, 106 interstitial cells, and 107 epithelial cells (types I and II) and contains 12 alveolar macrophages. The comparative cellular anatomy of an average alveolus from the mouse to the human is shown in Fig. 15. The relative cell composition of the alveolar septa is similar across species. The larger alveoli of larger species are generally contain more cells of the same average size rather than larger cells. The differences in cellular size and shape between cells of different function are dramatic, as shown in Table 2, with the alveolar type I epithelial cell being four times larger than a capillary endothelial cell and having a sixfold greater surface area. Thus, cellular function, not species or organ size, determines characteristics of each class of cell.

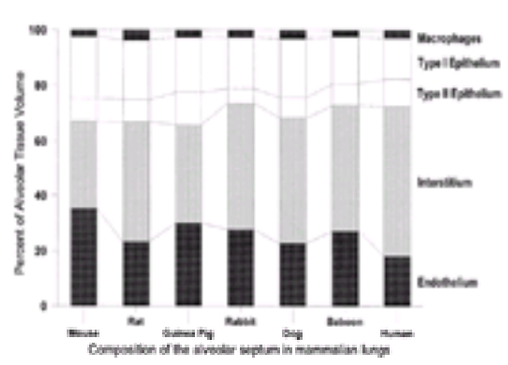

FIG. 14. Composition of the tissues of the alveolar region in mammalian lungs. The ratios of endothelium, interstitium, epithelium, and alveolar macrophages are shown. Note that the human lung has proportionally more interstitium than do the other species illustrated. This is likely related to the extensive environmental pollutants to which human lungs are exposed, leading to microscopic fibrotic interstitial reactions.

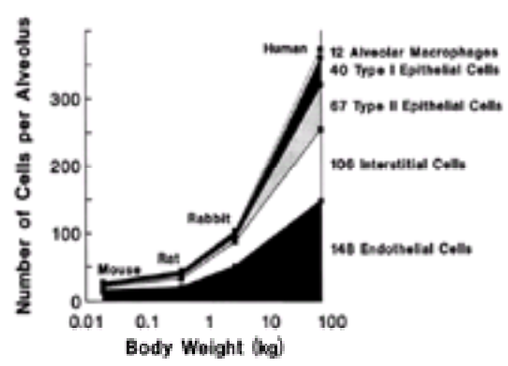

FIG. 15. The cellular makeup of alveoli in mouse, rat, rabbit, and human. Numbers along the right vertical axis correspond to the data for human lungs. The typical human alveolus is made up of almost 400 cells.

Pulmonary Circulation

The main pulmonary artery and the next several generations of pulmonary arteries with diameters greater than 0.5 cm are called *elastic arteries.* The walls of these vessels contain multiple concentric elastic lamina as well as smooth muscle and collagen layers. These vessels enter the lung at the hilum and lie adjacent to and branch with each of the bronchi. Arteries with diameters ranging from 0.1 to 0.5 cm are termed *muscular pulmonary arteries.* These vessels contain circular smooth muscle located between an internal and external elastic lamina. Muscular pulmonary arteries begin at the level of smaller bronchi, have the same approximate diameter as the bronchi, and travel and branch with the bronchi. These arteries continue to follow bronchioles and respiratory bronchioles and enter into the center of the acinus, branching with alveolar ducts. Their size decreases as they move peripherally, and by the time they reach the acinus they are substantially smaller than the alveolar ducts.

Pulmonary veins travel in the peripheral walls of acini and along the connective tissue planes of sublobular and lobular septa. Thus, blood enters the acinus alongside the airways and then moves outward across the acinus to the periphery, where pulmonary veins collect blood from multiple adjacent acini. Each vein drains a much larger zone than is supplied by a single small muscular pulmonary artery.

A separate circulation and nutrient supply to the bronchi and the walls of their adjacent pulmonary arteries arises from the systemic circulation via bronchial arteries. These arteries come directly from the aorta or from the internal mammary, subclavian, or intercostal arteries. This systemic arterial supply to the bronchi travels as small vessels in the walls of the bronchi and extends to the level of the bronchioles. Bronchial veins exist only in the most central bronchi and empty into the azygos and hemiazygos veins. The remainder of the bronchial arterial circulation drains into pulmonary veins and moves by that circuit to the left atrium.

The relative surface areas and volumes of different components of the pulmonary vascular bed are given in Table 3. The volume of blood in the lung is normally approximately equally distributed between the arterial system, capillary network, and venous system. Ninety-six percent of the pulmonary vascular surface area is in the capillary bed. The capillary network has the capacity for substantial expansion if all capillary beds are recruited and functional, as under conditions of exercise. When the capillary network is fully recruited, the proportion of the pulmonary blood volume in the capillary bed can increase from 30% to 50%–60%.

Vessel	Surface area	Volume
Arteries > 500 μm	0.4 m^2	68 cm^3
Arterioles 13–500 μm	1.0 m^2	18 cm^3
Capillaries	70 m^2	60–200 cm^3
Venules 13–500 μm	1.2 m^2	13 cm^3
Veins > 500 μm	0.1 m^2	58 cm^3

TABLE 3. *Human pulmonary vascular system*

The pulmonary vascular system is a low-pressure circulation, and the pulmonary arteries are substantially more distensible than are systemic arteries. Pulmonary veins are also highly distensible at relatively low transmural pressures. Distensibility of the pulmonary vascular bed makes it possible for the blood volume to change readily in response to vasomotor stimuli or hydrostatic/orthostatic conditions. The pulmonary vascular bed acts as a capacitance reservoir for the left side of the heart. Sufficient blood is contained in the elastic reservoir to support two to three heartbeats. Pulmonary blood volume can increase 30% during a change of position from standing to lying. Up to half of the pulmonary blood volume can be forced out of the lungs by Valsalva's maneuver (increasing intrathoracic pressure against a closed glottis).

The vertical height of a normal human lung is about 25 cm, with the hilum situated about one-third the distance from the top of the lungs (Fig. 2). Pulmonary capillary pressure varies from the top to the bottom of the lung. With an average pulmonary arterial pressure of 20 cm H_2O, the pulmonary arterial pressure from the top to the bottom of the lung varies from 12 cm H_2O to 36 cm H_2O. Pulmonary venous pressure varies from approximately 0 at the top of the lung to 24 cm H_2O at the bottom, with a mean pressure of 6 to 8 cm H_2O at the hilum. Thus, with a highly distensible pulmonary vascular bed, pulmonary blood volume is preferentially distributed toward the dependent portions of the lung. The effects of gravity and distensibility are balanced by vasomotor tone regulating blood flow across the pulmonary vascular bed. Because muscular arteries extend into the acinus, local vasomotor control can influence distribution of blood flow to each lung unit and thereby determine the ventilation-perfusion ratio of each of these units.

Blood flow in the pulmonary capillaries is pulsatile except under conditions of severe pulmonary hypertension. Blood flow in the capillary network has been estimated to have a velocity averaging about 1000 μm/sec.

The pulmonary capillary bed is made up of an extensive network of interconnected small tubules. There has been substantial debate regarding whether pulmonary capillary blood flow is best modeled as tubular flow or sheet flow. Anatomically, as illustrated in Fig. 16, the capillary bed is a combination of the two. The capillary network crosses multiple alveoli as blood flows from the central arteriole in an acinus to the venules at the acinar margins. This creates a fairly long path length over which gas exchange can occur. The average transit time of a red cell through the pulmonary capillary bed has been estimated to be 0.1 to 0.5 sec. Under normal resting conditions, red blood cells are fully saturated with oxygen during the first third of their transit through the pulmonary capillary bed. The lung has a sufficient gas exchange reserve that even heavy exercise does not produce arterial desaturation, and in fact increased blood flow throughout the entire capillary bed generally results in an increased arterial partial pressure of oxygen (PaO_2) under conditions of exercise. Red cells are likely to leave the capillary bed not fully saturated with oxygen only when the inspired oxygen tension is low or when disease prevents adequate ventilation of individual gas exchange units. One of the important ventilation-perfusion regulatory pathways in the lung is hypoxic pulmonary vasoconstriction. Relative hypoxemia in small gas exchange units leads to constriction of the corresponding muscular pulmonary arteries, which maintains balanced ventilation-perfusion ratios. The pulmonary venous system also contains smooth muscle and has been shown to be equally sensitive to vasoactive mediators, thus regulating venous pooling in the lung.

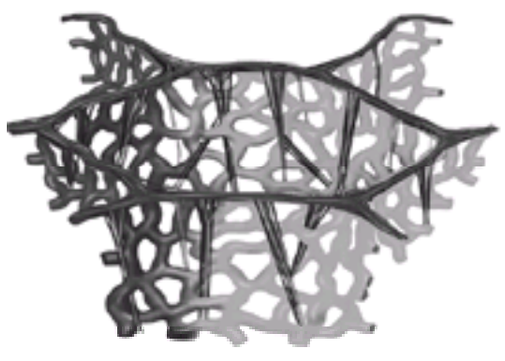

FIG. 16. Schematic illustration of the pulmonary capillary bed showing the high density of short, highly interconnected capillary segments in the alveolar walls. The distribution of collagen and elastin fibers in the lung parenchyma is also shown. The drawing illustrates the high concentrations of connective tissue fibers along the alveolar duct septal edges that form the alveolar duct walls. Elastin fibers tend to be located over the major collagen bundles lining the alveolar entrance rings. Thus, the alveolar entrance rings are rich in both elastin and collagen. The alveolar walls contain thin collagen strands that interconnect adjacent alveoli by weaving between

capillary segments.

The pulmonary capillary bed acts as an efficient filter of the systemic vascular system. Approximately three quarters of the blood volume of the body is contained in the systemic venous system. This blood passes through the pulmonary capillary bed on each circulation, and any microemboli forming in the systemic venous system will therefore be filtered by the lung. These microemboli produce no dysfunctional or pathologic effects in the lung and are rapidly cleared by lytic pathways or the pulmonary reticuloendothelial system. The physiologic effects of resection of one lung clearly demonstrate that up to half the pulmonary vascular system can be obstructed or removed without serious change in the hemodynamics of the remaining pulmonary vascular bed. This design of the pulmonary vascular system allows it to be an efficient filter of the body's blood supply.

Capillary endothelial cells form a continuous lining of alveolar capillaries. These cells are connected by tight junctions that, however, are more permeable to macromolecules than are the junctions between airway epithelial cells. Endothelial cell junctions contain one to three junctional strands, in which discontinuities exist. In comparison, airway epithelial cell junctions have three to five junctional strands. In addition, because alveolar type I epithelial cells are substantially larger (Table 2) and cover a much greater surface area per cell than do capillary endothelial cells, the total junctional area over which fluid and macromolecular transport can occur is substantially lower at the alveolar epithelium than it is along the pulmonary capillary endothelium. The impermeability of the alveolar epithelium to fluid and electrolyte movement explains why pulmonary vascular congestion (failure of the left side of the heart) leads to pulmonary interstitial edema substantially sooner than intra-alveolar pulmonary edema occurs.

The pulmonary capillary epithelium has a number of metabolic functions. Because it is the only capillary bed that receives the entire blood flow of the body during each circulation, the pulmonary capillary bed is in a critical position to regulate reactive bloodborne materials. Pulmonary endothelium plays a role in either activating or degrading a number of vasoactive mediators. Some substances are metabolized by enzymes on the capillary endothelial cell surface, whereas others require uptake into the endothelial cells. For example, angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II on the surface of pulmonary capillaries, producing a vasoconstrictive molecule of substantially greater physiologic potency. The same enzyme, ACE, inactivates bradykinin. Bradykinin is a highly potent, locally released vasodilator, and its inactivation in the lung prevents it from causing systemic hypotension. Other mediators, such as serotonin and norepinephrine, are metabolized by endothelial cells but require uptake into the cellular cytoplasm. Pulmonary capillary endothelium also synthesizes prostacyclin and tissue plasminogen activator. These cells are a rich source of thrombomodulin, a cell surface protein with anticoagulant properties. The endothelium secretes nitric oxide, a local vasorelaxant, and secretes endothelins, which are potent vasoconstrictor peptides. Vascular endothelium metabolizes adenonucleotides and both prostaglandins E_2 and F_{2a}. Vascular endothelium also plays a role in regulating phagocytic cell function via the expression of cell surface adhesion molecules. The adhesion molecules interact with receptors on phagocytic cells and regulate the movement of phagocytic cells through the vascular bed as well as their migration into subjacent tissues.

Alveolar Macrophages

Alveolar macrophages are the principal means by which the lungs process the normal burden of inhaled particles. Alveolar macrophages are also secretory and regulatory cells and prevent injurious actions of other lung cells. For instance, it has recently been demonstrated that macrophage engulfment of neutrophils significantly contributes to the resolution of pulmonary inflammation. Once phagocytosis of the ingested particle has been accomplished by alveolar macrophages, the cell and/or toxicant is eliminated by internal digestion or mucociliary transport of the macrophage to the oropharynx. In an additional mechanism, particle-laden macrophages have been shown to traverse the interstitial spaces to reach the mediastinal lymph nodes. Figure 17 demonstrates an airway macrophage beneath the electron-dense lining layer of a rat bronchiole. Airway macrophages are approximately five times more numerous per unit of airway surface area than they are per unit of alveolar surface (Table 4). However, because of the large surface area of the alveolar gas exchange region, alveolar macrophages account for approximately 99% of total air space macrophages.

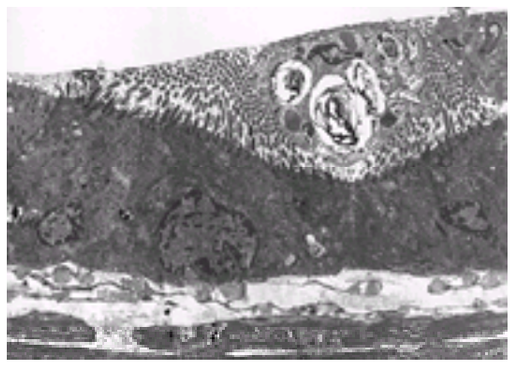

FIG. 17. Electron micrograph of an airway macrophage beneath the electron-dense lining layer of a rat bronchiole.

Region	Density on surface (No./cm^2)	Total No. (millions per both lungs)
Airways	25,000 ± 6400	62 ± 8
Alveoli	5861 ± 1860	5990 ± 1900

TABLE 4. *Macrophage distribution and number*

Alveolar macrophages are unique mononuclear phagocytes. These cells contain numerous lysosomes in their cytoplasm, consume oxygen and secrete neutral proteases at a high rate, and are more active than other tissue macrophages. Although these cells are individually active, they are poor antigen-presenting cells and poor accessory cells. The primary antigen-presenting cell in the lung is a dendritic cell. The primary role of alveolar macrophages is thought to be in defense of alveoli against dust and pathogens. They appear to be able to carry out this role without activating excessive inflammatory processes in the alveolar septa. The vast majority of antigens reaching the small airways and alveolar septa are processed without activation of lymphocyte-based immune recognition and neutrophils. The lung contains very few lymphocytes in alveolar septa.

Alveolar macrophages arise in bone marrow. There is also an interstitial macrophage pool in the lung, and alveolar macrophages proliferate on the alveolar surfaces. Regeneration of the alveolar macrophage population has been shown to occur in all three of these sites.

Mast Cells

Mast cells are a normal, albeit small, component of lung cells. They are identified by the presence of numerous membrane-bound intracytoplasmic granules with variable intragranular inclusions. These granules are 0.6 to 0.8 µm in diameter. The cells also have long filiform microvilli on the surface. Mast cells have high-affinity IgE membrane-bound receptors that are specific for inhaled allergens. On activation, these cells release allergic mediators, such as histamine, prostaglandin D_2 (PGD_2) and leukotriene C_4 (LTC_4). Mast cells also produce neutral proteases (tryptase and chymase), lysosomal enzymes, myeloperoxidase, eosinophil chemotactic factor of anaphylaxis, high-molecular-weight neutrophil chemotactic factor, and heparin. Although the specific role of mast cells is unclear, they clearly play a role in airways secretory and bronchoconstrictor responses of hypersensitivity reactions such as anaphylaxis, hay fever, and asthma. Increased numbers of mast cells are found in

pulmonary edema and pulmonary fibrosis.

Neutrophils

Neutrophils are terminally differentiated cells that are distributed in the bone marrow, blood, and tissue compartments. In the normal lung, neutrophils are almost exclusively found within the circulation, and almost half of the total body circulating neutrophils may be marginated along the walls of pulmonary capillaries and venules. Neutrophils are found in significant numbers in the pulmonary tissue spaces only in cases of pulmonary inflammation, such as in the adult respiratory distress syndrome (ARDS). Migration into tissue spaces occurs in response to chemotactic agents produced by invading microorganisms, toxin-derived products, and complement-activated chemoattractants, such as C5. Following phagocytosis, invading organisms are killed within neutrophils by an oxidant-mediated mechanism, by microbicidal proteins contained in neutrophil granules, or both. In the oxidant-mediated process, a membrane-bound NADPH oxidase generates O_2^-, which can enzymatically or spontaneously dismute to generate H_2O_2. These species react to form hydroxyl radical, another potent oxidant. These agents individually or in combination kill bacteria. Neutrophil granules contain a host of bactericidal agents, including myeloperoxidase, cathepsin G, acid hydrolases, elastase, and lysozyme.

Eosinophils

Eosinophils are not normally present in lung tissue spaces. However, the presence of significant numbers of these cells and their synthesis products has been shown to occur in allergically induced lung inflammation, and they are believed to play a major role in the development of reactive airways disease.

Eosinophils develop in the bone marrow and are transported via the circulation to the tissue spaces of the gastrointestinal and respiratory tracts. The host defense function is less well defined for eosinophils than for neutrophils. Eosinophils may be capable of some bactericidal activity. However, the principal function of these cells is likely their antiparasitic activity. Eosinophils synthesize and secrete potent inflammatory mediators, such as platelet-activating factor and LTC_4.

Innervation of the Lung

Motor neurons in the pulmonary nervous system influence airway tone, pulmonary blood flow, and secretion of mucus. Sensory neurons modulate the cough reflex, the Hering-Breuer reflex, and responses to irritant dusts and gases, and they may respond to interstitial fluid pressure. In addition, a variety of neural peptides released by afferent nerves may modulate airway tone, vascular tone, and airway secretions.

The primary motor and sensory innervation of the lung comes from the vagus nerve (cranial nerve X). In addition, sympathetic fibers arising from the second to the fourth thoracic sympathetic ganglia innervate the lung. Fibers from both the vagus nerve and the thoracic sympathetic plexus comingle as they enter the hilum of the lung and then divide into plexuses that follow bronchi, arteries, and veins. Along the airways, the nerve plexuses lie both internally and externally to the cartilage, with the larger external plexus containing ganglia along the first three bronchial divisions. Nerve fibers continue in airway walls to the level of respiratory bronchioles.

The arterial nerve plexus travels in the media and distally reaches the full extent of muscular arterioles. The venous nerve plexus reaches all the way to the visceral pleura and even supplies subpleural alveolar walls.

In addition, small unmyelinated nerve fibers have been identified in alveolar walls. They are rare, and their source has not been clearly identified. These fibers are thought to represent J (juxtacapillary) receptors, which in animals have been shown to respond to interstitial fluid pressure and certain chemicals. They cause a transitory reflex apnea and shallow rapid respiration.

The primary motor innervation for the lung is parasympathetic (cholinergic). Stimulation of the vagus nerve leads to bronchoconstriction and enhanced secretion of mucus. These actions are blocked by atropine. Parasympathetic nerves arising from the vagus nerve synapse in the ganglia of the first generations of intrapulmonary bronchi. The primary neural inhibitor of bronchial muscular tone is vasoactive intestinal peptide (VIP). This neuropeptide is stored and released by parasympathetic neurons and may coexist with acetylcholine. Thus, the same group of neurons may release acetylcholine, which contracts airway smooth muscle, and VIP, which counteracts the action of acetylcholine to act as a bronchodilator. There are multiple examples of neurotransmitters with opposing actions being released from common nerve elements in the lung; for example, neuropeptide Y, a bronchial and vascular constrictor, coexists in pulmonary adrenergic nerves with norepinephrine. The complex interactions of the parasympathetic, sympathetic, and nonadrenergic, noncholinergic (NANC) nervous systems in the lung and the coexistence of opposing neurotransmitters has made the study of neural control of lung function difficult. It is clear, however, that motor innervation of the airways is predominantly parasympathetic and that there is no significant direct adrenergic innervation of bronchial smooth muscle.

The NANC nerve supply to the lung is thought to regulate primarily mucous secretion and bronchial blood flow. NANC nerves can be either inhibitory or excitatory, and their function is not yet well characterized. The inhibitory functions include relaxation of bronchial smooth muscle, perhaps by the release of nitric oxide or VIP. VIP is a potent relaxant of human bronchi *in vitro* but appears to have little effect on smaller airways. Excitatory responses of the NANC system include bronchoconstriction, possibly mediated by the release of tachykinins, such as substance P. By means of neural stains and electron microscopy, unmyelinated nerve fibers have been shown to pass through the airway epithelial basement membrane and be distributed between columnar bronchial epithelial cells. These fibers contain neuropeptides thought to be released as a reflex response to activation of local irritant receptors. The major neuropeptides identified in the lung are shown in Table 5. In addition, Kultschitsky neuroendocrine cells may play a role in afferent nerve function. These cells have been found to release neuroactive peptides, including serotonin, calcitonin, and bombesin.

Neuropeptide	Functions
Vasoactive intestinal peptide	Enhanced secretion Bronchorelaxation
Peptide histidine methionine	Bronchorelaxation Vasorelaxation
Neurokinin A	Vasorelaxation
Substance P	Enhanced secretion
Calcitonin gene-related peptide	Enhanced secretion
Neuropeptide K	Bronchoconstriction
Neuropeptide Y	Bronchoconstriction Vasoconstriction Decreased secretion

TABLE 5. *Neuropeptides in the human lung*

Neural control of the pulmonary vascular system has been a substantial area of investigation. Despite this, the role of the nervous system in regulating blood flow in the human lung is not well understood. Nerves arising from both the sympathetic and parasympathetic systems innervate the pulmonary vascular system. In most animals, adrenergic supply of the pulmonary arterial system predominates over cholinergic innervation. Electric stimulation of the nerves of the lung has been shown to cause both vasoconstriction and vasodilation. Pulmonary arterioles are thought to be the primary site for pulmonary vascular resistance. The pulmonary venous system is well innervated and may also play a role in regulating resistance and capacitance of the pulmonary vascular system. Sympathetic stimulation in animals has been shown to cause pulmonary venous constriction.

The sensory system in the lung travels upward through both the vagus nerve and the thoracic sympathetic plexus. Receptors in the main bronchi mediate the cough reflex. Small airways contain irritant receptors that respond to irritant gases, irritant dust, and mechanical stimuli to produce bronchoconstriction, hyperventilation, and chest discomfort. The Hering-Breuer reflex involves mechanoreceptors located in airway walls. These receptors increase their rate of firing under stretch and thus inhibit the central inspiratory center as a progressive reflex response to lung expansion. The nerves mediating this reflex are thought to be located in the smooth muscle of the bronchial walls.

RESPIRATORY TRACT DEFENSE MECHANISMS

For the exchange of gases, conditioning of inspired air, and defense against inhaled toxicants to be accomplished simultaneously, highly synergistic interactions between respiratory tract clearance and secretion and biochemical and cellular defense mechanisms are required. In the normal lung, defense functions are mediated by epithelial cells of the airways and alveolar regions, resident alveolar macrophages, and numerous proteins in the extracellular spaces and mucous lining layers.

Resident lung macrophages carry out the normal tasks of lung defense by selective phagocytosis of foreign particles; secretion of proteases, oxygen free radicals, and cytokines; and antigen presentation. In the presence of toxicants or other pathologic conditions, infiltration of bloodborne phagocytes, such as neutrophils, and toxicant-specific immunologic mechanisms, such as antibody production by B lymphocytes and cellular cytotoxic actions by T lymphocytes, augment the normal defense functions. Inflammatory cells recruited into the lungs tend to produce indiscriminate injury to resident lung cells and tissues by nonselective release of proteases, oxygen free radicals, and other cytotoxic agents. The lung appears to be designed to clear normal levels of inhaled pollutants without activating these inflammatory patterns, but it can activate them when more severely stressed.

Deposition of Inhaled Gaseous Toxicants

Because the physical mechanisms of transport and chemical uptake vary significantly between different airborne toxicants, no single approach can be used to estimate the pulmonary uptake of all inhaled agents. For instance, formaldehyde and ozone are both highly reactive gaseous toxicants with an inspiratory uptake of greater than 90%. However, the solubility of formaldehyde in aqueous biologic solutions is approximately 12 times greater than that of ozone. Because of their different solubilities, the critical target sites of injury for formaldehyde and ozone are at opposite ends of the respiratory tract. The major sites of uptake and toxic reactions of formaldehyde are in the nose and other parts of the upper respiratory tract. The uptake of formaldehyde in the upper respiratory tract is so rapid that virtually none of it reaches the lower respiratory tract. In contrast, because of the lower solubility of ozone, more of it reaches the lower respiratory tract. Significant uptake of ozone does occur in the nasal passages and upper respiratory tract; however, this uptake is associated with reaction of ozone with components of the thick mucous layer lining this region. The site of greatest injury from inhalation of ozone, and similar oxidant gases, is the alveolar epithelium at the transition between airways and the gas exchange region. In this region, the surface lining fluids are thin, so that the probability of ozone reacting directly with the underlying alveolar epithelial cells is greater. The critical respiratory targets and the toxic responses to all airborne pollutants depend on their inhaled concentrations, the resulting concentration gradient in different regions of the respiratory tract, and the effects of scrubbing and/or detoxification of the reactive gas by the mucous lining layer overlying the epithelial layer in each region.

Deposition of Inhaled Particles

The alveolar septal region is continually bombarded by a variety of organic and inorganic materials ranging from transition metals to animal and human proteins. Although the upper respiratory tract and upper airways filter most inhaled particulate matter, it is well documented that particles of 1 µm in size are not effectively filtered by the upper respiratory tract and that a significant fraction of these particles deposit on the intrapulmonary airways or reach the alveolar region. Normal ambient air can contain on the order of 10,000 respirable particles, defined as less than 10 µm in size with a mass median aerodynamic diameter (MMAD) of 0.3 µm, per cubic centimeter. Up to 30% of these particles deposit on medium and small airways, and about 10% deposit in the alveolar region. Thus, if a minute ventilation of 10 L is assumed, 30 million particles deposit per minute on smaller airways and 10 million particles deposit per minute on alveoli and alveolar ducts. Although the human lung contains 500 million alveoli, the particles tend to deposit proximally, and the load can be estimated to be up to one particle per minute per alveolus in the proximal alveolar ducts. The lung handles this steady, normal load of particulate matter without inducing inflammatory amplification.

These same pollutants would cause a strong inflammatory reaction if injected into another organ, yet they appear to cause virtually no reaction in alveolar septa in normal lungs. This is remarkable when one considers that the alveolar-capillary gas exchange membrane in most regions is thinner than 1 µm. If the organic and inorganic materials reaching the airways and alveolar surface were to stimulate the type of inflammatory reactions that occur in many other tissues, white cells would be rapidly recruited into these spaces and a progressive inflammation would result, leading to acute bronchitis, acute alveolitis, and/or interstitial fibrosis. The absence of an injurious response to normal lung particle burdens appears to be the result, in part, of the unique role of resident lung defense cells, such as alveolar macrophages. Each alveolus contains an average of 12 macrophages, which are thought to process all particles reaching this region under normal conditions. Alveolar macrophages have been shown to have a blunted capacity for antigen presentation and mitogen production compared with other monocytic phagocytes, and thus they are able to process inhaled particles without stimulating excessive immunologic responses or lung inflammation. The lipids and/or proteins of the alveolar surface lining layer have been shown to have anti-inflammatory actions. High particle loads given experimentally have been shown to overload these and other anti-inflammatory defense mechanisms and induce alveolar inflammation. The dose-response relationship for the onset of particle-induced inflammation is not known, nor are the mechanisms controlling this process.

Pulmonary disorders in which particle deposition and/or clearance plays a major role include hypersensitivity pneumonitis, silicosis, asbestosis and other mineral fiber disorders, and a number of metal- and organic antigen-specific disorders. In most of these cases, the biologic association between toxicant dose and health effects has been clearly demonstrated.

Epidemiologic studies demonstrate a significant association between particulate exposure and increases in hospital admissions, morbidity, and mortality. Children, whose small airways are potentially more susceptible to particle-induced inflammation and limitations of air flow, are thought to be at high risk. Airborne particulate levels as low as 150 µg/m^3 are statistically associated with increases in elementary school absenteeism. The association between particle concentration and increased mortality appears to be maximal when the experimental results are averaged over a 3- to 5-day period. Such studies have been the primary means of identifying human health risks associated with particle inhalation. These studies taken as a whole suggest that ambient levels of particles on the order of 100 µg/m^3 are associated with adverse health effects. Each increase of 10 µg/m^3 in the PM_{10} (particulate matter with an aerodynamic diameter of 10 µm) is associated with an approximate 1% increase in mortality. The increased mortality appears to occur largely among the sick and elderly. The underlying biologic mechanisms responsible for these epidemiologic associations have not been determined. Interactions between particles and other pollutants, such as sulfur dioxide and nitrogen dioxide, and the effects of climate have been suggested as critical factors. High levels of trace metals in the particulate matter from urban and industrial sources have been suggested as possible causative agents. Table 6 illustrates the significant differences that exist in trace element composition between air sampled at a remote natural site and in various North American cities. In cities with a large number of anthropogenic sources, the potentially toxic trace elements of nickel, copper, and zinc are present at substantial levels. Particle samples from natural sites that are not contaminated by anthropogenic sources do not contain significant levels of these elements.

Trace element	Grand Canyon, Arizona	Houston, Texas	Washington, D.C.	Ottawa, Canada
Nickel, ng/m^3	0.1	5.0	1.0	4.4
Copper, ng/m^3	0.3	16.0	3.4	73.0
Zinc, ng/m^3	0.6	122.0	13.9	114.0
Selenium, ng/m^3	0.2	0.2	2.5	0.3
Arsenic, ng/m^3	0.2	0.1	0.6	0.5
Total mass PM_{10}	9400.0	29,000.0	34,900.0	44,500.0

PM_{10}, particulate matter <10 µm in aerodynamic diameter (ng/m^3).

TABLE 6. *Comparison of ambient dust concentrations*

Deposition of inhaled particles occurs according to physical mechanisms of inertial impaction, gravitational sedimentation, diffusion, and interception. A variety of factors, such as aerosol particle size, density, shape, hygroscopic/hydrophobic character, and electrostatic charge, may also play important roles in determining how these mechanisms control the location and efficiency of deposition in the lungs. Because particles are present in a range of sizes and shapes, an aerosol is typically described by a size distribution or a mass/count weighted mean. In toxicologic evaluations, the Mass Median Aerodynamic Diameter (MMAD) is typically used to describe an aerosol in terms of the aerodynamic behavior of its particles, site(s) of particle deposition, and deposited mass. Particles in the size range of 1 to 10 µm deposit with relatively high efficiency in the upper respiratory tract and large airways, where inertial deposition is driven by high flow rates. Particles in the size range of 0.01 to 0.1 µm deposit by diffusion and are primarily taken up in the alveolar regions, where the large surface area enhances deposition by diffusion and sedimentation. The small airways do not have a single dominant mechanism of deposition.

Both empiric and mathematical approaches have been used to assess the dosimetry of inhaled particles. Direct measurements of deposition demonstrate that the human upper respiratory tract efficiently removes particles with an Mass Median Aerodynamic Diameter (MMAD) of approximately 5 µm. For particles in the 1- to 5-µm range, the total respiratory tract (upper respiratory tract plus conducting airways plus gas exchange region) deposition efficiency is on the order of 20%. Mathematically based estimates of the alveolar deposition efficiency of inhaled 1- and 5-µm aerosol particles are 5.2% and 17%, respectively.

Because of the nature of the mechanisms of deposition, deposited particles are not uniformly distributed on respiratory tract surfaces. Aerosols have been shown to deposit preferentially on the ridges of airway bifurcations, both in theoretical models and in direct observation of aerosol behavior using airways casts. Experimental observations of ciliary activity and mucous flow suggest that the concentration of particles on the ridges of airway bifurcations could, in part, result from trapping of

particles on these ridges as they are cleared from more distal airways. Particles on airway ridges or branch points are cleared with a half-life of approximately 1 hour.

Particles deposited in the airways are rapidly cleared by the mucociliary escalator and by airway macrophages. Within 24 hours, most particles with a diameter of 1 µm are cleared from the airways. Particles initially deposited in the alveolar region are primarily cleared by macrophage phagocytosis. Clearance from the alveolar region is considerably slower than clearance from the airways, and removal of insoluble particles may require weeks to months.

Immunologic Responses

Immunologic responses can be classified as nonspecific or innate immune responses (actions of macrophages, monocytes, lymphocytes, and granulocytes) or agent-specific immune responses (immunologic memory of T and B cells). The innate defense mechanisms include a combination of phagocytosis and cytotoxic effects by effector cells and activation of the complement cascade. In the adaptive response, a large population of antigen-specific lymphocytes is produced that results in a potentially greater and prolonged immune system response. The adaptive response occurs when an antigen derived from the toxicant exposure is processed and presented by a dendritic cell, macrophage, or monocyte to a lymphocyte. The lymphocyte then undergoes clonal expansion to produce large numbers of cells that are specific for the particular toxic agent. Cytotoxic T-cell production occurs by this process when major histocompatibility (MHC) is expressed by the antigen-presenting cells in association with toxicant-derived antigen. Activated T cells produce numerous cytokines, such as tumor necrosis factor, that significantly enhances the immune response and the inflammatory responses of resident lung cells. Antibodies specific to the antigen are produced by B cells, which are stimulated by the interleukins to produce memory cells and plasma cells.

The effects of inhaled particles on human health are likely to involve inflammation, hypersensitization, and immunologic memory of T and B cells. These mechanisms are capable of amplifying injury initiated by repeated, low-dose exposures to antigens and therefore have the potential to produce significant effects at ambient levels of exposure. The pulmonary immune system differs from the systemic immune system in its ability to produce localized cell-mediated immune responses on repeated exposure to inhaled antigenic materials. Such localized response may play a significant role in hypersensitivity pneumonitis. Particles that contain metals have been shown to produce these responses. For instance, nickel and other transition metals are highly toxic and known to produce delayed hypersensitivity. Recent studies indicate that T-cell recognition of metal-complexed haptens plays a role in T-lymphocyte immune responses.

The airway epithelium and the alveolar epithelium are the primary lung surfaces on which inhaled toxicants may be initially distributed and/or react. The airway epithelium is a likely critical target site for an inhaled toxicant, as it is the first cellular barrier to inhaled toxicants and the most densely populated of the target surfaces. These aspects are offset to a large extent by the protection afforded by the thick mucous layer overlying airway epithelial cells and the efficient ciliary propulsion system. The alveolar epithelium of the gas exchange region has a large surface with a relatively low density of cells covered by a thin surface film. The thin surface film of the alveolar epithelial layer constitutes a critical site of possible action for pollutants not filtered by proximal airways. The outermost region of the respiratory path is the pleura, and this site is typically involved in toxic processes only after secondary transport following initial uptake of the reactive substance in more proximal air spaces. At each level, the presence or absence of adverse effects of inhaled particles and reactive gases is primarily determined by the unique immune response system in the lung.

CHAPTER

2 Control of Ventilation

Steven G. Kelsen

S. G. Kelsen: Division of Pulmonary Medicine, Temple University Hospital, Philadelphia, Pennsylvania 19140.

INTRODUCTION

The respiratory system, along with cardiovascular structures, operates as part of an intricate organization controlled by the central nervous system (CNS) to ensure optimal cell performance, providing sufficient oxygen to meet metabolic requirements and removing enough carbon dioxide so that cell function is not impaired by excessive changes in hydrogen ion concentration. The major function of the respiratory system is to maintain the arterial tension of oxygen (PaO_2) and carbon dioxide ($PaCO_2$) within acceptable limits in the face of changing metabolic needs and environmental conditions. To achieve this, the system is equipped with multiple sensors that monitor changes in blood chemistry (chemoreceptors) and changes in the mechanical properties of the lung and chest wall (mechanoreceptors). The chemoreceptors and mechanoreceptors allow ventilation to be continuously readjusted in accordance with metabolic needs, despite changes in body posture that alter the mechanical advantage or movement of the respiratory muscles. In addition, these receptors coordinate the contraction and relaxation of the respiratory muscles, so that adequate gas exchange is carried out with minimum expenditure of energy.

In addition, the respiratory chemoreceptors and mechanoreceptors participate in a protective network that adjusts the pattern of breathing and the mechanical conditions of the airways to minimize the deleterious effects on the lung of inhaled, noxious material.

Ventilation, unlike blood pressure and cardiac output, can be controlled consciously (voluntarily) as well as automatically (involuntarily). Indeed, the pathways for voluntary and automatic control of the respiratory muscles are anatomically separate. Voluntary as well as automatic control is essential for using the respiratory muscles in speech. In humans, afferent information continuously fed back to the CNS by mechanoreceptors in the airways, lungs, and chest wall allows the force of contraction of the respiratory muscles to be coordinated smoothly in volitional acts.

Besides inputs from respiratory system sensors, ventilation is influenced by projections from the vasomotor neurons to respiratory neurons and by signals received from thermoreceptors and vascular receptors. The multiplicity of inputs to the respiratory neurons ensures that ventilation is maintained when disease affects one or more afferent pathways or when the perception of some sensory cue is blunted by a depressed state of consciousness (e.g., sleep or anesthesia). However, conflicting demands and signals from different receptors may be responsible for dyspnea, a common symptom in respiratory disease.

CENTRAL RESPIRATORY NEURONS

The precise organization of the central respiratory neurons is still a matter of contention. Although there may be respiratory pacemaker cells in which spontaneous changes in transmembrane potential occur, in the intact system, the respiratory rhythm depends on interconnections between different respiratory neurons.

Because breathing is preserved in anesthetized animals even after removal of the brain rostral to the pons, it is believed that the neurons on which respiratory rhythm critically depends are located in the bulbopontine region. Many investigators believe that the essential features of the respiratory rhythm remain even after separation of the pons from the medulla, and that the central pattern generator must be anatomically located within the confines of the medulla. There is evidence, however, that pontine neurons, particularly the complex composed of the nucleus parabrachialis medialis (NPBM) and the Kölliker-Fuse nucleus (KFN), as well as nuclei in the tegmentum (magnocellular and gigantocellular nuclei), significantly modify breathing.

In addition to these pontine and medullary respiratory neuronal aggregates, neurons with activity that is modulated by respiration can be found all through the brain stem intermixed with nonrespiratory neurons. It also has been shown that when breathing is stimulated, respiratory modulation of the activity of these neurons decreases according to level of anesthesia and sleep state.

A number of neurons whose firing patterns demonstrate a respiratory modulation but whose phase relationships with phrenic motor activity and with one another differ have been identified in the brain stem. Some of these neurons project to the spinal cord (bulbospinal) and are therefore true premotor cells. The remainder have axons that project to other parts of the brain (propriobulbar). Only the function of the bulbospinal neurons has been determined with any degree of certainty. It is generally believed, however, that the propriobulbar cells actively inhibit or excite other neurons involved in the respiratory cycle. The precise function of these propriobulbar neurons remains under investigation, although it is generally agreed that they are organized into networks whose complicated interactions determine the level of excitation of the bulbospinal neurons and produce respiratory phase switching.

MEDULLARY RESPIRATORY NEURONS

The respiratory neurons in the medulla seem to be aggregated into two groups (Fig. 1). One collection, the ventral respiratory group (VRG), forms a longitudinal column of neurons in the ventrolateral part of the medulla. It extends rostrally from the upper border of the spinal cord almost to the bulbopontine boundary. The other group, the dorsal respiratory group (DRG), is more circumscribed anatomically. It is located in a more medial and dorsal part of the medulla in the region of the ventrolateral nucleus of the tractus solitarius (NTS) and extends from the obex about 2.5 mm rostrally.

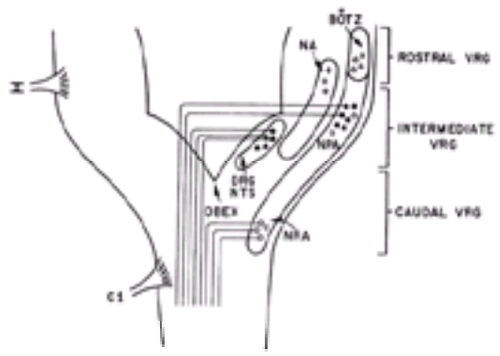

FIG. 1. Schematic depicting the organization of medullary respiratory neurons in the dorsal and ventral respiratory groups (DRG and VRG, respectively). Structures on one side only are shown. Axons from inspiratory bulbospinal neurons in the nucleus tractus solitarius (NTS) and the nucleus para-ambigualis (NPA) decussate rostral to the obex and extens caudally in the contralateral cord. Axons from expiratory bulbospinal neurons in the nucleus retroambigualis (NRA) decussate caudal to the obex. Bötz = Bötzinger complex in the nucleus retrofacialis; NA = nucleus ambigualis.

The nuclei of the solitary tract appear to function as relay stations for important respiratory and cardiovascular information. Afferents from pulmonary stretch receptors and carotid chemoreceptors and baroreceptors appear to synapse for the first time in the brain at this location.

Dorsal Respiratory Group

The DRG contains almost entirely inspiratory neurons. One kind of inspiratory neuron, the I_a neuron, like the phrenic motor neurons, demonstrates an augmenting pattern of firing that peaks at end-inspiration. Axons from these cells decussate in the medulla at or immediately rostral to the obex and connect with phrenic and inspiratory intercostal motor neurons in the spinal cord. Collaterals are sent to the ipsilateral inspiratory neurons in the VRG, but a few also are distributed to the expiratory neurons in the VRG.

The firing of I_b neurons, as of I_a neurons, occurs primarily in inspiration but, in contrast to the discharge of I_a neurons, is augmented by inputs from pulmonary stretch receptors. In animals, the discharge peak of I_b is not as sharp and the decline in activity during expiration is slower than for I_a. In the absence of excitatory input from vagal stretch receptors, however, the discharge patterns of I_a and I_b neurons are similar.

Like I_a neurons, some of the I_b neurons project to the spinal cord. Those I_b neurons that do not project to the cord appear to undergo extensive axonal arborization in the NTS. I_b neurons seem to be responsible for the shortening of inspiratory time induced by lung inflation. Their responsiveness to stretch-receptor input is less during expiration than during inspiration.

The DRG also contains late-onset inspiratory neurons that reach their peak firing rate in the transition from inspiration to expiration. Their activity, like that of I_b neurons, is facilitated by stretch-receptor activity. These neurons may participate in the short phase of graded inhibition of inspiratory activity seen with volume changes occurring toward the terminal portion of inspiration.

Recently, a small number of early-expiratory neurons have been observed in the DRG (and possibly also in the VRG) intermingled with inspiratory cells. They begin their firing shortly before the end of inspiration and reach peak discharge rates quickly, and then their activity slowly diminishes during expiration, disappearing before inspiration begins. Increases in lung volume slow the rate of decline in activity of these cells, whereas prevention of lung inflation does the opposite. The activity of these neurons is related to postinspiration inspiratory activity (PIIA), which occurs in the diaphragm and intercostal and laryngeal muscles and retards expiratory flow and the rate of lung deflation.

Ventral Respiratory Group

The VRG in the medulla comprises several anatomically and probably functionally distinct populations (Fig. 1). One classification divides the neurons of the VRG into three aggregates: the nucleus retroambigualis (NRA), the nucleus para-ambigualis (NPA), and the nucleus retrofacialis (NRF).

The nucleus ambigualis (NA) is composed primarily of subnuclei of motor neurons innervating the laryngeal, pharyngeal, and facial muscles. This nucleus also contains the vagal motor neurons innervating the bronchial smooth muscles and the smooth muscles of the thoracic and abdominal viscera. These neurons are almost completely inactive during deep anesthesia, suggesting that they are not essential to respiratory rhythmogenesis.

The NPA is located in the region medial to the NA and 1 mm caudal to 3.5 mm rostral to the obex. The NPA is composed primarily of premotor inspiratory neurons, but some expiratory cells are present.

Most of the inspiratory neurons of the NPA (like I_a cells in the DRG) fire in a ramplike fashion, with peak activity occurring at the conclusion of the inspiratory phase. The NPA also contains a few inspiratory propriobulbar, so-called early-burst neurons. These cells begin to discharge slightly before the onset of the phrenic discharge, peak rapidly, and then demonstrate a decline and disappearance of activity in the latter half of inspiration. They send no projections to spinal motor neurons, but they have a rich pattern of arborization with expiratory neurons in the contralateral NRA, whose activity they appear to inhibit.

The activity of other neurons in the VRG (located in the NRA and NRF) is mainly directed to expiration. The expiratory neurons in the NRA demonstrate a slowly augmenting pattern of activity, with peak discharge late in expiration. Input from pulmonary stretch receptors prolongs the time of firing of these neurons. Hypercapnia causes these neurons to discharge earlier in inspiration and increases the steepness with which their rate of discharge rises. Lesioning experiments indicate that neurons in the NRA are the sole source of expiratory premotor neurons but are not of fundamental importance in generating the respiratory rhythm.

Respiratory neurons in the NRF (also called the *Bötzinger complex*) and in an area immediately rostral to it, called the *pre-Bötzinger complex,* have been described. Bötzinger neurons discharge mainly in expiration with a slowly augmenting firing pattern that peaks at end-expiration. They send projections to the DRG on the opposite side and seem to inhibit the inspiratory neurons located there. On the other hand, pre-Bötzinger neurons fire during inspiration, demonstrate pacemaker-like activity, and appear to be exclusively propriobulbar in type. In the neonatal rat, lesions in this pre-Bötzinger complex eliminate respiratory rhythmogenesis. Some pharyngeal motor neurons also can be found in the NRF.

Interrelationship Between Dorsal and Ventral Respiratory Groups

The precise interactions between the DRG and VRG remain unclear. Earlier studies indicated that inspiratory neurons of the DRG projected to the VRG, but a reciprocal connection was not apparent. These studies suggested that the central pattern generator was composed only of inspiratory cells and was located in the DRG. In this view, the DRG was the prime mover in the genesis of the respiratory rhythm, dominating the cells in the VRG and governing their activity. More recent studies indicate that cells from the VRG (Bötzinger complex) may inhibit inspiratory neurons in the DRG. Ablation experiments eliminating either the entire DRG or the Bötzinger complex in the VRG do not eliminate rhythmogenesis, indicating that substantial redundancy is present in the system.

The functional significance of the interconnections between groups of inspiratory cells in the DRG and VRG is also unclear. These interconnections may serve to synchronize the timing of neuronal firing in anatomically separate locations. For example, midline incisions through the medulla are associated with asynchronous firing of the two phrenic nerves.

TIMING OF RESPIRATORY MOTOR ACTIVITY

During inspiration, firing rates increase monotonically in both inspiratory propriobulbar and bulbospinal neurons. Early in expiration, inspiratory propriobulbar neurons are silenced, but the activity of inspiratory bulbospinal neurons stops only momentarily, reappearing after a brief period of silence and then gradually declining as expiration proceeds. This PIIA corresponds in time to the period of firing of early-expiratory neurons in the DRG and VRG. Expiratory bulbospinal neurons are silent during this early phase of expiration, whereas inspiratory propriobulbar neurons are actively inhibited. Furthermore, because the time course of inhibition of the

respiratory propriobulbar neurons is similar to the time course of activity of the early-expiratory units, it has been suggested that the respiratory rhythm is caused by inhibition of an inspiratory ramp generator by these early-expiratory neurons.

Based on these observations, it has been proposed that expiration be divided into two phases, E_I and E_{II}. The E_I phase corresponds to the period of PIIA, whereas the E_{II} phase corresponds to the period in which PIIA is absent and expiratory neuronal activity may be present. In some situations, PIIA may extend throughout expiration, suggesting that the respiratory rhythm does not depend on the occurrence of activity in expiratory neurons.

PIIA appears to be associated with “braking” of expiratory air flow by contraction of the inspiratory muscles. Increases in PIIA and prolongations in E_I occur, for example, when the larynx is bypassed so as to decrease upper airway resistance. PIIA (E_I) is markedly reduced or eliminated by vagotomy, suggesting that mechanoreceptors that sense lung volume and/or tracheal air flow are important inputs. Hypercapnia decreases the duration of E_I, whereas hypoxia appears to do the reverse. Increases in PIIA may contribute to the increase in functional residual capacity (FRC) observed during hypoxia.

Respiratory timing can be significantly affected by the rostral pontine pneumotaxic center, which comprises the NPBM and KFN. This structure contains a number of neurons that have different patterns of firing: inspiratory, expiratory, or phase-spanning. When the vagi are intact, discharge patterns in the NPBM are mainly tonic, but they become more clearly phasic after vagotomy. Both the VRG and the DRG send projections to the pneumotaxic center, so that the respiratory activity seen in this center appears to be of medullary origin. Depending on the region involved, stimulation of the pneumotaxic center can either terminate or prolong inspiration. Stimulation of the dorsolateral region terminates inspiration. The earlier in inspiration the stimulation is applied, the stronger is the stimulus needed. If the pneumotaxic center is lesioned and the vagi are cut, an apneustic breathing pattern develops in anesthetized animals that is characterized by prolonged inspiratory time. If time is allowed for recovery, however, and the animal regains consciousness, breathing loses its apneustic quality. If the animal is then given anesthesia or allowed to go to sleep, the apneustic pattern returns. These observations suggest the lack of importance of the pneumotaxic center in generating the respiratory pattern, and indicate that an interaction between states of alertness and the activity of higher brain centers and the brain stem bulbopontine respiratory neurons can significantly affect respiratory rhythm.

It is not clear whether some or any of the different respiratory neurons described in fact make up the central pattern generator. Three different ways in which the central respiratory pattern may be produced in the brain have been proposed. In one, the pattern generator is composed only of inspiratory neurons; an inspiratory ramp continues until it is terminated by the activity of off-switch neurons. The off-switch neurons are triggered after some predetermined time or after the inspiratory ramp reaches some threshold level of activity. Both trigger and ramp neurons could be stimulated by hypoxia and hypercapnia. In this scheme, inspiration is a self-terminating process carried out by cells whose activity is confined to inspiration.

In a second hypothesis, the central pattern generator may include both inspiratory and expiratory cells affected by chemical drives causing tonic increases in the activity of each. The increasing ramplike discharge seen in inspiratory intercostal and phrenic nerves may result from a gradual decline in inhibition rather than a gradual increase in excitation. This hypothesis is based on the observation that during apnea induced by hypocapnia, decreases in PO_2 elicit inspiratory tonic activity. Progressive decreases in PO_2 during apnea elicit progressive increases in tonic inspiratory activity until at a critical level of hypoxia the respiratory rhythm reappears. On the other hand, hypocapnia under hyperoxic conditions produces continuous firing of expiratory neurons, which increases as PCO_2 rises until rhythmic breathing resumes. This suggests hypoxia exerts an excitatory effect predominantly on inspiratory activity, and that hypercapnia affects expiratory motor activity.

The third idea is that respiratory rhythmogenesis arises in the antagonistic activity of inspiratory and early-expiratory neurons and does not depend on the activity of conventional expiratory neurons that peaks late in the expiratory phase.

PATTERN OF MOTOR OUTFLOW TO THE INSPIRATORY MUSCLES

The firing of the bulbospinal inspiratory neurons projecting to the diaphragm and intercostal muscles increases progressively throughout inspiration and is terminated abruptly (off-switching). The ramplike increase in activity of these bulbospinal neurons (the central inspiratory activity) causes a progressive increase in excitation of the inspiratory muscles and hence their force of contraction (Fig. 2). The electrical and mechanical analogues of central inspiratory activity are, respectively, the integrated activity of the phrenic neurogram and diaphragmatic electromyogram (EMG) and the pleural pressure waveform. The progressively augmenting shape of central inspiratory activity allows the inspiratory musculature to overcome the progressive increase in elastic recoil of the lung during inspiration despite progressive shortening and a decrease in the intrinsic ability of the inspiratory muscles to generate force (i.e., the length-tension relationship).

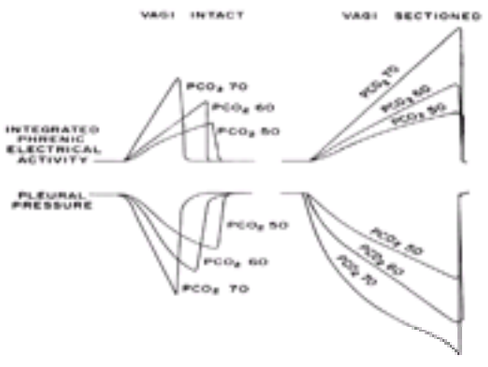

FIG. 2. Effect of hypercapnia on the duration of the phrenic nerve electrical activity integrated as a moving time average and its rate of increase and the pleural pressure waveform. Note the similarity in shape of the integrated phrenic neurogram and the pleural pressure tracing. Following bilateral vagotomy, the duration of inspiration remains relatively constant despite the progressive increase in PCO_2.

Control of the rate of rise in central inspiratory activity and hence the rate of lung inflation differs from control of inspiratory off-switching. Both chemical (e.g., hypoxia and hypercapnia) and nonchemical (e.g., thermal and mechanoreceptor afferents) inputs affect the steepness of the ramp of central inspiratory activity. On the other hand, the timing of inspiratory off-switching depends largely on inputs from pulmonary stretch receptors and from higher CNS structures, such as the NPBM and the KFN.

In anesthetized animals, phasic increases in lung volume resulting from the ramp of central inspiratory activity progressively increase pulmonary stretch-receptor activity. Integration of inputs from pulmonary stretch receptors and projections reflecting the intensity of the central inspiratory activity by as yet incompletely described pools of neurons terminates inspiration. Vagotomy eliminates stretch-receptor input, prolonging inspiration and increasing tidal volume, but the rate of rise in central inspiratory activity and hence the rate of inspiratory air flow are virtually unchanged. On the other hand, hypoxia and hypercapnia increase the steepness of the ramp of inspiratory activity and hence increase the rate of inspiratory air flow and tidal volume, but they have little effect on the duration of inspiration and frequency of breathing.

When the vagus is intact, so that respiratory neurons receive input from the stretch receptors as well as inputs reflecting central inspiratory activity, the duration of inspiration is reduced, because the inspiratory off-switch is activated earlier. Because central inspiratory activity increases with time, more stretch-receptor input (i.e., a greater change in lung volume) is needed early in inspiration to terminate a breath. This accounts for the curvilinear relationship between tidal volume (V_t) and inspiratory time (t_{insp}) that has been noted in studies of anesthetized animals (Fig. 3).

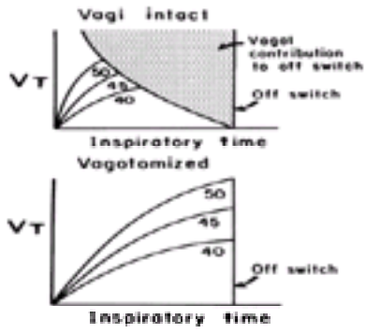

FIG. 3. Effect of lung volume information in determining off-switch and, hence, t_{insp}. Vagal input allows the off-switch threshold to be reached earlier in inspiration. The numbers refer to the PCO_2 with the vagi intact. Inspiratory time declines and tidal volume rises with increasing hypercapnia. Without lung volume information (vagotomy), t_{insp} is fixed.

Consistent with these observations is the idea that ventilatory responses to hypercapnia and hypoxia depend on the sensitivity of both stretch receptors and chemoreceptors. Chemoreceptor sensitivity, because it influences the rate of increase in central inspiratory activity, is more closely related to the average level of air flow during inspiration than to minute ventilation. That is, the change in the ratio of tidal volume to inspiratory time, rather than the change in ventilation itself, most closely reflects chemical drive. On the other hand, the change in inspiratory time as a fraction of total breath duration indicates the activity of stretch receptors.

Although ventilation is conventionally thought to be equal to tidal volume times frequency (f), the concept of central respiratory neuronal organization suggests that ventilation should more realistically be considered to be the product of the following:

$$\frac{V_T}{t_{insp}} \times \frac{t_{insp}}{t_{insp} + t_{exp}}$$

where t_{insp} is inspiratory time and t_{exp} is expiratory time.

Some studies in humans have tried to separate neural and chemical responses to hypoxia and hypercapnia by analyzing ventilatory responses with this approach. In some cases, depressed ventilatory responses to CO_2 seem to be caused by altered mechanoreceptor function rather than by depressed chemosensitivity.

It is important to remember that this concept originated from experiments carried out in anesthetized animals and accordingly does not include the effects on breathing of inputs eliminated by anesthesia. These additional inputs, occurring during both wakefulness and sleep, may greatly distort the basic relationships between the medullary respiratory neurons observed in animals during anesthesia. Thus, in awake humans, increases in breathing frequency produced by hypercapnia and hypoxia are associated mainly with a shortening of expiratory time, whereas inspiratory time remains relatively constant. Rapid-eye-movement (REM) sleep is associated with an irregular breathing pattern and seems to eliminate ventilatory increases to hypercapnia, but not to hypoxia. In non-REM sleep, breathing is more regular, but responses to changes in CO_2 remain lower than during wakefulness.

Even in anesthetized animals, influences from thermal and circulatory receptors can affect breathing. For example, temperature increases accelerate the frequency of breathing without changing tidal volume.

CENTRAL CHEMORECEPTORS

When CO_2-enriched gas is inspired, ventilation increases. The increase in ventilation tends to minimize the rise in $PaCO_2$. Because the amount of CO_2 delivered to the chemoreceptors depends on the CO_2 carried to them by the arterial blood, the $PaCO_2$ determines the PCO_2 in the immediate environment of the chemoreceptors.

The effect of increases in ventilation on $PaCO_2$ can be determined by the following equation:

$$PaCO_2 = \frac{\dot{V}CO_2 \times K}{\dot{V}_A} + PICO_2$$

where $\dot{V}CO_2$ is the metabolic production of CO_2 each minute, $\dot{V}_A$ is the alveolar ventilation, $PICO_2$ is the partial pressure of inspired CO_2, and K is a proportionality constant.

It can be seen that the greater the increase in ventilation caused by a change in $PICO_2$, the lower is the $PaCO_2$. In conscious humans, central chemoreceptors located within the medulla account for 70%–80% of the increase in ventilation. The peripheral chemoreceptors account for the remainder of the increase in ventilation when CO_2-enriched gas is inspired and for all the increase in ventilation produced by hypoxia.

The exact location of the central chemoreceptors is still disputed, although most experimental data indicate that they (1) are distinct from the inspiratory motor neurons themselves, (2) are not located in the dorsal and ventral groups described earlier, and (3) respond to changes in hydrogen ion concentration of brain interstitial fluid but also may respond directly to changes in PCO_2 (perhaps through a change in intracellular pH).

Studies in which drugs and temperature probes have been applied to the ventrolateral surface of the medulla have demonstrated abrupt and striking ventilatory effects, suggesting that many of the neurons comprising the central chemoreceptors or their associated axons may be located near the surface. Chemoreceptor activity can be influenced from three different superficial areas (Fig. 4). Recent studies suggest that respiratory cells near the ventral surface are intermingled with cells that also have significant vasomotor effects. Many agents that increase ventilation when applied superficially to the ventral medullary surface (e.g., nicotine, acetylcholine, kainic acid) also raise blood pressure. On the other hand, agents that decrease respiration when similarly applied (e.g., t-amino butyric acid, taurine, enkephalins) also decrease blood pressure. Nonetheless, discrete areas have been described from which either respiratory or vasomotor effects predominate (e.g., the nucleus paragigantocellularis, a collection of cells close to the ventral medulla).

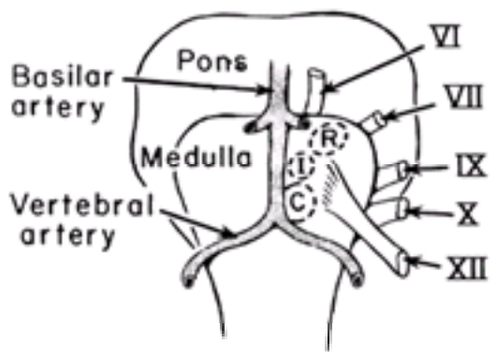

FIG. 4. Ventrolateral medulla and its rostral (R), intermediate (I), and caudal (C) chemosensitive areas.

The crucial experiments in which activity from the central chemoreceptors would be directly recorded have never been performed. Hence, it has been possible to evaluate central chemoreceptor activity only indirectly. This is usually accomplished by measuring the increase in ventilation or phrenic nerve activity produced when the P_ICO_2 is changed. Changes in ventilation theoretically should be related to changes in hydrogen ion concentration in the brain, but this concentration cannot be measured easily, either in humans or in animals. Instead, changes in ventilation are conventionally related to the measured levels of $PaCO_2$. This kind of indirect estimation of central chemoreceptor activity is valid only under restricted circumstances and only if certain assumptions are made. It is assumed, for example, that in a steady state, after CO_2 has been inspired for 10 to 20 minutes, changes in $PaCO_2$ reflect changes in the hydrogen ion concentration of the brain. By the Henderson-Hasselbalch equation, hydrogen ion concentration in the brain, as in other tissues, varies according to the ratio PCO_2/ HCO^-_3, where PCO_2 is the partial pressure of CO_2 at the chemoreceptor in the interstitial fluid and HCO^-_3 is the bicarbonate concentration of the medullary interstitial fluid. Hence, increases in bicarbonate concentration decrease hydrogen ion concentration, whereas decreases in bicarbonate concentration have the opposite effect.

The relationship between arterial PCO_2 and PCO_2 in the brain interstitial fluid depends on cerebral venous PCO_2 and therefore on cerebral blood flow. The greater the cerebral blood flow, the smaller the difference between PCO_2 in arterial blood and in interstitial fluid. As cerebral blood flow increases with PCO_2, the change in ventilation produced by a change in $PaCO_2$ depends on the CO_2 responsiveness of cerebral blood vessels as well as on the sensitivity of the central chemoreceptors. This may be a significant factor in patients with cerebrovascular disease.

Changes in blood bicarbonate levels are not immediately mirrored in the brain interstitial fluid. In addition, evidence suggests that hydrogen ion concentration in interstitial fluid is actively regulated by cellular pumps at the blood-brain barrier or by the metabolism of brain cells. This means that in metabolic acidosis or alkalosis, neither $PaCO_2$ nor hydrogen ion concentration in blood may reliably indicate the status of hydrogen or bicarbonate ion concentrations in interstitial fluid.

The stimulatory effect of acid injected into the blood on the peripheral chemoreceptors lowers PCO_2. Because the transfer of PCO_2 between blood and brain interstitial fluid is faster than the transfer of hydrogen or bicarbonate ions, the brain interstitial fluid may actually become alkaline when the blood PCO_2 is acutely made acidic. Direct administration of acid into the cerebrospinal fluid to bypass the blood-brain barrier increases the hydrogen ion concentration in brain interstitial fluid and drives the $PaCO_2$ down by stimulating central chemoreceptors.

With chronic acid-base disturbances, hydrogen ion changes in cerebrospinal fluid are usually qualitatively the same as those in the blood but are quantitatively less.

The effect of chronic metabolic acidosis and alkalosis on ventilatory responses to CO_2 is shown in Fig. 5. It can be seen that in metabolic acidosis the level of ventilation is greater at any given level of PCO_2, whereas in metabolic alkalosis ventilation decreases. These changes in ventilation reflect the altered level of bicarbonate in the brain interstitial fluid. If the same ventilation results are plotted as a function of hydrogen ion concentration in brain interstitial fluid, the response lines are identical.

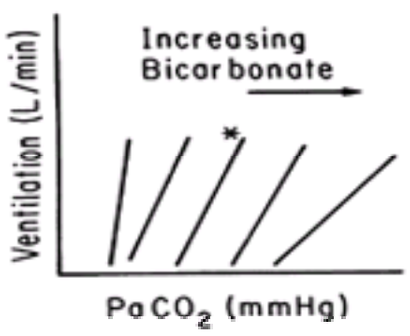

FIG. 5. Effect of changes in blood bicarbonate on the relationship between ventilation and PCO_2. The asterisk indicates the response line at the usual level of HCO^-_3.

In humans and animals, increases in PCO_2 over a wide range cause a virtually linear increase in ventilation. At levels of $PaCO_2$ >80 to 100 mmHg, the response to hypercapnia diminishes and may plateau. Decreases in $PaCO_2$ below the usual level depress ventilation. In anesthetized and sleeping animals and humans, artificial hyperventilation with progressively reduced PCO_2 eventually produces apnea. In a normal, awake human, however, active voluntary hyperventilation rarely causes apnea. In most cases, when voluntary hyperventilation is suspended, the increase in ventilation persists for perhaps 30 to 50 seconds. The persistence of ventilation in awake subjects at low levels of PCO_2 has been attributed to a “wakefulness drive” caused by the continued impingement of other stimuli (e.g., noise, mechanoreceptor input, and light input) on the respiratory neurons. However, continuation of phrenic nerve activity at low levels of PCO_2 has been described even in anesthetized animals made to hyperventilate actively by electrical stimulation of the carotid body nerves. This effect, which has been attributed to persisting reverberations in medullary respiratory neuron circuits, probably contributes to the wakefulness drive and helps stabilize breathing.

PERIPHERAL CHEMORECEPTORS

Sensors in both the carotid body (innervated by the ninth cranial nerve) and the aortic body (innervated by the tenth cranial nerve) respond to hypoxia by increasing ventilation. If the carotid and aortic bodies are removed, hypoxia depresses breathing. In most species, the increase in ventilation with hypoxia is more a consequence of carotid than of aortic body activity. The carotid body also responds, to a limited extent, to changes in PCO_2 and hydrogen ion concentration, and it appears to be particularly important in the immediate increase in ventilation seen in metabolic acidosis. However, the increase in peripheral chemoreceptor activity caused by CO_2 appears to be inconsequential under hyperoxic conditions.

With decreases in PaO_2, afferent fibers from the carotid body increase their discharge hyperbolically. Reduction in PO_2 rather than in O_2 content in the arterial blood is mainly responsible for the increasing activity. The biochemical and physiologic mechanism that allows the carotid body to respond to even relatively mild hypoxia has not been completely elucidated, but some details are known. Although blood flow in the carotid body is unusually high, so is the metabolic rate. Vascular shunts through the carotid body as well as its high metabolic rate may produce areas of hypoxia within the carotid body, even when the arterial blood is fully saturated with O_2. Measurements of carotid body PO_2 have shown some extremely low tensions, but the range of tensions is wide. Cytochrome enzymes within the carotid body may have an especially low affinity for O_2, thus accounting for the sensitivity of the carotid body to changes in PO_2. Although the primary function of the peripheral arterial chemoreceptors is to transduce changes in arterial PO_2, PCO_2, and/or hydrogen ion levels into nerve signals, there is no general agreement as to how this is accomplished, nor is it known whether all stimuli act through a common mechanism.

Ultrastructural studies of the carotid and aortic bodies demonstrate the presence of two distinct types of cells. Afferent nerve terminals from the carotid sinus nerve appose type I glomus cells, which contain abundant, dense, clear-cored synaptic vesicles, mitochondria, and conspicuous rough endoplasmic reticulum. The cytology of type II (sustentacular) cells resembles that of Schwann cells. They envelop the afferent terminal-glomus cell complex.

Whereas it was originally proposed that the afferent terminals are chemosensitive and that the type I cells function as modulatory interneurons, subsequent studies have suggested that the integrity of the glomus cells (type I and perhaps type II cells) is essential for the process of chemoreception. After the glomus cells are destroyed, nerve endings alone seem unable to respond to physiologic stimuli.

Glomus cells (type I cells) contain a variety of agents, including acetylcholine, norepinephrine, dopamine, and 5-hydroxytryptamine. Recent immunocytochemical studies also have shown the presence of at least three polypeptides in the carotid body of cats and rats (i.e., substance P, vasoactive intestinal polypeptide [VIP], and enkephalins), suggesting that neuropeptides may play important roles in the transmission of nerve signals. Substance P, a member of the tachykinin group of polypeptides, has been proposed as a general transmitter/modulator for primary afferent fibers sensing nociceptive stimuli. In addition, substance P enhances the discharge of carotid body preparations in vivo and in vitro. These excitatory effects of substance P are dose-dependent, seem to be slow in onset, and last several seconds after intracarotid administration. Hypoxic excitation of the carotid body is markedly attenuated by substance P antagonists. The mechanism(s) for sensing O_2

in the carotid body remains unclear. However, hypoxia depolarizes type I cells and increases cytosolic calcium, perhaps through effects on O_2-sensitive, voltage-gated potassium channels and cytochrome protein(s) with a low affinity for O_2. Depolarization of glomus cells in turn causes neurotransmitter release and activation of sinus nerve afferent terminals.

Efferent discharge to the carotid body from the CNS depresses afferent activity provoked by hypoxia. This efferent inhibition may prevent saturation of the carotid body response, allowing the carotid body to respond to a wider range of PO_2 than it could otherwise. In part, efferent control depends on sympathetic nervous regulation of carotid body blood flow. However, other inhibitory efferent fibers that have no effect on the carotid body vasculature are also present.

With hypoxia, ventilation, like carotid body activity, increases hyperbolically (Fig. 6). Also, changes in PCO_2 seem to enhance the ventilatory response to hypoxia, and vice versa (i.e., CO_2 and hypoxia interact multiplicatively). Single carotid body fibers respond to both CO_2 and hypoxia, so that some of the interaction of hypoxia and hypercapnia occurs at the cellular level in the sensor itself. However, other evidence suggests that convergence of input from central and peripheral chemoreceptors at the level of the CNS helps enhance the interaction of hypoxia and hypercapnia as ventilatory stimulants. Experimental studies on the effect of carotid nerve stimulation in different phases of breathing show that carotid body discharge is more effective in stimulating breathing during inspiration than during expiration. Carotid body discharge varies spontaneously during the breathing cycle as a result of variations in PaO_2. The relationship between oscillations in carotid body activity and phase of breathing depends on the circulation time between the lungs and the carotid body. Thus, changes in cardiac output theoretically might affect both the level and pattern of breathing. When central chemoreceptor activity and the response to CO_2 have been eliminated by destruction of the ventrolateral medullary surfaces, input from the carotid body alone is sufficient to maintain rhythmic breathing. Both central and peripheral chemoreceptors respond proportionally as the level of PCO_2 is altered. Some studies suggest that increases in the rate of change of CO_2 but not in the rate of change of PO_2 also stimulate the carotid body.

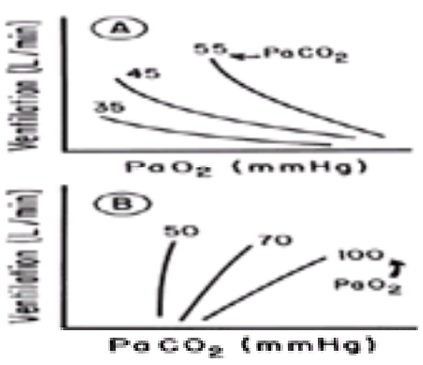

FIG. 6. Effect of changing $PaCO_2$ on (A) the ventilatory response to hypoxia and (B) the ventilatory response to hypercapnia.

RESPIRATORY SENSORY RECEPTORS

The receptors of the lungs and airways are innervated through the vagi and superior laryngeal and trigeminal nerves, and respond, as in other hollow visceral structures, to irritation of the lining layers and changes in distending forces. The mechanoreceptors associated with the respiratory muscles are innervated by spinal nerves and, like those in other skeletal muscles, monitor changes in joint movement and in the length and tension of the muscle itself.

Pulmonary Receptors

There are basically three types of pulmonary receptors: stretch receptors in the smooth muscles of the airway, irritant receptors in the airway epithelium, and J (juxtacapillary) receptors situated in the lung interstitium.

Stretch Receptors

Stretch receptors are innervated by large myelinated fibers. As the lung is inflated, these receptors inhibit inspiration, promote expiration, and initiate the Hering-Breuer reflex. In animals, lung inflation cuts short inspiration and produces expiratory apnea; the duration of apnea is proportional to the degree of inflation.

Direct measurements of stretch-receptor activity indicate that stretch receptors in humans are excited by even small changes in lung volume during quiet breathing. In humans, however, unlike what occurs in animals, vagal blockade to abolish stretch-receptor input does not affect breathing frequency or tidal volume at rest. Vagal blockade in both humans and animals does, however, prevent the increase in breathing frequency that occurs when ventilation is stimulated by hypercapnia or hypoxia and tidal volume is larger.

In animals, stretch-receptor activity helps to preserve tidal volume whenever the usual movements of the lung are hindered by changes in airways resistance or respiratory system compliance. Anything that retards lung inflation diminishes inspiratory inhibitory stretch-receptor activity. Therefore, inspiration is prolonged and tidal volume tends to approach its usual level when the airway is obstructed or respiratory compliance is reduced, despite mechanical interference. When expiration is hindered and lung deflation slowed, increased stretch-receptor activity heightens the force of contraction of the expiratory muscles and also prolongs expiratory time. Both these stretch-receptor actions tend to prevent mechanical impediments to expiration from increasing end-expiratory volume and, as a consequence, decreasing the resting length of the inspiratory muscle. Stretch-receptor activity, by promoting full expiration, helps preserve inspiratory muscle function.

Although stretch receptors are not important in humans in shaping resting breathing patterns, they may help maintain tidal volume when breathing is stimulated or lung or chest-wall mechanical performance is impaired. The increase in breathing frequency caused by stretch-receptor activity in animals and during stimulated breathing in humans decreases the work of breathing of the respiratory muscles, conserving the energy that has to be expended to produce gas exchange. Although it is well-known that peripheral inputs from lung mechanoreceptors strongly affect the timing of respiratory motor activity, at the present time it is difficult to separate clearly the ventilatory effects of the pulmonary stretch-receptor afferents from those of other vagal sensory components (e.g., irritant and C-fiber afferents). However, changes in vagal afferent activity elicited by phasic lung volume changes seem to control predominantly the duration of inspiration, whereas tonic inputs predominantly affect the duration of expiration.

Irritant Receptors

Irritant receptors, like the stretch receptors, are innervated by myelinated fibers, whereas unmyelinated fibers supply the J receptors. Unlike the stretch receptors, both irritant and J receptors are rapid-adapting (within seconds). Neither irritant nor J receptors have a pattern of firing that is related to the phases of inspiration and expiration. Consequently, it is believed that neither receptor has an important influence in determining the pattern of breathing at rest.

Mechanical stimulation of the airways or the inhalation of potentially noxious agents (e.g., particulate matter, nitrogen dioxide, sulfur dioxide, ammonia, and antigens) seems to excite irritant receptors and produce airway constriction. Stimulation of irritant receptors augments the activity of the inspiratory neurons and, by interaction with the stretch receptors, promotes rapid, shallow breathing. This pattern of breathing, in combination with airway constriction, may limit penetration of dangerous agents into the lung and prevent them from reacting with the gas-exchanging surfaces.

The inspiratory augmenting effect of irritant-receptor excitation and the increase in breathing frequency it produces may help maintain ventilation in asthmatic patients, even when the work of breathing is massively increased.

Irritant receptors can be excited by traction on the airways and are stimulated if atelectasis reduces lung compliance. These receptors seem to cause augmented breathing and the large sighs that occur sporadically during normal breathing, and help to open collapsed areas of the lung. As a consequence, irritant receptors help maintain adequate gas exchange.

J Receptors

J receptors are stimulated by pulmonary interstitial edema, but they also can be activated by various chemical agents, such as histamine, halothane, and phenyldiguanide. Activation of the J receptors causes laryngeal closure and apnea, followed by rapid, shallow breathing. When pulmonary edema develops as a result of exercise, J receptors seem to depress the activity of the exercising limbs by a somatic reflex involving cingulate gyrus. J receptors, together with irritant receptors, may be responsible for the tachypnea seen in patients with pulmonary embolus, pulmonary edema, and pneumonia.

Laryngeal Receptors

Mechanoreceptors and chemoreceptors in the upper airway reflexively affect the level and pattern of breathing, motor outflow to the upper airway and chest-wall muscles, and airway tone. The best-studied of the upper airway receptors are the laryngeal receptors. In fact, all areas of the laryngeal mucosa and deeper structures contain sensory nerve endings. Several types of laryngeal receptors have been described: (1) pressure receptors, (2) “drive” receptors, and (3) cold receptors.

Pressure receptors, the most numerous of the laryngeal receptors, are activated by increases in negative (intraluminal less than extraluminal pressure) or positive transmural pressure. Pressure receptors fire in response to both dynamic and static pressure changes, and are slow-adapting. Approximately, two thirds of the pressure receptors respond to negative pressure; the remaining third respond to positive pressure. Approximately one half of laryngeal pressure receptors demonstrate a respiratory modulation in the absence of air flow in the isolated, bypassed upper airway, suggesting that they respond to laryngeal muscle shortening in response to descending motor drive. These so-called drive receptors fire primarily during inspiration. Their firing pattern is diminished by paralysis of the intrinsic muscles of the larynx.

Reflexes elicited by laryngeal pressure receptors tend to stabilize the upper airway, retard its tendency to collapse in response to subatmospheric pressure, and re-establish its patency following occlusion. Laryngeal pressure receptors reflexively activate upper airway muscles while inhibiting inspiratory muscles of the chest wall. Negative transmural airway pressure reflexes increase the activity of inspiratory upper airway muscles (e.g., genioglossus, sternohyoid, cricothyroid, levator alae nasi, posterior arytenoids), advance the onset of the upper airway-muscle EMG relative to that of the diaphragm, increase the duration of inspiration and expiration, and decrease the average rate of rise of diaphragmatic and inspiratory intercostal EMG activity. (Normally, activation of upper airway muscles occurs 50 to 100 ms before the outset of diaphragmatic activation.) Reflex responses to negative pressure in the upper airway mediated by pressure receptors may explain the greater tidal volume, expiratory time, and ventilation during nasal than in tracheostomy breathing in conscious animals and humans.

In contrast to pressure receptors, laryngeal cold receptors are silent near body temperature but are activated by decreases in laryngeal temperature to 34°C or below. When active, cold receptors demonstrate a phasic, inspiratory firing pattern and, in contrast to pressure receptors, appear to adapt rapidly. Cold receptors appear to be located superficially in the mucosa on the edge of the vocal cords near the arytenoid process. Increases in lower airway resistance elicited by laryngeal cooling may be mediated by these receptors.

Finally, mechanical or chemical irritation of the larynx (e.g., probe contact or application of acid) elicits cough, laryngeal closure, bronchoconstriction, an increase in tracheal production of mucus, and a decrease in heart rate and blood pressure. These reflex responses to laryngeal irritation suggest that laryngeal chemoreceptors and mechanoreceptors function to protect the lower airway from aspiration or inhalation of toxic fumes.

Of interest, reflex responses to laryngeal stimulation appear to be state-dependent and are qualitatively different during wakefulness and sleep. For example, in the dog, application of distilled water to the larynx during wakefulness consistently elicits cough and bronchoconstriction. In contrast, the same maneuver performed during REM sleep does not stimulate cough, but rather elicits apnea and bradycardia.

Chest-Wall Receptors

Three types of receptors in the chest wall—joint, tendon, and spindle receptors—signal changes in the force exerted by the respiratory muscles and movement of the chest wall. Specialized Ruffini receptors, as well as pacinian and Golgi organs, are present in joints. Joint-receptor activity, which can be consciously perceived, varies with the degree and rate of change of rib movement.

Inputs arising from muscular receptors, both proprioceptive (particularly muscle spindle) and nociceptor afferent (types III and IV) endings, influence the level and timing of respiratory activity. Proprioceptor afferents (chiefly from the intercostal and abdominal muscles) project to the phrenic motor neurons, where their effect is on firing rate only, and to medullary respiratory neurons in the DRG and NRA, where their predominant effect is on respiratory timing.

Tendon organs in the intercostal muscles and diaphragm monitor the force of muscle contraction and produce an inspiratory inhibitory effect. It was once thought that tendon organ activity was provoked only by unusual levels of muscle force, but it is now believed that tendon organs are stimulated by even small changes in force. Tendon organ input may be important in regulating both intercostal muscle and diaphragmatic contraction during breathing at rest.

Muscle spindles, which are abundant in the intercostal muscles but scarce in the diaphragm, are involved in several kinds of intercostal respiratory reflexes and also help coordinate breathing during changes in posture and speech.

Figure 7 shows schematically the operation of the spindle and its neural connections. Spindles are located on intrafusal muscle fibers aligned in parallel with extrafusal fibers, which move the ribs. Motor innervation of the extrafusal fibers originates in alpha motor neurons, whereas the intrafusal fibers receive motor innervation from gamma (fusimotor) motor neurons. Passive stretch of an intercostal spindle by lateral flexion of the trunk, for example, increases spindle afferent activity and activates a monosynaptic segmental reflex that causes contraction of the parent extrafusal fiber and restores the upright position. The spindles also can be stretched by an efferent fusimotor discharge, which causes contraction and shortening of the intrafusal fiber itself. Some fusimotor fibers fire phasically, so that their rate of discharge rises during inspiration and falls during expiration; other fusimotor fibers are tonically active. The cerebellum determines the balance between tonically and phasically active fusimotor fibers. Without phasic fusimotor activity, spindle discharge would decrease when the extrafusal fibers contract during inspiration. Simultaneous activation of fusimotor and alpha motor neurons causes the spindles to be under continuous stretch during inspiration and enhances the contribution made by the intercostal muscles to respiration. If inspiratory movements are impeded, afferent activity from a spindle innervated by a phasically active fusimotor fiber is enhanced, thus increasing inspiratory muscle force and helping to preserve tidal volume. Activity from lower intercostal muscle spindles, through an intersegmental spinal reflex, also enhances diaphragmatic contraction, allowing the diaphragm to contribute to the compensatory increase in muscle force that occurs when respiratory movements are hindered. In contrast, stretch of the intercostal spindles in the midthoracic region of the chest decreases the duration of inspiration and diminishes the force of inspiratory muscle contraction. This reflex may cut short ineffective inspirations. Ineffective inspirations sometimes are seen in the newborn when the negative intrathoracic pressure produced by powerful diaphragmatic contraction causes paradoxical inward movement of the flexible infant rib cage.

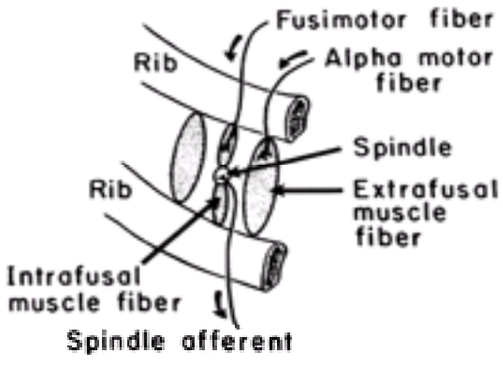

FIG. 7. Intercostal muscle spindle.

Of considerable importance, spindle afferents reach the highest level of the central nervous system, the sensorimotor cortex. Projection of spindle afferent activity to the cerebral cortex allows respiratory muscle length and tension to be sensed consciously and modulated with great precision, thereby allowing complex volitional acts to be performed (e.g., speaking, playing a wind instrument). Spindle afferent activity also likely contributes to the sense of breathlessness. It has been suggested that dyspnea occurs when spindle afferent activity is “high” relative to the intensity of central motor activity to the inspiratory muscles. This concept, which has been termed *length-tension inappropriateness,* explains the dyspnea that arises in the setting of lung diseases that increase inspiratory muscle load and impede muscle shortening. Of interest, the sense of breathlessness can be affected in patients with chronic obstructive pulmonary disease (COPD) by application of vibratory stimuli to the

intercostal muscles, which changes spindle afferent activity. Dyspnea is ameliorated by vibratory stimuli applied in phase with muscle contraction and worsened when the vibratory stimulus is applied out of phase with muscle contraction.

Integration of Afferent Input

Although it is clear that afferent input to the medullary respiratory neurons from mechanoreceptors in the lungs, respiratory muscles, and cardiovascular and thermal regulatory systems (and even the exercising limbs) have significant effects on breathing, the precise manner in which these inputs are integrated is poorly understood. However, the changes in respiratory motor activity elicited by changes in these inputs are not stereotyped. The reflex responses to these inputs may affect the motor output to some respiratory muscles more than others. Pulmonary stretch-receptor input inhibits chest-wall muscle activity (i.e., diaphragm and external intercostal muscles) but increases the activity of the upper airway-dilating muscles (i.e., posterior cricoarytenoid) and the chest-wall expiratory muscles. Even more interesting, some receptors seem to have opposing effects on muscles that normally act as agonists. For example, stimulation of esophageal mechanoreceptors by balloon distension of the distal esophagus reflexively inhibits diaphragmatic activity, both costal and vertebral, but enhances external intercostal activity.

CONTROLLED SYSTEM EFFECTS ON REGULATION OF BREATHING

The translation of the output of the inspiratory neurons to ventilation involves, as shown in Fig. 8, the successive transformation of nerve impulses to muscle electrical activity, muscle shortening, force, and then ventilation. Usually, moderate changes in the mechanical properties of the muscles or chest bellows have little or no effect on the resting blood gas tensions. Compensating effects by the chemoreceptor and mechanoreceptor reflexes, conscious adjustments, and the intrinsic force-velocity relationships of the muscles themselves allow the force of contraction to increase whenever the rate of contraction is slowed. In the presence of sufficiently severe chest disease, however, gas exchange is inadequate despite all efforts to compensate.

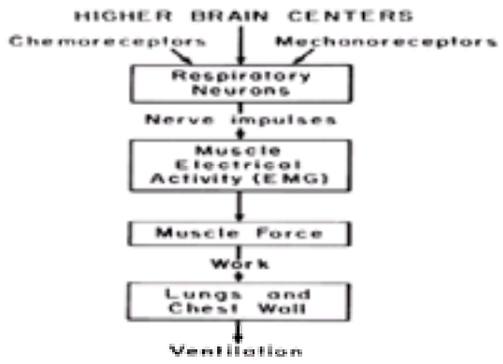

FIG. 8. Steps by which respiratory neural activity is translated into ventilation.

Even when the compensatory responses prove ultimately to be adequate, changes in mechanical conditions (or metabolic rate) cause a transient period in which gas exchange is disturbed and gas tensions are abnormal. The degree to which blood gas tensions deviate from normal in such situations depends on the volume and arrangement of the body stores of O_2 and CO_2.

CO_2 is contained in the body in large amounts as gas in the lungs, but mainly in the form of bicarbonate and carbonate solutions in blood and tissues. O_2, on the other hand, is stored in much smaller amounts in alveolar gas, in solution, and in combination with hemoglobin and myoglobin. Disturbances in gas exchange cause small changes in PCO_2 because of the large size of the CO_2 stores, but large changes in PO_2.

Rates of change of PO_2 and PCO_2 depend not only on the volume of gas stores, but also on organization—that is, the way O_2 and CO_2 contained in different body tissue compartments are linked by the circulation, rates of perfusion, and metabolic rates in the various body compartments—and the ability of the tissues in each compartment to bind CO_2 and O_2.

The rate at which peripheral and central chemoreceptors respond to changes in inspired CO_2 and O_2 depends on the arrangement of the body gas stores. The small size of the arterial compartment and the high rate of carotid body blood flow allow peripheral chemoreceptors to respond quickly to changes in both O_2 and CO_2. The larger CO_2 stores of the brain cause the central chemoreceptors to respond more slowly to changes in inspired CO_2. This difference in response time of central and peripheral chemoreceptors has been used to distinguish the contribution of each receptor to the CO_2 response.

TESTS OF CHEMORECEPTOR SENSITIVITY

When lung function is normal, the sensitivity of the peripheral and central chemoreceptors to CO_2 can be evaluated by measuring the ventilatory response to inspired CO_2. In the conventional steady-state test, the inspired CO_2 is increased in steps, and ventilation at each step is related to the change in $PaCO_2$. Sensitivity to CO_2 is determined from the slope of the line relating ventilation to CO_2. Although the central chemoreceptors are readily accessible to CO_2, the size of cerebral CO_2 stores increases the time required for ventilation to reach a steady state when PCO_2 changes. Usually, the inspired CO_2 concentrations at each step must be maintained constant for 10 to 20 minutes to ensure equilibration. Relative rates of equilibration of PCO_2 in arterial and brain venous blood (Fig. 9) indicate that $PaCO_2$ reaches its steady-state level long before the venous PCO_2. It is apparent from Fig. 9 that if ventilation, which closely tracks cerebral venous PCO_2, is measured too soon, chemosensitivity will be underestimated.

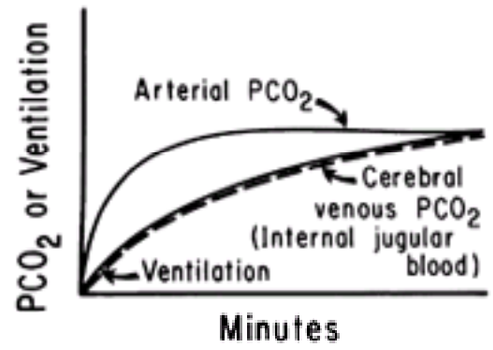

FIG. 9. Changes of ventilation, $PaCO_2$, and cerebral venous $PaCO_2$ when inspired CO_2 is changed.

When CO_2 is rebreathed from a bag containing CO_2 at the mixed venous level together with O_2, arterial and venous blood equilibrate more rapidly. After a brief transition period, PCO_2 at all sites in arterial, cerebral, and mixed venous blood and alveolar air rises at the same rate. Consequently, the rate of change of PCO_2 in alveolar air can be used as an index of the rate of change in PCO_2 in the central chemoreceptors. The exact length of the transition period depends on the size of the rebreathing bag. When the volume of the rebreathing bag is about the same as the vital capacity, chemosensitivity can be estimated by continuous recording of ventilation and PCO_2 after 45 to 60 seconds of rebreathing. Measurements for wide variations in PCO_2 can be obtained in a few minutes. Estimates obtained by this rebreathing method agree with those obtained by the more prolonged steady-state technique. However, the rebreathing tests measure CO_2 sensitivity at much higher levels of PCO_2 than are usually encountered. Moreover, differences have been noted between rebreathing and steady-state ventilatory response to CO_2 when

metabolic acidosis or alkalosis is present. With the steady-state technique, moderate alkalosis and acidosis produce larger changes in the position of the ventilatory response line but relatively small changes in its slopes, whereas the reverse is true in the rebreathing tests. The explanation for this difference is obscure, but it may be related to the different levels of PCO_2 at which steady-state and rebreathing tests are performed.

The average ventilatory response to CO_2 is about 2.5 L/min/mmHg in normal adult men. It is somewhat less in women than in men and tends to decline with advanced age. It varies greatly between individuals but is much more constant in repeated measurements from a single subject. Some of this variability is caused by differences in personality, genetic makeup, and body size, and it is reduced when the CO_2 response is corrected for differences in vital capacity.

Cortical activity is known to affect the response to CO_2. Ventilatory responses to CO_2 measured with the subject's eyes open are greater than ventilatory responses to CO_2 measured with the subject's eyes shut.

TESTS OF PERIPHERAL CHEMORECEPTORS

The peripheral chemoreceptors also respond to CO_2 and contribute about 20%–30% of the total ventilatory increase observed when CO_2 is inhaled. Because peripheral chemoreceptors react rapidly to changes in CO_2, peripheral chemoreceptor responses have been evaluated by measuring the immediate increase in ventilation caused by a few breaths of inspired CO_2 or by measuring the immediate decrease in ventilation observed when CO_2 is abruptly removed.

The response to hypoxia, like the response to hypercapnia, can be measured by either rebreathing or steady-state techniques. Because of the prominent effects of CO_2 on breathing, it is important to keep the CO_2 constant while the response to hypoxia is measured. Because O_2 stores are small, the peripheral chemoreceptor response to O_2 also can be evaluated by measuring the effect on ventilation of a few breaths of N_2 or 100% O_2.

No matter how it is measured, the ventilatory response to hypoxia is curvilinear, making quantitation difficult. The response can be made linear, however, by relating ventilation to the reciprocal of PO_2 or to the arterial O_2 saturation.

There are insufficient data to establish the range of normal values of the ventilatory response to hypoxia; however, available information indicates that it is closely related to the metabolic rate and is at least as variable as the CO_2 response.

Prolonged periods of hypoxia, particularly early in life, are associated with depression of the chemoreceptor response to hypoxia. The ventilatory response to hypoxia is reduced in native residents of regions at high altitudes and in children with congenital cyanotic heart disease. The carotid body appears to be larger in native residents of high altitudes. The change in size may be caused by increased carotid body vascularity, which raises PO_2 and decreases responsiveness.

In the newborn, hypoxia causes only a transient increase in ventilation, which then subsides to nearly prehypoxic levels. It has been recently appreciated that in adult humans, hypoxia lasting for as short a time as 5 minutes produces a gradual reduction in ventilation from its initial peak level.

The initial increase in ventilation is of course mediated by the carotid body. The subsequent decrease seems to represent a depressant effect of hypoxia on central respiratory neurons by hypoxia-induced increases in cerebral blood flow and probably the release of inhibitory neuromodulators, such as adenosine.

Lung disease or respiratory muscle weakness can depress ventilatory responses to chemical stimuli. The depressant effect seems to be greater for the response to CO_2 than for the response to hypoxia. As a result of studies in which airway resistance was increased by requiring subjects to breathe through external resistance, either during inspiration or expiration, it was suggested that the inspiratory work of breathing at a given level of PCO_2 is fixed, so that when the ratio of inspiratory muscle work to ventilation is increased by disease, ventilation decreases. The hypercapnia observed in severe obstructive lung disease was explained by the increase in flow-resistive work associated with chronic airway obstruction.

More recent studies have indicated that small increases in airway resistance have little effect on resting ventilation or CO_2 response in normal subjects and may even heighten ventilation. The mechanisms responsible for the preservation of ventilation under these circumstances could include intrinsic properties of the respiratory muscles, increased inspiratory augmenting output from lung and chest-wall mechanoreceptors, readjustment in the sequence of contractions of the respiratory muscles so that mechanical advantage of the muscles and their coordination is improved, and increased inspiratory drive originating from the motor cortex. This last mechanism may depend on the conscious perception of changes in airway resistance. It is interesting that the ability to detect changes in airway resistance varies, decreasing with increasing airway resistance, and that it decreases further when airway obstruction is chronic than when it is acute.

Because mechanical changes may limit the ventilatory response to chemical stimuli, other methods of assessing the output of respiratory motor neurons have been devised. Two methods have been employed: measurement of occlusion pressure and EMG of the diaphragm. Neither is perfect, but both are useful under certain circumstances.

In the measurement of occlusion pressure, the force of contraction of the inspiratory muscles under quasi-isometric conditions is determined as follows: The airway is momentarily blocked at the beginning of inspiration, and the negative pressure developed during inspiration is measured. In conscious subjects, the reproducibility of the response is greater when the airways are occluded for just a fraction of a second. The occlusion pressure increases with hypercapnia and hypoxia and can be related to change in PCO_2 and PO_2 to estimate chemosensitivity.

Airway occlusion at FRC produces a no-flow state at the relaxed position of the respiratory system. The absence of air flow and prevention of significant volume change during inspiration prevent increases in airway resistance or decreases in compliance from affecting this index of respiratory output. In patients with mechanical abnormalities of the ventilatory pump caused by diseases of the lung or chest wall, occlusion pressure therefore more accurately reflects the neuromuscular drive to breathe than does ventilation.

Because the tensions developed by the inspiratory muscles theoretically depend on their initial length, the occlusion pressure in patients with lungs hyperinflated by disease may not reflect respiratory drive accurately. Increased FRC in animals reduces occlusion pressure responses. However, studies in conscious humans in whom FRC has been changed by altering body position show little effect on occlusion pressure, even when changes in FRC are fairly large (1000 mL). A conscious person apparently maintains constant muscle tension successfully, despite changes in initial muscle length, by altering neural output.

Measurement of the electrical activity of the diaphragm is probably the most direct way of evaluating respiratory neuronal output. This can be accomplished by passing a catheter containing electrodes down the esophagus and positioning the electrodes so that they straddle both surfaces of the diaphragm.

Various ways have been devised to quantitate diaphragmatic electrical activity measured this way. In the method most used currently, diaphragmatic activity is integrated over small intervals of time (100 to 200 ms), and the average activity per time limit is recorded (the so-called moving average). Electrical activity measured in this way depends on the exact positions of the electrodes in relation to the diaphragm during breathing, so that it is difficult to compare one individual with another. It is possible, however, to use this method to determine the effect of different therapeutic interventions in the same person.

CLINICAL IMPLICATIONS

The most important cause of respiratory failure is derangement of lung mechanics. However, respiratory failure does not develop in all patients, even those with severe impairment of pulmonary function. It has long been suspected that those patients who have the poorest chemosensitivity are the ones in whom CO_2 retention is most likely to develop when the performance of the chest bellows is reduced. The evidence for this is indirect. For example, normal offspring of hypercapnic subjects with COPD demonstrate significantly lower ventilatory and occlusion pressure responses to hypoxia and hypercapnia (~60% lower) than do normal offspring of eucapnic subjects with COPD.

The CO_2 sensitivity of children who have retained CO_2 because of upper airway obstruction resulting from hypertrophy of the adenoids and tonsils is depressed, even after the tonsils and adenoids have been removed. Asthmatic patients who have retained CO_2 during an asthmatic attack also show persistently low ventilatory responses to CO_2, even after recovery from the asthmatic episode. Moreover, subjects who have had asphyxial, near-fatal episodes of asthma display lower ventilatory and occlusion pressure responses to hypoxia than do either age-matched normal subjects or asthmatic subjects with no history of near-fatal episodes.

There is also a small group of subjects who retain CO_2 even though lung function is normal. In some of these patients, the cause of the depressed CO_2 sensitivity is not known, but in others it seems to be associated with specific diseases, certain metabolic abnormalities, such as alkalosis, or the long-term administration of respiratory depressant drugs, such as methadone. These conditions are summarized in Table 1. In a few conditions listed in Table 2, only the ventilatory response to hypoxia is depressed. Individuals with these conditions are able to maintain blood gas tensions within usual limits because of their normal CO_2 drive. However, when CO_2 sensitivity is reduced by the administration of drugs (e.g., premedication before surgery), significant hypoxemia can develop. Depressed ventilatory responses to hypoxia may also increase the tendency for CO_2 retention to develop in COPD and may be a risk factor for acute mountain sickness.

Genetic factors
Obesity-hypoventilation syndrome
Bulbar poliomyelitis
Metabolic alkalosis
Parkinson's disease
Narcotic addictions (temporary)
Myxedema
Bilateral spinothalamic lesions
Severe hepatic failure

TABLE 1. *Conditions sometimes associated with depressed responses to hypercapnia and hypoxia*

Narcotic addictions (long-term)
Carotid endarterectomy
Cyanotic congenital heart disease
Familial dysautonomia
Semistarvation
Arnold-Chiari syndrome

TABLE 2. *Conditions associated mainly witha decreased response to hypoxia*

Certain conditions seem to predispose to heightened responses to CO_2 or hypoxia, even when the lungs are normal. These conditions are listed in Table 3.

Hyperthyroidism
Salicylism
Fever
Hemodialysis for uremia
Luft's syndrome
Pregnancy
Mild hepatic failure

TABLE 3. *Conditions associated with increased responses to carbon dioxide and/or hypoxia*

Abnormalities in mechanoreceptor function also can influence gas exchange. Patients with chronic airway obstruction who breathe with small tidal volumes tend to retain CO_2, whereas those who breathe with larger tidal volumes do not. The small tidal volumes are caused by abbreviated inspiratory time and perhaps by heightened pulmonary or chest-wall receptor activity. Heightened mechanoreceptor activity may also be responsible for dyspnea in some patients with interstitial lung disease, as vagal blockade at times alleviates this sensation.

EFFECTS OF SLEEP ON VENTILATION

State-related changes in CNS activity associated with the transition from wakefulness to sleep exert complex effects on ventilatory control that profoundly affect the level and pattern of breathing. In general, withdrawal of cortical and higher CNS influences that provide excitatory inputs to the medullary respiratory neurons during wakefulness cause the chemical regulation of ventilation to assume greater importance.

The transition from wakefulness to slow-wave sleep (i.e., stages 1, 2, 3, and 4 non-REM) is associated with increases in $PaCO_2$ and decreases in PO_2, an increase in the threshold of the ventilatory response to CO_2, and elimination of the "dog leg" in the ventilatory response to CO_2 attributable to the wakefulness drive. In normal subjects, elimination of wakefulness drives and decreases in chemosensitivity typically increase $PaCO_2$ and decrease PO_2 by 4 to 8 mmHg. Small reductions in PCO_2 in the order of 4 to 6 mmHg regularly induce apnea in normal subjects, in contrast to what occurs during wakefulness, when breathing persists despite marked hypocapnia. Steady-state changes in PCO_2 during slow-wave sleep appear to be inversely related to the magnitude of the ventilatory response to CO_2 during wakefulness.

Breathing during stages 1 and 2 of slow-wave (i.e., light) sleep is frequently periodic and often characterized by apnea (i.e., cessation of air flow for >10 seconds) with or without occlusion of the airway (see below). Periodic breathing resembles the Cheyne-Stokes respiration occurring during wakefulness. On the other hand, stages 3 and 4 of non-REM sleep are generally characterized by a slow, deep, regular pattern of breathing. Interestingly, this phase of sleep is associated with a greater depression of ventilatory responses to CO_2 and O_2 than are stages 1 and 2.

Breathing during REM sleep is rapid and irregular, with marked variation in the duration of inspiration and expiration, tidal volume, and average inspiratory air flow rate. Periods of hyperpnea appear to coincide with REM sleep. Electrical activity (EMG) of the rib cage and upper airway respiratory muscles is profoundly depressed in REM sleep, in keeping with the marked muscular atonia observed in the limb muscles. Diaphragmatic EMG activity is relatively spared, but abrupt, irregular periods of inhibition during inspiration may occur. A disproportionate reduction in intercostal relative to diaphragmatic activity in REM sleep leads to paradoxical inward movement of the rib cage on inspiration. Profound inhibition of upper airway muscle electrical activity considerably increases upper airway resistance. Ventilatory responses to CO_2 and O_2 are at their lowest during this stage of sleep. In subjects with underlying lung disease, the greatest disturbances in PaO_2 and $PaCO_2$ occur during this stage of sleep, presumably because of the rapid, shallow pattern of breathing, increased ratio of volume of dead space to tidal volume, and uncoordinated pattern of rib cage

and abdominal movement.

Periodic Breathing During Sleep

Recent studies have suggested several possible mechanisms for the periodic breathing and airway occlusion that occur during the transition from wakefulness to light sleep, each of which causes instability in the ventilatory control system. First, removal of the wakefulness drive depresses ventilation, with concomitant large and rapid increases in PCO_2 and reductions in PO_2 that stimulate peripheral and central chemoreceptors. Second, alterations in blood gas tensions and mild reductions in metabolic activity that decrease CO_2 production and O_2 consumption increase plant gain—that is, the change in blood gas tensions induced by a given change in ventilation. Increased plant gains in stage 1 and stage 2 sleep may offset the mild reductions in ventilatory responses to CO_2 and O_2 that occur during these stages and increase controller gain. Third, progressive increases in respiratory effort during occlusive apnea lead to arousal, the primary mechanism whereby occlusive apnea is terminated. Collapse of the upper airway and arousal destabilize breathing by producing large and rapid changes in PCO_2 and PO_2. Fourth, arousal may be followed by a rapid return to sleep, removal of the wakefulness drive, and rapid deterioration in blood gases. Cycles of airway occlusion and arousal superimposed on sleep-related changes in controller gain may be mutually reinforcing and lead to sustained, progressively amplifying oscillations in breathing and blood gas tensions. Breathing in stages 3 and 4 of sleep is likely to be more stable than in stages 1 and 2, because overall controller gain may be diminished and because changes in ventilation caused by external stimuli are less likely than in stages 1 and 2. Depression of CO_2 and O_2 chemosensitivity in stages 3 and 4 may more than offset increases in plant gain.

Changes in respiration with periods of apnea, profound arterial desaturation, and disturbed sleep appear to be especially common in patients with congestive heart failure. Periodic breathing in these subjects may be explained by a prolongation in circulation time with information delays and increases in plant gain as a result of decreases in pulmonary stores of O_2 related to pulmonary edema.

Airway Occlusion During Sleep

The pathogenesis of airway occlusion during sleep has now been elucidated. Patency of the upper airway during sleep depends on a balance between the subatmospheric “sucking” pressures in the posterior nasopharyngeal space generated by the inspiratory muscles of the chest wall and the opposing dilating forces generated by the upper inspiratory airway muscles, which tend to enlarge and “stiffen” the upper airway. In essence, collapse of the upper airway during inspiration occurs when there is an imbalance of forces in favor of the subpharyngeal pressures. Collapse of the upper airway therefore depends on three factors: (1) activity of the dilator muscles, (2) intraluminal airway pressure, and (3) mechanical properties of the passive upper airway.

The activity of the respiratory skeletal muscles of the upper airways, which originate on the mandible, tongue, larynx, and hyoid bone and dilate the upper airway (i.e., genioglossus, geniohyoid, sternohyoid, posterior arytenoids, cricothyroid), demonstrate a respiratory modulation—that is, the EMG and tension of these muscles increase during inspiration, thereby augmenting the caliber of the upper airway and its tendency to remain patent. Hypercapnic and hypoxic chemical stimuli to breathing increase upper airway muscle electrical activity (e.g., genioglossus, posterior arytenoids) in a manner qualitatively similar to that seen in the pump muscles of the chest wall. All stages of sleep are associated with depression of EMG activity of upper airway muscles at any given level of PO_2 or PCO_2 out of proportion to changes in chest-wall muscle EMG. REM sleep is associated with the greatest inhibition of upper airway muscle electrical activity, in keeping with the generalized muscular atonia that occurs during this stage of sleep. Airway collapse during sleep is favored, therefore, by depression of the electrical activity of dilating upper airway muscles. Re-establishment of airway patency in the setting of obstructive apnea requires arousal and increases in upper airway EMG activity. Of interest, administration of alcohol in amounts that have no effect on ventilation or pattern of breathing depress genioglossus EMG activity during eucapnia or hypercapnia. This finding may explain the greater tendency for obstructive sleep apnea to develop after alcohol ingestion or sedative use.

In addition, end-expiratory lung volume (FRC) oscillates during periodic breathing and demonstrates progressive reduction during the several breaths preceding occlusion. Reductions in lung volume *per se* reduce the cross-sectional area of the posterior nasopharynx and increase the mechanical advantage of the inspiratory muscles of the chest wall (i.e., the inspiratory pressure generated for a given EMG activity is increased).

Classic control system theory indicates that increased controller gain predisposes to control system instability and oscillation. However, it seems likely that the precise mechanisms by which periodic breathing with apnea develop during sleep vary from individual to individual and may depend on the magnitude of the wakefulness drive, the propensity to awaken and undergo rapid, state-related changes in ventilation, and the proclivity of the upper airway to collapse.

CHAPTER

3 Respiratory Functions of the Lung

Claude A. Piantadosi · Yuh-Chin Tony Huang

C. A. Piantadosi and Y. C. T. Huang: Division of Pulmonary and Critical Care Medicine, Duke University Medical Center, Durham, North Carolina 27710.

INTRODUCTION

When the human body is at rest, the lungs receive 5 L of pulmonary blood flow and nearly 5 L of fresh gas/min. The blood in the circulation exchanges metabolic gases within the lung's approximately 300 million alveoli, each of which is about 300 μm in diameter. The alveoli provide a huge surface area of approximately 75 m^2 for gas exchange, with a thickness of <0.5 μm. The alveoli are intertwined with a complex pulmonary capillary network having a surface area of approximately 50 m^2. In the pulmonary capillaries, the erythrocytes traverse the microcirculation in about three quarters of a second. Within the first third of this brief transit time, oxygen and carbon dioxide exchange is such that as the blood exits from the pulmonary capillaries, the concentrations of oxygen and carbon dioxide in the erythrocyte are in equilibrium with those of the alveoli. This system is relatively simple but highly efficient and capable of accommodating as much as a sixfold increase in the rate of blood flow and a twenty-fold increase in the rate of oxygen consumption by the body. The first portion of this chapter describes how the lungs match ventilation with blood flow to insure efficient gas exchange under normal and diseased conditions.

VENTILATION

The adult human lung is described most simply as a system containing conducting airways and the air spaces, or alveoli. The conducting airways consist of bronchi (cartilaginous airways) and bronchioles (noncartilaginous airways), but they contain no alveoli and therefore do not participate in gas exchange. They constitute the “anatomic dead space.” Generally speaking, beginning with the trachea, the conducting airways comprise the first 19 generations of bronchi, ending in terminal bronchioles (Fig. 1). Each terminal bronchiole subtends a terminal respiratory unit, or acinus. The acinus consists of respiratory bronchioles that have alveoli arising from their walls, and alveolar ducts that are lined with alveoli. These structures constitute the “respiratory zone” of the lung, and comprise generations 20 through 27 in Fig. 1. The respiratory zone makes up most of the lung, and for the adult, its volume is approximately 3000 mL.

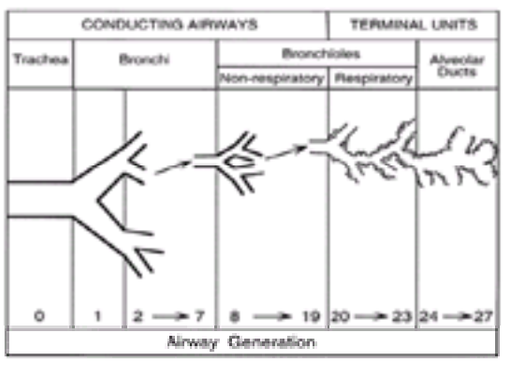

FIG. 1. Weibel's lung model. Note that generation number begins with the trachea. For details, see text. (Adapted and reprinted with permission from Weibel ER. *Morphometry of the Human Lung.* Berlin: Springer-Verlag; 1963:111.)

The Weibel lung model of Fig. 1 conveniently includes some obvious simplifications. For example, some respiratory bronchioles conduct gas in series to more distal respiratory bronchioles and their alveolar ducts and alveoli. In some regions of the human lung, there are fewer than 27 bifurcations from the trachea to the alveoli, whereas other regions contain more than 27 bifurcations. This type of airway branching is known as an *irregular dichotomous pattern.* The presence of shorter pathways may be one of the mechanisms by which gas exchange is sufficient to support life even when tidal volume is less than the dead space, as occurs during

high-frequency ventilation.

Despite its limitations, the simple lung model works quite well for simulating the gas exchange behavior of the lung under resting conditions. The utility of the approach is shown in Fig. 2, where the Weibel model is used to examine the nature of gas flow in the lung. The model indicates little change in the total cross-sectional area of the airways until the terminal bronchioles are reached, where the cross-sectional area increases dramatically. The physical effect of this rapid increase in cross-sectional area is to decrease the forward velocity of the gas flow dramatically, such that the primary mechanism of gas transport changes from convective to "diffusive" in the regions of terminal bronchioles. Indeed, molecular diffusion of the gas phase is essentially the only mechanism of gas entry into the alveoli.

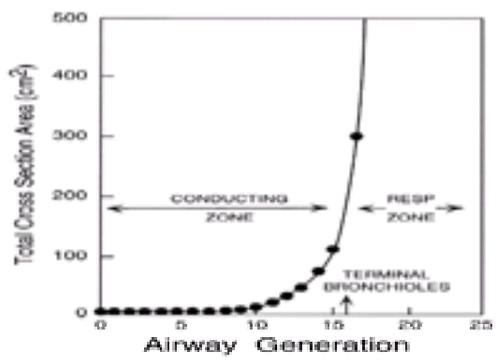

FIG. 2. Diagram of total cross-sectional area of the airways in the respiratory (*resp*) zone. The rapid increase in cross-sectional area in the respiratory zone is predicted from Weibel's model (Fig. 1). (Reprinted with permission from West JB. *Respiratory Physiology—The Essentials.* 4th ed. Baltimore: Williams & Wilkins; 1990.)

Alveolar Ventilation and Dead Space

The alveolar ventilation ($\dot{V}_A$) is the amount of fresh inspired air reaching the alveoli per minute. It can be calculated by subtracting the ventilation not involved in gas exchange (dead space ventilation, $\dot{V}_D$) from total ventilation (or minute ventilation, $\dot{V}_E$).

$$\dot{V}_A = f(V_T - V_D) = \dot{V}_E - \dot{V}_D$$

where f is the respiratory rate; V_T is tidal volume; and V_D is the dead space. Because an appreciable part of each tidal volume does not reach the regions of the lungs in which gas exchange occurs, this fraction of the tidal volume is exhaled largely unchanged and comprises the dead space of the breath. Therefore, it is useful to think of dead space as a fraction of the tidal volume (V_D/V_T) when evaluating the efficiency of carbon dioxide elimination.

Another way to measure the alveolar ventilation in normal subjects is by way of the alveolar ventilation equation:

$$\dot{V}_A = \dot{V}CO_2/P_ACO_2 \times K$$

where $\dot{V}CO_2$ is the volume of CO_2 exhaled per minute, P_ACO_2 is the partial pressure of CO_2 in the alveoli, and K is a proportionality constant (0.863). Because in normal lungs the PCO_2 of alveolar gas and that of arterial blood ($PaCO_2$) are virtually identical, the $PaCO_2$ can be used in the equation to substitute for the P_ACO_2. The same equation also can be used in patients with underlying lung disease, but the solution would yield the "effective" alveolar ventilation. This value is not the same as the alveolar ventilation defined by the anatomic dead space. The "effective" alveolar ventilation would be the volume of fresh inspired gas involved in gas exchange with the capillary blood. Regardless of how it is measured, it is the alveolar ventilation, and not the total ventilation, that determines the effectiveness of CO_2 elimination. This principle can be illustrated by the example of a patient with severe lung disease requiring mechanical ventilation. Such a patient may require as much as 20 L/min of total ventilation to maintain an acceptable PCO_2, because the majority of the gas is used to ventilate air spaces in the lung that are not perfused with pulmonary arterial blood.

Components of the Dead Space

The *anatomic dead space* is the internal volume of the conducting airways from the nose and mouth to the terminal bronchioles. In adults, the anatomic dead space in milliliters is approximately equal to the ideal body weight in pounds. The value increases slightly as lung volume increases or with agents that relax smooth muscle and dilate the airways. Anatomic dead space is also greater during hyperventilation and during exercise, because radial traction is exerted on the bronchi by the surrounding parenchyma of the lung. This traction increases the caliber of the conducting airways.

The volume of the anatomic dead space can be determined easily by Fowler's method (Fig. 3). For this measurement, the patient takes a single inspiration of 100% oxygen, and the nitrogen concentration at the mouth is measured during a slow exhalation. Initially, pure oxygen from the dead space is measured (phase I); nitrogen concentration begins to rise as the dead space gas is washed out by the alveolar gas (phase II). Then, an almost uniform gas concentration is recorded, which represents alveolar gas (phase III). The nitrogen concentration of the final part of the expiration (phase IV) rises because the small airways progressively close at the bases of the lungs. The anatomic dead space is calculated by transforming phase II into an ideal square front (vertical dashed line) and determining the expired volume on the abscissa. The anatomic dead space is not measured routinely in the clinical pulmonary function laboratory because it has little diagnostic value.

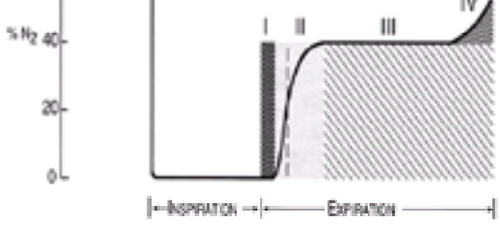

FIG. 3. A single-breath N_2 washout analysis to calculate anatomic dead space. The subject is requested to take a deep breath of O_2 and breathe out slowly and evenly. At the beginning of expiration, pure O_2 (0% N_2) is expired (phase I). This is followed with a rapidly rising N_2 concentration, which represents the washout of the remainder of the dead space gas by alveolar gas, and then by pure alveolar gas (phase III). The N_2 concentration in the last part of the expiration (phase IV) rises because of the progressive closure of the small airways at the bases of the lungs. The anatomic dead space is calculated by transforming phase II into a rectangle and determining the expired volume on the abscissa. (Reproduced with permission from Forster RE, et al., eds. *The Normal Lung: Physiological Basis of Pulmonary Function Tests.* 3rd ed. Chicago: Year Book; 1986.)

Whereas anatomic dead space is determined solely by the structure of the lung, physiologic dead space represents the part of the lungs not involved in carbon dioxide elimination. It is equivalent to the "wasted" ventilation, a term preferred by some authors because physiologic dead space is neither "physiologic" nor "dead." Physiologic dead space can be calculated from the Bohr equation:

$$V_D/V_T = (P_ACO_2 - P_ECO_2)/P_ACO_2$$

where A and E refer to alveolar and mixed expired gas, respectively. In subjects with normal lungs, the PCO_2 of alveolar gas (P_ACO_2) and that of arterial blood ($PaCO_2$) are virtually identical, so that the $PaCO_2$ is often substituted for the P_ACO_2.

The volume of the physiologic dead space is about the same as the anatomic dead space for the normal lung. In the presence of ventilation-perfusion mismatch, however, physiologic dead space increases, mainly from ventilation of lung units with abnormally high ventilation-perfusion ratios. The inspired air that enters these lung units is less effective in eliminating carbon dioxide from the venous blood and produces marked inefficiency of exchange between the blood and gas phases.

Distribution of Ventilation

Regional Distribution of Ventilation

In normal human lung, the alveolar ventilation is not distributed uniformly throughout the air spaces. Using a radioactive tracer gas (e.g., ^{133}Xe) to assess gas distribution, the ventilation per unit volume of the lung in normal upright individuals is found to be the greatest near the base and becomes progressively lower toward the apex. When the subject lies supine, this difference decreases, but the ventilation of the dependent (posterior) lung exceeds that of the nondependent (anterior) lung. In the lateral decubitus position, the dependent lung also is ventilated more effectively.

The topographic distribution of ventilation in the upright lung may be explained by the pleural pressure gradient (Fig. 4). Experimental studies in the upright position show that there is a gradient of intrapleural pressure of 0.6 to 0.7 cm H_2O per centimeter of vertical distance such that the intrapleural pressure is more negative in the upper compared with the lowermost regions of the lungs. The lower transpulmonary pressure (intra-alveolar pressure minus intrapleural pressure) at the base of the upright lung produces two effects: First, the volume of the alveoli at the base is lower, as indicated by the pressure-volume curve at the bottom of Fig. 4. Second, the change in volume for a small change in transpulmonary pressure is greater, because the alveoli are operating on a steeper part of the pressure-volume curve (i.e., the compliance is greater). Thus, the ventilation measured as change in volume per resting volume is greater at the base than at the apex.

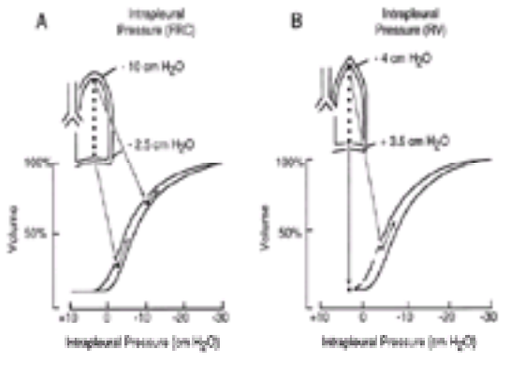

FIG. 4. The topographic distribution of ventilation of the upright lung. **A:** An inspiration from FRC. **B:** An inspiration from RV. (Reproduced with permission from West JB. *Respiratory Physiology—The Essentials.* 4th ed. Baltimore: Williams & Wilkins; 1990.)

The dependent portion of the lung receives more ventilation when a breath is initiated from the functional residual capacity (FRC). If a normal subject makes a small inspiration from residual volume (RV), however, most of the ventilation goes to the apex of the upright lung. This is because the intrapleural pressures in the lowermost lung regions become positive and exceed intra-alveolar pressure, causing the small airways to close. A small decline in transpulmonary pressure that does not exceed the critical opening pressure of the small airways does not allow gas to enter the extreme base of the lung, and only the apex is ventilated (Fig. 4).

The volume at which the basal airways close on exhalation (probably in the region of the respiratory bronchioles) is called the *closing volume.* This closure occurs only at lung volumes below FRC in young normal subjects, but the lung volume at which closing begins increases with advancing age and obesity. This is one of the reasons why the dependent portions of the lungs of older and heavier individuals are more susceptible to atelectasis under conditions that decrease the FRC, such as general anesthesia.

The factors that contribute to vertical gradient of intrapleural pressure are complex. In small animals with compliant thoracic cages, the effects of gravity on the shape of the chest wall appears to be the major determinant of the pressure gradient. In contrast, in large animals with less compliant rib cages, the weight of the lung appears to be the major factor causing the regional gradient of intrapleural pressure and, hence, regional variations in transpulmonary pressure. It also should be noted that in large animals, factors other than lung weight also contribute to the regional distribution of ventilation. For example, the vertical gradient of intrapleural pressure evident in dogs studied in the supine position disappears when they are turned to the prone position. Voluntary breathing with different groups of respiratory muscles also affects the distribution of intrapleural pressure and regional ventilation. Thus, a complete explanation for the nonuniformity of ventilation and the regional differences in intrapleural pressure should take into account the effects not only of lung weight but also of the physical stresses on the lung tissue and thorax.

Unlike the topographic distribution of ventilation, the distribution of ventilation in small regions of the lung cannot be measured easily, because it is beyond the resolution of existing external detectors, such as gamma cameras. Several physiologic factors cause uneven ventilation at the lobular or even the acinar level of the lung.

Time Constants

The time constant of a unit of the lung is determined by the product of its resistance and compliance. Lung units with different time constants inhale and exhale at different rates. A lung unit with a long time constant (i.e., greater resistance and compliance) does not completely fill by the end of inspiration and empties slowly during expiration. In contrast, a lung unit with a short time constant (i.e., smaller resistance and compliance) fills and empties rapidly. The higher the respiratory rate, the greater the discrepancy in filling and emptying between these two kinds of units, and thus the greater the inhomogeneity of ventilation.

When a lung unit with a long time constant is located adjacent to a lung unit with a short time constant, the unit with the long time constant may withdraw gas from the adjacent lung unit with a short time constant rather than fresh inspired gas. This “to and fro” behavior is known as *pendelluft,* and it can occur in abnormal lungs. In addition, a lung unit with a short time constant may receive a higher proportion of dead space gas, which reduces its alveolar ventilation. This effect is prominent in chronic obstructive lung disease, in which compliant lung units with extremely long time constants behave essentially as dead space.

Structural Asymmetry

The inherent asymmetry of the anatomy of the lung produces lung units of different sizes. As expected, smaller lung units receive greater penetration of gas by diffusion than larger units. As a consequence, incomplete mixing of gases may occur in the larger unit, a behavior functionally similar to that caused by stratified inhomogeneity (see below). This mechanism becomes most prominent in bullous lung diseases.

Stratified Inhomogeneity

Another reason for uneven ventilation of small lung units is a gradient of gas concentration along the small airways. This condition is called *stratified inhomogeneity.* Inspired gas reaches approximately the region of the terminal or respiratory bronchioles by convective flow, but gas flow over the rest of the distance to the alveoli is accomplished principally by molecular diffusion within the airways. When airway calibers are altered (e.g., in centrilobular emphysema), the process of gas diffusion may be incomplete for each breath. Thus, alveoli more distal to the conducting airways are less well ventilated than proximal alveoli.

The overall inhomogeneity of ventilation of the lung can be estimated in the laboratory using single-breath or multiple-breath washout techniques. For example, a single breath of air can be inspired containing a small concentration of a chemically inert, relatively insoluble gas (e.g., helium or methane) and then slowly and evenly exhaled into a spirometer or flow meter while concentration of the tracer gas is recorded continuously. Nonuniformity of ventilation can be assessed by measuring the slope of the alveolar plateau (phase III) in Fig. 3. A multiple-breath technique also can be used based on the rate of washout of nitrogen gas when pure oxygen is breathed (nitrogen washout). Inhomogeneity can be judged by the number of breaths required to obtain 90% of the equilibrium value compared with the number

calculated assuming the tidal gas is distributed uniformly.

Factors Counteracting Ventilation Inhomogeneity

Several mechanisms tend to preserve the uniform distribution of ventilation in the lung. One of these mechanisms is the *pendelluft* phenomenon described above. Another mechanism is gas exchange through collateral air channels between adjacent lung units. *Collateral ventilation* can occur between alveoli (pores of Kohn), neighboring terminal units, contiguous lobules (canals of Lambert), and foramina of Martin. The factors affecting flow through these channels, including lung volume and the PCO_2 in alveolar gas, have been studied in several species of experimental animals. Studies in humans, however, are limited. It appears that in normal subjects breathing near FRC there is little gas flow going through collateral channels. Collateral flow becomes more important in determining the mechanical behavior and distribution of ventilation of lungs with airway obstruction.

Another factor that tends to improve uniformity of ventilation is the *interdependence* of peripheral lung units. This concept originates from the observation that contiguous lung units are attached integrally to each other by the connective tissue framework of the lung parenchyma. The behavior of one unit must therefore influence the behavior of its neighbors. This framework serves to offset the tendency for regional differences in compliance to make lung units larger or smaller than they should be for optimal performance. Finally, the pulsatile action of the heart promotes mixing of gas by imparting physical motion to the surrounding lung tissue. The effects of such *cardiogenic mixing* on distribution of ventilation, however, are probably quite small compared with the other factors mentioned above.

PERFUSION

The pulmonary circulation consists of a pump (the right ventricle), a distribution system (arteries and arterioles), a gas exchange surface (the capillary bed), and a collecting system (venules and veins). In a normal-sized adult, the pulmonary circulation contains about 500 mL of blood, of which approximately 150 mL is in the capillary bed. The capillary bed opposes the alveolar epithelium and provides an extensive interface for the uptake of oxygen and elimination of carbon dioxide. It is a readily expandable bed that can tolerate blood flow of several times the resting cardiac output with only a small rise in the pressure (Table 1).

Condition	Rest (sitting)	Exercise
Oxygen consumption	300	2000 mL/min
Blood flow		
Cardiac output	6.3	16.2 L/min
Heart rate	70	135 beats/min
Stroke volume	90	120 mL/beat
Intravascular pressure		
Pulmonary arterial pressure	20/10	30/11 mmHg
Mean	14	20 mmHg
Left atrial pressure, mean	5	10 mmHg
Brachial arterial pressure	120/70	155/78 mmHg
Mean	88	112 mmHg
Right atrial pressure, mean	3	1 mmHg
Resistances		
Pulmonary vascular resistance	1.43	0.62 units[a]
Systemic vascular resistance	13.5	6.9 units[a]

[a] Units = mmHg/L/min.

TABLE 1. *Pulmonary and systemic hemodynamic variables during rest and moderate exercisein a normal adult man*

Hemodynamic Properties of the Pulmonary Circulation

The pressure within the pulmonary circulation is quite low (about one fifth of that of the systemic circulation), although the blood flow to the lungs is comprised of the entire cardiac output. This feature of the pulmonary circulation is responsible for much of its special behavior. A comparison of pulmonary and systemic hemodynamic variables at rest in the normal adult is given in Table 1. The following three concepts about pressure in the pulmonary vessels are important to understanding the behavior of the pulmonary circulation.

Intravascular Pressure

The actual blood pressure inside the lumen of any vessel referenced to atmospheric pressure is the intravascular pressure. Some intravascular pressures, such as pulmonary arterial pressure and pulmonary venous pressure, can be measured directly by placing catheters into the bloodstream at specific points. Pulmonary capillary pressure, on the other hand, is difficult to measure directly. In fact, there is still uncertainty about the exact values of capillary pressure in the pulmonary circulation. Obviously, as blood flows from the pulmonary arterioles through the capillaries to the pulmonary venules, the capillary pressure must be less than arteriolar and greater than venular pressure. In clinical practice, capillary pressure can be estimated by wedging a catheter into a lobar branch of pulmonary artery. The “wedge” pressure measured under conditions of “no flow” reflects pressure downstream within the vascular network at the site of the next freely communicating channels, that is, pulmonary capillaries or small pulmonary venules.

Transmural Pressure

Transmural pressure is the difference between the pressure inside a vessel and the pressure in the tissue around it (perivascular pressure). Transmural pressure is related to the diameter of the vascular lumen. For example, the pressure around the pulmonary arteries and veins is approximately equal to the intrapleural pressure. The pressure around the capillaries is approximately the intra-alveolar pressure. It is this difference in transmural pressure that leads to the different behavior of alveolar and extra-alveolar vessels under conditions such as lung inflation (discussed later). At the capillary level, the transmural pressure is also an important determinant of the rate of transudation of fluid across the capillary bed.

Pulmonary Driving Pressure

Driving pressure is the difference in intravascular pressure between one point in a vessel and another point downstream. It is the pressure involved in overcoming the frictional resistance that impedes blood flow between two points. The driving pressure for the pulmonary circulation is the difference between the intravascular pressure in the main pulmonary artery and that immediately after the pulmonary circulation in the left atrium.

It is important to recognize the differences among these three pressures. For example, if mean pulmonary arterial pressure is 15 mmHg and mean left atrial pressure is 5 mmHg, the driving pressure across the lung would be 10 mmHg (15 – 5). In the presence of mitral stenosis, the mean left atrial pressure may rise to 20 mmHg and the mean pulmonary pressure to 30 mmHg. In this case, the driving pressure for the pulmonary circulation remains at 10 mmHg, but the behavior of the circulation has changed dramatically. The work of the right ventricle has doubled and the transmural pressure at each point along the pulmonary circulation is increased (assuming no change in extravascular pressures), so that pulmonary edema is more likely to develop. There are also situations in which increased pulmonary arterial pressure is associated with normal pulmonary capillary pressure (e.g., primary pulmonary hypertension). In such cases, there is unusually high resistance in the arteries or arterioles. There may be evidence of severe right ventricular strain and failure without an additional tendency for fluid transudation across the pulmonary capillary bed.

Because the pulmonary circulation is a low-pressure system, the pulmonary arteries, both large and small, contain much less smooth muscle than comparable vessels in the systemic circulation. Two exceptions to this generalization occur in the normal lung. One exists in the fetus, where the pulmonary artery connects with the aorta via the patent ductus arteriosus, and therefore the pulmonary artery is exposed to systemic pressures. Another exception occurs in long-term residents of high altitudes, who have elevated pulmonary arterial pressures through the mechanism of chronic hypoxic pulmonary vasoconstriction. As a consequence, these individuals have increased amounts of smooth muscle in the walls of their pulmonary arteries. The extension of vascular smooth muscle into distal pulmonary arteries is found in arterioles as small as 20 μm in diameter.

Different segments of the pulmonary vessels are subject to different perivascular pressures, which strongly influences their internal calibers. This effect occurs because intravascular pressures in the pulmonary circulation are low and vascular diameter depends heavily on transmural pressure. Extrapulmonary vessels are exposed to subcostal pleural pressure modified by local mechanical effects. These extrapulmonary vessels include the large pulmonary arteries and pulmonary veins. Intrapulmonary vessels, on the other hand, can be exposed to perivascular pressures ranging from those at the pleura to those at the alveolus, depending on their anatomic location.

Intrapulmonary Vessels

Differences in the behavior of intrapulmonary vessels were first observed by Macklin, who showed that the volume of the larger vessels increased with lung inflation and decreased with deflation. These observations were extended by Howell and associates, who used the surface tension differential produced by kerosene to separate larger from smaller vessels. These investigators observed that positive-pressure inflation of the lungs compressed small vessels, which were not filled by kerosene, while larger kerosene-containing vessels were expanded.

Intrapulmonary vessels can be divided into alveolar, corner, and extra-alveolar vessels, depending on the perivascular pressures to which they are exposed. The *alveolar vessels* are largely capillaries contained within the interstitium that separates adjacent alveoli. The pressure to which they are exposed is very close to alveolar pressure. When the lung expands, the alveolar walls unfold and the connective tissue elements around them are rearranged. This process compresses the alveolar vessels.

Corner vessels are located at sites where three alveoli meet and therefore are insulated from the surrounding alveolar pressure. These corner vessels are usually about 30 µm in diameter. Morphologic evidence suggests that corner vessels are contained within pleats in the alveolar septa. At low lung volume, the cell structures and connective tissue elements are displaced inward away from the surface of the alveoli. Thus, the enfolded capillaries behave like extra-alveolar vessels, because they are not exposed to alveolar pressure. When the septa unfold, however, the same capillaries behave like alveolar vessels, because the pressure around them is now much closer to the pressure in the adjacent alveoli. Functionally, such corner vessels are probably the vessels that remain open in the zone 1 lung (see below).

The *extra-alveolar vessels,* by definition, are vessels not affected by changes in alveolar pressure but that do enlarge during lung inflation. These vessels can be arteries, arterioles, veins, venules, or precapillaries. The key anatomic feature of the extra-alveolar vessels is their location within a perivascular interstitial space surrounded by a connective tissue sheath. Measurements of pressure with micropipettes inserted into the perivascular interstitial spaces have revealed pressures that are slightly more negative than pleural pressure. The perivascular interstitial pressures become even more negative as the lungs inflate, resulting in dilation of extra-alveolar vessels.

Pressure-Flow Relationships in the Lung

In the upright position, the relationship between pressure and flow in the normal pulmonary circulation is not linear. This is a consequence of the distensibility of the vessels and recruitment of additional vessels when flow is increased. This principle is readily demonstrated in the isolated lung preparation. If pulmonary blood flow is plotted against pulmonary arterial pressure while pulmonary venous pressure and transpulmonary pressure (alveolar pressure minus intrapleural pressure) are held constant (thus fixing lung volume), the slope of the line describing the pulmonary vascular resistance decreases until it reaches a constant value.

Two mechanisms are responsible for the fall in pulmonary vascular resistance in the above system. These are vascular recruitment, that is, the opening of previously closed blood vessels, and distention, or an increase in the caliber of the open vessels. Figure 5 shows experimental data from lungs (of dogs) quick frozen in situ that indicate the importance of recruitment as the pulmonary arterial pressure is raised from low values. The number of open capillaries per millimeter of length of alveolar wall increased from about 25 to >50 as the pulmonary arterial pressure was raised from 0 to nearly 15 cm H_2O. Figure 5 also shows the importance of distention of pulmonary capillaries. The mean width of the capillaries increased from about 3.5 to nearly 7 µm as the capillary pressure was increased to approximately 50 cm H_2O. Beyond that, very little change in diameter occurs with increases in pressure.

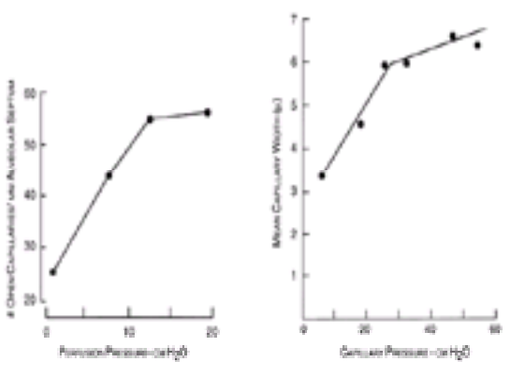

FIG. 5. Left panel: Importance of recruitment of pulmonary capillaries as the pulmonary arterial pressure is raised. (Reproduced with permission from Warrell DA, Evans JW, Clarke RO, Kingaby GP, West JB. Pattern of filling in the pulmonary capillary bed. *J Appl Physiol* 1972;32:346–356.) **Right panel:** Importance of distention of pulmonary capillaries as their pressure is increased. (Reproduced with permission from Glazier JB, Hughes JMB, Maloney JE, West JB. Measurements of capillary dimensions and blood volume in rapidly frozen lungs. *J Appl Physiol* 1969;26:65–76.)

The mechanisms of recruiting pulmonary capillaries are not fully understood. As the pulmonary arterial pressure is increased, it has been suggested that the critical opening pressures of various arterioles are overcome successively. In a dense network of numerous interconnected capillary segments, it can be shown that individual capillary segments require a very small critical pressure before flow begins. Because the network contains a distribution of these critical pressures, recruitment can occur over a large range of arterial pressures. For example, in a network with as many elements as the human pulmonary capillary bed, a critical pressure on the order of only 0.02 cm H_2O for individual segments would be required to recruit vessels over a range of arterial pressures from 0 to 30 cm H_2O. Such a very small critical pressure could result from the basic flow properties of blood, especially when red blood cells fill the capillary lumen.

Just where and how critical opening occurs in pulmonary microvessels is debatable. The variation in red blood cell concentration within areas supplied by single arterioles is probably sufficient to account for the variation between areas supplied by different arterioles. This suggests that recruitment may occur at the capillary rather than the arteriolar level. This would be consistent with the notion that blood flow to the gas-exchanging regions of the lung is regulated at the alveolar level. Thus, under special conditions (e.g., regional gas trapping and edema), closure of alveolar vessels by pericapillary forces may divert blood flow from one pulmonary capillary to another.

The mechanism by which pulmonary capillaries distend is related simply to the ability of the alveolar wall to bulge when the transmural pressure is raised in the capillaries. It has sometimes been argued that the mechanism of distention of pulmonary capillaries cannot be analogous to the behavior of some systemic capillaries. For example, in frog mesentery, the intracapillary pressure can be raised to 100 mmHg without measurable distention. This apparent capillary rigidity, however, can be explained by the support offered by the surrounding interstitial tissue rather than by the stiffness of the capillary walls themselves. This kind of support for the capillaries by the interstitial tissue is lacking in the alveolar region of the lung. One analogy sometimes used to describe the pulmonary capillary network is that of Swiss cheese: the open holes are supported by the cheese around them. Indeed, photomicrographs of pulmonary capillaries in rapidly frozen lungs at high intracapillary pressures show remarkable distention. This finding supports the notion that pulmonary capillaries are passively distensible with increased transmural pressure.

When the capillary pressure is raised to very high levels, the capillary walls are damaged. This damage allows protein or red blood cells to leak out, causing high-permeability pulmonary edema or even frank hemorrhage. In rabbits, this occurs at a capillary transmural pressure of about 40 mmHg, and the ultrastructural changes in the lungs include disruption of the capillary endothelial layer, the alveolar epithelial layer, or both. Because the calculated stress across the interstitium is very high under these conditions, the phenomenon is known as *stress failure.*

There are five conditions in which stress failure of capillaries may be involved. These are as follows: (1) Increased pressure causes high-permeability edema—for example, neurogenic pulmonary edema or high-altitude pulmonary edema (HAPE)—in which the pulmonary edema is of the high-permeability type despite an increased capillary pressure. In neurogenic pulmonary edema, the increased capillary pressure is related to excessive sympathetic activity. In HAPE, intense hypoxic vasoconstriction raises pressure in small pulmonary arterioles. The vasoconstriction, however, is heterogeneous, and some capillaries are not protected by arterial constriction and are exposed to high pressure. The stress failure hypothesis in HAPE is supported by the patchy distribution of pulmonary edema and the observation that exercise at high altitude is a provocative factor. (2) Increased pressure causes hemorrhage—for example, exercise-induced pulmonary hemorrhage in race horses and possibly top-notch human athletes. Pulmonary systolic pressures as high as 120 mmHg can develop in race horses while galloping. The fact that increased capillary pressure causes bleeding rather than high-permeability edema may be related to the very abrupt rise in pressure. (3) Increased pressure causes edema and hemorrhage—for example, in mitral stenosis and pulmonary veno-occlusive disease. (4) Overinflation or hyperinflation of the lung increases the longitudinal tension in the alveolar wall, some of which is transmitted to the capillary wall. This could explain the increased capillary permeability at high lung volumes. The increased

permeability is caused by high lung volume rather than alveolar pressure, because banding the chest prevents the increased permeability. (5) In cases of an abnormal extracellular matrix—for example, Goodpasture's syndrome—the strength of the capillary wall is diminished by the attack by antibodies on the collagen of the basement membrane. Alveolar hemorrhage may occur even at normal vascular pressures.

Pulmonary Vascular Resistance

A variety of approaches have been used to measure changes in pulmonary vascular resistance *in vivo.* These include measurement of pressure-flow curves and the pressure gradient across the pulmonary vascular bed at end-diastole. Pulmonary vascular resistance for the pulmonary circulation is calculated from the following equation:

$$R = (P_{pa} - P_{pv})/\dot{Q}$$

where R is pulmonary vascular resistance; P_{pa} is mean pulmonary arterial pressure (mmHg); P_{pv} is mean pulmonary venous pressure (mmHg; often the pulmonary wedge pressure is used), and $\dot{Q}$ is pulmonary blood flow (L/min). For the normal pulmonary circulation the value for R is approximately 2.0 mmHg/L/min. To express pulmonary vascular resistance in dynes sec^{-1} cm^{-5}, the numerator of the equation is multiplied by 80 (1.332 × 60 sec); the normal value is then »160.

Although the resistance equation has the form of Ohm's Law for electrical circuits (voltage difference divided by current flow), the resistance of an electrical resistor does not depend on either the voltage drop or the flow of current. This is not true for the pulmonary vascular resistance, which is affected by both driving pressure and blood flow. For example, in the normal pulmonary circulation, as pulmonary arterial pressure is increased at constant left atrial pressure, pulmonary vascular resistance falls. Of course, this is associated with an increase in pulmonary blood flow (Fig. 6). Also, pulmonary vascular resistance decreases when venous pressure is raised (with pulmonary arterial pressure held constant). In this case, however, pulmonary blood flow decreases (Fig. 6). Thus, it should be apparent that a single value for pulmonary vascular resistance is an incomplete description of the pressure-flow properties of the pulmonary circulation. Nonetheless, pulmonary vascular resistance measurements are useful in clinical practice for the diagnosis of pulmonary vascular diseases and for monitoring therapeutic interventions.

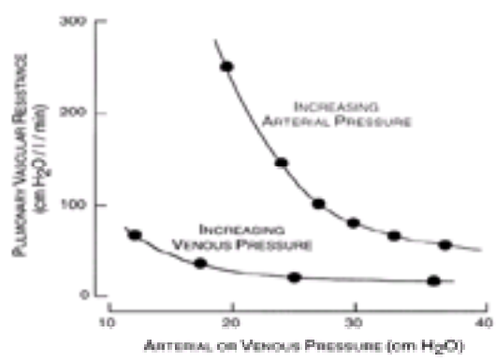

FIG. 6. Relationship between pulmonary vascular resistance and pulmonary arterial or venous pressure. Experiments in a dog lung preparation in which one pressure was changed while the other was held constant. (Reproduced with permission from West JB. *Respiratory Physiology—The Essentials.* 4th ed. Baltimore: Williams & Wilkins; 1990.)

In humans, the pressure drop across the pulmonary vascular bed is »10% of the pressure drop across the systemic circulation. Different approaches have been used to determine the pattern of pressure drop along the pulmonary blood vessels. These include measuring the transudation pressure on the pleural surface of isolated lung; measuring the pressure transient resulting from the injection of a bolus of low- or high-viscosity blood into the pulmonary artery; measuring transient pressure following rapid occlusion of the venous outflow, the arterial inflow, or both; determining pressure-flow curves under zone 2 conditions, and direct puncture of different-sized vessels along with direct measurement of hydrostatic pressure. The values obtained from the various measurements are surprisingly consistent; in the normal lung, precapillary and postcapillary resistances are about equal, favoring a slightly higher precapillary resistance. Morphologically, the major site of pulmonary vascular resistance is in the small muscular arteries (100–1000 µm) and arterioles (<100 µm), because the cross-sectional area of the vascular network expands suddenly at the precapillary level.

Effect of Lung Volume on Vascular Resistance

The pulmonary vascular resistance depends greatly on the degree of inflation of the lung. The relationship between lung volume and pulmonary vascular resistance is shown in Fig. 7. The *solid line* in Fig. 7 indicates the total vascular resistance. *Two dashed lines* denote vascular resistances contributed by alveolar and extra-alveolar vessels. The lung normally operates near the minimal value of vascular resistance, which occurs at approximately FRC. Both increases and decreases in lung volume from the resting position are associated with increased resistance to blood flow. As shown in Fig. 7, increasing pulmonary vascular resistance with decreasing lung volume results mainly from increases in the resistance of extra-alveolar vessels. This is most likely related to the decrease in caliber of the extra-alveolar vessels caused by decreases in the forces of radial traction exerted by the surrounding parenchyma. At states of high lung inflation, the increase in pulmonary vascular resistance is probably caused by distortion of the pulmonary capillaries. This distortion increases the resistance of blood moving through it. Direct measurements on frozen lungs of dogs show that the average width of the capillaries decreases greatly at high levels of lung inflation.

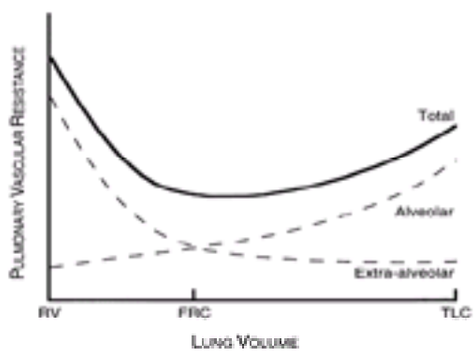

FIG. 7. Relationship between lung volume and pulmonary vascular resistance. The effects of changes in vital capacity on total pulmonary vascular resistance and the contributions to the total afforded by alveolar and extra-alveolar vessels are depicted. Note that changes in total pulmonary vascular resistance form a U-shaped curve during lung inflation, with the nadir at FRC. *RV,* residual volume; *TLC,* total lung capacity. Active Versus Passive Modulators of Pulmonary Vascular Resistance

Pulmonary vascular resistance is modulated by various factors that can be divided conveniently into “passive” and “active” processes. Passive factors change the caliber of pulmonary blood vessels without a significant response in the tone of vascular smooth muscle. Table 2 summarizes the pertinent passive factors. Of these passive factors, the effect of blood viscosity on pulmonary vascular resistance is the most difficult to quantify, but it appears to depend on the capillary hematocrit, the physical properties of red blood cells, and the composition of plasma. In the isolated lung, as hematocrit increases, progressively greater pressure is required to overcome the contribution of blood viscosity to resistance and to maintain the blood flow. In contrast, active factors alter pulmonary vascular resistance by contracting or relaxing the smooth muscles of blood vessel walls. These factors can be humoral, neural, or chemical in nature. Some of the important active factors are shown in Table 3.

Factor	Response
Pulmonary arterial pressure (P_{PA})	Increased P_{PA} causes decreased PVR
Left atrial pressure (P_{LA})	Increased P_{LA} causes decreased PVR
Transpulmonary pressure (P_t)	Increase and decrease of P_t from value at FRC cause increased PVR
Total interstitial pressure (P_{is})	Increased P_{is} causes increased PVR
Pulmonary blood volume	Shift of blood from systemic vessels into lung vessels causes decreased PVR
Whole-blood viscosity	Increase in viscosity causes increased PVR

PVR, pulmonary vascular resistance; FRC, functional residual capacity.

TABLE 2. *Factors causing "passive" changes in pulmonary vascular resistance and direction of responses*

Factor	Response
Neurogenic stimuli	
Sympathetic stimulation	Increases PVR in experimental animals; no effect in humans
Parasympathetic stimulation	Decreases PVR in experimental animals with pre-existing vasoconstriction; no effect in humans
Humoral stimuli	
Norepinephrine, serotonin, histamine, angiotensin, fibrinopeptides, prostaglandin $F_{2\alpha}$	Vasoconstriction
Acetylcholine, bradykinin, prostaglandin E_1, prostacyclin (prostaglandin I_2)	Vasodilation; bradykinin affects humans with pulmonary hypertension
Nitric oxide	Vasodilation
Chemical stimuli	
Alveolar hypoxia	Increases PVR
Alveolar hypercarbia	Increases PVR in experimental animals; no effect in humans
Acidemia (decreased pH)	Increases PVR

PVR, pulmonary vascular resistance.

TABLE 3. *Important causes of "active" changes in pulmonary vascular resistance and direction of responses*

The pulmonary circulation is exposed constantly to passive influences, making it sometimes difficult to demonstrate that changes in pulmonary vascular resistance are caused by active pulmonary vasoconstriction or dilation. Notable exceptions occur when the vasomotor responses are opposite to and prevail over responses to passive factors. Similarly, changes in pulmonary arterial pressure alone cannot be interpreted as indicating changes in pulmonary vascular resistance unless left atrial pressure and cardiac output are known.

Advanced lung diseases such as pulmonary fibrosis and pulmonary emphysema can cause increases in pulmonary vascular resistance and thus pulmonary hypertension. Pulmonary vasoconstriction is caused by alveolar hypoxia, but distortion of lung architecture by the disease processes and increased interstitial fluid in the perivascular spaces of the extra-alveolar vessels (pulmonary edema) also play important roles. When edema is severe, fluid also may accumulate in the interstitium of the alveolar wall, thus encroaching on alveolar vessels and increasing their vascular resistance.

Distribution of Perfusion

The distribution of pulmonary blood flow can be measured with tracer methods. Radioactive carbon dioxide ($C^{15}O_2$) was the first test substance to be used to study the distribution of pulmonary blood flow. After the tracer gas is breathed into the lung, regional perfusion can be determined by monitoring the disappearance of the gas, whose uptake from alveoli depends on the blood flow to the alveoli. Insoluble tracer gases such as ^{133}Xe also can be dissolved in saline solution and injected into a peripheral vein. When the xenon reaches the pulmonary capillaries, it is transferred into the alveolar gas. The tracer pattern within the lung then reflects the perfusion of gas-filled alveoli in various regions. The distribution of blood flow also can be measured with labeled particles, such as radioactive- or fluorescent-labeled microspheres. These particles are sized appropriately to be trapped within small pulmonary vessels as they pass into the pulmonary circulation.

Each of these procedures has advantages and disadvantages, but all have detected the presence of a vertical gradient of blood flow in a normal upright lung. The vertical gradient is largely the consequence of differences in hydrostatic pressure in the pulmonary circulation associated with gravity. As the adult upright human lung is about 30 cm high, the hydrostatic difference in pressure between the extreme apex and the bottom of the base can be as much as 30 cm of blood (23 mmHg). This means that the intravascular pressure in vessels at the lung base can be higher than that in apical vessels by as much as 23 mmHg. When the pulmonary venous pressure and intra-alveolar pressure are held constant, this translates to a greater transmural pressure for the vessels at the base. As a result, the diameter of blood vessels at the base of the lung is greater and more blood flows through them. The difference between apical and basal blood flow no longer exists when the lung is supine, but a perfusion gradient can be detected between the independent (uppermost) and dependent (lowermost) regions of the lung. In the upright position, exercise increases apical blood flow more than basal blood flow because of the recruitment of collapsed vessels (West zone 1; see below), and the perfusion gradient is reduced greatly.

Gravity-Dependent Distribution of Blood Flow

The intravascular pressures of the pulmonary circulation are influenced by the hydrostatic pressure created by gravity. As alveolar pressure is relatively independent of gravity, the relationships among pulmonary arterial, pulmonary venous, and alveolar pressures must also influence the distribution of pulmonary blood flow. This principle was predicted by Dock. West subdivided the lung into four zones with differing patterns of blood flow. Figure 8 shows this zonal distribution.

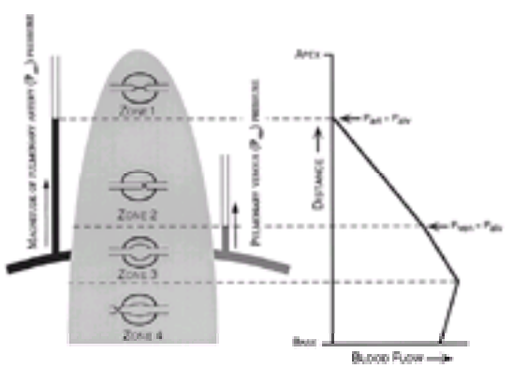

FIG. 8. Schematic representation of the four zones of the lungs in which different hemodynamic conditions govern blood flow. Alveolar pressure (P_{alv}) is assumed to be 0; the heights of the *blue column* and the *red column* represent the magnitude of pulmonary arterial (P_{art}) and pulmonary venous (P_{ven}) pressures, respectively. (Reprinted with permission from Hughes JM, et al. Effect of lung volume on the distribution of pulmonary blood flow in man. *Respir Physiol* 1968;4:58–72.)

Zone 1 is the region of the lung wherein alveolar pressure exceeds both the pulmonary arterial and venous pressures. In zone 1, the alveolar vessels are collapsed and there is no pulmonary blood flow. In the presence of corner vessels that are protected from alveolar pressure, however, some flow still occurs in this zone.

Zone 2 is the part of the lung in which pulmonary arterial pressure exceeds alveolar pressure, but alveolar pressure exceeds venous pressure. Under these conditions, the resistance to blood flow is determined by the difference between pulmonary arterial and alveolar pressures, rather than by the expected arterial-venous pressure difference. This behavior has been referred to variously as the *waterfall* or *sluice effect* and can be simulated in a Starling resistor model made of rubber tubing. The

flow properties of capillaries, however, are very different from those of a Starling resistor. For one thing, capillary flow tends to be laminar. This differs from the Starling resistor, which usually oscillates and creates turbulent flow. In addition, the capillaries contain trains of red blood cells that essentially fill the diameter of the small vessels. These vessels cannot collapse in the same way as a rubber tube. Nevertheless, the lung in zone 2 conditions has essentially the same pressure-flow characteristics as a Starling resistor. Also in zone 2, blood flow increases progressively down the lung because of the increasing hydrostatic effect on pulmonary arterial pressure, which increases the driving pressure in this region (pulmonary arterial pressure minus alveolar pressure).

Zone 3 is the part of the lung in which pulmonary venous pressure exceeds alveolar pressure. Blood flow also increases down this zone, although the rate of increase in relation to distance is less than in zone 2. Because the arterial-venous pressure difference is responsible for flow and is constant, it is not immediately apparent why blood flow would increase down this zone. Because the transmural pressure across the vessel wall increases with distance down zone 3, however, pulmonary arterial and venous pressures both increase while alveolar pressure remains constant. Thus, if the vessels are distensible, their caliber will increase and their vascular resistance will decrease down the zone. Indeed, micrographs of rapidly frozen lung confirm an increase in vessel caliber down zone 3. It is also possible that retrograde recruitment of capillaries contributes to the increase in blood flow.

In zone 4, the relationships between intravascular and alveolar pressures are the same as in zone 3, but the blood flow decreases. Zone 4 occurs in the lowermost region of the upright human lung and diminishes as lung volume increases. Conversely, as lung volume decreases, this region of reduced blood flow extends farther and farther up the lung, so that at FRC blood flow decreases progressively down the bottom half of the lung. At residual volume, zone 4 extends nearly all the way up the lung, so that blood flow at the apex exceeds that at the base. This condition obviously cannot be explained by the interactions among the pulmonary arterial, venous, and alveolar pressures. Instead, the reduced blood flow in zone 4 can be attributed to narrowing of extra-alveolar vessels at the lung base that results from lower lung inflation. The increased contribution of extra-alveolar vessels to pulmonary vascular resistance results in the presence of a zone of reduced blood flow in that region. This explanation is supported by the observation that vasoconstrictor drugs such as serotonin cause zone 4 to extend farther up the lung. The opposite effect is seen when vasodilator drugs are infused into the pulmonary circulation.

Zone 4 would be expected to increase in the presence of interstitial pulmonary edema, because the edematous fluid increases interstitial pressure in the vascular sheath and thereby narrows the extra-alveolar vessels. This is a plausible mechanism for the inverted distribution of blood flow (cephalization of pulmonary vasculature on chest x-ray) in pulmonary edema. The interaction of interstitial edema with blood flow distribution, however, remains poorly understood.

Gravity-Independent Distribution of Blood Flow

Not all the inhomogeneity of blood flow in the lung can be explained by gravitational effects. In normal people flying Keplerian arcs in aircraft, where periods of up to 25 sec of microgravity are possible, much of the normal topographic inhomogeneity disappears. Indirect measurements of inhomogeneity of pulmonary blood flow have been made in astronauts in space shuttles by monitoring the magnitude of cardiogenic oscillations on the expired carbon dioxide tracing. A striking reduction in inhomogeneity of blood flow was detected during weightlessness compared with that observed in the upright posture before or after the flight. Interestingly, substantial inhomogeneity of blood flow still remained, indicating that some gravity-independent mechanism was also present. Variations in the length of the pathways from the main pulmonary artery to the terminal respiratory units and variations within a single terminal respiratory unit may contribute to this process. The unequal length of pathways leads to different transit times for red blood cells and earlier perfusion of first-order respiratory bronchioles and their alveoli than of the more distal ones. Another suggestion is that regions of intrinsically high resistance (low conductance) exist normally because of differences in caliber or geometric features of the pulmonary vascular bed. Evidence for this has been obtained in isolated dog lungs. It also has been suggested that isogravitational inhomogeneity of blood flow can be explained by fractal geometry. According to this concept, the inhomogeneity is a consequence of a fractal configuration of vascular branching that is replicated from larger to smaller blood vessels. Such a fractal model might also explain the radial gradient of perfusion and the regional differences in conductance mentioned above.

Pulmonary Blood Flow in Cardiopulmonary Diseases

The normal distribution of pulmonary blood flow is altered by many cardiopulmonary diseases. The redistribution of blood flow frequently increases mismatching of ventilation and perfusion and may result in hypoxemia or increases in dead space (see below, Ventilation-Perfusion Distribution and Gas Exchange). For example, localized structural lung disease resulting in the formation of bullae or cysts usually causes local reductions in flow. The same is also true of pulmonary embolism, in which the local blood flow is obstructed by the presence of clots. Such abnormalities of perfusion are usually coupled with normal ventilation and hence increase the dead space. This pattern of ventilation-perfusion abnormality provides an important diagnostic clue on ventilation-perfusion scan. The blood flow to the lung on the side of a pneumothorax may be compromised because of compression or kinking of large or small pulmonary vessels. Blood flow may be reduced to some parts of the lung because of destruction of the pulmonary vasculature or distortion of pulmonary vascular geometry in diffuse lung diseases such as pulmonary fibrosis or chronic obstructive pulmonary disease. In patients with pulmonary hypertension or increased blood flow secondary to left-to-right shunts, the blood flow is usually distributed more uniformly. During severe hypotension and circulatory shock, perfusion to the lung apices is reduced significantly. Increased pulmonary venous pressure, as in mitral stenosis, initially causes a more uniform distribution than normal. In more advanced disease, inversion of the normal distribution of blood flow is frequently seen, with more perfusion to the upper than to the lower lung zones. The mechanism for this shift is not understood fully, but, as indicated earlier, it may be related to perivascular edema causing an increased resistance within the extra-alveolar vessels.

Control of the Pulmonary Circulation

The distribution of pulmonary blood flow and the pressure-flow relations of the pulmonary circulation are highly influenced by the “passive” factors shown in Table 2. Thus, gravity and the mechanisms of recruitment and distention can account for most of the behavior of the normal circulation. By contrast, when the amount of smooth muscle is increased—for example, in the lungs of fetuses, of long-term residents of high altitudes, or of patients with prolonged pulmonary hypertension—“active” regulatory factors begin to play a more significant role in the control of the pulmonary circulation.

One example of active control of the pulmonary circulation is hypoxic pulmonary vasoconstriction. The precise mechanism of this response is unknown. It clearly does not depend on central nervous system input, as it occurs in excised isolated lungs. Furthermore, the local action of hypoxia on the artery itself is important, because excised segments of pulmonary artery can be shown to constrict in hypoxic environments. It is also known that hypoxic pulmonary vasoconstriction can be elicited by lowering the partial pressure of oxygen (PO_2) in the alveolar gas or mixed venous blood.

The stimulus-response curve for hypoxic pulmonary vasoconstriction is very nonlinear. When the alveolar PO_2 is altered in the region above 100 mmHg, little change in vascular resistance is seen; however, when alveolar PO_2 is reduced to 60 mmHg, vasoconstriction may occur. At PO_2 values approaching that of mixed venous blood, local blood flow may be almost abolished. The intensity of hypoxic vasoconstriction varies from subject to subject, among different species, and in different parts of the same lung.

The site of hypoxic vasoconstriction is still not certain, but some evidence suggests it occurs in pulmonary precapillary vessels (small muscular pulmonary arteries and arterioles). Some studies also suggest alveolar vessels may be, at least in part, responsible for the increased resistance, and contractile cells have been described in the interstitium of the alveolar wall; these cells conceivably could distort capillaries and increase their resistance.

The cellular mechanisms of hypoxic pulmonary vasoconstriction remain obscure despite a great deal of research. Some chemical modulators of the response, including catecholamines, histamine, angiotensin, and prostaglandins, have been studied extensively. None of these substances, however, meets all the necessary criteria for the mediator of hypoxic pulmonary vasoconstriction. Recently, it has been suggested that inhibition of endothelium-derived relaxing factor (EDRF) or nitric oxide may be involved. As the biosynthesis of nitric oxide requires molecular oxygen, hypoxic vasoconstriction may in part represent loss of vasodilator effects normally provided by nitric oxide.

Hypoxic pulmonary vasoconstriction has the effect of directing blood flow away from hypoxic regions of lung. This tends to reduce the extent of ventilation-perfusion mismatching in diseased lungs and limits the decline in the arterial PO_2. A good illustration of this effect is seen in patients with pulmonary hypertension who are treated with systemic vasodilators, such as calcium channel blockers, in an attempt to reduce pulmonary arterial pressure. This treatment can be associated with nonspecific vasodilation that causes an increase in blood flow to poorly ventilated areas. The process may lead to a reduction in arterial PO_2. Hypoxic pulmonary vasoconstriction also occurs in both newcomers and in permanent residents of high altitudes. At altitude, the increase in pulmonary arterial pressure is especially marked during exercise. These responses result in improvement in gas exchange.

GAS EXCHANGE

The composition of normal gas changes in various lung compartments during inspiration (Fig. 9). As can be seen, the partial pressure of oxygen (PO_2) decreases as soon as the ambient gas reaches conducting airways. This is caused by warming of the inhaled air and its saturation with water vapor. These processes dilute the inspired mixture of N_2 and O_2. At body temperature of 37°C, water vapor pressure adds 47 mmHg of pressure to dry gas. Once the inspired gas reaches the terminal respiratory units, gas exchange takes place. Slightly more O_2 is removed than carbon dioxide (CO_2) is added (at a normal respiratory exchange ratio of 0.8), which

causes the volume of each gas exchange unit to diminish slightly and raises the concentration of N_2 within the alveoli slightly. The gas composition of the blood in the pulmonary capillaries leaving the alveoli is approximately the same as the gas phase of the terminal units. The PO_2 in the arterial blood is slightly lower because local matching of ventilation and perfusion in normal lungs is imperfect and unoxygenated blood is added to capillary blood from postpulmonary shunt.

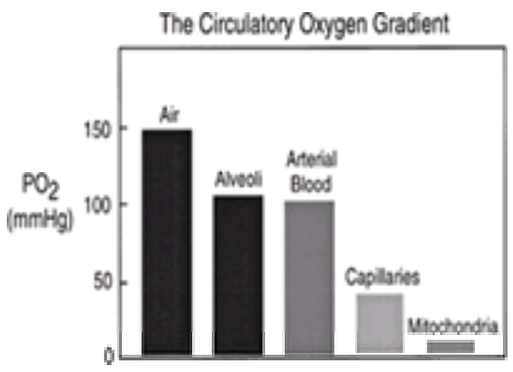

FIG. 9. The O_2 gradient from the alveolar space to the mitochondria. Note that there is a stepwise decrement in PO_2 from 100 mmHg in the alveolar space to values of a few mmHg at the mitochondria, where most of the O_2 is consumed.

Ventilation-Perfusion Distribution and Gas Exchange

Exchange of O_2 and CO_2 between blood in the pulmonary arterial system and alveolar gas occurs continuously in more than 100,000 terminal respiratory units of the lungs. The adequacy of function of each gas exchange unit is determined by local matching of ventilation and perfusion ($\dot{V}_A/\dot{Q}$). In general, inadequate ventilation relative to perfusion (i.e., low $\dot{V}_A/\dot{Q}$ regions and shunt) has the greatest effect on O_2 uptake by the lung and thus may result in hypoxemia. On the other hand, excessive ventilation relative to perfusion (i.e., high $\dot{V}_A/\dot{Q}$ regions and dead space) has more influence on CO_2 elimination by the lung and predisposes to hypercapnea.

The effects of $\dot{V}_A/\dot{Q}$ matching on the efficiency of gas exchange in the lung can be understood using the two-compartment lung model. In an ideal lung consisting of two alveolar units (A and B), each receiving 2.0 L/min of alveolar ventilation and 2.5 L/min of blood flow, the $\dot{V}_A/\dot{Q}$ ratio is 0.8 for the individual units A and B, and 0.8 for the entire lung. Assuming no barrier to diffusion of O_2 and a normal PO_2 in the pulmonary artery, the PO_2 of alveolar gas is the same as the PO_2 of end-capillary and arterial blood. There is no O_2 gradient from alveolus to capillary (alveolar-arterial PO_2 difference). A “normal” lung has a slight degree of $\dot{V}_A/\dot{Q}$ mismatch, which is caused primarily by the greater effects of gravity on the distribution of perfusion than on ventilation (Fig. 10). Thus, in the “normal” lung, while the $\dot{V}_A/\dot{Q}$ ratio for the whole lung remains at 0.8, the $\dot{V}_A/\dot{Q}$ ratios for the two units A and B are 1.0 and 0.6, respectively. This causes the mean PO_2 in the blood leaving the lung to decrease slightly and produces an alveolar-arterial PO_2 difference of 4.4 mmHg. Uneven distribution of blood flow may also result in similar effects, especially in the upright lung.

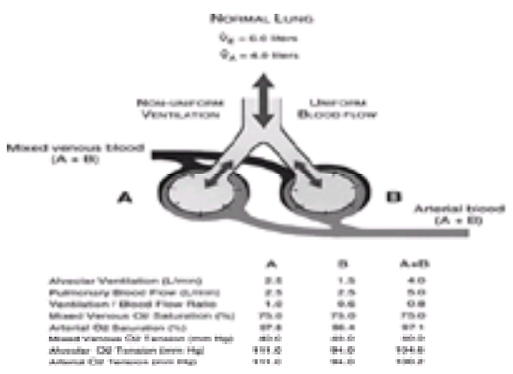

FIG. 10. Ventilation-perfusion relationship of a normal lung is illustrated using a two-compartment model. Note that the ventilation-perfusion maldistribution is responsible for an alveolar-arterial PO_2 difference of about 4.4 mmHg; the remainder of the normal PO_2 difference is caused by postpulmonary shunts (ignored in this illustration). (Reproduced with permission from Forster RE, et al., eds. *The Normal Lung: Physiological Basis of Pulmonary Function Tests.* 3rd ed. Chicago: Year Book; 1986.)

Assessment of Abnormalities in Gas Exchange

The effectiveness of gas exchange (and thus the distribution of $\dot{V}_A/\dot{Q}$ ratios) can be assessed by several methods. The simplest approach is to sample the composition of arterial blood and alveolar gas. More complicated approaches rely on tracer gases and modeling of gas exchange—for example, the multiple inert gas elimination technique. No measurement technique, however, allows an exact description of the complex behavior of gas exchange in the lung.

Arterial PO_2

The arterial PO_2 certainly provides some information about the degree of ventilation-perfusion matching. The major advantage of the measurement is its simplicity. In general, a low PO_2 almost always indicates the presence of $\dot{V}_A/\dot{Q}$ mismatch or shunt, but a normal PO_2 (greater than 80 mmHg) does not necessarily imply that the $\dot{V}_A/\dot{Q}$ distribution of the lung is “normal.”

Alveolar-Arterial PO_2 Difference

The alveolar-arterial PO_2 difference ($A–aDO_2$) is calculated readily from the alveolar PO_2 (P_AO_2) and the arterial PO_2 (PaO_2). The alveolar PO_2 is computed from the alveolar gas equation:

$$P_AO_2 = F_IO_2 (P_B - PH_2O) - (P_ACO_2/R)$$

where P_B is barometric pressure; PH_2O is water vapor pressure at body temperature (47 mmHg at 37°C); F_IO_2 is the fractional concentration of O_2 in inspired gas (0.21 in air); and R is the respiratory exchange ratio. The equation simplifies to

$$P_AO_2 = F_IO_2 (713) - 1.25\ PaCO_2$$

by substituting the arterial for alveolar PCO_2 and 0.8 for the respiratory exchange ratio. The alveolar-arterial PO_2 difference is more informative than the arterial PO_2

alone because it takes into account the level of ventilation.

The alveolar-arterial PO_2 difference in healthy adults breathing room air increases with age. As a general rule, the alveolar-arterial PO_2 difference for an individual should be no more than half of the chronologic age, with a maximum of 25 mmHg. The alveolar-arterial PO_2 difference is caused by the combination of $\dot{V}_A/\dot{Q}$ mismatch and right-to-left postpulmonary shunting of blood. Each of these mechanisms is responsible for about half of the total alveolar-arterial PO_2 difference in normal adults. None of the alveolar-arterial PO_2 difference at normal barometric pressure is caused by failure of diffusion equilibrium to occur, even during heavy exercise. Diffusion disequilibrium may occur during exercise at high altitudes.

The alveolar-arterial PO_2 difference increases with increasing alveolar PO_2, in part because the upper part of the oxygen-hemoglobin dissociation curve is concave. The alveolar-arterial PO_2 difference reaches a maximum and then decreases at higher PO_2. The decline in the alveolar-arterial PO_2 difference occurs when inspired PO_2 exceeds 350 to 450 mmHg, because alveolar PO_2 rises to more uniform levels despite the nonuniform distribution of $\dot{V}_A/\dot{Q}$ ratios.

Physiologic Shunt

The presence of right-to-left shunt can be differentiated from low $\dot{V}_A/\dot{Q}$ causes of hypoxemia by having the patient breathe 100% O_2. While the patient is breathing pure O_2, the alveolar PO_2 in different lung units differs according to differences in alveolar PCO_2. Lung units with low $\dot{V}_A/\dot{Q}$ ratios, even though they may be ventilated only poorly via collateral pathways or intermittently at high lung volumes, will show an increase in PO_2 nearly maximally with elevation of the inspired PO_2. This response also occurs with impairment of diffusion for O_2 between alveolar gas and capillary blood. This maneuver usually increases the arterial PO_2 to >600 mmHg. The size of the shunt can be calculated using the following equation:

$$Q_s/Q_T = (CcO_2 - CaO_2)/(CcO_2 - C\bar{v}O_2)$$

where Q_s/Q_T is the shunt as a fraction of cardiac output; CcO_2 is end-capillary O_2 content; CaO_2 is arterial O_2 content; and $C\bar{v}O_2$ is mixed venous O_2 content. End-capillary blood is assumed to have a PO_2 equal to that in the alveolar gas. The O_2 contents are measured in samples of arterial and mixed venous blood. Alternatively, a value for the arterial-mixed venous difference in O_2 content, which is relatively constant among patients, normally can be assumed to be 5 mL/dL. Healthy individuals have a small “anatomic shunt” that amounts to 2%–5% of the cardiac output. This shunt occurs because some venous blood normally drains into pulmonary veins, left atrium, or left ventricle from bronchial and myocardial (thebesian) circulation.

The use of 100% O_2 to measure Q_s/Q_T can exclude shunt as a cause of hypoxemia. The procedure does not determine the location of a shunt, which may be intracardiac or intrapulmonary. Alveoli with low $\dot{V}_A/\dot{Q}$ ratios (<0.1) also may collapse completely during O_2 breathing if O_2 diffuses into the blood faster than fresh gas is added by ventilation. These collapsed alveoli can lead to overestimation of the true shunt fraction, as they allow pulmonary arterial blood to bypass the alveoli.

Physiologic Dead Space

Whereas physiologic shunt reflects the amount of blood flow going to lung units with near-zero ventilationperfusion ratios ($\dot{V}_A/\dot{Q} = 0$), physiologic dead space is a measure of the amount of ventilation going to units with unusually high ventilation-perfusion ratios ($\dot{V}_A/\dot{Q} \gg ¥$). The physiologic dead space can be computed from the Bohr equation:

$$V_D/V_T = (P_ACO_2 - P_ECO_2)/P_ACO_2$$

where V_D is physiologic dead space, V_T is tidal volume, P_ECO_2 is expired PCO_2, and P_ACO_2 is alveolar PCO_2. The P_ACO_2 is assumed to be equal to the $PaCO_2$. The Bohr equation requires a measurement of mixed expired gas, which is not conveniently obtained in many clinical settings. Instead, V_D/V_T can be estimated from the $\dot{V}_E$ and $PaCO_2$ using an isopleth nomogram (Fig. 11).

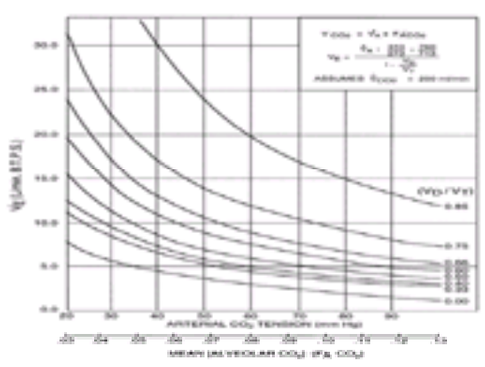

FIG. 11. An isopleth nomogram for estimating V_D/V_T from minute ventilation ($\dot{V}_E$) and arterial PCO_2. Assumptions and calculations are given in the *box in the right upper corner.*

Distribution of Ventilation-Perfusion Ratios

It has long been recognized that the lungs must contain some sort of distribution of ventilation-perfusion ratios. Major conceptual advances became possible with the introduction of the multiple inert gas elimination technique (MIGET). The MIGET is based on the straightforward principles governing inert gas elimination by the lung. When an inert gas in solution is steadily infused into the venous circulation, the proportion of gas that is eliminated by ventilation from the blood by a unit of the lung depends only on the solubility of the gas and the ventilation-perfusion ratio. The relationship is given by the following equation:

$$\frac{Pc'}{P\bar{v}} = \frac{\lambda}{\lambda + \dot{V}_A/\dot{Q}}$$

where Pc´ is the partial pressure of the gas in end-capillary blood and l is the blood-gas partition coefficient. The end-capillary partial pressure divided by the mixed venous partial pressure ($P\bar{v}$) is known as the *retention.*

In practice, a saline solution containing low concentrations of six gases (such as sulfur hexafluoride, ethane, cyclopropane, halothane or isofluorane, diethyl ether, and acetone) of differing solubilities is infused slowly into a peripheral vein until a steady state is reached (about 20 min). During measurements, simultaneous samples of arterial and mixed venous gases and expired gas are collected and analyzed for the inert gases by gas chromatography. Retention and excretion values for the inert gases are graphed against their solubility in blood, as shown in Fig. 12. The data for inert gas retention plotted against solubility are joined by a *broken line* in the upper panel of Fig. 12. Below this are the data points for excretion against solubility, also joined by the *broken line.* The *two solid lines* show how retention and excretion would behave for an ideal lung with no ventilation-perfusion maldistribution but with the same overall ventilation and blood flow. The *broken* and *solid lines* are very close together in normal lung (Fig. 12).

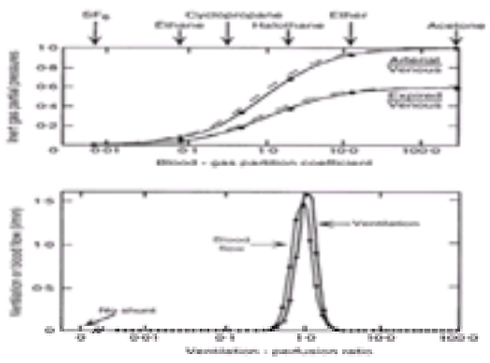

FIG. 12. Distribution of ventilation-perfusion ratios determined by the multiple inert gas elimination technique. Data from a 22-year-old normal subject are illustrated. **Upper panel:** Data points for inert gas retention (*upper curve*) and excretion (*lower curve*). *Broken lines* join the points. The *two solid lines* show the values of retention and excretion for a lung with no ventilation-perfusion inequality. **Lower panel:** Recovered distribution of ventilation-perfusion ratios. SF_6, sulfur hexafluoride. (Reproduced with permission from Wagner PD, Laravuso RB, Uhl RR, West JB. Continuous distributions of ventilation-perfusion ratios in normal subjects breathing air and 100% O_2. *J Clin Invest* 1974;54:53–68.)

The retention-solubility plots from the MIGET contain information about the distribution of $\dot{V}_A/\dot{Q}$ ratios in the lung. For example, a lung containing units that are perfused but not ventilated (shunt) will show increased retention of the least soluble gas, sulfur hexafluoride. Conversely, a lung having large amounts of ventilation to lung units with very high $\dot{V}_A/\dot{Q}$ ratios will show increased retention of the high-solubility gases, ether and acetone. In practice, the distribution of ventilation-perfusion ratios that best fits the pattern of inert gas retention and excretion based on a 50-compartment model can be obtained by an iterative process using a computer.

The use of the multiple gas elimination technique requires certain assumptions about the behavior of the lung. The method assumes no diffusion barrier for O_2 and negligible O_2 consumption by the lung. The fitted $\dot{V}_A/\dot{Q}$ distribution from a set of measurements is not unique, but in most cases the range of possible distributions compatible with the data is small. Also, more than three modes of a distribution can be recovered, and only smooth distributions can be obtained. Despite these limitations, the technique provides much more information about the distribution of $\dot{V}_A/\dot{Q}$ ratios in patients with lung disease than was previously available. In addition, the MIGET is very sensitive. A shunt of only 0.5% of the cardiac output approximately doubles the arterial concentration of sulfur hexafluoride.

The retention and excretion solubility curves and the derived distribution of ventilation-perfusion ratios from a 22-year-old normal volunteer is shown in Fig. 12. It is apparent from Fig. 12 that the recovered distributions for both ventilation and blood flow (*lower panel*) are narrow and span only one log of ventilation-perfusion ratios. Essentially no ventilation or blood flow occurs outside the range of approximately 0.3 to 3.0 on the ventilation-perfusion ratio scale, and no significant intrapulmonary shunt (i.e., regions with blood flow but no ventilation) is detected.

In older normal subjects, the dispersion of the $\dot{V}_A/\dot{Q}$ distribution has been found to increase. For example, some older people with apparently normal lungs have a “shoulder” to the left of the main blood flow distribution, with some 10% of the total blood flow going to lung units with ventilation-perfusion ratios of <0.1. Despite this region of low $\dot{V}_A/\dot{Q}$, there may still be no shunt. The cause of such age-related $\dot{V}_A/\dot{Q}$ mismatch is believed to be degenerative processes in the small airways with aging.

Ventilation-Perfusion Distributions in Lung Disease

The distribution of ventilation-perfusion ratios from a patient with chronic obstructive lung disease is shown in Fig. 13. The $\dot{V}_A/\dot{Q}$ distribution is typical of that seen in patients believed to have predominantly emphysema. The $\dot{V}_A/\dot{Q}$ distribution is bimodal, and large amounts of ventilation go to lung units with extremely high $\dot{V}_A/\dot{Q}$ ratios (alveolar dead space) (Fig. 13A). Presumably, the high $\dot{V}_A/\dot{Q}$ regions reflect ventilation to lung units in which many capillaries have been destroyed by the emphysematous process. The presence of a small shunt (3.1%) and slight shift to the left of the main mode of blood flow can explain mild arterial hypoxemia found in this patient (PaO_2 of 63 mmHg).

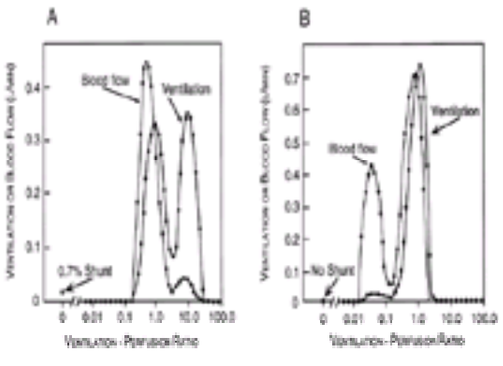

FIG. 13. Examples of the distribution of ventilation-perfusion ratios in patients with chronic obstructive pulmonary disease. **A:** Type A (patients with predominantly emphysema) tends to have areas of very high $\dot{V}_A/\dot{Q}$. **B:** Type B (patients with predominantly chronic bronchitis) often has areas of very low $\dot{V}_A/\dot{Q}$. Shunt ($\dot{V}_A/\dot{Q} = 0$) is rarely seen in either type. (Reproduced with permission from Wagner PD, Dantzker DR, Dueck R, Clausen JL, West JB. Ventilation-perfusion inequality in chronic obstructive pulmonary disease. *J Clin Invest* 1977;59:203–216.)

Patients with chronic obstructive lung disease who have predominantly bronchitis generally show a different pattern of $\dot{V}_A/\dot{Q}$ distribution (Fig. 13B). The main abnormality in these patients is the large amount of blood flow distributed to lung units with very low $\dot{V}_A/\dot{Q}$ ratios, between 0.003 and 0.1, explaining the more severe hypoxemia generally found in this type of patient. Presumably, the low ventilation-perfusion ratios in chronic bronchitis are the result of diseased airways blocked by retained secretions. It also should be emphasized that the $\dot{V}_A/\dot{Q}$ distributions found in severe chronic bronchitis show considerable variability.

Ventilation-Perfusion Mismatch and Carbon Dioxide Retention

It is important to appreciate that ventilation-perfusion mismatch interferes with the efficiency of CO_2 elimination by the lung, although patients with ventilationperfusion mismatch often have a normal or even low $PaCO_2$. The reason for this is that the regulatory chemoreceptors increase the ventilatory drive whenever they sense a rising $PaCO_2$. Such patients can maintain a normal PCO_2 by increasing the total ventilation at a cost of increasing the work of breathing. A significant portion of this increased ventilation, however, goes to lung units with high $\dot{V}_A/\dot{Q}$ ratios, which are inefficient at eliminating CO_2 (physiologic dead space).

When high $\dot{V}_A/\dot{Q}$ areas predominate in diseased lungs, the capacity to hyperventilate is readily exceeded and CO_2 retention may ensue. Patients with CO_2 retention are sometimes said to be “hypoventilating” as a result of the hypercapnia. Such patients with chronic lung disease and ventilation-perfusion mismatch, however, actually have “relative” hypoventilation, because the total ventilation is almost always increased.

Regulatory Control of Ventilation-Perfusion Matching

The alveolar PO_2 appears to be the most important factor involved in regulating the distribution of ventilation-perfusion within the lung. In this respect, hypoxic pulmonary vasoconstriction can be considered as part of a negative feedback loop. For example, in lung units with low $\dot{V}_A/\dot{Q}$ ratios, there is a fall in the local alveolar PO_2, and constriction of the associated microvessels reduces the local pulmonary blood flow. This tends to restore the local $\dot{V}_A/\dot{Q}$ ratio toward its normal value. This effect can be appreciated in residents of high altitudes, who are exposed constantly to lower ambient O_2 concentrations. Residents of high altitudes have better $\dot{V}_A/\dot{Q}$ matching than sea level residents, as reflected by a smaller alveolar-arterial PO_2 difference. The intensity of hypoxic pulmonary vasoconstriction varies among different lung regions, and probably depends on the smooth muscle tone in different vessels. The effectiveness of hypoxic pulmonary vasoconstriction on preserving $\dot{V}_A/\dot{Q}$ ratios also depends on the type of inhomogeneity. For example, when collateral ventilation is present, the regulatory effectiveness of hypoxic vasoconstriction may be greater than it would be if there were a parallel ventilatory arrangement between lung units. More recently, a role for nitric oxide in regulating local ventilation-perfusion matching has been suggested. The hypothesis is reasonable for the following reasons: (1) Nitric oxide is produced endogenously by endothelial cells and may regulate the local blood flow through its vasodilating effect, and (2) nitric oxide inhibits hypoxic pulmonary vasoconstriction. The nitric oxide-mediated mechanism may be especially important in patients with inflammatory lung diseases, in whom production of nitric oxide is increased. The loss of local hypoxic vasoconstriction would worsen ventilation-perfusion mismatch.

DIFFUSION CAPACITY

O_2 from the ambient air is carried into the lungs by two physical processes: bulk flow, which occurs in the conducting airways, and molecular diffusion, which is the main mechanism of gas transfer in the distal alveolar units. From the alveolar region, O_2 must diffuse across the alveolar-capillary membrane and enter the plasma and red cell membrane before it reacts with hemoglobin. The diffusion gradient for O_2 is determined by the PO_2 difference between alveolar gas and mixed venous blood at the entry to the pulmonary capillaries. Because of the high affinity of hemoglobin for O_2, the PO_2 in the capillary blood quickly rises to that in the alveolar gas, and the diffusion gradient for O_2 falls from approximately 60 mmHg to almost nil. At rest, this diffusion process is virtually complete in the first third of the mean capillary transit time of 0.75 sec.

The physical process of diffusion of gases across the alveolar capillary membrane behaves according to Fick's Law of Diffusion. Fick's Law states that for a given gas, the amount of gas transferred across a tissue sheet ($\dot{V}_{gas}$) is proportional to the area (A), a diffusion constant, and the difference in partial pressure ($P_1 - P_2$), and is inversely proportional to the thickness of the barrier (T):

$$\dot{V}_{gas} = \frac{A}{T} \times D(P_1 - P_2)$$

where D is a diffusion constant that depends on the properties of the tissue and the particular gas.

The lung is too complex to determine the area and thickness of the blood-gas barrier during life. Instead, the diffusion equation is written to combine the factors A, T, and D into one constant, D_L, as follows:

$$\dot{V}_{gas} = D_L \times (P_1 - P_2)$$

where D_L is called the *diffusing capacity of the lung.* The diffusing capacity includes the area, thickness, and diffusion properties of the membrane as well as the properties of the diffusing gas. Thus, the diffusing capacity for a gas is given by the following equation:

$$D_L = \frac{\dot{V}_{gas}}{(P_A - P_C)}$$

where P_A and Pc are the partial pressures of the gas in alveolar space and capillary blood, respectively.

Carbon monoxide (CO) is usually the gas of choice for measuring the diffusion properties of the lung, because its transfer is limited almost entirely by diffusion. The partial pressure of CO in capillary blood is very low because of its high affinity for hemoglobin (200 times greater than that of O_2), so that Pc in the above equation can generally be neglected. In this case, the above equation can be simplified as follows:

$$D_LCO = \frac{\dot{V}CO}{P_ACO}$$

The diffusing capacity of the lung for carbon monoxide (D_LCO) is thus expressed in units of milliliters of CO transferred per minute per millimeter of mercury of alveolar partial pressure. Of note, this unit is analogous to that for conductance. Some people—heavy cigarette smokers, for example—have sufficient carboxyhemoglobin in their blood that the partial pressure of CO in the pulmonary capillaries cannot be neglected. In this case, the partial pressure of CO can be measured in alveolar gas using a rebreathing technique and a correction made for back-diffusion of CO during the D_LCO maneuver.

The capacity for O_2 diffusion in the lungs can be estimated by multiplying the diffusing capacity for CO by 1.25. The uptake of O_2 by the lung is typically limited by perfusion under normal conditions. This process becomes limited partly by perfusion and partly by diffusion under hypoxic conditions. For this reason, measurements of diffusion using O_2 are often difficult to interpret.

The diffusing capacity of the lung can be separated into two components: (1) the alveolar-capillary membrane plus the erythrocyte cell membrane and (2) the reaction with hemoglobin (Fig. 14A). These components can be regarded as “resistances” in series to the transfer of O_2. This type of analysis was carried out by Roughton and Forster, who showed that the following relationship exists:

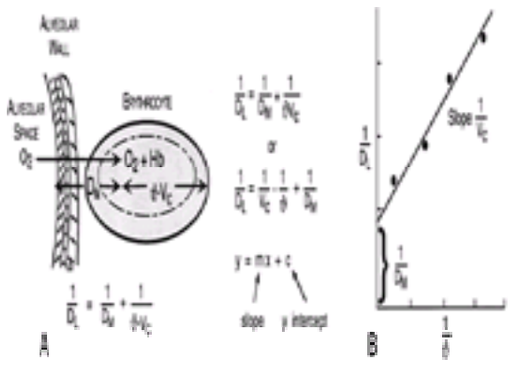

FIG. 14. The two components of the measured diffusing capacity (D) of the lung. **A:** Components attributable to the diffusion process itself and the time taken for O_2 (or CO) to react with hemoglobin. **B:** The graphic solution of DM and Vc according to the Roughton and Forster analysis. DM and Vc are derived by plotting against 1/DL. (Reproduced with permission from West JB. *Textbook of Respiratory Medicine.* 2nd ed. Philadelphia: WB Saunders; 1994.)

$$1/D_L = 1/D_M - 1/\theta Vc$$

where D_L refers to the diffusing capacity of the lung, D_M is the diffusing capacity of the membrane (which includes the plasma and red cell membrane), q is the rate of reaction of O_2 (or CO) with hemoglobin, and Vc is the volume of blood in the pulmonary capillaries. In the equation, values for D_M and Vc can be obtained graphically by measuring the diffusing capacity for CO at both high and normal alveolar PO_2 values (Fig. 14). Increasing the alveolar PO_2 reduces the value of q for CO, because the CO has to compete with a higher pressure of O_2 for the hemoglobin. When the values of $1/D_L$ obtained at two different values of PO_2 are plotted against 1/q, as shown in Fig. 15, the slope of the line is 1/Vc and the intercept on the vertical axis is $1/D_M$.

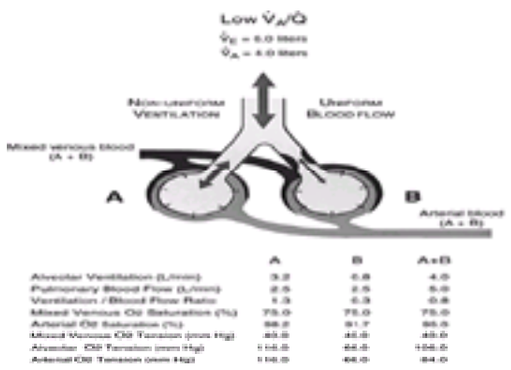

FIG. 15. Effects of nonuniform distribution of ventilation with uniform blood flow on gas exchange in a two-compartment lung model. Note that uneven ventilation produces a low $\dot{V}_A/\dot{Q}$ unit (*unit B*) and results in an alveolar-arterial PO_2 difference of 22 mmHg. (Reproduced with permission from Forster RE, et al., eds. *The Normal Lung: Physiological Basis of Pulmonary Function Tests.* 3rd ed. Chicago: Year Book; 1986.)

The Roughton-Forster equation is useful to demonstrate the factors that influence the diffusing capacity of the lung. Thus, the diffusing capacity can be reduced if D_M is increased, as when the thickness is increased or the area is reduced. The diffusing capacity also can be altered if the rate at which CO combines with blood (q) is reduced (e.g., in anemia) or if capillary blood volume (Vc) is reduced (e.g., in pulmonary embolism).

According to the Roughton-Forster equation, the term D_M should be just as important as qVc in determining the diffusing capacity of the lung. In clinical practice, however, the most important factor affecting the diffusing capacity is Vc; this is true in normal subjects as well as in many patients with pulmonary diseases. Changes in D_M are much less significant. It can be shown that raising the pulmonary arterial pressure when left atrial pressure is low increases the D_L substantially. This occurs because higher perfusion pressure recruits and distends pulmonary capillaries, and thus increases Vc. This effect is diminished if left atrial pressure is already elevated. Capillary recruitment and thus increased Vc probably also account for the increase in D_L measured during exercise and during changes from the upright to the supine position. Similarly, changes in D_L induced by certain drugs can be explained best by their effects on Vc. This is also true in diseases associated with increased thickness of the alveolar membrane (e.g., idiopathic pulmonary fibrosis). The reduced diffusing capacity under these conditions usually can be attributed to decreased Vc that results from decreased lung volume caused by destruction and distortion of lung parenchyma. In addition to desaturation of the test gas, a decreased D_L is seen in emphysema, partly because destruction of pulmonary capillaries decreases the Vc.

Measurements of Diffusing Capacity

Single-Breath Method

The single-breath method was first described by Marie Krogh in 1914. The patient performs a single inhalation of a dilute mixture (about 0.3% each) of CO and an inert tracer gas (e.g., helium or methane), followed by a 10-sec breath-hold. The rate of disappearance of CO from the alveolar gas during the 10-second breath-hold is calculated. At the end of the breath-holding period, a sample of alveolar gas is obtained after discarding the dead space. The exhaled sample is then analyzed for CO using an infrared analyzer. The inert tracer gas is used to measure alveolar volume by dilution. The single-breath equation is as follows:

$$D_LCO_{sb} = K \times V_A \times \ln\left(\frac{F_ACO_i/F_ACO_s}{F_AHe_i/F_AHe_s}\right) \{(P_B - 47) \times t\}$$

where V_A is the alveolar volume in liters, t is breath-holding time in sec, and K is a constant. The fractional concentrations of CO and helium in inspired and sample gas (F_ACO_i/F_ACO_s and F_AHe_i/F_AHe_s, respectively) are indicated by the appropriate terms.

The analysis of data based on the single-breath method involves several assumptions. The inhalation is assumed to be instantaneous, although in reality it is not. As the alveolar concentration of CO continues to decrease during breath-hold period, calculation of D_L can be affected by the breath-hold time. Alternative methods have been proposed to circumvent these problems. For example, equations for changes in the alveolar concentrations of CO can be developed to fit each of the three phases of the single-breath maneuver (inhalation, breath-hold, and exhalation). The three-equation method appears to give a more accurate measurement of the diffusing capacity.

In many patients with lung diseases, the single-breath diffusing capacity is reduced. The decrease in D_LCO is usually caused by uneven ventilation-perfusion distribution and diffusion-perfusion properties in diseased lungs rather than by true changes in diffusion across the alveolar-capillary membrane. Such diseased lungs tend to empty unevenly, and the post-dead space sample of expired gas that is analyzed for CO is not representative of the whole lung. For this reason, the diffusing capacity is sometimes referred to as the *transfer factor* (especially in Europe), to emphasize that it is more a measure of the lung's overall ability to transfer gas into the blood than a specific test of diffusion. Nevertheless, the test gives considerable information about gas exchange in the normal lung. Even in patients with severe disease, the results are useful for assessing the severity and type of lung disease in the pulmonary function laboratory.

Steady-state Method

In this method, the subject breathes a low concentration of CO (about 0.1%) for about 30 sec, until a steady state of gas exchange has been reached. The constant rate of disappearance of CO from alveolar gas is then measured for a further short period, along with the alveolar concentration of the gas. This technique is better suited for measurements during exercise, when breath-hold becomes a problem. The normal value of the diffusing capacity for CO depends on age, sex, and height (as is the case for most pulmonary function tests), and appropriate regression equations are available.

Intrabreath Method

More recently, with the development of rapidly responding infrared analyzers, the diffusing capacity can be measured using a single-breath–slow exhalation, or “intrabreath,” technique. The gas concentrations are monitored continuously during slow inhalation and exhalation. Multiple estimates of D_L can be made during a single exhalation, giving D_L as a function of lung volume. Alternatively, a single estimate of D_L can be obtained by applying a linear regression to exhaled CO concentration continuously measured during slow exhalation. Regression equations for the “intrabreath” diffusing capacity for CO based on age and height have been published.

Distribution of Diffusing Capacity

The Roughton-Forster approach to analyzing diffusing capacity assumes a homogeneous pulmonary system. The interpretation of the results is affected by heterogeneity in alveolar ventilation, alveolar lung volume, alveolar perfusion, and pulmonary diffusing capacity. The relative importance of heterogeneity in each of these factors and their interactions vary according to individual characteristics and the particular method chosen to measure D_L.

A single acinus is sufficiently small so that ventilation and perfusion within such units can be assumed to be homogeneous. In the whole lung, however, perfusion depends on gravity as well as other regional stress factors. The higher perfusion pressure in the bottom of the lung results in greater recruitment of capillaries and

therefore a larger capillary volume and capillary surface area for diffusion. In addition, larger regional differences in lung volume and alveolar ventilation are known to occur. These variations may result in significant local variations in diffusing capacity. This was demonstrated experimentally by Hamer, who showed, using a breath-hold technique, that overall D_L, D_M, and Vc vary as a function of lung volume. Using a single-exhalation technique, Denison et al. measured regional $\dot{V}_A$, $D_L/\dot{V}_A$, and $\dot{Q}/\dot{V}_A$ through a bronchoscope within individual lobes of the lungs of normal human subjects. They found a vertical gradient for $D_L/\dot{V}_A$ in the sitting position. $D_L/\dot{V}_A$ ranged from 0.86 in the upper lobe to 1.13 in the lower lobe. Clinically, diffusing capacity measured by the breath-hold method gives little information about its distribution in the lung. Since use of the rapid infrared analyzer has been combined with the single-exhalation method, the regional distribution of diffusing capacity can be measured in the lung.

MECHANISMS OF HYPOXEMIA

An arterial PO_2 value below the range for normal subjects of the same age establishes the presence of hypoxemia. In general, arterial hypoxemia is defined by PO_2 values of <80 mmHg in adults breathing room air at sea level.

Hypoventilation as a Cause of Hypoxemia

The simplest derangement of gas exchange occurs when insufficient fresh air is breathed. Such hypoventilation decreases the arterial PO_2 and increases the arterial PCO_2. If $\dot{V}_A/\dot{Q}$ distribution remains uniform, no alveolar-arterial difference develops for either O_2 or CO_2. The common causes of hypoventilation-associated hypoxemia are anesthetics or narcotics that depress the central nervous system, and neuromuscular diseases that affect respiratory muscle function.

Ventilation-Perfusion Mismatch as a Cause of Hypoxemia

Ventilation-perfusion mismatch (low $\dot{V}_A/\dot{Q}$ regions) is the most common cause of hypoxemia in lung disease. Figure 15 illustrates the effects of $\dot{V}_A/\dot{Q}$ mismatch on hypoxemia using a two-compartment lung model. If the total ventilation remains constant at 4 L/min but unit A receives four times as much ventilation as unit B (3.2 L/min vs. 0.8 L/min), and if the distribution of perfusion is uniform (2.5 L/min for each unit), the $\dot{V}_A/\dot{Q}$ ratio for unit A becomes 1.3, whereas that for unit B is 0.3. O_2 tension and saturation must decrease in blood leaving the hypoventilated unit B; O_2 saturation must rise in blood leaving the hyperventilated unit A. Because of the nearly linear nature of the hemoglobin dissociation curve, the final PO_2 in the pulmonary venous blood, which is derived from the blood flow-weighted average of O_2 content, has to decrease. Thus, the high PO_2 in the blood leaving high $\dot{V}_A/\dot{Q}$ unit A is not sufficient to compensate for the low PO_2 contributed by low $\dot{V}_A/\dot{Q}$ unit B. The arterial blood would then have a PO_2 of 84 mmHg instead of 100 mmHg, as in the normal lung.

Right-to-Left Shunt as a Cause of Hypoxemia

A shunt is defined as a region where there is blood flow from the right side of the heart to the left, but no ventilation ($\dot{V}_A/\dot{Q} = 0$). The effects of a right-to-left shunt on gas exchange are shown schematically in Fig. 16. In this example, 33% of the total blood flow (2.0 L/min) is shunt. Although gas exchange in units A and B is unimpaired, the net result from mixing of blood from these two units and the shunt pathway is a reduction of arterial PO_2 and the creation of the alveolar-arterial O_2 gradient. This effect on PO_2 is similar to that caused by $\dot{V}_A/\dot{Q}$ mismatch. In fact, a shunt in mathematical terms is the ultimate ventilation-perfusion mismatch, one in which there is perfusion but no ventilation. Because of the absence of ventilation, hypoxemia resulting from shunt cannot be corrected by breathing 100% O_2. This technique allows $\dot{V}_A/\dot{Q}$ mismatch to be differentiated from shunt as the cause of hypoxemia.

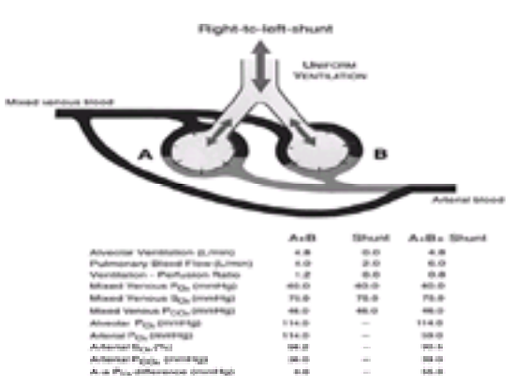

FIG. 16. Effects of right-to-left shunt on gas exchange in a two-compartment lung model. (Reproduced with permission from Forster RE, et al., eds. *The Normal Lung: Physiological Basis of Pulmonary Function Tests.* 3rd ed. Chicago: Year Book; 1986.)

When a normal, healthy person breathes 100% O_2, an alveolar-arterial PO_2 difference of between 30 and 50 mmHg can usually be detected. This is consistent with the presence of a right-to-left shunt of approximately 2%–3% of the cardiac output. The multiple inert gas method, which measures only intrapulmonary shunt, indicates virtually no right-to-left shunt through the normal lung. These two results, taken together, imply that most of the shunt in normal subjects occurs distally to the gas exchange units (i.e., “postpulmonary shunt”). The main sources of the normal postpulmonary shunt are bronchial and mediastinal veins that empty into pulmonary veins and the Thebesian vessels of the left ventricle, which empty directly into the left ventricular cavity. When shunt occurs in patients with lung disease, it is usually accounted for by the perfusion of nonventilated lung regions through relatively normal vascular channels. Sometimes, shunt flow may occur through intracardiac communications, as in patent foramen ovale, when pressure in the right atrium is increased—for example, from pulmonary hypertension.

Diffusion Impairment as a Cause of Hypoxemia

In normal subjects at rest, O_2 equilibrates quickly between the blood and gas phases in the alveolar region of the lung, and there is no diffusion limitation. This is true for healthy persons at sea level and at low altitude. During exercise at higher altitudes (>10,000 ft), the alveolar-arterial PO_2 difference can increase due to diffusion disequilibrium (Fig. 17).

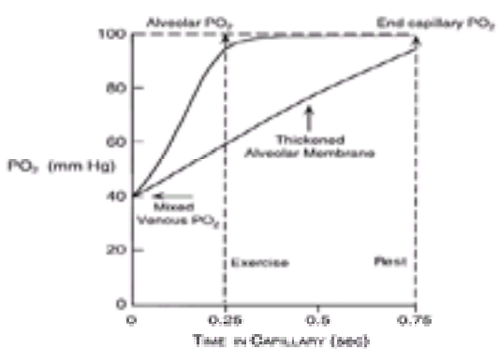

FIG. 17. Typical time courses for the change in PO_2 in the pulmonary capillary when diffusion is normal and the blood-gas barrier is abnormally thick. The time course for CO uptake is also shown.

Many patients with lung disease have abnormal diffusing capacity measured by the single-breath CO method. A diffusion impairment causing an increased alveolar-arterial PO_2 difference is unusual in these patients while at rest. As mentioned earlier, the major reason for a decreased diffusion capacity measured in the pulmonary function laboratory in patients with lung disease is maldistribution of ventilation-perfusion. Abnormal diffusion as a cause of an increased alveolar-arterial PO_2 difference is much more likely during exercise in these patients. Exercise-induced diffusion abnormalities result from lengthening of the diffusion pathway across the alveolar-capillary membranes or, more commonly, from a decrease in pulmonary blood volume in combination with an increase in the rate of blood flow, thus shortening the capillary transit time for the erythrocytes. Similar to hypoxemia caused by $\dot{V}_A/\dot{Q}$ mismatch, hypoxemia caused by diffusion impairment can be corrected by having the patient breathe 100% O_2.

Decreased Mixed Venous Oxygen Content as a Cause of Hypoxemia

The O_2 content of pulmonary arterial (mixed venous) blood usually has little effect on arterial PO_2 in persons with normal lungs. In patients with very low cardiac output (e.g., patients in cardiogenic shock), a decrease in $C\bar{v}O_2$ contributes substantially to hypoxemia provided the amount of venous admixture is small. In the presence of lung disease with a substantial amount of venous admixture, resulting from either ventilation-perfusion abnormality, a large right-to-left shunt, or both, the O_2 content in the mixed venous blood has a considerable effect on arterial PO_2. For a given amount of ventilation-perfusion mismatch, the lower the mixed venous O_2 content, the lower the arterial PO_2. This mechanism of hypoxemia is particularly important in critically ill patients with serious cardiopulmonary diseases.

MECHANISMS OF HYPERCAPNIA

Ideally, CO_2 exchange should be characterized by (1) complete equilibration between aqueous and gaseous phases before blood leaves the pulmonary capillary, (2) identical PCO_2 in mixed alveolar gas and arterial blood, and (3) an inverse relationship between these gas tensions and the amount of ventilation of the alveolar spaces. Although it is not likely that all three postulates are ever achieved completely, CO_2 exchange is so close to the ideal that for practical purposes they can be assumed to hold true in the normal lung. This situation is certainly not the case for the abnormal lung.

Increased Dead Space as a Cause of Hypercapnia

As ventilation in the lung is cyclical—that is, gas enters and leaves by the same conduit—a portion of the inhaled gas never reaches the exchange surface. The last portion of each inspired breath remains in the tracheobronchial tree and is exhaled without its participating in either O_2 or CO_2 exchange. This portion of each tidal volume, V_D/V_T, is calculated from the difference between the PCO_2 of arterial blood and mixed expired gas and is expressed by the Bohr equation (see above). If tidal volume itself is measured, physiologic dead space can be described as a volume rather than a ratio. The *anatomic dead space* varies little in disease but does vary moderately with tidal volume, as airway volume increases slightly at higher lung volumes. The volume of anatomic dead space is important to consider when assessing ventilation, particularly during mechanical ventilation, but it does not need to be measured, because its size is not affected by disease.

Alveolar dead space for the most part is a conceptual space rather than an actual anatomic volume. A complete lack of gas exchange is present only in alveoli in which $\dot{V}_A/\dot{Q}$ equals infinity (i.e., ventilated but not perfused at all). This situation is relatively rare. Far more commonly, alveoli have an excess of ventilation in relation to blood flow, and all the ventilation to such alveoli participates in gas exchange, but with lower efficiency than normal. This decrease in efficiency, measured in terms of its effect on CO_2 exchange, contributes to the alveolar dead space.

It is difficult to separate alveolar from anatomic dead space because of the difficulty of obtaining an expired gas sample that represents alveolar gas. Nor is it important, because both are factors in gas exchange and must be taken into consideration. Physiologic dead space (V_D/V_T) represents the sum of the anatomic dead space and the alveolar dead space, the latter usually resulting from ventilation-perfusion imbalance. The V_D/V_T describes CO_2 exchange as if the tidal volume were divided into a portion that does not participate at all in CO_2 exchange (physiologic dead space) and a remaining volume that exchanges CO_2 in a completely normal fashion. In reality, almost all the tidal volume, exclusive of the anatomic dead space, participates in CO_2 exchange, but to a degree that varies with the local $\dot{V}_A/\dot{Q}$. In the sitting position, V_D/V_T is about 30% and varies little with age. It can increase to 60% or more in disease, reflecting gas exchange units with elevated $\dot{V}_A/\dot{Q}$. In the normal individual, V_D/V_T decreases with exercise, because changes in the physiologic dead space volume are small compared with the increases in tidal volume accompanying exercise. The responses of V_D/V_T to exercise in disease are variable, but usually V_D/V_T decreases, although not generally to normal levels.

Because physiologic dead space is a clearance index, it is affected by any factor that influences the efficiency of CO_2 exchange. It is useful in assessing $\dot{V}_A/\dot{Q}$ inequality only because this abnormality has a far greater effect on CO_2 exchange than all other factors combined.

Ventilation-Perfusion Mismatch as a Cause of Hypercapnia

Although maldistribution of ventilation and blood flow is not usually characterized by hypercapnia, there is no question that CO_2 exchange is affected by $\dot{V}_A/\dot{Q}$ imbalance. As $\dot{V}_A/\dot{Q}$ falls, local PCO_2 rises, reaching the value of the mixed venous PCO_2 when $\dot{V}_A/\dot{Q}$ equals zero. The maximum increase is slight in terms of gas tension but represents a considerable change in content because of the steep slope of the CO_2 dissociation curve. Besides the direct effect of the decrease in ventilation on CO_2 excretion, the simultaneous failure to oxygenate blood completely further hinders CO_2 exchange. With oxygenation, the carrying capacity of blood for CO_2 decreases, facilitating CO_2 excretion (Haldane effect). A quantity of CO_2 equal to that retained in alveoli with low $\dot{V}_A/\dot{Q}$ must be excreted in other gas exchange units to avoid hypercapnia. As noted previously, this can be accomplished in alveoli in which $\dot{V}_A/\dot{Q}$ is higher than normal. Because CO_2 is excreted less efficiently in these alveoli, alveolar dead space is increased, and the total ventilation must be increased to keep the alveolar exchange at a normal level. The incremental ventilation is achieved rapidly because of the sensitivity of central chemoreceptors to altered levels of PCO_2.

The ventilatory work required for this compensation is usually small, as can be illustrated by an extreme example. If one-half the cardiac output went to alveoli that were no longer ventilated, the remaining alveoli would have to excrete twice the normal amount of CO_2 to prevent hypercapnia. This could be accomplished by maintaining a PCO_2 in the low 30s in these units, and it would require an increase in ventilation of 25%–30% over that needed to exchange the same quantity of CO_2 with an ideal ventilation-perfusion distribution. This is only a small fraction of the normal ventilatory reserve. The ease of this compensation and the magnitude of normal ventilatory reserve account for the low incidence of hypercapnia in patients with $\dot{V}_A/\dot{Q}$ disturbances. As the disparity of $\dot{V}_A/\dot{Q}$ throughout the lung becomes greater, however, compensation becomes more difficult to achieve. In the previous example, if retained CO_2 was excreted in only 10% rather than 50% of the alveoli, a much higher $\dot{V}_A/\dot{Q}$ would be present in the compensating alveoli, and alveolar dead space would increase correspondingly. In this circumstance, a 200% increase in ventilation would be required to maintain normocapnia. Although it is unlikely that normal ventilatory reserve would be exceeded except in an extreme $\dot{V}_A/\dot{Q}$ disturbance, the reserve may be minimal in disease. Moreover, the work of breathing can be increased substantially in disease. CO_2 produced by respiratory muscles may place an undue burden on the lungs when increments in ventilation require high levels of muscular work. Thus, a decreased ventilatory reserve combined with a high work of breathing and severe $\dot{V}_A/\dot{Q}$ imbalance can lead to an increase in alveolar dead space that cannot be overcome easily. These processes result in hypercapnia.

Hypoventilation as a Cause of Hypercapnia

In the homogeneous lung, the definition of alveolar ventilation is quite simple. Under these conditions, alveolar dead space does not exist, because early inspired gas in the anatomic dead space does not exchange CO_2. A discussed earlier in this chapter, alveolar ventilation can be defined as follows:

$$\dot{V}_A = \dot{V}CO_2/P_ACO_2 \times 0.863$$

where $\dot{V}CO_2$ is CO_2 output and P_ACO_2 is alveolar PCO_2 (assumed to be the same as arterial PCO_2). The definition of alveolar ventilation becomes more difficult when the lung is not ventilated uniformly. Alveolar and arterial PCO_2 are then no longer identical, and it is not possible to obtain an expired sample that is known to represent

alveolar gas. Indeed, the term *alveolar gas* is misleading, as the composition of gas in the alveoli varies widely depending on local $\dot{V}_A/\dot{Q}$ relationships. Classically, the response to this problem has been to define alveolar ventilation in a functional manner by using the right side of the above equation. Hence, if arterial PCO_2 is elevated, alveolar ventilation is decreased and insufficient to excrete CO_2 in a normal fashion. Likewise, hyperventilation is signaled by a less-than-normal arterial PCO_2. With this approach, alveolar ventilation is equal to the difference between total expired ventilation and the physiologic dead space. In this context, there are two reasons for alveolar hypoventilation (i.e., arterial hypercapnia). First, if total minute ventilation is decreased, the alveolar component decreases and arterial PCO_2 rises. Second, alveolar hypoventilation occurs if physiologic dead space increases because of ventilation-perfusion imbalance and the necessary increase in total ventilation cannot be sustained to compensate for the change in dead space. In the latter circumstance, the $\dot{V}_A/\dot{Q}$ disturbance can be so severe that hypercapnia may be present, even though the total minute ventilation measured at the mouth is greater than normal. This is the result of defining alveolar ventilation in terms of alveolar PCO_2.

West has challenged this functional definition, arguing that the quantity of ventilation of the alveolar space is normal in $\dot{V}_A/\dot{Q}$ mismatch and that the approach based on arterial PCO_2 overlooks the underlying problem. This viewpoint defines alveolar ventilation in an anatomic rather than a functional manner by making use of the concept of *effective ventilation* when the arterial PCO_2 is used as an index of ventilation. The term *alveolar ventilation* has a long tradition and is unlikely to be changed, although it would be more useful to identify the precise mechanisms involved in producing hypercapnia. No simple bedside techniques are available, however, to sort out accurately the degree of hypercapnia resulting from inadequate ventilation and that caused by severe ventilation-perfusion mismatch.

BLOOD GAS TRANSPORT

In air-breathing vertebrates, the metabolic processes of the body are supported by the integrated functions of the heart, lungs, and blood. Atmospheric oxygen, brought into proximity with the blood in the alveolar capillaries of the lungs, diffuses into the erythrocyte and is bound reversibly to hemoglobin. The erythrocyte circulates to the tissue capillaries, where oxygen dissociates from hemoglobin and diffuses down its concentration gradient into the cells to be consumed by mitochondria. The erythrocyte then carries carbon dioxide generated in the mitochondria to the alveolar capillaries, where it diffuses down its concentration gradient into the air spaces of the lung. These physiologic processes make use of the physical processes of diffusion, chemical reaction, convection, and diffusion again. This portion of the chapter describes the remarkable properties of the blood that enable it to carry oxygen and carbon dioxide and maintain acid-base homeostasis. It also summarizes the processes of convective oxygen transport to the microcirculation, diffusion of oxygen into the tissues, and cellular respiration. Examples have been selected to describe the effects of disease processes such as anemia, hypoxemia, ischemia, and heterogeneity of blood flow on oxygen delivery and cellular metabolism.

The Metabolic Milieu of the Body

The gas transport mechanisms in the blood are designed primarily to handle large quantities of the metabolic gases O_2 and CO_2, although soluble inert gases, such as N_2, also are transported in dissolved form. The circulation supports a basal metabolic rate for O_2 of about 3.0 mL/min and a CO_2 production rate of 2.4 mL/min per kilogram of body weight for the adult human. The demands on the circulation, however, can increase as much as 20-fold under conditions of extreme exercise. The large size and high metabolic requirements of vertebrate animals for molecular O_2 confounds diffusion as a transport mechanism, because the distances and the rates of O_2 consumption become too great. These requirements can be met only by an efficient convective transport system to deliver O_2 to more dense regions of the circulation, where diffusion again becomes an effective process for its distribution. In addition, having a carrier molecule for O_2 is adaptive, because the amount of the gas that can be dissolved in the blood at normal barometric pressures is not adequate to meet the metabolic requirements of higher organisms.

When the plasma comes in contact with a gas such as O_2, its concentration rises to a value determined by the partial pressure of the gas and the solubility coefficient of plasma for O_2. As the solubility of O_2 in plasma is quite low (0.0224 mL O_2 per milliliter of plasma at body temperature), the amount of O_2 dissolved in plasma at normal barometric pressure is quite low. The number of milliliters of dissolved O_2 in a liter of blood plasma at STPD (standard temperature and pressure, dry) is given by the following simple relationship:

$$\begin{aligned}\text{Dissolved } O_2 &= [0.0224\ PO_2\ (P_B - PH_20)] \times 100\ \text{mL} \\ &= [0.0224\ PO_2\ (760 - 47)] \times 100\ \text{mL} \\ &= 0.0031\ PO_2\end{aligned}$$

where P_B is the barometric pressure, PH_2O is water vapor pressure, and PO_2 is the partial pressure of O_2 in the blood. Hence, for a PO_2 in the blood of 100 mmHg, the dissolved O_2 content is only 0.3 mL/dL or 3.0 mL/L of blood. To meet a basal requirement for O_2 of 3 mL/kg/min, the minimum cardiac output would have to be 1.0 L/kg/min, or, for an adult of normal size, about 70 L/min. During exercise at an O_2 consumption rate of 3.0 L/min, the cardiac output would have to increase to an amazing 1000 L/min. To circumvent this problem, hemoproteins capable of carrying large quantities of O_2 have evolved in higher animals. These hemoproteins are the hemocyanins of invertebrates and the hemoglobins of vertebrates.

Structural Biology and Molecular Properties of Hemoglobin

Hemoglobin is the major protein of erythrocytes. It allows vertebrates to transport molecular O_2 from the lungs to the tissues and CO_2 from the tissues to the lungs. Human hemoglobin is a tetramer of two a and two b polypeptides, each containing a heme moiety. The tetramer consists of 547 amino acids and has a molecular weight of 64,800 Da. The heme and the globin interact with each other in a way that determines the O_2-binding characteristics of hemoglobin. The heme groups to which the O_2 binds are harbored within the protein parts of the molecule. Heme is the complex of chelated iron in a cyclic tetrapyrrole (porphyrin) ring. The porphyrin of hemoglobin is called *protoporphyrin IX.* The iron atom is kept in the center of the porphyrin ring between four nitrogen atoms. The porphyrin carries side chains that maintain the heme group in the proper orientation within the protein portion of the hemoglobin molecule. Double bonds in the heme moiety cause hemoglobin to have a bright red color when oxygenated and a purple color when deoxygenated.

The location of the heme group in the globin portion of the molecule is important for maintaining the iron in a ferrous valence state (Fe^{2+}). Normally, when iron reacts with O_2, the iron valence state changes to ferric (Fe^{3+}) and an oxide (rust) is formed. In the folds of the globin chain, ferrous iron is protected and its reaction with O_2 is reversible. One important part of this mechanism is the linkage of the heme iron to the amino acid histidine, which supplies a negative charge and enables the iron to form a weak bond with O_2. Thus, the interactions between heme and globin in the molecule are responsible for the reversible linkage of O_2 with the heme group. The basic features of the molecular physiology of hemoglobin, including the interactions of heme with globin, are summarized below, along with the chemical mechanisms for inducing conformational changes in hemoglobin in the presence of O_2, organic phosphates, protons, and CO_2.

Hemoglobin consists of four globin molecules: two identical a subunits and two identical b subunits. In the evolution of the globin molecule in higher vertebrates, the amino acids responsible for proper heme orientation and cooperative O_2 binding have been conserved. The secondary structure of a and b subunits of hemoglobin is characterized by a high content of a helices (about 75%), which vary in length between 7 and 23 amino acids. The surfaces of the a and b subunits have nonpolar regions that allow them to form an a_2b_2 tetramer. The four subunits make a total of six contacts and are held together by hydrophobic interactions, by hydrogen bonds, and by electrostatic interactions of salt bridges. These noncovalent interactions allow the subunits to move easily during reversible binding of O_2 with the heme group. Among the contacts between the subunits, only the most extensive one, the a_1b_1 contact, remains the same on O_2 binding. The surface of the hemoglobin molecule contains many polar groups that are all hydrated and therefore contribute to the high water solubility of hemoglobin. This feature allows dense packing of hemoglobin within erythrocytes, each of which contains about 3 trillion molecules of tetrameric hemoglobin.

The binding of O_2 to the heme iron provides the crucial triggering mechanism for the conformational change of the globin part of hemoglobin (Fig. 18). Molecular O_2 is bound to the iron atom by an end-on geometry with an Fe-O-O angle of 155°. Iron in deoxyhemoglobin is five-coordinated with the four pyrrole nitrogens of porphyrin and the imidazole nitrogen of the proximal histidine, resulting in four unpaired electrons in the iron atom. In oxyhemoglobin, the iron is six-coordinated, leading to a state in which all the electrons are paired. This pairing of electrons leads to a reduction of magnetic moment in oxyhemoglobin compared with that in deoxyhemoglobin. The magnetic changes in iron accompanying the binding of O_2 give rise to stereochemical changes in the heme that produce the conformational changes in globin responsible for cooperative O_2 binding and allosteric effects, such as the Bohr effect. The mechanism that triggers the changes in the structure of the hemoglobin molecule when O_2 is bound or released is the movement of the heme iron. When heme iron reacts with O_2, it reorients the iron in the porphyrin ring. The bond between the imidazole nitrogen is shortened in deoxyhemoglobin by about 0.6 Å compared with that of oxyhemoglobin. In addition, the porphyrin structure is flexed in deoxyhemoglobin but not in oxyhemoglobin. These changes in electronic configuration are transmitted to the globin part of the molecule.

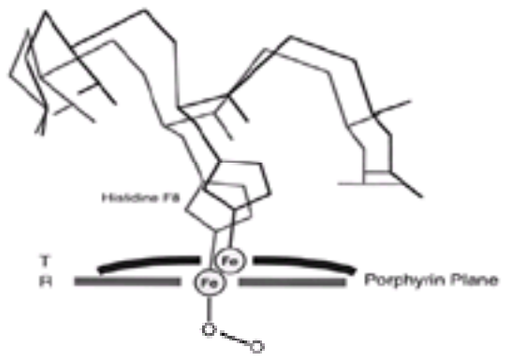

FIG. 18. Schematic illustration of the hemoglobin molecule. Changes in globin structure with O_2 binding to heme in hemoglobin are shown for the R (oxy) and T (deoxy) states.

A standard terminology is used for the different properties of deoxyhemoglobin and oxyhemoglobin to describe how changes in the heme structural affect the globin. Deoxyhemoglobin is said to be in the T or tense state, and oxyhemoglobin is said to be in the R or relaxed state. The T state of hemoglobin has a low O_2 affinity, whereas the R state has an O_2 affinity about 150 times greater than that of the T state. The transition between these conformational states is induced by the shift of the heme iron when O_2 is bound or released. The most important changes that occur in hemoglobin on binding or release of O_2 occur in the a_1b_2 and a_2b_1 contacts. These contacts fit together, and the respective hydrogen donor and acceptor sites are constructed so that only two positions of the two subunits are stable. This is the structural basis for the two-state model that explains most of the physiologic properties of hemoglobin. The cooperativity of O_2 binding is also a direct consequence of the fact that hemoglobin assumes only these two stable structures: the R structure whose O_2 affinity is high and the T structure whose O_2 affinity is lowered by molecular interactions such as salt bridges and the binding of organic phosphates.

Diphosphoglycerate

The erythrocytes of humans and most other mammals contain high concentrations of the glycolytic intermediate 2,3-diphosphoglycerate (DPG). Its concentration within human erythrocytes is normally about 5 mmol/L of erythrocytes, equivalent to the concentration of tetrameric hemoglobin. DPG is negatively charged at physiologic pH values and binds to deoxyhemoglobin in a 1:1 molar ratio. It binds to deoxyhemoglobin much more tightly than to oxyhemoglobin. The overall reaction is as follows:

$$Hb_4(DPG) + 4O_2 \rightleftharpoons Hb_4(O_2)_4 + DPG$$

Deoxyhemoglobin has a DPG binding site that is complementary in shape and charge to the phosphate that is able to stabilize the T structure of hemoglobin. The binding of O_2 results in a loss of complementarity and expulsion of the DPG molecule. The presence of O_2 decreases the binding constant of DPG and hemoglobin by two orders of magnitude at physiologic pH, temperature, and salt concentrations. O_2 binding changes the quaternary structure of deoxyhemoglobin by increasing the distance between the partners of the salt bridges, causing them to break. When a salt bridge is broken, the apparent pK value of the two partners falls. Therefore, protons tend to be set free by oxyhemoglobin and taken up by deoxyhemoglobin. This difference in proton binding between oxyhemoglobin and deoxyhemoglobin is the basis for the dependence of the O_2 affinity of hemoglobin on pH, also known as the *Bohr effect.* Quantitatively, about 2.0 H^+ are set free on oxygenation at neutral pH in the absence of DPG according to the following reaction:

$$Hb_4(H)_2 + 4O_2 \rightleftharpoons Hb_4(O_2)_4 + 2H^+$$

Protons are released from four pairs of salt bridges on O_2 binding. The sum of the changes in the apparent pK of these groups gives rise to the Bohr effect (effect of pH on O_2 affinity) and to the difference in proton binding between oxyhemoglobin and deoxyhemoglobin (Haldane effect).

Carbon Dioxide

The hemoglobin molecule, like other proteins, directly binds CO_2. The chemical interaction of CO_2 with the unprotonated forms of protein amino groups occurs according to the following reactions:

$$Hb{-}NH_2 + H^+ \rightleftharpoons Hb{-}NH_3$$
$$Hb{-}NH_2 + CO_2 \rightleftharpoons Hb{-}NHCOO^- + H^+$$

The carbon atom of CO_2 and the amino group of hemoglobin form a complex known as a *carbamate.* Carbamate formation proceeds only when the amino group is unprotonated; therefore, 50% of the N-terminal a-amino groups but less than 1% of the e-amino groups within the protein can bind with CO_2 in the physiologic pH range. Deoxyhemoglobin binds more CO_2 as carbamate than does oxyhemoglobin, and about 80% of this oxygen-labile carbamate is confined to the b subunits at physiologic pH. The pK value of the a-amino groups of the a subunits increases with deoxygenation from 7.0 to 7.8, thereby inhibiting carbamate formation. The pK value of the N-terminal a-amino groups of the b subunits remains nearly constant at around 7.0, regardless of oxygenation. Carbamates formed at the N-terminal a-amino group of the b subunits is stabilized by positively charged groups near the N-termini of the b subunits in deoxyhemoglobin. During the process of oxygenation, these positively charged groups move apart, destabilizing the carbamate and releasing CO_2 from the binding sites. This process is discussed in more detail in the section on CO_2 transport.

The Oxygen Equilibrium Curve of Hemoglobin

The relationship between the fractional saturation of hemoglobin with O_2 and the PO_2 under equilibrium conditions is the sigmoid O_2 equilibrium curve (OEC) of hemoglobin (Fig. 19). The sigmoid shape of the hemoglobin OEC determines the loading and unloading of O_2 under physiologic conditions. Its position is often expressed by the PO_2 at half-saturation (P_{50}). The normal P_{50} for human hemoglobin is approximately 27 mmHg. When the O_2 affinity increases, the OEC shifts to the left (reduced P_{50}). When the O_2 affinity decreases, the OEC shifts to the right (increased P_{50}). The principal physiologic determinants of the functional OEC within erythrocytes are H^+, 2,3,-DPG, and CO_2. Other effectors, such as Cl^- and adenosine triphosphate (ATP), also decrease O_2 affinity, but their physiologic roles are minor. One of the most powerful ways to decrease O_2 affinity is to bind CO to hemoglobin. CO has 200 times the affinity for heme as does O_2, and when CO binds to one heme site, it increases the O_2 affinity of the other binding sites. The OEC is also very sensitive to changes in temperature; hypothermia decreases the P_{50} approximately 2 mmHg per degree centigrade.

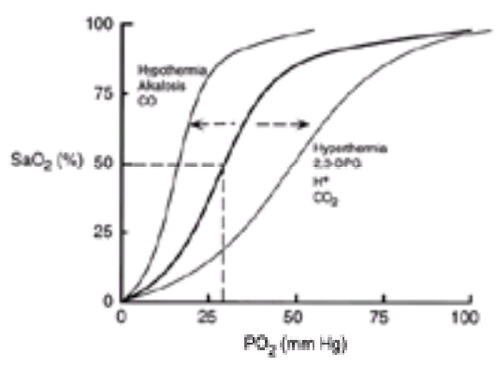

FIG. 19. OEC of hemoglobin. The normal P_{50} value is indicated by the *dashed lines.* The changes in position of the OEC associated with various effector molecules are indicated by the *dashed arrows.*

The first physiologists to observe the sigmoid nature of the OEC concluded that O_2 affinity increased during progressive oxygenation. They called this phenomenon *cooperativity.* This cooperativity was described mathematically by Hill using an equation that empirically relates hemoglobin saturation to O_2 tension. The Hill plot for the OEC falls on a straight line with a slope determined by the degree of cooperativity. This empiric description of the OEC, however, provides no information about the mechanism of O_2 binding. A more general approach to the quantitation of the oxygenation of hemoglobin was made by Adair, who recognized that hemoglobin was made up of four subunits, each of which could bind a single O_2 molecule. Adair derived equations for the stepwise oxygenation of hemoglobin:

$$Hb(O_2)i + O_2 \rightarrow Hb(O_2)i + 1$$

where i ranges from 0 to 3. The association constants for the sequence of equilibrium reactions are difficult to determine experimentally because of the interdependence among the parameters. In addition, the approach says nothing of molecular structure; thus, it is not useful for understanding structure-function relationships.

The two-state model provides a better functional description of the physiologic behavior of hemoglobin, because each of the two states of hemoglobin, R (relaxed) and T (tense), has its own unique O_2 affinity. The equilibrium constants for their reactions with O_2 are K_R and K_T. The ratio of these constants,

$$C = K_T/K_R$$

is less than 0.01 for human hemoglobin A; that is, the affinity of molecules in the R state for O_2 is much greater than the affinity of those in the T state. The constant C is characteristic of a given hemoglobin structure. The equilibrium between the two conformations is given by the allosteric constant:

$$L = [Hb]_T/[Hb]_R$$

This is influenced by mutations in the globin chains and by several small allosteric molecules. These small molecules react with hemoglobin at nonheme sites in such a way as to stabilize the T conformation. Thus, a mixture of R and T hemoglobin molecules will show a reactivity with O_2 related to the position of the T-R equilibrium. For deoxyhemoglobin, the equilibrium is almost entirely on the T side. The T (deoxygenated) state is constrained by salt and hydrogen bonds to a much greater degree than the R state. Successive oxygenation of the heme groups causes some of these bonds to break, decreasing the stability of the T structure. When the molecules transit from the T to the R state, the constraints are released and the oxygen affinity increases. The shift from T to R during oxygenation accounts for cooperativity of O_2 binding. For normal hemoglobin, the shift from T to R occurs primarily between binding of the second and third O_2 molecules; hence, the OEC is steepest in the middle part of the curve.

The behavior of the OEC can affect O_2 transport to tissues. For instance, certain genetic alterations in the hemoglobin molecule may lead to polycythemia. A reduced O_2 affinity may improve O_2 delivery to tissues when arterial oxygenation is inadequate. In animals, chemical modifications of hemoglobin that shift the OEC to the right will increase PO_2 in the tissues during normoxia. During CO poisoning, the OEC is shifted to the left by CO binding to hemoglobin. This leftward shift exacerbates the tissue hypoxia resulting from the CO-mediated decrease in O_2 carrying capacity. An extreme leftward shift in the OEC caused by respiratory alkalosis is also a feature of O_2 transport in humans at high altitude. The effects of other changes in the position or shape of the OEC on O_2 transport, however, have been difficult to demonstrate in humans.

The actual shape and position of the OEC in vivo is influenced most strongly by hydrogen ion concentration, although O_2 and CO_2 also interact with hemoglobin in a very complex way to regulate the position and shape of the OEC. Hydrogen ion effects are regulated by PCO_2 and the buffering capacity of hemoglobin. Buffering by hemoglobin, in turn, is determined by hemoglobin concentration and the degree of O_2 saturation. The O_2 saturation is determined by the PO_2 and O_2 affinity of hemoglobin. These complex interactions are difficult to sort out in the efficiency of gas exchange by blood. Other properties of erythrocytes that affect O_2 transport include the rates of binding of physiologic ligands (O_2, CO_2, H^+, 2,3-DPG), buffering capacity, the barrier to diffusion of the red blood cell membrane, the unstirred plasma layer immediately surrounding the cell, and the blood viscosity.

An increase in 2,3-DPG normally augments tissue oxygenation by shifting the OEC to the right. At high altitude, if O_2 uptake by the lung is limited by diffusion, a lower O_2 affinity of hemoglobin would limit O_2 loading of hemoglobin, whereas a higher O_2 affinity would augment it. Whether or not the latter effect would be offset by lower tissue unloading remains unclear, because few measurements of venous PO_2 are available under severely hypoxic conditions. The 2,3-DPG effect does not seem well suited to O_2 delivery at high altitude, but the traditional view that shifting the OEC to the right facilitates O_2 unloading in tissue sites also may not be appropriate under certain conditions. Barcroft et al. first proposed that increased O_2 affinity was an important adaptation to high altitude based on analogy with the placental circulation, in which fetal blood has a higher affinity than that of the mother. Chemical modification of hemoglobin to increase its O_2 affinity confers better survival in hypoxic rats, and mutant hemoglobins with increased O_2 affinity may protect against the effects of hypoxia. On the summit of Mt. Everest, respiratory alkalosis decreases the P_{50} of whole blood to about 19 torr, a value that would help maintain the O_2 saturation of arterial blood. The arterial desaturation during exercise in extreme hypoxia might be ameliorated by the increase in the O_2 affinity of hemoglobin, although its effects on O_2 release to the tissues are uncertain.

Carbon Dioxide Transport and the Carbon Dioxide Dissociation Curve

The CO_2 dissociation curve of hemoglobin describes overall CO_2 transport as a function of CO_2 tension. The CO_2 dissociation curve is relatively steep in comparison with the O_2 equilibrium curve (Fig. 20). Consequently, large volumes of CO_2 can be exchanged by the lungs with relatively small changes in blood PCO_2. These small changes in blood PCO_2 minimize oscillations in blood pH, and the hydrogen ion concentration of blood at rest varies only 10% between arterial and mixed venous values. The steepness of the CO_2 dissociation curve also permits continued excretion of CO_2 even in the presence of significant mismatching of pulmonary ventilation and blood flow.

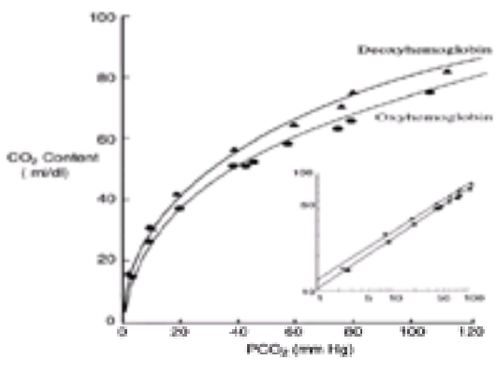

FIG. 20. CO_2 dissociation curve of blood. *Inset* shows log arithmetic transformation of the curve that linearizes the relationship between CO_2 content and PCO_2.

Most of the CO_2 in blood exists in the form of bicarbonate ion. CO_2 also is transported in a physically dissolved state in blood, and it is bound to amino groups of

proteins as carbamate compounds. Although CO_2 has an aqueous solubility approximately 20 times that of O_2, CO_2 dissolved in physical solution accounts for only 5% of the CO_2 content of arterial or venous blood. Dissolved CO_2, however, is important for CO_2 transport and exchange because the bicarbonate and carbamate pools are linked through dissolved CO_2. Molecular CO_2 is highly lipid-soluble and diffuses rapidly across cell membranes. Exchange of CO_2 in both the lung and peripheral tissues occurs via diffusion of molecular CO_2 across the vascular endothelium. CO_2 diffuses across the alveolar capillary membrane so rapidly that limitation of the process cannot be measured in vivo.

Hydration of CO_2 produces carbonic acid (H_2CO_3), which is almost completely ionized to hydrogen and bicarbonate in blood because the pK of carbonic acid (»3.8) is much lower than the pH of blood:

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^- \quad \textbf{(1)}$$

This process involves two steps. The first step is the hydration of CO_2 to carbonic acid, and the second step is the ionization of carbonic acid to bicarbonate. Bicarbonate ion can further dissociate into hydrogen and carbonate ions; however, little carbonate is formed in the body, because the pK of this reaction is greater than 10.0. CO_2 is hydrated to H_2CO_3 inside erythrocytes at a very slow rate. This reaction when catalyzed by carbonic anhydrase in the erythrocyte, however, occurs so quickly that the process is completed during the passage of the red cell through the peripheral capillaries. The reverse reaction, the dehydration of H_2CO_3 to CO_2, occurs during pulmonary excretion of CO_2 and similarly requires enzymatic catalysis. Carbonic anhydrase is present within the erythrocyte in high concentrations but is virtually absent from plasma. Carbonic anhydrase also is found in the capillary endothelium of the lung and other organs, but the quantity of enzyme there is small.

Human erythrocytes contain two isoforms of carbonic anhydrase. Carbonic anhydrase I is a low-activity enzyme that is inhibited by anions such as chloride. This isoform probably does not catalyze reactions of CO_2 in vivo. The other isoform, carbonic anhydrase II, has high catalytic activity and is resistant to anion inhibition. Human carbonic anhydrase II is comprised of 259 amino acids and has modest homology with carbonic anhydrase I. All isoforms of carbonic anhydrase contain a zinc atom that is essential for enzymatic activity. Activity is lost with binding of an unsubstituted—SO_2 NH_2 group of aromatic sulfonamides to the zinc ion. Acetazolamide is the most widely known of these inhibitors.

CO_2 and hydrogen ions reversibly bind to uncharged amino groups of proteins as described for hemoglobin:

$$R—NH_2 + H^+ \rightarrow R—NH_3^+$$

$$R—NH_2 + CO_2 \rightarrow R—NHCOOH$$

where R represents the protein moiety and R—NHCOOH is the carbamic acid. Under physiologic conditions, carbamic acids release protons and form carbamate ions, $R—NHCOO^-$. Because both molecular CO_2 and protons compete for uncharged amino groups, carbamate formation is pH-dependent and increases with alkalinity. Transport of CO_2 as carbamates is also influenced by PCO_2 and by the pK of the amino groups on the protein. The pK values of a-amino groups of the N-termini of blood proteins lie within the physiologic range of pH. Therefore, these frequently exist in the uncharged $R—NH_2$ form and are available to bind CO_2. In contrast, e-amino groups, which are located throughout the protein chains, have a pK well above the physiologic pH range. This means that most e-amino groups are bound to hydrogen ions and cannot bind CO_2. The concentration of carbamates in plasma is approximately 0.6 mM, and binding of CO_2 to a-amino groups accounts for 60% of this quantity. Plasma carbamates, however, do not participate in CO_2 exchange, because the steep slope of the CO_2 dissociation curve minimizes changes in pH and PCO_2 between arterial and venous blood. This effect in turn minimizes changes in plasma carbamate concentration in the lung and systemic capillaries.

Under physiologic conditions, binding of CO_2 to a-amino groups of hemoglobin is an important factor in CO_2 exchange. The total concentration of hemoglobin-carbamates in blood is relatively low, but as pointed out earlier, deoxyhemoglobin binds more CO_2 as carbamate than does oxyhemoglobin. The difference in bound CO_2 between the deoxygenated and oxygenated hemoglobin, or “oxylabile carbamate,” has a role in CO_2 exchange. When O_2 is released by hemoglobin in the tissues, it is accompanied by increased binding of CO_2 to a-amino groups. Conversely, oxygenation of hemoglobin in the lung promotes release of CO_2 bound as carbamate. The presence of 2,3-DPG decreases the total CO_2 content, and binding of oxylabile carbamate to hemoglobin relates inversely to 2,3-DPG concentration. The interaction between 2,3-DPG and CO_2 binding involves inhibition of carbamate formation when 2,3-DPG is bound to the N-terminal amino groups of the b chains of hemoglobin. Because the a chains of hemoglobin do not bind 2,3-DPG, organic phosphates do not affect carbamate formation in these subunits of the molecule. Carbamate binding measurements indicate that both the a and b chains of hemoglobin participate equally in oxylabile carbamate formation at physiologic PCO_2 in the presence of 2,3-DPG. This effect of organic phosphates on oxylabile carbamate formation decreases the role of this pathway in CO_2 exchange. The oxylabile carbamate accounts for perhaps 10% of total CO_2 exchange.

The CO_2 content of deoxygenated blood is greater than that of oxygenated blood at any PCO_2. This feature of CO_2 transport is referred to as the *Haldane effect.* The CO_2 dissociation curve of blood is nonlinear, but when plotted on logarithmic axes it becomes linear (Fig. 20). The slope of the line depends on the hemoglobin concentration of blood. The logarithmic expression of the CO_2 dissociation curve also permits definition of the curve by measuring a single experimental point and the hemoglobin concentration. The most important physiologic value is the slope of the CO_2 dissociation curve, as this determines the efficiency of CO_2 exchange. The slope of the CO_2 dissociation curve is essentially constant at a constant hemoglobin concentration. Thus, calculations of arterial-venous content differences and other parameters of gas exchange from CO_2 dissociation curves are correct as long as the appropriate slope and hemoglobin concentration are used.

Two thirds of the total CO_2 contained in whole blood is distributed in the plasma, and one third in erythrocytes at equilibration. The CO_2 in circulating blood is increased by the large internal buffering capacity of erythrocytes, the presence of cellular carbonic anhydrase, and the exchange of bicarbonate and chloride ions across the erythrocyte membrane. Similarly, two thirds of the bicarbonate in blood is distributed in the plasma and one third in the erythrocytes. The plasma volume is about 55% and the erythrocyte volume about 45% of whole blood, and bicarbonate ion is transported primarily in the aqueous phase. Plasma also has a greater fraction of water than do the erythrocytes, owing to the high concentration of hemoglobin inside the red cells. The Donnan effect, a consequence of charge restriction by negatively charged hemoglobin molecules inside the erythrocyte, also leads to a lower intracellular concentration of diffusible anions, such as bicarbonate.

Despite the lower bicarbonate content of erythrocytes, they are essential for almost all bicarbonate transport. CO_2 entering the blood from the tissues diffuses into the erythrocytes, where the large buffering capacity favors bicarbonate formation. Formation of bicarbonate from CO_2 is catalyzed rapidly by carbonic anhydrase within the erythrocytes, and CO_2 in minimal amounts remains hydrated as carbonic acid during the short period of capillary transit. The erythrocyte membrane facilitates the rapid exchange of intracellular bicarbonate ions for extracellular chloride ions, thereby shuttling bicarbonate ions produced within the erythrocyte into the plasma. Coupling of bicarbonate and chloride in the exchange process is accomplished via a transport protein, so that transmembrane potential is not altered and electrical potentials are not established that would prevent bicarbonate from moving out of the erythrocyte. This facilitated transport permits rapid exchange of bicarbonate across the cell membrane during the short period of capillary transit. Thus, even though the majority of bicarbonate is carried within the plasma, it is almost exclusively formed within the red cells. The entire process is reversed in the lungs as bicarbonate is converted to molecular CO_2, which is able to cross the alveolar-capillary membrane.

The facilitated exchange of bicarbonate and chloride across the erythrocyte membrane is mediated by an anion exchange protein (AE1, formerly band 3 protein). There are approximately 10^6 molecules of AE1 in each erythrocyte membrane. A variety of anions are transported by this carrier transmembrane, but bicarbonate and chloride ions exhibit the fastest rates of exchange. The actual mechanism of the exchange is characterized by 1:1 bidirectional anion flux associated with a conformational change in the protein structure.

The influence of O_2 on the CO_2 dissociation curve, the Haldane effect, has received less attention than the converse relationship, the effect of CO_2 on the O_2 dissociation curve of blood, the Bohr effect. The Bohr effect is responsible for only 2% of total O_2 exchange in the tissues, whereas the Haldane effect accounts for nearly half of resting CO_2 exchange. Oxygen-dependent exchange of CO_2 occurs via both the carbamate and bicarbonate pathways and is a function of pH, PCO_2, and the concentration of 2,3-DPG. With normal 2,3-DPG concentrations, the Haldane effect increases with increasing pH, reaching its maximal value under normal acid-base conditions. The importance of the carbamates in this process increases as the pH increases, because carbamate formation is promoted by the lack of protons and by less 2,3-DPG binding at higher pH. The contribution of the bicarbonate pathway to CO_2 transport peaks in the physiologic range of pH, but it decreases at higher pH as a result of increasing prominence of carbamates. When protons are released from deoxyhemoglobin on O_2 binding, some are consumed by the carbamate reaction, thereby leaving fewer protons to combine with bicarbonate ion to form CO_2. CO_2 exchange would occur without a functioning Haldane effect despite the fact that half of CO_2 excretion normally occurs by this mechanism. The cost of such a loss would be greater changes in arterial-venous CO_2 content,

increased tissue hypercarbia, and altered acid-base status.

ACID-BASE PHYSIOLOGY

A discussion of respiratory acid-base problems requires a basic understanding of the chemical behavior of acids and bases in aqueous solution. Chemical reactions proceed at a velocity that is proportional to the active concentrations, or "activities," of the reactants. In a reaction that may proceed in either direction, the Law of Mass Action may be written as follows:

$$[A] + [B] \rightleftharpoons [C] + [D]$$

Rate constants of the reactions in both the forward (k_1, [A] + [B] ® [C] + [D]) and reverse (k_2, [C] + [D] ® [A] + [B]) directions determine the concentrations of reactants until chemical equilibrium is reached, when

$$k_1/k_2 = [C][D]/[A][B]$$

The term k_1/k_2 is the equilibrium constant, K_e. For an acid in solution, the equilibrium constant is known as the dissociation constant:

$$K_a = [H^+][A^-]/[HA]$$

K_a determines the concentration of hydrogen ion, $[H^+]$. If the acid is "strong," K_a is large and $[H^+]$ and $[A^-]$ are much higher than [HA].

In 1909, L. J. Henderson used the Law of Mass Action to express the hydrogen ion equilibrium for carbonic acid:

$$[H^+] = K \times [CO_2]/[HCO_3^-]$$

Using the convention in which $[H^+]$ is expressed as pH, in which p is the negative power of 10, Hasselbalch rearranged Henderson's equation and applied it to the carbonic acid buffer system to obtain the following:

$$pH = pK + \log([HCO_3^-]/[CO_2])$$

When methods for the measurement of PCO_2 became available, $[CO_2]$ was replaced by PCO_2 and the equation written as follows:

$$[H^+] = 24\ PCO_2/[HCO_3^-]$$

where $[H^+]$ is in nEq/L, PCO_2 is in mmHg, and $[HCO^-_3]$ is in mEq/L. The familiar form of the Henderson-Hasselbalch equation is obtained by substituting 6.1, the pK_a of the system, and 0.0301, the solubility constant for CO_2 in plasma, into the equation:

$$pH = 6.1 + \log([HCO_3^-]/0.0301\ PCO_2)$$

As the PCO_2 of arterial plasma is regulated by alveolar ventilation, it is used to indicate the respiratory component of the acid-base state. The $[HCO^-_3]$ is an estimate of the nonrespiratory, or "metabolic," contribution to $[H^+]$. Although the Henderson-Hasselbalch equation accurately describes the equilibrium relationships between these variables, it does not describe how acid-base balance is regulated. The regulation of acid-base balance could be described by the Henderson-Hasselbalch equation only if both PCO_2 and $[HCO^-_3$ acted independently without influencing each other significantly or being affected by the other systems involved in acid-base control. This assumption is not valid, because the bicarbonate buffer system is influenced by the independent and direct effect of PCO_2 on $[HCO^-_3]$. Hence, changes in $[HCO^-_3]$ do not indicate "metabolic" changes alone. This difficulty was addressed by titration studies of plasma to produce the Siggaard-Andersen nomogram, along with normalizing the PCO_2 to 40 mmHg. This approach produced the concept of "base excess," the excess $[HCO^-_3]$ in arterial plasma that accounts for changes in ventilation. The concept of the base excess, however, did not hold when applied to whole blood or to plasma changes in which the acid-base adjustments were made *in vivo.* This issue required standardizing in vitro data to whole blood having a constant hemoglobin concentration.

The contribution of strong electrolytes to $[H^+]$ in the blood is another problem that has been approached conventionally by analyzing the difference between the concentrations of anions and cations. In plasma, cations predominate and exert a basic, or alkalizing, effect. The effect of strong ions other than Na^+, K^+, and Cl^- is expressed as the "anion gap," the anion concentration that cannot be explained by the inorganic anions and bicarbonate ($[Na^+] + [K^+]$) – ($[Cl^-] + [HCO^-_3]$). An excessive anion gap represents unmeasured anions, such as lactate or ketones. The working principle of the strong ion difference ([SID]) is similar to that of the anion gap, but it has the advantage of functioning as an independent variable in acid-base regulation.

The Physicochemical Approach to Acid-Base Interpretation

Acid-base problems are best approached by identifying and assessing changes in the buffer systems that contribute to changes in $[H^+]$. The recognition of both independent variables (those not altered by changes outside the system) and dependent variables (those influenced by the independent variables and by changes in other systems) can be described in a series of equations in which the independent variables are specified. This physicochemical approach identifies the dependent and independent variables that determine the acid-base status of plasma, cells, and body fluids.

Because body fluids are dilute aqueous solutions, the chemical behavior of water underlies all acid-base physiology. There is a small dissociation in pure water expressed in the following reaction:

$$2H_2O \rightleftharpoons H_3O^+ + OH^-$$

The extent of the dissociation defined by the Law of Mass Action is as follows:

$$K_W = [H^+][OH^-]/[H_2O]$$

In this equation, $[H_2O]$ in pure water is 55 mol/L, and because $[H^+]$ and $[OH^-]$ are 10^{-7} Eq/L or less, the $[H_2O]$ is effectively a large constant, and

$$K'_W = [H^+][OH^-]$$

where K'_W, the ion product for water, is $K_W \times [H_2O]$. In pure water, H^+ and OH^- are the only ions and are equal in concentration (neutral pH). At 25°C, K'_W has a value of 1.008×10^{-14} Eq_2-L^{-2}. This value is usually rounded off to 1.0×10^{-14}; thus,

$$K'_W = [H^+][OH^-] = 10^{-14}$$

and

$$[H^+] = [OH^-] = 10^{-7}$$

Neutral $[H^+]$ is 10^{-7} (pH = 7.0) at 25°C. At body temperature (37°C), however, neutral $[H^+]$ is not be 10^{-7} Eq/L because

$$K'_w = 4.4 \times 10^{-14}$$

and

$$[H^+] = (4.4 \times 10^{-14})/[OH^-] \text{ Eq/L} \quad \textbf{(1)}$$

Thus, neutral $[H^+]$ is the square root of 4.4×10^{-14}, or 2.1×10^{-7} (pH = 6.68).

In aqueous solutions, strong electrolytes are dissociated completely, and they are defined as having K values that are greater than 10^{-4} (strong acids) or less than 10^{-12} (strong bases). In blood and body fluids, K can be ignored for strong electrolytes because they are dissociated; that is, strong acids (HA) exist only as H^+ and A^-, and strong bases (BOH) exist only as B^+ and OH^-. In physiologic fluids, the main strong electrolytes are Na^+, K^+ and Cl^-. These strong ions influence $[H^+]$ by the Law of Electrical Neutrality and the dissociation of water. This means that in any system at equilibrium the net charge must be zero; thus, in a solution of Na^+, K^+, and Cl^- in water,

$$[Na^+] + [K^+] + [H^+] - [Cl^-] - [OH^-] = 0$$

The effect of strong ions may be lumped into a single term that expresses the net negative or positive charge that they exert. This is the “strong ion difference” ([SID]), which in plasma is normally $[Na^+] + [K^+] – [Cl^-]$. Strong organic ions, such as lactate or ketones, also contribute to [SID], as they may be present in high concentrations. Other strong inorganic ions are usually ignored, as they are present in low concentrations. Therefore,

$$[SID] + [H^+] - [OH^-] = 0$$

where the independent variable is the [SID] and the dependent variables are $[H^+]$ and $[OH^-]$. In normal plasma, $[Na^+]$ is 140 mEq/L, $[K^+]$ is 4 mEq/L, and $[Cl^-]$ is 104 mEq/L. Thus, the normal [SID] is approximately 40 mEq/L. Without bicarbonate or other basic electrolytes in plasma, $[OH^-]$ would have to be close to 40 mEq/L (4×10^{-2} Eq/liter). If true, then

$$[H^+] = 4.4 \times 10^{-14}/4 \times 10^{-2} \text{ Eq/L}$$
$$= 1.1 \times 10^{-12} \text{ Eq/L}$$

or a pH of nearly 12. This calculation shows how important strong ions, weak acids, and the HCO^-_3 buffer system are for the control of $[H^+]$ in body fluids. With these systems in plasma, the $[H^+]$ is 4×10^{-8} (pH = 7.4).

Total weak acids (A_{tot}) are the buffers present in a partially dissociated state in the physiologic pH range. These acids have dissociation constant (K_a) values between 10^{-4} and 10^{-12}; however, only weak acids with a K_a close to pH 7.4 are effective buffers. Buffer systems include plasma proteins ($K_a = 3 \times 10^{-7}$), proteins and phosphates in cells ($K_a = 5.5 \times 10^{-7}$), and hemoglobin in red cells. The K_a of the imidazole group of the histidine residues in proteins is virtually identical to the neutral $[H^+]$ of water, while in hemoglobin, the imidazole groups are associated closely with the heme, and the imidazole groups become less acidic when the heme structure tenses on the release of O_2. For oxyhemoglobin, K_a is 2.5×10^{-7}, and for deoxyhemoglobin, it is 6.3×10^{-9}. For plasma proteins at 37°C:

$$[H^+] \times [A^-] = (3 \times 10^{-7}) \times [HA] \text{ Eq/L} \quad \textbf{(2)}$$

The effectiveness of weak acids as buffers depends not only on the dissociation constant, but also on total concentration ($[A_{tot}]$) of the acid. The sum of the dissociated (A^-) and undissociated (HA) forms of any weak acid remains constant:

$$[HA] + [A^-] = [A_{tot}] \text{ Eq/L} \quad \textbf{(3)}$$

where $[A_{tot}]$ is an independent variable and [HA] and $[A^-]$ are dependent variables. In plasma, $[A_{tot}]$ represents the ionic equivalent of the plasma proteins and may be estimated by multiplying the protein content by 0.24. Thus, at a normal total protein levels of 70 g/L, $[A_{tot}]$ is 17 mEq/L. This value is comprised of $[A^-]$ of 15 mEq/L and [HA] of 2 mEq/L at pH 7.4. Hence, even though plasma proteins behave as weak acids, they are mostly dissociated (15/17) at normal arterial pH.

Carbon Dioxide and the Bicarbonate Buffer System

The CO_2 buffer system acts mainly through variations in total CO_2 content brought about by variations in PCO_2 and $[H^+]$. As indicated earlier, the two components of the system are hydration of CO_2 and the dissociation of carbonic acid into HCO^-_3 and H^+. These two equations can be combined and solved for $[H^+]$ to yield an equation containing two constants and $[H_2O]$. These constants may all be incorporated into a single overall ionization constant (K'_a) to obtain:

$$[H^+] = K'_a[CO_2]/[HCO^-_3]$$

where $[CO_2]$ is the concentration of dissolved CO_2 and is related to the PCO_2 by the solubility constant for CO_2 (3.01×10^{-5} Eq/L/mmHg). Substituting the solubility constant into the equation:

$$[H^+] = K'_a (3.01 \times 10^{-5} PCO_2)/[HCO^-_3] \text{ Eq/L}$$

For K'_a of 7.94×10^{-7} the single constant can be used:

$$K_c = (7.94 \times 10^{-7}) \times (3.01 \times 10^{-5})$$
$$= 2.4 \times 10^{-11}$$

Thus,

$$[H^+] = (2.4 \times 10^{-11}) \times PCO_2/[HCO^-_3] \text{ Eq/L} \quad \textbf{(4)}$$

For PCO_2 expressed in torr and $[HCO^-_3]$ in mEq/L,

$$[H^+] = 24 \times PCO_2/[HCO^-_3] \text{ nEq/L}$$

This is Henderson's equation. PCO_2 is the independent variable of the CO_2 system, whereas $[H^+]$ and $[HCO^-_3]$ are both dependent variables. Using the pK_a of the bicarbonate system in the expression yields the Henderson-Hasselbalch equation. At a normal $PaCO_2$ of 40 mmHg, if $[H^+]$ is 40 mEq/L, then $[HCO^-_3]$ is 24 mEq/L.

The hydration of CO_2 to carbonic acid in aqueous solution is a slow process, but as noted earlier, it is accelerated greatly by carbonic anhydrase. Carbonic acid

dissociates into H^+ and bicarbonate, and bicarbonate itself dissociates into H^+ and carbonate ion. The equilibrium equation is as follows:

$$[H^+] = (6 \times 10^{-11})[HCO_3^-]/[CO_3^{2-}] \text{ Eq/L} \quad \textbf{(5)}$$

where 6×10^{-11} is the K_a for the reaction. All three variables in this equation depend on changes in the CO_2 and other systems.

The interactions between the different buffer systems in the body must satisfy the Law of Electrical Neutrality when the systems are in equilibrium. Hence, all the charges of ions in the systems must be summed, including $[H^+]$ and $[OH^-]$ for water, the net positive charge of [SID] for strong electrolytes, $[A^-]$ for weak electrolytes, and CO_2, $[HCO^-_3]$, and $[CO^{2-}_3]$. Thus,

$$[SID] + [H^+] - [HCO_3^-] - [CO_3^{2-}] - [A^-] - [OH^-] = 0 \quad \textbf{(6)}$$

The $[H^+]$ and $[OH^-]$ in plasma cannot be computed from this equation because the [SID], $[HCO^-_3]$, and $[A^-]$ are orders of magnitude greater than $[H^+]$ and $[OH^-]$ in body fluids. The equation must be satisfied, however, to quantify the effects of the variables governing electrolyte physiology. The calculated $[H^+]$ and $[OH^-]$ also have to satisfy each equation in which they appear as dependent variables. Because the relationships between the variables are complicated, the six numbered equations (Eq. 1,Eq. 2,Eq. 3,Eq. 4,Eq. 5 and Eq. 6) must be solved simultaneously to account fully for all the interactions. The three independent variables only appear once in the series: $[A_{tot}]$ (Eq. 3), PCO_2 (Eq. 4), and [SID] (Eq. 6). The dependent variables appear in more than one equation: $[H^+]$, $[OH^-]$, $[HCO^-_3]$, $[CO^{2-}_3]$, and $[A^-]$.

The equations can be solved simultaneously for any values of [SID], $[A_{tot}]$, and PCO_2 in plasma, or by changing parameters to fit the acid-base status of any other body fluid or any other conditions. Also, the equations may be combined into a single fourth-order polynomial from which $[H^+]$ can be computed. This computation has no practical role in the assessment of the acid-base status of plasma, in which pH can be measured directly, but the measured $[H^+]$ and calculated $[H^+]$ generally agree because the acid-base systems have been defined rigorously in terms of their dependent and independent components. This enables identification of the mechanisms that lead to changes in $[H^+]$ in plasma, cells, and interstitial fluid. Calculations of “base excess” and the “anion gap” are replaced by the variables [SID] and $[A^-]$. This approach also clarifies some fuzzy concepts, including the use of the Henderson-Hasselbalch equation to imply that $[H^+]$ is controlled by changes in $[HCO^-_3]$, the concept of protons being produced or eliminated, and concepts implying that $[HCO^-_3]$ may be produced, removed, or retained (by the kidneys), or administered as a useful therapy.

The use of graphs or solutions of the equations to obtain the variables that satisfy the measured arterial $[H^+]$ and PCO_2 are useful clinically. Also, plasma electrolyte measurements yield a measured inorganic [SID] ($[Na^+] + [K^+] – [Cl^-]$) that may be compared with the value of [SID] that satisfies $[H^+]$ and PCO_2 for possible effects of other strong ions. A difference between the inorganic [SID] and total [SID] indicates the presence of unmeasured ions, such as lactate or ketoacids. This exercise is similar to the calculation of the anion gap, except that $[A^-]$ is a variable rather than a constant. Because $[H^+]$, $[OH^-]$, and $[CO^{2-}_3]$ are in micromolar concentrations or less, Eq. 6 may be simplified as follows:

$$[SID] - [HCO_3^-] - [A^-] = 0$$

This simplification makes it possible to evaluate the effects of the three independent variables ([SID], PCO_2, and protein) and to determine whether unmeasured strong anions are contributing to the acid-basis status.

Variations in the relative magnitude of the independent variables involved in control of acid-base status produce differing effects in different fluid compartments and different tissues (Fig. 21). In intracellular fluid, [SID] is large and dominated by a high $[K^+]$. Large protein and phosphate concentrations (A_{tot}) also minimize the effects of reductions in [SID] resulting from falls in $[K^+]$ or accumulation of strong organic ions such as lactate. In tissues, PCO_2 is high and increased by metabolism, but $[HCO^-_3]$ is low. Changes in PCO_2 in tissue influence $[H^+]$ much less than in plasma. Control of intracellular $[H^+]$ is achieved through buffering by A_{tot} and exchange of strong ions with extracellular fluid, thereby changing the [SID], and by diffusion of CO_2 out of the cell. In interstitial fluid and other ultrafiltrates of plasma, such as lymph or cerebrospinal fluid, $[H^+]$ is influenced only by changes in [SID] and PCO_2, because protein is virtually absent and there is no role for the weak acid system. In plasma, the [SID] also tends to regulate the pH, but variations in PCO_2 may bring about large and rapid changes in arterial $[H^+]$.

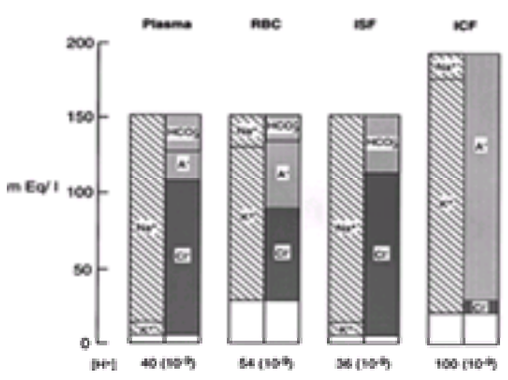

FIG. 21. Diagrams of ionic status of various body fluid compartments: *RBC,* red blood cell; *ISF,* interstitial fluid, *ICF,* intracellular fluid. Electrical neutrality is shown by equal heights of the two panels in each plot. The strong ion difference [SID] is occupied by the $[A^-]$ and $[HCO^-_3]$. The $[H^+]$ is shown beneath each plot.

Inside erythrocytes, all three systems have similar values, because [SID] and $[A_{tot}]$ are high and PCO_2 is in equilibrium with the PCO_2 of the surrounding plasma. The situation is also complicated because the state of oxygenation influences the dissociation constant. These considerations emphasize the importance to acid-base balance of fluid, strong ion, and CO_2 shifts between the different body compartments, because the molecules making up A_{tot} (e.g., proteins) do not move readily.

Intracellular pH and the Alphastat Hypothesis

For many years, partly because of the difficulty in studying pH changes within tissues, acid-base physiology has dealt primarily with the status of the blood. Marked changes in biochemical and physiologic function, however, accompany alkalosis and acidosis in the systemic organs. For example, alkalosis stimulates glycolysis, whereas increases in $[H^+]$ impair membrane function, blunt hormonal responses, and inhibit enzyme activity. Such effects appeal to the concept of control of the intracellular $[H^+]$; however, good evidence in living systems suggests that regulatory mechanisms are attempting to keep a constant state of protein ionization. This concept is based on the parallel effects of temperature on tissue pH and on the pK of the imidazole group of histidine in proteins, which is very close to neutral pH. This principle was first pointed out by Rahn et al., who suggested that regulation protected the fractional dissociation of the cellular imidazole—NH groups. They termed the fractional dissociation *alpha,* and they called the control mechanism the *alphastat.* The close involvement of imidazole groups in enzyme regulation, receptor function, and the operation of membrane pores and ion exchangers explains many physiologic effects of acid-base perturbations previously explained by changes in $[H^+]$.

In clinical circumstances, intracellular acid-base measurements are not usually available; however, intracellular $[H^+]$ is important because of its influence on cellular metabolic processes. Large variations clearly exist in pH in different tissues in different clinical situations. Experimental studies in animals and humans have attempted to establish the magnitude of intracellular fluid (ICF) changes relative to those of extracellular fluid (ECF). Studies in which arterial PCO_2 has been raised or lowered have shown that ICF $[H^+]$ is well defended in a range of arterial PCO_2 between 40 and 80 mmHg. This can be explained in terms of the differences in [SID] and $[A_{tot}]$ between ICF and ECF. Studies of metabolic acidosis and alkalosis have similarly shown good control of $[H^+]$ in ICF, but the defense against alkalosis appears to be less effective than that against acidosis. The reasons for this difference probably lie in the different extent to which ECF changes in [SID] are capable of influencing the

[SID] in the ICF.

Erythrocytes and Acid-Base Control

Erythrocytes buffer sudden changes in ions or PCO_2 and help maintain relatively constant conditions in plasma and thus in the ECF. The ICF composition of the erythrocyte lies between that of ICF and plasma. The $[K^+]$ is not as high as in ICF, but $[Na^+]$ and $[Cl^-]$ are higher, although still well below plasma values. The erythrocyte [SID] is 60 mEq/L, compared with 130 mEq/L in ICF. Hemoglobin also provides an $[A_{tot}]$ of 60 mEq/L, which compares with 20 mEq/L in plasma and 200 mEq/L in ICF. The R and T forms of hemoglobin also provide a variable K_a, which enables deoxyhemoglobin to buffer venous acidity more effectively. The carbonic anhydrase in the erythrocyte enables the hydration of CO_2 to proceed rapidly, and carbonate formation enhances CO_2 content without a comparable increase in $[H^+]$. Cell membrane transport systems also facilitate ion exchange between the plasma and erythrocyte while controlling erythrocyte volume.

When O_2 dissociates from hemoglobin, $[H^+]$ inside the erythrocyte tends to decrease. As CO_2 enters the erythrocyte, this decrease in $[H^+]$ is offset by the ionization of carbonic acid. Bicarbonate moves out of the cell, and Cl^- moves into the cell. This tends to increase plasma [SID] and leads to a rise in plasma $[HCO^-_3]$. At the same time, CO_2 forms carbamates very rapidly. This reaction is facilitated by deoxygenation, which allows the a-amino groups of the b chain of deoxyhemoglobin to form carbamates. In addition to these reactions associated with the deoxygenation of hemoglobin and CO_2 content of venous blood, the erythrocyte can modulate rapid changes in plasma ion concentration.

Ventilation and Acid-Base Control

The PCO_2 in arterial plasma is controlled mainly by changes in ventilation, as shown in the alveolar ventilation equation, which expresses the simple inverse relationship between $PaCO_2$ and $\dot{V}_A$. The equation is useful because neither metabolic rate nor ventilation needs to be measured to assess the adequacy of breathing in relation to metabolic demand. Arterial PCO_2 represents the balance between metabolic CO_2 production and ventilation. In tissues and venous blood, PCO_2 is regulated primarily by the balance between metabolism and blood flow. The extent to which arterial PCO_2 reflects the adequacy of ventilation also depends on the activity of carbonic anhydrase in allowing rapid equilibration of PCO_2 between pulmonary capillary blood and alveolar gas. Thus, it is affected by carbonic anhydrase inhibition.

The alveolar ventilation equation expresses the combined effects of changes in $\dot{V}_A$ and $\dot{V}CO_2$ on $PaCO_2$. In patients with severely impaired ventilatory capacity, respiratory failure may be worsened by changes in $\dot{V}CO_2$. In patients with an increase in PCO_2, several factors may contribute to underventilation, including inefficient gas exchange leading to dead space ventilation ($\dot{V}_D$), increased work of breathing, impaired respiratory muscle strength and endurance, and disorders of respiratory control. The ventilatory responses to acid-base disorders of nonrespiratory origin are extremely important for regulating $[H^+]$, because they may change rapidly. In long-term responses to acid-base disturbances, the response of the central medullary chemoreceptors is the most important factor in the ventilatory set point. The major effector is the $[H^+]$ in cerebrospinal fluid, and because cerebrospinal fluid is protein-free, the PCO_2 and [SID] are the two important independent variables in central control of ventilation.

The Kidneys and Acid-Base Control

The kidneys influence acid-base status mainly by changing the [SID] of the plasma. In the glomerulus, Na^+ reabsorption from plasma ultrafiltrate in the tubules is an active process that lowers both $[Na^+]$ and osmolality in the tubules, leading to water reabsorption. This process in the distal tubule is under the control of antidiuretic hormone. Chloride reabsorption is mediated in part electrically and in part by an active process related to ATPase-driven membrane pumps on renal tubular cells. If Cl^- is reabsorbed less rapidly than Na^+, urinary $[Cl^-]$ increases relative to $[Na^+]$ and urinary [SID] falls and increases urinary $[H^+]$. If Na^+ is less rapidly reabsorbed than Cl^-, the opposite occurs. In the tubular lumen, a fall in [SID] and an increase in $[H^+]$ tend to increase PCO_2. The increase in PCO_2 occurs because the tubule is partly closed to the circulation and the removal of CO_2 by the renal capillary blood flow may not keep pace with its production. The $[HCO^-_3]$ tends to fall with the increase in $[Cl^-]$, and when urinary pH has fallen to <6, urinary $[HCO^-_3]$ is very low. In this way, the excretion of Cl^- in excess of Na^+ and K^+ contributes to control of plasma [SID] and $[H^+]$.

When $[H^+]$ has increased because of accumulation of organic anions such as lactate, the renal tubular cells can excrete the lactate, Cl^-, or both. Because the reabsorption of strong organic anions is less efficient, Cl^- is reabsorbed in preference to lactate, resulting in a very high urinary $[La^-]$ and low $[Cl^-]$. In this situation, the kidney prevents urinary pH from becoming too low by excreting more water and Na^+, if they are available, and by excreting ammonia and phosphates. This allows reabsorption of Na^+ or excretion of Cl^- without an increase in urinary $[H^+]$. Both effects tend to increase plasma [SID] and decrease plasma $[H^+]$. As ammonia and phosphate excretion have limited capacities, adequate Na^+ and water delivery to the distal tubule in an organic acidosis is very important. The kidneys normally are able to adjust to ranges of water excretion between 0.5 and 25 L/d and to ranges of Na^+ excretion between 0.05 and 25 g/d.

Disorders of Acid-Base Physiology

The primary acid-base disorders may be thought about in terms of abnormalities in the three acid-base variables capable of independent action: the [SID], $[A_{tot}]$, and PCO_2 in arterial blood. Primary acid-base changes are modified by “compensatory” changes that, to be effective, have to involve independent variables—for example, changes in ventilation leading to changes in PCO_2, or movement of strong ions into cells or urine to modify [SID].

Primary Metabolic Acidosis and Alkalosis

Processes that reduce [SID] (e.g., an increase in $[Cl^-]$) tend to increase $[H^+]$, leading to a primary metabolic acidosis (Table 4). A number of compensatory responses take place to minimize this effect. Reductions in [SID] may be offset by responses to increase [SID]; for example, in diabetic acidosis, dehydration may increase $[Na^+]$, and more Cl^- excretion in urine may help to reduce plasma $[Cl^-]$. These two changes help compensate for the effects of the increase in plasma ketoacid concentration. In disease states (e.g., uremic acidosis), these adaptive responses may not be available. Measurement of urinary electrolyte excretion may be helpful in assessing the role of the kidneys in an acidosis. A tendency for $[H^+]$ to increase also leads to an association of weak acids (plasma proteins, A_{tot}) and thus to a reduction in $[A^-]$, which may amount to 3 to 4 mEq/L (slightly more in very severe acidosis). Increases in $[H^+]$ also stimulate ventilation, leading to a decrease in $PaCO_2$. The effectiveness of this response depends on the ventilatory capacity, the efficiency of pulmonary gas exchange, and ventilatory control mechanisms. If none of these physiologic mechanisms is impaired, the increase in $[H^+]$ expected for a given reduction in [SID] may be used to identify the adequacy of the responses.

TABLE 4. *Causes of primary metabolicacidosis and alkalosis*

An increase in [SID] (e.g., a decrease in $[Cl^-]$) tends to reduce $[H^+]$, producing a metabolic alkalosis. The causes of primary metabolic alkalosis are given in Table 4. The compensatory responses to an increase in [SID] may be considered in terms similar to those seen in low [SID] states. These are retention of Cl^- by the kidneys in patients with normal renal function, and sometimes movement of Na^+ into ICF. Although $[H^+]$ may be defended by dissociation of weak acids with an increase in $[A^-]$,

this effect usually amounts to 1 mEq/L or less. Decreases in plasma [H^+] are usually accompanied by a reduction in ventilatory responsiveness, and $PaCO_2$ rises by about 1.0 mmHg for each increase in [SID] of 10 mEq/L. In some cases of metabolic alkalosis, severe loss of K^+ may accompany Cl^- in the kidneys, leading to depletion of intracellular [K^+] and a fall in ICF [SID]—an intracellular acidosis complicating the extracellular alkalosis. This effect may lead to respiratory muscle weakness.

Plasma Proteins and Total Weak Acid Concentration

Normally, the weak acid concentration [A_{tot}] is determined by the plasma protein concentration alone. The [A_{tot}] may increase if plasma proteins or other weak acids (such as phosphate) increase. Increases of more than 2 or 3 mEq/L in [A_{tot}] are uncommon, but because they act as weak acids, the effect of increasing [A_{tot}] is similar to a reduction in [SID]—a metabolic acidosis. The effects of increases in plasma proteins, as in multiple myeloma, vary depending on the isoelectric points of the class of globulin involved. Most globulins have isoelectric points similar to that of albumin, a pK of around 6.5, and thus act as weak acids. The IgG class has an isoelectric point that is close to pH 9.0.

When plasma protein concentration is reduced, the [A_{tot}] is reduced, leading to a fall in [A^-]. The effects are similar to increases in [SID] of equimolar size—a metabolic alkalosis. Quantitatively, the effect may be assessed by multiplying the total protein concentration in grams per liter by 0.24 [A_{tot}] and by taking 0.9 of this value as [A^-], as A_{tot} is about 90% dissociated in most situations. This value may then be added to [Cl^-] and [HCO^-_3] to identify the presence of any unmeasured anions. The major exception is an increase in IgG paraproteins in myeloma; these act as weak bases because of the basic amino acids lysine and arginine, whose isoelectric points are close to pH 9.0. They have a weak positive charge in the physiologic pH range, and [A_{tot}] and [A^-] appear falsely low their presence.

Primary Respiratory Acidosis and Alkalosis

An elevated $PaCO_2$ indicates alveolar hypoventilation, and when it is not a response to a metabolic alkalosis, it is termed a *primary respiratory acidosis.* The common cases of alveolar hypoventilation are shown in Table 5. The potential effect of an increase in $PaCO_2$ on plasma [H^+] may be seen by moving to the right along the normal [SID] isopleth in a plot of [H^+] versus $PaCO_2$ (Fig. 22). Similarly, it may be seen that the effect of an increase in $PaCO_2$ may be minimized by an increase in [SID]. Virtually the only compensatory mechanism that is effective and well tolerated is a reduction in plasma [Cl^-]. Acutely, this occurs through a shift of Cl^- into erythrocytes; over a longer time, excretion of Cl^- in excess of Na^+ and K^+ in urine leads to a fall in plasma [Cl^-]. In general, [Cl^-] falls acutely by 1 mEq/L and in chronic states by 3 to 4 mEq/L for each increase of 10 mmHg in $PaCO_2$. These changes in [$C1^-$] are accompanied by increases in [HCO^-_3] of similar magnitude.

Causes of CO_2 retention and respiratory acidosis
With normal lungs
Anesthesia
Sedative drugs
Neuromuscular disease (e.g., poliomyelitis, myasthenia gravis, Guillain-Barré syndrome)
Obesity-hypoventilation syndrome
Brain injury
With abnormal lungs
Chronic obstructive pulmonary disease (e.g., chronic bronchitis, emphysema)
Diffuse interstitial pulmonary disease (late)
Severe kyphoscoliosis
Causes of excess CO_2 elimination and respiratory alkalosis
With normal lungs
Anxiety
Fever
Drugs (e.g., salicylates)
Hypoxemia (e.g., high altitude)
Central nervous system lesions (e.g., tumors, meningitis)
Sepsis
Hormonal excess (e.g., progesterone, thyroxine)
With abnormal lungs
Pneumonia
Diffuse interstitial pulmonary disease (early)
Acute bronchial asthma
Pulmonary vascular disease
Congestive heart failure

TABLE 5. *Causes of primary respiratoryacidosis and alkalosis*

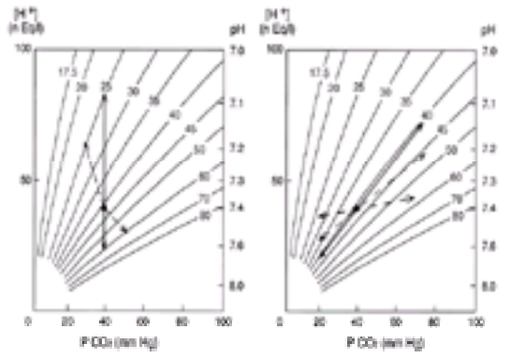

FIG. 22. Acid-base isopleths. Isopleths are for different values of [SID] in mEq/L at a normal weak acid concentration. **Left panel:** Changes in [H^+] accompanying changes in [SID] without respiratory compensation (*solid black arrow*) and with respiratory compensation (*dashed red arrow*). **Right panel:** Changes in $PaCO_2$. *Solid arrow* shows [H^+] changes with $PaCO_2$ in absence of changes in [SID]. *Dashed arrows* show changes in [SID] with acute (*red*) and chronic (*blue*) respiratory acidosis and alkalosis.

The effectiveness of increases in [SID] in limiting increases in [H^+] also may be appreciated by looking at Fig. 22. The figure may be used to assess the presence of superimposed metabolic acidosis, in which [SID] increases are less than expected for the rise in $PaCO_2$, or metabolic alkalosis, in which [SID] increases are more than expected. In recovery from ventilatory failure, resolution of the changes in [SID] is also time-dependent. If the reduction in $PaCO_2$ toward normal occurs rapidly, there is a delay in the increase in [Cl^-] (*posthypercapnic metabolic alkalosis*).

Reductions in $PaCO_2$ are caused by hyperventilation. When the reduction in $PaCO_2$ is the primary disturbance, the condition is termed *primary respiratory alkalosis.* Conditions that give rise to this situation are shown in Table 5. Reductions in $PaCO_2$ tend to reduce [HCO^-_3] in plasma, but unless a decrease occurs in [SID], this reduction is quite limited and a marked fall in [H^+] results, especially in acute hyperventilation. Reductions in [SID] minimize the fall in [H^+], and they are the result of two compensatory responses. These are retention of Cl^- through a fall in its renal excretion and a small accumulation of lactate resulting from the stimulation of glycolysis in erythrocytes and liver. Retention of Cl^- tends to characterize chronic states of hyperventilation, but increases in [La^-] may occur very rapidly. These compensatory changes are associated with increases in [H^+] toward normal and a fall in [HCO^-_3]. The usual reduction in total [SID] that results from an increase in both [Cl^-] and [La^-] accompanying an acute fall in $PaCO_2$ amounts to only 1 to 2 mEq/L for each fall of 10 mmHg in $PaCO_2$; this increases to 3 to 4 mEq/L when hyperventilation is sustained for several days. The reductions in $PaCO_2$ and [H^+] in hyperventilation are accompanied by a surprisingly large increase in [CO^{2-}_3], predisposing to hypocalcemia and tetany.

Complicated Acid-Base Disorders

Complicated acid-base disturbances are those disorders defined as either mixed (acidosis plus alkalosis) or combined (respiratory plus metabolic acidosis, or respiratory plus metabolic alkalosis). Not infrequently, complicated problems occurs in which the expected compensatory responses are inefficient or absent because of coexisting impairment of function. The most common functional impairments are the presence of renal disease or ventilatory failure. Usually, such situations have to be considered within the clinical context and need to be identified by the response to the primary disorder. For example, a patient with a metabolic acidosis resulting from poor control of diabetes may have a $PaCO_2$ that is higher than expected in response to the accumulation of ketoacids that reduces the [SID]. The poor ventilatory response may be caused by impaired ventilatory capacity resulting from air flow obstruction or respiratory muscle weakness. Poor renal function also may lead to an inappropriate compensatory response. For example, in chronic respiratory failure, the kidneys may be unable to excrete Cl^-, adding a metabolic acidosis to the

respiratory acidosis. Urinalysis, including measurement of electrolytes and pH, may be valuable in assessing these situations.

OXYGEN TRANSFER FROM BLOOD TO MITOCHONDRIA

Convective Oxygen Delivery

The net uptake of O_2 from the lungs to the body tissues is determined by the blood flow rate multiplied by the difference between the O_2 contents of arterial and venous blood ($avDO_2$). This relationship is expressed as Fick's First Principle:

$$\dot{V}O_2 = \dot{Q}_T [CaO_2 - C\bar{v}O_2]$$

where $\dot{V}O_2$ is the O_2 consumption of the body, $\dot{Q}_T$ is the cardiac output, and CaO_2 and $C\bar{v}O_2$ are the values for arterial and mixed venous O_2 content, respectively. The O_2 content (CO_2) of blood is determined as follows:

$$CO_2 = [Hb]\ (1.34)\ (SO_2) + 0.0031 \times PO_2$$

where [Hb] is hemoglobin concentration in grams per deciliter, 1.34 is the binding capacity of hemoglobin for O_2 in mL (O_2) per gram (Hb), and SaO_2 is the O_2 saturation of hemoglobin as a fraction of 1.0. The term 0.0031 PO_2 represents the dissolved O_2 per mmHg of O_2 partial pressure. At the resting metabolic rate with a cardiac output of 5 L/min (50 dL/min) and an arterial-venous difference in O_2 content of 5 mL/dL,

$$\begin{aligned}\dot{V}O_2 &= 50\ \text{dL/min} \times 5\ \text{mL}\ O_2\text{/dL} \\ &= 250\ \text{mL/min}\end{aligned}$$

The convective delivery of O_2 to the body tissues ($\dot{D}O_2$) is defined as $\dot{Q}_T \times CaO_2$. Solving the Fick equation, this is normally

$$\begin{aligned}&(50\ \text{dL/min})\ (15\ \text{g/dL})\ (1.34\ \text{mL}\ O_2\text{/dL})\ (1.0) \\ &\quad = 50 \times 20\ \text{mL}\ O_2\text{/min} \\ &\quad = 1000\ \text{mL}\ O_2\text{/min}\end{aligned}$$

At an $avDO_2$ of 5 mL/dL, approximately 250 mL O_2 is extracted by the body per minute. This results in a mixed venous hemoglobin saturation of 75% and an O_2 extraction ratio of 250 mL O_2/1000 mL O_2, or 0.25. In other words, only one fourth of the O_2 delivered to the tissues is utilized by the body at rest. During work, increased metabolic demands by the tissues for O_2 can be met by increasing $\dot{D}O_2$, the O_2 extraction ratio, or both. $\dot{D}O_2$ can be altered by changes in any of the variables in the Fick equation, including cardiac output, hemoglobin concentration, changes in O_2 binding capacity of hemoglobin, and hemoglobin O_2 saturation. In general, alterations in one of these parameters is compensated for by adjustments in one or more of the others to maintain “adequate” $\dot{D}O_2$ to the tissues. For example, anemia is compensated for by increases in cardiac output, whereas chronic hypoxia causes increases in both cardiac output and hemoglobin concentration. At extremes of exercise, the $\dot{D}O_2$ can increase as much as sixfold and the O_2 extraction ratio as much as threefold.

The distribution of cardiac output to the different tissues of the body under normal conditions is determined by the local metabolic needs. Normally, the O_2 consumption of tissues is independent of $\dot{D}O_2$ provided that more than the critical amount of O_2 is delivered. For example, the human brain receives approximately 20% of the cardiac output to support its normal O_2 requirement. Increasing $\dot{D}O_2$ to the normal brain (e.g., during hypercapnia) does not increase the metabolic consumption of O_2 by the brain. Under pathologic conditions such as hypovolemia, however, the cardiac output is redistributed by autonomic mechanisms to tissues with high obligatory needs for O_2. This response preserves the functions of the heart and brain at the expense of blood flow to skin, skeletal muscle, and splanchnic organs.

In some diseases, such as adult respiratory distress syndrome (ARDS) and sepsis, concerns have been raised about whether at a particular $\dot{D}O_2$ the body can extract O_2 adequately to meet the needs of the tissues. If not, O_2 consumption will fall if O_2 delivery falls. This situation is called *pathologic supply dependence of O_2 consumption.* It is distinguished from physiologic supply dependence, which occurs when O_2 delivery falls below the point at which normal O_2 extraction has reached its maximal limit of approximately 75% (Fig. 23). Pathologic O_2 supply dependence has been reported in a variety of clinical conditions; however, the finding is difficult to interpret under most circumstances. It is difficult to determine the clinical significance of small changes in systemic $\dot{V}O_2$ without sensitive methods for measuring the adequacy of oxidative metabolism in individual tissues. Therapeutic attempts to improve systemic O_2 consumption by increasing O_2 delivery in septic shock and ARDS have met with limited success once the circulatory blood volume has been restored adequately. The pathophysiologic mechanisms that may contribute to pathologic O_2 supply dependence are discussed later in this chapter.

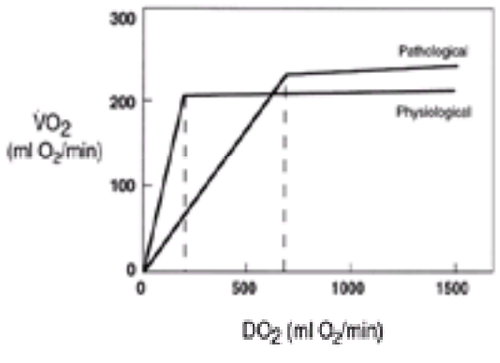

FIG. 23. Relationship between O_2 delivery and O_2 consumption for the body. Physiologic O_2 supply dependence shows a lower critical delivery than pathologic O_2 supply dependence. $\dot{D}O_2$, delivery; $\dot{V}O_2$, consumption.

In the intensive care unit, measurements of cardiac output by thermodilution, mixed venous oxygen content, and systemic O_2 consumption are made routinely using a flow-directed, balloon-tipped pulmonary arterial catheter (Swan-Ganz catheter). Alternatively, the $\dot{V}O_2$ can be measured by respiratory gas analysis. The $\dot{V}O_2$ represents the sum and venous O_2 content represents the flow-weighted average of all the tissues of the body. The measurements contain a number of potentially serious pitfalls in regard to interpretation, and misconceptions are common about the clinical utility of the information obtained from them. This is particularly true for an increase in the mixed venous O_2 saturation, which cannot be interpreted as an improvement in the hemodynamic status of a critically ill patient.

The coefficient of variation for the measurement of cardiac output by thermodilution is approximately 15%. Very few tissues of the body require 15% of the cardiac output to meet their normal O_2 requirements (the brain being a notable exception). As shown from the Fick equation, the cardiac output and $avDO_2$ can both be used to compute the systemic O_2 consumption. When pulmonary arterial catheter measurements are used to compute the $\dot{V}O_2$, then the $\dot{D}O_2$ measurement and $\dot{V}O_2$ measurement are linked mathematically, and errors in the measurement of cardiac output can produce systematic errors in $\dot{V}O_2$. This is the source of some of the

association between decreased $\dot{D}O_2$ and decreased $\dot{V}O_2$ in critically ill patients (O_2 supply dependence).

As systemic $\dot{D}O_2$ falls, mixed venous O_2 saturation also falls, because normal organ systems attempt to maintain $\dot{V}O_2$ by increasing O_2 extraction. If the organ system fails to extract O_2, systemic measurements show a fall only in the systemic $\dot{V}O_2$. If the $\dot{V}O_2$ of the organ system is low (e.g., for the kidney), then the change in systemic $\dot{V}O_2$ will be within the measurement error by thermodilution for the cardiac output. If an organ system with failing blood flow had been extracting O_2 nearly maximally, the complete loss of its perfusion will cause the mixed venous O_2 saturation to rise, not fall (Fig. 24). In this circumstance, the increase in venous O_2 saturation reflects the loss of the perfusion to the organ and not an improvement in tissue oxygenation. In other words, the mixed venous O_2 saturation is useful only as a measure of the degree of stress on the O_2 extraction mechanism; it cannot be used as a means to determine adequacy of tissue oxygenation. Thus, under most clinical circumstances in critically ill patients, a low mixed venous O_2 saturation indicates inadequate $\dot{D}O_2$ to some vascular bed(s); a normal mixed venous O_2 saturation means only a normal average O_2 extraction for tissues that are using O_2 at the time the measurement is taken. Tissues that are no longer extracting oxygen (e.g., because of ischemia or anoxia) are no longer represented in the mixed venous O_2 saturation value.

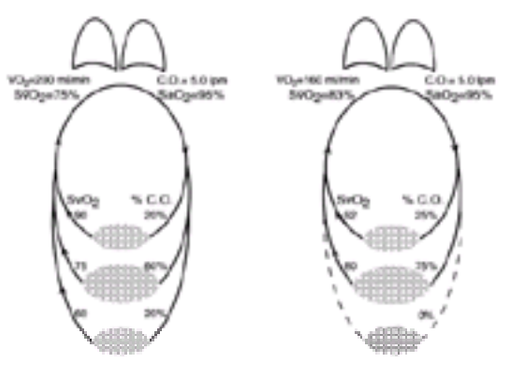

FIG. 24. Effects of loss of tissue perfusion on the mixed venous SaO_2 and O_2 consumption by the body. Note that SaO_2 increases when loss of perfusion occurs in a tissue previously extracting a large amount of O_2.

The Partial Pressure of Oxygen in Tissues

The convective delivery of O_2 from the lungs to the other body tissues produces a measurable PO_2 in the tissues. Measurements of PO_2 in living tissue, however, are difficult to make and difficult to interpret because of variability of the results. Predictions of tissue PO_2 from theoretical calculations also have led to conclusions that are sometimes inconsistent with experimental measurements. There is controversy concerning the effects of the serial resistances to O_2 transport from the erythrocyte to the mitochondria, and in particular concerning the question of whether the primary resistance resides at the capillary level or within the tissue. Although many aspects of this problem have been investigated, our understanding of tissue oxygenation is still quite incomplete, particularly for disease states.

The diffusion of O_2 from the capillaries into the tissues produces an O_2 distribution profile in the tissues. Tissue measurements of PO_2 with surface electrodes or indwelling microelectrodes usually yield very irregular PO_2 profiles. When various PO_2 values are plotted as percentages of their frequencies, a PO_2 histogram is obtained; the range and the peak PO_2 values provide an estimate of the dispersion of PO_2 values in the tissue. An example of a PO_2 histogram is provided in Fig. 25. The implications of the distribution of PO_2 values within a tissue are discussed below.

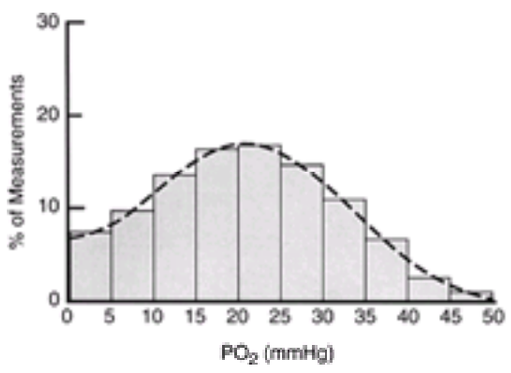

FIG. 25. PO_2 histogram of brain tissue. Measurements made in the brain of an anesthetized cat using platinum needle electrodes.

Before experimental measurements of tissue PO_2 became possible, the theoretical approach of Krogh, with his model of a tissue cylinder around a central capillary running parallel to resting muscle fibers, was used to calculate the PO_2 in an ideal tissue. Although it is quite simple, the Krogh model has been conceptually useful to describe the principles of tissue O_2 transport. In the Krogh tissue cylinder, the critical location for O_2 supply is at the periphery of the venous end of the cylinder. This is called the *lethal corner* (Fig. 26). Other models have been devised, in which O_2 is supplied to a solid cylinder from a homogeneous peripheral sheet of blood (Hill model) or, more realistically, from a number of peripheral capillaries. Most models assume an ideal cylindrical geometry and, for the most part, the delivery of O_2 from a uniform source of capillaries. In the Krogh cylinder, a single cylinder and capillary are considered assuming homogeneity of the tissue and its microcirculation; more complex models admit the possibility of differing numbers, distributions, and types of capillaries.

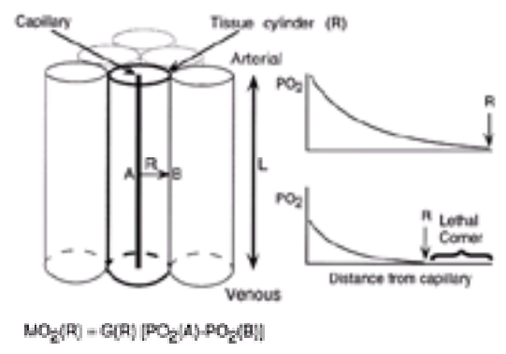

FIG. 26. Model of tissue oxygenation based on the Krogh cylinder. The predicted O_2 gradient in two regions of a single capillary and tissue cylinder are shown. The model assumes constant and uniform $\dot{V}O_2$ throughout the tissue cylinder. The diffusion of O_2 is given by the O_2 conductance (*G*) of the tissue and the difference in O_2 partial pressures between *points A* and *B* on the model.

The PO_2 gradient from capillary blood to tissue depends on the sum of convective and diffusive resistances to O_2 transport. The Krogh and Hill models stipulate a limitation by diffusion; however, there are circumstances in which $\dot{V}O_2$ may be limited not by diffusion but by O_2 delivery. The Krogh model also does not predict O_2 supply dependence because of its assumptions or its inherent limitations. The ideal $\dot{D}O_2/\dot{V}O_2$ relationship appears to be similar for anemic, hypoxic, and stagnant hypoxia as long as the intercapillary distance (ICD) is small (below 80 µm). The calculated O_2 extraction ratio, however, is too high. The high O_2 extraction predicted by the Krogh model may be caused by the assumption of tissue homogeneity and can be made more realistic by including an O_2 shunt of about 30%. Such precapillary O_2 loss has been demonstrated experimentally; however, its true magnitude is unknown. The O_2 extractions predicted by the Krogh model improve when ICD is increased (above 80 µm), but the critical point becomes higher for hypoxic hypoxia, indicating an effect of diffusion at large distance.

Support for the Krogh diffusion theory of capillary exchange has been found in controlled animal experiments suggesting that $\dot{V}O_{2max}$ is limited by O_2 diffusion during normoxia. It is not possible, however, to determine the location of the limiting resistance to diffusion from such experiments. Intracellular PO_2 values in working muscle also have been deduced from the myoglobin (MbO_2) dissociation curve in animal experiments. The MbO_2 saturation measured by cryomicrospectroscopy *ex vivo* suggests that the intracellular PO_2 is only a few torr and evenly distributed at $\dot{V}O_{2max}$. This finding has been ascribed to Mb-facilitated O_2 and a low apparent K_m for O_2 (PO_2 for half-maximal O_2 consumption) similar to that of isolated mitochondria. These findings suggest there is no lethal corner—that is, the muscle is "well stirred," tissue PO_2 is much lower than $P\bar{v}O_2$, and the main PO_2 gradient occurs across the capillary endothelium. In contrast, measurements of oxidized cytochrome a,a_3 in mitochondria in situ versus MbO_2 saturation diverge as $\dot{V}O_2$ increases *in vivo,* indicating the PO_2 gradient between cytosol and mitochondria increases with increasing $\dot{V}O_2$. Thus, the apparent behavior of the tissue PO_2 differs greatly between normal, isolated and *ex vivo* experiments. Isolated cells and tissues also differ from intact tissue, in which $\dot{V}O_2$ varies with the metabolic needs of the tissue. In living tissues, the functional microcirculation regulates many of the factors influencing the O_2 supply of tissues. These features of the microcirculation are summarized briefly in the following sections.

Effect of Oxygen Equilibrium Curve

Normally, only one fourth of the O_2 carried by oxyhemoglobin is unloaded in the tissues; however, because of countercurrent exchange of O_2 in precapillary vessels, hemoglobin in the capillaries probably operates closer to the steep, middle portion of the OEC. The effect of a shift of the OEC on O_2 unloading in tissues depends on the level of oxygenation. High P_{50} increases and low P_{50} decreases venous saturation in normoxia and mild hypoxia, whereas the opposite occurs in severe alveolar hypoxia. It is the steepness of the OEC that determines this difference. A P_{50} inadequate for a particular O_2 requirement can be compensated for by an increase in blood flow. The effect of a shift of the OEC on tissue oxygenation has been confirmed in many studies, but the significance of moderate shifts is often questioned. At normoxia, an increase in P_{50} (e.g., from the Bohr effect) makes the capillary blood maintain a higher PO_2 toward the venous end of the capillary.

Capillary Transit Time and Oxygen Shunting

Heterogeneous capillary geometry (e.g., variable spacing) leads to variable volume of perfused tissue, and variability of capillary transit time results in differing PO_2 patterns in various volumes of tissue. Capillaries with long transit times (low flow) are vulnerable to stagnant conditions with rapid depletion of O_2; capillaries with very short transit time (high flow) are prone to O_2 shunting. There must be optimal transit times for gas exchange somewhere in between these extremes for various tissues. There is also significant countercurrent exchange of O_2 between small arterioles and venules in some tissues (precapillary O_2 loss).

Heterogeneity of Perfusion

Many of the relevant variables that determine the adequacy of tissue O_2 availability are distributed inhomogeneously in the tissues. These variables include capillary density, capillary length and diameter, blood flow, transit time of erythrocytes through the capillary, $\dot{V}O_2$, and hemoglobin and myoglobin O_2 saturation values. The following example illustrates the problem. In resting skeletal muscle, most of the capillaries are perfused; however, blood flow rates in individual capillaries are inhomogeneous and often intermittent. This provides a physiologic reserve of capillaries in which the distribution of blood flow regulates tissue PO_2 over a range of changes in O_2 supply and/or $\dot{V}O_2$. In normal skeletal muscle, perfusion inhomogeneity may even increase during contraction and relaxation. Under conditions of submaximal exercise, however, all capillaries are open and flow is more homogeneous. Capillary heterogeneity during exercise, however, may decrease or increase at very high workloads. Heterogeneity also may markedly affect the O_2 supply at high $\dot{V}O_2$. On the other hand, local heterogeneity in O_2 delivery may be reduced by diffusion of O_2 between adjacent capillaries, particularly under conditions of high blood flow.

Capillary Hematocrit

The role of the capillary hematocrit in tissue gas exchange remains poorly understood. It is generally accepted, however, that capillary hematocrit is much lower than systemic hematocrit (perhaps as low as 10%), and it bears little relation to systemic hematocrit. Capillary hematocrit fluctuates in parallel with $\dot{V}O_2$ and the contractile state of the arterioles, which suggests it is a regulated variable in the maintenance of tissue oxygenation.

Venous PO_2 Versus Tissue PO_2

The venous PO_2 and mean tissue PO_2 generally agree for an organ under normal conditions, but there are significant deviations when changes occur in capillary density, $\dot{V}O_2$, hemoglobin concentration, and cardiac output. The change in venous PO_2 after an increase in capillary density provides a good estimate of mean tissue PO_2, even in conditions deviating from normal resting conditions. Misleadingly high venous PO_2 values, however, occur in the presence of functional arteriovenous O_2 shunting resulting from countercurrent blood flow, very short capillary transit times, preferential flow channels, or shock. Some of these problems have been discussed earlier in the context of clinical interpretation of the mixed venous O_2 saturation.

Oxygen Supply Dependence of Respiration

One of the simplifying concepts often used in thinking about tissue oxygenation is that cellular O_2 uptake has zero-order kinetics—that is, it is independent of PO_2 throughout the tissue. This assumption is based on the observation that the Michaelis-Menton constant (K_m) for O_2 is very low in well-stirred mitochondrial suspensions (order of 0.1 torr). Longmuir first showed that $\dot{V}O_2$ of cells depends on PO_2 up to considerably higher values than expected from zero-order kinetics; he ascribed this to intracellular resistance to O_2 diffusion. Slices of liver follow Michaelis-Menten kinetics rather than zero-order kinetics, with an apparent K_m about 100 times higher than that for mitochondrial suspensions. Thus, the difference between "true" mitochondrial K_m and "apparent" K_m for O_2 in cells and tissues must be appreciated.

In intact tissues, the mitochondrial oxidation-reduction state depends on PO_2 over a physiologic range of PO_2; thus, metabolic adjustment ensures a reasonably constant ATP supply and $\dot{V}O_2$ with decreasing PO_2. These findings imply that the critical PO_2 in intact cells is very low, and they diminish the potential effect of O_2 gradients on respiration rate. O_2 diffusion would be expected to limit $\dot{V}O_2$ only during an extreme lack of O_2 (e.g., ischemia or profound hypoxemia) or at extremes of $\dot{V}O_2$ with mild to moderate hypoxemia. Isolated small muscles and muscle slices in vitro show O_2 supply dependency, presumably caused by very low PO_2 values in the center of the tissue.

As discussed earlier, physiologic O_2 supply dependence is defined as a condition in which $\dot{V}O_2$ decreases with diminishing O_2 delivery below a low critical threshold. The slope below the critical threshold indicates optimal O_2 extraction. Above the critical threshold there is a horizontal plateau; decreases in O_2 delivery do not lower $\dot{V}O_2$ in the plateau region because O_2 extraction increases proportionately. When O_2 supply is reduced below the critical threshold, $\dot{V}O_2$ falls because O_2 extraction no longer increases proportionately and cannot compensate for the reduction in O_2 delivery (Fig. 23).

Pathologic O_2 supply dependence of $\dot{V}O_2$ has been reported over a wide range of O_2 delivery values in ARDS patients. This form of O_2 supply dependence is characterized by a higher critical O_2 supply, a lower slope below the critical PO_2, and a higher supercritical plateau or no plateau at all (Fig. 23). The lower slope indicates a deficiency in O_2 extraction from the blood with an increase in mixed venous PO_2. The underlying mechanisms that can contribute to this deficiency are complex and multifactorial. They include vascular microembolization, disruption of endothelial function resulting in a protein-rich permeability edema, microvascular dysregulation, and loss of mitochondrial function. Experimental injuries that produce O_2 supply dependency are characterized by a decrease in capillary reserve, an increase in capillary distances (loss of open capillaries and edema), heterogeneity of capillary distribution and flow, and an increase in capillary shunts. These problems contribute to derangements of the microvascular function and impaired O_2 extraction from the blood, with compromise of O_2 supply to the tissue.

CELLULAR ENERGY METABOLISM

Cellular Energy Requirements

The immediate energy source for practically all the energy-requiring processes in the cell is the hydrolysis of adenosine triphosphate (ATP) to adenosine diphosphate (ADP) and inorganic phosphate (P_i). ATP is replenished continuously by the cell through the processes of glycolysis and oxidative phosphorylation. In these processes, sequences of chemical reactions partially trap changes in chemical free energy in the synthesis of ATP. The ATP-ADP cycle (Fig. 27) constitutes a basic feature of energy metabolism in all cells and functions as the link between the energy-utilizing and the energy-consuming processes. The rate of ATP utilization can increase more than 100 times during exercise, utilizing the whole muscle store of ATP in about 3 seconds. For cellular homeostasis, the rate of ATP regeneration generally equals the rate of ATP utilization, and the cellular ATP content remains approximately constant. Of all the tissues of the body, cardiac and skeletal muscle are faced with the most intricate problems of metabolic regulation because of their unique need to change metabolic rate.

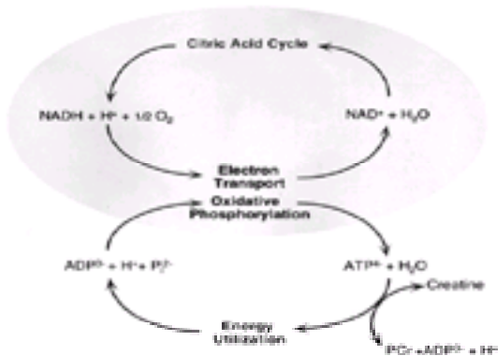

FIG. 27. The ATP-ADP cycle. The major means of conserving energy in the cell is oxidative phosphorylation, which is coupled to electron transport in the mitochondrion (*shaded area*). Oxidative phosphorylation generates ATP from ADP and P_i to support the energy needs of the cell. Additional energy can be stored in the form of PCr, which can be used later to phosphorylate ADP and regenerate ATP.

The ultimate and most efficient process for ATP formation in aerobic cells is the intramitochondrial oxidation of substrates by the citric acid cycle, with conservation of free energy by the coupled processes of electron transport and oxidative phosphorylation. In the final process, molecular O_2, the ultimate electron acceptor, is reduced to water. For a limited period of time, however, ATP can be produced through processes that do not require O_2 (e.g., glycolysis). Some species have evolved with a special ability to survive for a prolonged period under anaerobic conditions. The physiologic relationship between aerobic and anaerobic energy production is well illustrated by a discussion of exercise metabolism.

Metabolism During Exercise

Progressive muscular exercise is accompanied by proportional increases in $\dot{V}O_2$ until the maximal aerobic capacity is reached ($\dot{V}O_{2max}$). Workloads beyond those required to reach $\dot{V}O_{2max}$ produce no further increase in O_2 consumption. A major determinant of the $\dot{V}O_{2max}$ during exercise under normoxic conditions is the cardiac output. The cardiac output sets an upper limit of the capacity to deliver O_2 to the tissues. Heavy exercise with only 10 kg of muscle may be sufficient to elicit an average person's maximal O_2 uptake; however, the system for convective O_2 delivery also can be seen as being well matched to the ability of the muscle to consume O_2. At high muscle blood flow rates and extraction ratios, the availability of O_2 to the mitochondria may be limited by diffusion.

The type of fuel utilized during physical activity is determined by work intensity, duration, training status, and substrate availability. The major part of the energy demand during low-intensity exercise is supplied by oxidation of fat, whereas oxidation of carbohydrates is required during exercise at higher intensities. The amount of ATP that can be produced by glycolysis corresponds to about 20 seconds of maximal work. This limitation is caused by depletion of the store of creatine phosphate (PCr) and the accumulation of lactic acid in the muscles. ATP formed by glycolysis is therefore important during short bursts of high-intensity exercise or during ischemic conditions, but it is negligible in terms of energy provision for sustained exercise. During sustained exercise at low or moderate intensities, the rate of pyruvate oxidation is similar to the rate of glycolysis, but at higher intensities the entry of pyruvate into the mitochondrion is incomplete and lactic acid is formed and accumulates in the body fluids. Accumulation of lactate in muscle and blood begins at about 50%–70% of $\dot{V}O_{2max}$. At 100% of $\dot{V}O_{2max}$, 10%–20% of the total energy production is provided by glycolysis with lactate formation. Accumulation of lactate in blood is accompanied by an increased ventilation and CO_2 exchange. The exercise intensity when blood lactate and ventilation increase more than the increase in intensity and $\dot{V}O_2$ has been termed the *anaerobic threshold* or *lactate threshold.* This value is widely used in exercise physiology to define the training status of subjects.

During muscular work, the major store of high-energy phosphates in the cell is PCr. PCr can maintain the cellular ATP concentration approximately constant despite fluctuating energy demands. During maximal short-term exercise, the muscle content of PCr can become depleted, and the amount of energy provided corresponds to about 0.3 mol of ATP. The classic view of PCr is that it serves as a high-energy phosphate buffer during periods of high demand for energy. The concept is valid, but changes occur in the PCr level under other conditions. It has been shown that PCr decreases during submaximal exercise in relation to the intensity of the exercise. The decline in PCr occurs at the onset of exercise, and its value remains practically constant during the exercise.

The relative concentrations of ATP, ADP, and the other adenine nucleotides are important for the control of bioenergetic processes. Their concentrations are determined by the energy potential of the system and the adenylate kinase (AK) reaction. AK is considered to be close to equilibrium:

$$2\ ADP \overset{AK}{\leftrightarrow} AMP + ATP$$

The total cellular concentrations (including both the free and bound nucleotides) of AMP, ADP, and ATP are related to each other in a ratio of roughly 1:10:100. The cellular concentration of ATP remains fairly constant during most physiologic conditions, but because it is present in much greater concentrations than the other adenine nucleotides, a small decrease in ATP results in a large relative increase in ADP and in an even more pronounced increase in the relative concentration of AMP. The availability of ADP is a primary determinant of the mitochondrial respiratory rate.

Breakdown of PCr is catalyzed by creatine kinase, and because the enzymatic activity in muscle is high, the reaction appears to be close to equilibrium under most conditions. An increase in free ADP and H^+, both of which are products of ATP hydrolysis, promotes breakdown of PCr. Aerobic energy production through an increase in free ADP will therefore, through the creatine kinase equilibrium, result in a breakdown of PCr. Thus, depletion of PCr is not necessarily a sign of anaerobiosis but may reflect increased energy turnover and activation of aerobic metabolism.

In addition to ADP, signals of major importance for the control of the energetic processes are intracellular concentrations of Ca^{2+}, AMP, P_i, and the mitochondrial redox state. Increases in Ca^{2+}, ADP, AMP, and P_i are linked to the contraction process and the energy demand and ensure that the rate of ATP formation equals the rate of ATP utilization. Further control of the different pathways is achieved through substrate activation, feedback inhibition, and allosteric regulation. At low metabolic rates,

the rate of glycolysis is balanced by an equal rate of pyruvate oxidation, and there is no accumulation of pyruvate or lactate in the tissues despite a large increase in the rate of glycolysis. At higher metabolic rates, when either the availability of O_2 is limited or the maximal aerobic capacity of the tissue is approached, formation of pyruvate exceeds pyruvate oxidation and lactate accumulates. The metabolic signals to turn on pyruvate formation (glycogenolysis and glycolysis) and pyruvate oxidation (citric acid cycle and mitochondrial respiration) are similar: increases in ADP, P_i, and Ca^{2+}. An imbalance between these processes shown by lactate formation at higher exercise intensity or during hypoxia may be related to a change in the oxidation-reduction state of the NAD^+/NADH couple, which regulates pyruvate entry into the citric acid cycle.

As lactate formation and PCr breakdown during exercise are not necessarily related to anaerobiosis, the term *anaerobic threshold* is misleading. The term *lactate threshold* better describes the condition related to work intensity, when ATP synthesis occurs to a greater extent through glycolysis. Therefore, the lactate threshold does indicate an important functional point in metabolism. Experimental evidence suggests that a decrease in tissue O_2 availability has metabolic consequences (e.g., PCr breakdown and enhanced glycolysis) before cellular respiration is limited by hypoxia. These metabolic changes reflect the adaptation of the tissue to an increased metabolic rate relative to the availability of O_2.

Cellular Respiration and the Mitochondrion

As noted in the previous section, the primary role of cellular respiration is to produce ATP from O_2 consumption during the process of oxidative phosphorylation (Fig. 28). This fundamental process and its regulation occur within the mitochondria. In mitochondria, various nutrients are converted by intermediary metabolism to CO_2 and NADH for oxidation. This oxidation provides the energy to establish an electrochemical proton gradient (Dp) across the mitochondrial inner membrane. The Dp drives the influx of precursors for substrate oxidation, synthesis of ATP, export of products, and maintenance of osmotic stability. The cell depends on mitochondrial provision of ATP because glycolysis, the only other metabolic process to produce significant amounts of ATP, yields just four ATP molecules, compared with 26 from oxidative phosphorylation.

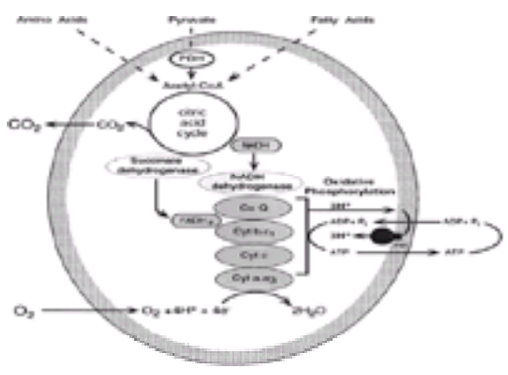

FIG. 28. Schematic drawing of mitochondrial respiration. CO_2 is produced from the oxidation of carboxylic acids in the citric acid cycle. Reducing equivalents in the form of NADH and $FADH_2$ are generated and supplied to the respiratory chain from the citric acid cycle. Molecular O_2 is reduced by cytochrome *c* oxidase as NADH and $FADH_2$ are reoxidized for use in the citric acid cycle. Energy in the form of ATP is generated from ADP by oxidative phosphorylation.

Supply of Oxidizable Substrates

Most of the substrates for cellular energy production are supplied by dietary fats, proteins, and carbohydrates. Carbohydrates and some amino acids are converted to three-carbon acids (e.g., pyruvate), whereas fats and other amino acids are converted to two-carbon acetyl compounds. Mitochondria convert pyruvate and hydrocarbon chains to acetyl-CoA and oxidize acetyl-CoA to CO_2. The systems involved in these processes directly supply the reducing equivalents (electrons) to the mitochondrial electron transport chain and are essential for mitochondrial ATP production.

Oxidation of acetyl-CoA to CO_2 is catalyzed by the enzymes of the citric acid cycle. The electrons from this oxidation are handled by three dehydrogenases that reduce NAD^+ to NADH, and one that reduces ubiquinone to ubiquinol. The enzymes involved in the production of NADH are isocitrate, a-ketoglutarate, and malate dehydrogenases. Succinate dehydrogenase contains a flavin coenzyme (FAD) and does not require NAD^+. Several other dehydrogenases transfer electrons to the electron transport chain through NADH and ubiquinone; however, these reactions contribute little relative to the citric acid cycle. The most important factors affecting turnover in the citric acid cycle are the availability of NAD^+, the rate of acetyl-CoA production, mitochondrial ADP concentration, and loss of tricarboxylic acid for other biosynthetic function. Under some conditions, the rate of flux through the cycle is limited by formation of citrate by condensation of acetyl-CoA and oxaloacetate. Because oxidation of NADH and ubiquinol are coupled to synthesis of ATP, regulation of respiration also occurs at the level of the dehydrogenases.

Mitochondrial Electron Transport

The electrons from NADH formed in the reactions of the citric acid cycle are transported to O_2 through a series of respiratory complexes in the mitochondrial inner membrane. These complexes catalyze three successive redox reactions in which the mobile carrier ubiquinone and cytochrome *c* catalytically oxidize NADH to NAD^+, culminating in the four-electron reduction of molecular O_2 to water. Each of the respiratory complexes also transports protons out of the mitochondrial matrix in response to the flow of electrons, thereby capturing the energy available from the oxidation-reduction process in the form of the electrochemical proton gradient (Dp) across the inner membrane. This Dp provides the energy to drive ATP synthesis from ADP and P_i by coupling the reaction to the movement of protons.

The electrochemical proton gradient has two components: a chemical gradient (DpH) and an electrical potential (Dy). The chemical gradient is the difference in the concentration of protons between the matrix space and the cytoplasm. The concentration of protons is expressed as pH, so that the chemical gradient is given as DpH. The matrix pH is about 7.6, whereas the cytoplasmic pH is approximately 7.0. The energy available from DpH is insufficient to drive ATP synthesis under normal conditions in the cell. Multiple transport systems enable the energy available from oxidation to maintain a large electrical potential across the inner membrane. This potential is about –160 mV inside the mitochondrion. It drives positively charged molecules into the matrix and supplies much of the energy needed for ATP synthesis.

ATP Synthesis

The synthesis of ATP from ADP and P_i during oxidative phosphorylation is catalyzed by an ATP synthase. This enzyme is an electrogenic proton transporter that utilizes energy from the Dp. Under most conditions, the Dp formed by electron transport is sufficient to support ATP synthesis. Without electron transport, as occurs during anoxia and with mitochondrial inhibitors, the ATPase can generate Dp by hydrolyzing ATP from glycolysis. The ATPase also can hydrolyze ATP when the membrane cannot maintain the pH gradient, as occurs in the presence of uncouplers of oxidative phosphorylation. The physiologic significance of the latter two modes of operation of the enzyme is unknown.

Mitochondrial Metabolite and Ion Transport Systems

Compartmentation of metabolites and ions across the inner mitochondrial membrane is tightly regulated and plays an integral part in respiratory control. The entry of carbon substrates into the mitochondrial compartment, along with extrusion of products (e.g., ATP) is achieved by specific transporter systems driven by components of the Dp. Electroneutral DpH-dependent transport systems for pyruvate and Pi effect the accumulation of pyruvate and P_i in the matrix according to the DpH across the inner membrane. The dicarboxylate and tricarboxylate carriers catalyze electroneutral exchange of P_i for citric acid cycle intermediates. Hence, the mitochondrial distribution of these anions depends indirectly on DpH. Some mitochondrial systems catalyze transport that is dependent on Dy and results in a net charge movement across the inner membrane. These systems can establish a potential (electrogenic movement) or can move charged species according to an existing potential (electrophoretic movement). The adenine nucleotide transporter catalyzes the exchange of matrix ATP^{4-} for cytosolic ADP^{3-}, allowing electrophoretic movement of a negative charge out of the matrix. This is the major mechanism for supplying ADP to the ATP synthase, and subsequently ATP to the cytoplasm.

Heterogeneity of Mitochondrial Distribution and Function

Although aerobic respiration occurs in all mammalian tissues, the maximal O_2 consumption rate, respiratory control characteristics, mitochondrial morphology, and mitochondrial distribution vary among tissues. In most cell types, the need for a continuous supply of energy to support function is met by specific associations of mitochondria with energy-requiring systems. Because energy demand varies with workload, there is no “normal” O_2 consumption rate; instead, cellular function determines the O_2 consumption rate. Changes in function can markedly alter the relative contributions of different tissues to the total O_2 consumption by the body.

Variations in energy needs and other functional demands are associated with differences in mitochondrial respiratory components and their regulation. In muscle, cycles of contraction require cyclical changes in mitochondrial shape and cellular oxygenation. Myocytes have features to accommodate these demands. Muscle mitochondria are found as networks, or reticula, and myocytes contain myoglobin to facilitate cellular transfer. Other types of cells also have highly specialized adaptations to function.

Mitochondria from various tissues also differ in protein composition. The contents of some enzymes and transporters vary qualitatively, whereas indispensable enzymes and transporters vary quantitatively. Molecular studies show that tissue-specific isoenzymes exist for essential components such as the adenine nucleotide transporter, cytochrome *c,* and cytochrome *c* oxidase. Mitochondrial function may be optimized by regulation of enzyme contents and activities per volume of mitochondria, volume percent of mitochondria in cells, and spatial distribution of mitochondria in cells. In various cells, the distribution of mitochondria is different at the morphologic level. The volume of mitochondria per cell (volume density) also varies up to 100-fold in different human tissues. Furthermore, mitochondria differ between tissues in size and shape, inner membrane folding, and buoyant density. Differences in mitochondrial structure and composition also occur in different cells of the same cell type.

Regulation of mitochondrial function occurs at several sites, especially those involving generation and utilization of Dp and volume regulation. Regulation of Dp involves control of electron flow into the electron transport complexes at the NAD^+-linked dehydrogenases and at cytochrome *c* oxidase. Several of the important NAD^+-linked dehydrogenases are regulated by Ca^{2+}, and cytochrome *c* oxidase contains regulatory subunits. Electrophoretic transport systems, including the adenine nucleotide transporter, also regulate the Dp. Variations at different sites could result in significant differences in regulation of respiratory function without changes in overall mitochondrial structure.

Adaptive changes in mitochondria can occur in response to physiologic challenges. These mitochondrial changes serve to adapt function to the prevailing conditions, and they include changes in volume density, adjustment of enzymatic and transport activities per unit mass, and spatial distribution of the organelles within cells. Changes in volume density are associated with altered aerobic work capacity; greater mitochondrial density provides a greater maximal ATP production under these conditions. This principle does not hold in disease, as impaired mitochondrial function can necessitate increased density to maintain function. Change in mitochondrial volume density also occurs in response to development and differentiation, exercise, conditioning, starvation, chronic hypoxia, changes in diet, and pharmacologic agents.

Altered expression of enzyme and transport activities per unit of mitochondrial volume occurs with adaptation to different physiologic states. For instance, thyroxine administration and recovery from hyperthyroidism result in changes in cytochrome *c* oxidase and citrate synthase. Urea cycle enzymes are increased by high-protein diets and by starvation. Chronic hypoxia causes a decrease in mitochondrial enzymes, whereas physical conditioning increases the concentrations of these enzymes. Thus, alterations in the composition of enzymes and transport systems provide another mechanism for cells to optimize ATP production.

At the cellular level, mitochondrial density and distribution are important determinants of the O_2 concentration required to maintain cellular ATP production. The distribution of mitochondria appears to represent a balance between the need to have a high capacity for ATP production at sites of high ATP demand and the need to oxygenate the cells adequately at physiologic blood PO_2. Most cells and tissues have a functional reserve that allows enhanced activity under physiologic or pathologic challenge. For tissues with high energy requirements, the metabolic demand is met by high volume density of mitochondria and, in some tissues, by clustering of mitochondria. The higher volume density and clustering can increase the O_2 concentrations required for function. Tissues with high mitochondrial volume density and clustering are inherently more susceptible to O_2 deficiency, and this susceptibility is increased by higher metabolic needs.

The effects of hypoxia on mitochondrial function indicate that different metabolic pathways are selectively vulnerable to tissue hypoxia. The apparent K_m of cytochrome *c* oxidase in many adult mammalian cells occurs at a PO_2 10 to 160 times greater than the isolated oxidase, which has a K_m of less than 0.1 mmHg. This means that failure of mitochondrial function can occur at a relatively high O_2 concentration compared with that of isolated mitochondria. Many reactions that depend indirectly on O_2 (i.e., those dependent on ATP) are vulnerable over the same O_2 concentration range. Studies of activities of different ATP-requiring systems in cells show that some are much more sensitive to ATP depletion, and hence to tissue hypoxia, than others. The order of these sensitivities is determined both by the K_m values of the enzymes for ATP and by the location of the enzymes in the cell relative to the mitochondria. Depending on whether changes in enzymatic activities cause irreversible injury, the different sensitivities of the O_2- and ATP-dependent enzymes to O_2 availability can affect cell viability directly.

All mammalian cells can survive some period of severe O_2 deficiency without irreversible injury. Such nonlethal hypoxic periods occur when cells function with reduced metabolic and respiratory capacity. These conditions are distinct from both normal and irreversible hypoxic or anoxic states. During brief anoxia, the mitochondrial Dp is maintained despite substantial decreases in cellular ATP concentrations. The energy required for maintenance of Dp is made available when specific ion transport systems are inhibited that drive ATP synthase activity. Such selective inhibition of ion transport allows cells to preserve the mitochondrial milieu and facilitates their recovery on reoxygenation. Similar metabolic suppression may occur in other tissues, such as the kidneys, where inhibition of transport functions protects against anoxic injury. The myocardium exhibits a response termed *stunning,* in which an ischemic episode results in inhibition of mitochondrial respiratory functions and reversible cessation of contractile activity. Suppression of synaptic function (*idling*) protects neurons from anoxic injury, and postanoxic suppression of cellular respiratory rate in the brain also may be the consequence of an endogenous mechanism to preserve viability. Whether such conditions occur in critically ill patients during ARDS, sepsis, or other shock states is unknown. The precise mechanisms regulating respiratory function in these diseases also are not clear, but the existence of such mechanisms clearly would influence cellular O_2 demand and the amount of O_2 that must be delivered to the tissues by the circulation.

INTRODUCTION

For effective respiration, air must be drawn through the airways and distributed among approximately 400,000,000 alveolar compartments within the lung parenchyma. Respiratory mechanics is the study of the forces involved in this task and how these forces govern the volumes and flows of gases, blood, and interstitial fluids in the lung. Abnormalities of respiratory mechanics are central to the pathophysiology of most disorders of the respiratory system. An understanding of respiratory mechanics is essential for the rational assessment and treatment of these disorders, and the purpose of this chapter is to provide a basis for such understanding.

We emphasize the mechanical properties of the lung and passive chest wall. Intersecting topics, such as the function of the respiratory muscles, gas exchange with the pulmonary circulation, and the control of ventilation, are developed in detail in other chapters. We start by describing the passive respiratory system as a simple *viscoelastic* system, which means that the forces developed can be resolved into those in phase with flow (viscous forces) and those in phase with volume (elastic forces). This approach is useful, because these viscoelastic properties and their derangements in disease can be clearly assigned to specific structures (e.g., lung versus chest wall, airway caliber, loss of surfactant) and easily evaluated. We then turn to a very different mechanical phenomenon—namely, expiratory flow limitation. This operates only at high rates of ventilation in normal subjects but is responsible for the ventilatory disability of patients with obstructive lung diseases. Next, we discuss the mechanical basis governing the distributions of volume and ventilation among the gas-exchanging air spaces of the lung. In health, there is a degree of nonuniformity of volume and of ventilation that is ordinarily of little physiologic consequence. In disease, however, there may be sufficient nonuniformity to impair gas exchange. We also discuss the impact of lung mechanics on blood flow and interstitial fluid balance in the lung. This becomes particularly important during mechanical ventilation. Finally, we deal with the energetics of breathing, describing the mechanical loads placed on the respiratory muscles in terms of work of breathing, and the physiologic costs incurred in terms of oxygen consumption by the respiratory muscles.

MECHANICAL PROPERTIES OF THE PASSIVE RESPIRATORY SYSTEM

The mechanical loads that the muscles of respiration must overcome to ventilate the lungs are imposed by the passive components of the respiratory system—the airways, lungs, and chest wall. To assess these passive loads, measurements must be made with the muscles relaxed; the assumption is made that the properties of the passive components remain the same in the presence or absence of respiratory muscle activity.

Respiratory mechanics deals primarily with the *flows, velocities, volumes,* and *pressures* developed by the respiratory system and the gas contained within it. Flow is a measurement of the volume of gas per unit time (e.g., peak expiratory flow of 10 L/s). It is different from velocity, which is a measurement of the distance per unit time (e.g., a mean of 15 m/s, for a peak flow of 10 L/s in a trachea with a cross-sectional area of 6.7 cm^2). Volume generally refers to the gas contained in a space (e.g., a volume of gas in the lung at ordinary end-expiration, or functional residual capacity, of 3.5 L). Pressure is the force per unit area applied perpendicularly to a surface (i.e., no shear force). Generally, the absolute pressure (e.g., ambient pressure of 1000 cm H_2O) is of no interest in respiratory mechanics, and the pressure in a given location is reported relative to the ambient air pressure (e.g., a pleural pressure of –5 implies a pressure 5 cm H_2O below the ambient pressure). More often than not, the pressure *difference* across the wall of a structure (transmural pressure) is of more importance than the absolute pressures, because it is the pressure differences that have mechanical effects. For example, the pressure difference between the alveolar gas and the pleural space is the same at a given lung volume during a maximal inspiratory effort against a closed glottis (Müller's maneuver) as it is during a maximal expiratory effort against a closed glottis (Valsalva's maneuver), because that difference depends only on the elastic tensions in the lung parenchyma, which in turn depend on lung volume.

Viscoelastic Properties

Viscoelastic Model

Elasticity is the property of matter that causes it to return to its resting shape after deformation by an external force. The passive components of the respiratory system exhibit elastic properties, storing energy during inspiration as would a steel spring. That stored energy is the source of the pressure difference across the relaxed respiratory system. It is available to return the respiratory system to its original volume when the inspiratory muscles relax during expiration. *Viscosity* is the frictional property of fluids (gaseous or liquid). It is the major source of the flow-related pressure differences across the respiratory system.

In quiet breathing, the passive respiratory system behaves very much like a simple viscoelastic structure. The viscoelastic properties of the respiratory system may be modeled by two passive elements arranged in series, so that the airways contribute the pressure difference between the airway opening and the alveolar gas, $P_{ao} - P_{alv}$, and the alveolar parenchyma and passive chest wall contribute the pressure difference between the alveolar gas and the body surface, $P_{alv} - P_{bs}$. Their sum, measured during relaxation of the respiratory muscles, is the pressure difference across the passive respiratory system:

$$P_{rel,rs} = P_{ao} - P_{bs} = (P_{ao} - P_{alv}) + (P_{alv} - P_{bs}) \quad \textbf{(1)}$$

The first term in parentheses is the viscous, flow-related pressure difference, and the second mostly represents the elastic, volume-related pressure difference. The behavior of such a model during a volume excursion can be described by the equation of motion:

$$P_{rel,rs} = P_{rel,rs,o} + (1/C_{rs})\,\Delta V + R_{rs}\,\dot{V} \quad \textbf{(2)}$$

where $P_{rel,rs,o}$ is the initial passive transrespiratory system pressure, DV is the volume excursion, $\dot{V}$ is instantaneous flow, and C_{rs} and R_{rs} are characteristic moduli of the elastic (compliance) and viscous (resistance) components, respectively. This behavior can be displayed as a plot of passive transrespiratory system pressure against lung volume (Fig. 1). When the volume is cycled very slowly to minimize the viscous contribution, the plot describes a narrow loop (*solid tracing*). The overall slope of this loop reflects the elastic properties, $1/C_{rs}$. When volume is cycled more rapidly, the loop widens (*interrupted tracings*). The width of the loop divided by the difference of flow reflects the viscous properties, R_{rs}. In addition to the elastic and viscous contributions to the transrespiratory system pressure equation, an additional pressure component is sometimes added to represent the inertial effects of the gas and chest wall structures as they accelerate and decelerate. At ordinary breathing frequencies, however, inertial factors are small and are usually ignored.

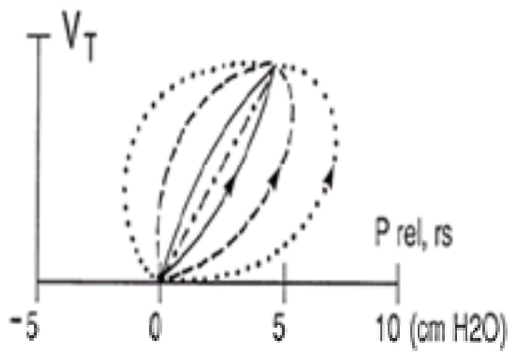

FIG. 1. Idealized viscoelastic behavior during passive ventilation in a normal subject, showing the pressure difference across the relaxed respiratory system, $P_{rel,rs}$, as a function of tidal volume, V_T, during very slow flow (*solid curve*) and sequentially higher flows (*dashed and dotted curves*). The viscoelastic model envisions an elastic component, represented by the *thin line* drawn between the points of no flow, with a slope of $1/C_{rs}$, and a viscous component, represented by the flow-related departures from the thin line, adding to the elastic pressure during inflation and subtracting from it during deflation, and accounting for the counterclockwise looping.

Elastic Recoil Properties of the Respiratory System

Typical elastic properties of the relaxed respiratory system are shown in Fig. 2. Over the range of about 20%–80% of the vital capacity (VC), the curve is reasonably linear, and the elastic properties can be characterized simply by specifying the recoil pressure and slope at a specified volume. In the example illustrated, the curve crosses the zero pressure axis at about 3 L of lung gas volume and has a slope (elastance or its inverse, compliance) of about 100 mL for every 1 cm H_2O. Away from this volume in either direction, the elastic forces act to return the respiratory system toward this zero pressure point. Thus, a normal subject at rest expires passively to this zero elastic recoil position by the end of each breath, and under these conditions, the end-expiratory lung volume, or functional residual capacity (FRC), is elastically determined.

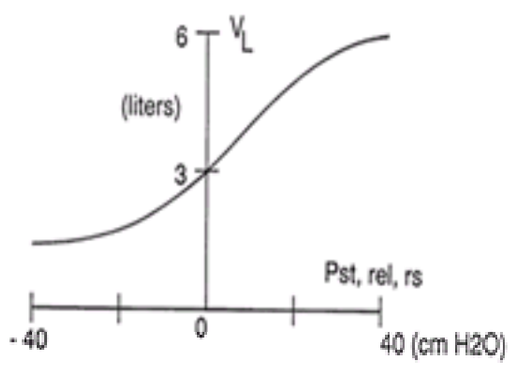

FIG. 2. Idealized elastic behavior of the respiratory system, as shown by the pressure at the airway opening measured statically (no flow) in the relaxed subject, $P_{st,rel,rs}$, as a function of lung gas volume.

The pressure at any given volume on the passive curve indicates the elastic load, that is, the inspiratory or expiratory forces that would be required to hold the respiratory system at that volume. The elastic load increases as volume increases, reaching about 40 cm H_2O at total lung capacity (TLC) in the example shown. Note that the slope of the curve decreases at high and low lung volumes, that is, the positive and negative elastic loads increase sharply. At these extremes of volume, the strength that the muscles can apply with a maximal inspiratory or expiratory effort also wanes sharply. The volume at which the elastic load and the maximal inspiratory strength available to overcome that load converge is the limit to further inspiration (e.g., TLC). For this reason, a decrease of TLC (restriction) signifies an increase in elastic recoil, a decrease in the effective strength of the inspiratory muscles, or both. The converse mechanism sets the limit to expiration in healthy young subjects, the residual volume (RV). (The dynamic mechanism that sets RV in older subjects and patients with obstructive airways disease is discussed later.)

The separate contributions of the lung and chest wall to the elastic properties of the respiratory system can be readily distinguished. That of the lung is the pressure difference across the visceral pleura, $P_{alv} - P_{pl}$, and that of the relaxed chest wall is the pressure difference between the parietal pleura and the external surface of the body, $P_{pl} - P_{bs}$. Although direct measurements of alveolar and pleural pressures are difficult, they can be inferred from relatively noninvasive measurements. P_{alv} is the same as P_{ao} when measured statically, and P_{pl} is the same as esophageal pressure, P_{es}, which is easily measured with a thin-walled balloon introduced *per nares.* Thus, a plot of lung volume versus the static transpulmonary pressure difference ($P_{st,L} = P_{ao} - P_{es}$) characterizes the elastic properties of the lung (*dashed curve,* Fig. 3), and a plot versus the pressure difference across the relaxed chest wall ($P_{rel,cw} = P_{es} - P_{bs}$) characterizes the elastic properties of the chest wall (*dotted curve*). The latter measurement requires complete relaxation of the respiratory muscles, which is difficult to ensure in the awake subject. Surface electromyograms have been helpful by providing a feedback reference for adequacy of voluntary relaxation, and reliable data have been obtained in subjects who are anesthetized and paralyzed.

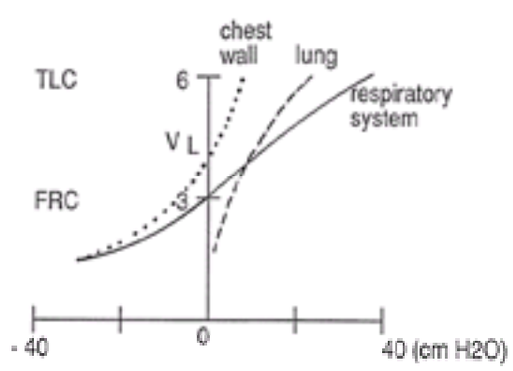

FIG. 3. Similar display to Fig. 2, showing the elastic contributions of the lung, P_L (*dashed curve*), and of the relaxed chest wall, $P_{rel,cw}$ (*dotted curve*). Note that the curves sum to the transrespiratory system pressure, $P_{rel,rs}$.

Elastic Properties of the Lung

A typical normal curve is shown in Fig. 3. Elastic recoil is about 4 cm H_2O at FRC, and compliance, C_L, is about 200 mL/cm H_2O over most of the volume range, but elastic recoil increases and compliance decreases markedly near TLC. The recoil pressure is positive over the full range of attainable volumes, reflecting the remarkable fact that the lung is under tension, inflated above its resting volume, for its entire life.

Elastic tensions in the lung are borne mainly by two components: (1) the fibrous network of collagen and elastin that supports the alveolar septa, airways, and pleura, and (2) the air-liquid interface of the alveolar septa. Elastin fibers have the requisite extensibility to sustain tensile force, F, over the full range of operating lung volumes. The elastic fiber network of the lung elastically increases tension when the network is stretched during inflation. Collagen fibers, by contrast, are very stiff and produce large increases in tension when stretched by only a small amount. The collagenous component of the fibrous network has been thought to serve as a safety

net against overdistension, coming under tension at high lung volume and accounting for the pronounced stiffening (decrease in C_L) seen near TLC. The complex anatomic relationship of collagen fibers with elastin fibers suggests that collagen also participates at lower volumes. The energy stored as a result of elastic work during inspiration by the increase in length of the fibrous components, dl, under tension, F, is the integral $\int F\,dl$ and is equal to the area under the inspiratory limb of the static volume-pressure curve.

Surface or interfacial tension, t, provides a second force that contributes to the elastic recoil of the lung. Evidence for this is the substantial reduction of recoil that occurs when the air-liquid interface is obliterated by filling the lung with saline solution. The physical basis for interfacial tension is the attraction between the molecules of the liquid phase, which far exceeds the attraction between the liquid and gas molecules. As a result, the forces acting on each liquid molecule at the interface are unbalanced, with a net force directed into the liquid phase, away from the gas phase. With every such molecule being pulled down out of the interface, the favored, least-energy configuration is that with the smallest surface area—that is, the surface is always "trying" to get smaller. For this reason, fine drops of water, as in a fog, are nearly spherical, the shape with the smallest surface area for a given volume. The elastic energy stored by the increase in area, dA, of the interface under tension, t, is the integral $\int t\,dA$. In the lung, interfacial tension is substantially reduced by the presence at the interface of pulmonary surfactant, produced by the type II alveolar cells. (The biology and biochemistry of pulmonary surfactant are treated in detail in Chapter 17; only its mechanical effects are dealt with here.)

The manner in which these tension-bearing structures interact with each other can be inferred from their anatomic relationships. First, the pseudoplanar alveolar septum connects along most of its edges to other alveolar septa, forming a continuously interconnected network, suggesting that septal elastic tension is directly transmitted from one septum to the next throughout the alveolar parenchyma. The alveolar parenchyma attaches to the inner aspect of the visceral pleura, so that its elastic tensions pull inward on the visceral pleura, lowering pleural pressure, P_{pl}, relative to alveolar gas pressure, P_{alv}, and accounting for the measurable $P_{st,L}$. Second, the alveolar septum is constructed like a sandwich, with a pseudoplanar fibrous network placed between two air-liquid interfaces. The mechanical consequence of this parallel physical arrangement is that the elastic tensions of the fibrous network and air-liquid interfaces are additive, so that elimination of the two air-liquid interfaces when the lung is filled with saline solution eliminates a substantial portion of lung recoil.

On the other hand, a series relationship exists at the point where alveoli open onto alveolar ducts. Here, tensions are transmitted directly from the septum to a structure of very different composition, the curved "cables" of the alveolar entrance rings, composed of relatively heavy, elastin-rich connective tissue and smooth muscle. The mechanical consequence of such a series relationship is that although the tensions in the two components must be in equilibrium, changes in the mechanical state of either structure cause distortion. For example, constriction of the smooth muscle of the entrance ring narrows the duct and pulls the radial septa inward toward the lumen of the duct. Conversely, increased tension in the septum, as with a deficiency of surfactant, draws the radial septa away from the center of the duct, dilating it. Despite the very different shapes and compositions of the duct and its surrounding alveolar tissues, their elastic properties are relatively well-matched, such that they expand and contract nearly proportionally with inflation and deflation.

Third, peribronchial and perivascular pressures, $P_{p\text{-}br}$ and $P_{p\text{-}vasc}$, can be considered to be nearly the same as pleural pressure, because the elastic elements of the alveolar parenchyma surround the bronchovascular structures, and elastic recoil at that site lowers $P_{p\text{-}br}$ and $P_{p\text{-}vasc}$ relative to P_{alv}, just as it lowers P_{pl} relative to P_{alv} at the visceral pleura.

The effects of disease on these tension-bearing components have predictable functional effects. Emphysema, by damaging the elastin fibers and destroying alveolar septa, reduces lung recoil, shifting the volume-pressure curves of the lung and respiratory system to the left and increasing compliance. This reduction of elastic recoil permits inspiration to higher volumes, accounting in part for the increase in TLC seen in emphysema. It also reduces the tethering forces applied to the airways, which causes them to be narrower at a given lung volume. This results in increased resistance and allows them to obstruct more readily at low lung volumes, thereby leading to a markedly decreased expiratory flow limit (see below). Conversely, the increase of collagenous fibers seen in pulmonary fibrosis restricts the lung by increasing lung recoil. This reduces TLC and FRC and tends to keep the airways open, thereby decreasing airways resistance and allowing them to remain open at lower lung volumes. Most significantly, the increase in elastic recoil increases the elastic load on the inspiratory muscles.

Reduced levels of surfactant or surfactant with an abnormal composition has similar "restrictive" effects, increasing lung recoil. The most significant functional consequences, however, are a decrease in end-expiratory lung volume (FRC) and a marked increase in the tendency of regions of the parenchyma to collapse at low lung volumes. This mechanism is responsible for the microatelectasis found in the adult respiratory distress syndrome (ARDS) and the respiratory distress syndrome of premature neonates.

There are two important additional mechanical effects of impaired surfactant, both a consequence of the pressure difference across the curved air-liquid interface. The first is the effect on the "critical opening pressure" of collapsed portions of lung. When portions of lung deflate during expiration to the point that the airways serving them close, gas is trapped in the distal alveolar regions; a plug of liquid may be found in the lumen of the closed airway. At both ends of the plug are air-liquid interfaces, concave to the air phase. Surface tension in these interfaces lowers the pressure in the fluid of the plug relative to that in the gas, and this pressure difference is described by the Laplace relationship:

$$P_{alv} - P_{liq} = \tau/r_1 + \tau/r_2 \qquad \textbf{(3)}$$

where r_1 and r_2 are the radii of curvature of the surface. This negative pressure holds the airway walls together until distending pressure is applied at a level great enough to open the airway (critical opening pressure). As long as the airway remains shut, the compliance of the region is zero. This mechanism operates where and when distending pressures are low: at end-expiration at the bases of lungs of elderly subjects, in obese subjects, or in patients with diaphragmatic paralysis in the supine position. Critical opening pressures may be increased further in areas of the lung in which the distal air spaces are gas-free (e.g. microatelectasis of ARDS). In such cases, airway opening pressures may be as high as 10 to 20 cm H_2O.

The second effect is on lung fluid balance. Although the air-liquid interface is relatively flat over much of the surface of the alveolar septum, it is concave in the corners of the alveolus, and consequently the pressure in the liquid phase in the corner is lower than that in the gas phase. Interfacial tension, then, becomes important in determining the Starling equilibrium governing fluid balance in the lung. High t favors pulmonary edema, drawing liquid from the capillaries into the interstitial space and into the alveolar spaces. Conversely, pulmonary surfactant, by reducing t, permits the alveoli to remain dry despite their small size.

Elastic Properties of the Chest Wall

A typical chest wall volume-pressure curve is shown in Fig. 3. The recoil pressure of the relaxed chest wall is about –4 cm H_2O at FRC. The curve for the chest wall, like that of the lung, is quite linear over most of the range of lung volumes, and it has a similar compliance, $C_{rel,cw}$, of about 200 mL/cm H_2O. In contrast to the lung, which stiffens near TLC, the chest wall stiffens near RV.

Elastic energy is stored in and released from the passive chest wall by bending, stretching, and raising the abdominal wall, diaphragm, rib cage, and spine during inspiration and expiration. In particular, the marked stiffening of the chest wall near RV is caused by inward bending of the ribs and stretching of the diaphragm up into the thoracic cavity.

The elastic properties of the chest wall may be adversely affected by specific disease processes. The chest wall may be restricted by skeletal changes, such as ankylosing spondylitis or kyphoscoliosis, or by abdominal changes, as in massive ascites, pregnancy, or morbid obesity. Each of these conditions increases the recoil pressure of the passive chest wall, displacing the volume-pressure curves of the passive chest wall and respiratory system to the left, increasing the passive load on the inspiratory muscles, and decreasing the maximal end-inspiratory lung volume, TLC, and the relaxed end-expiratory lung volume, FRC.

Viscous Properties of the Respiratory System

The major source of the pressure differences in phase with flow is frictional pressure losses along the conducting airways. These losses produce a pressure difference between the airway opening and the alveolus, $P_{ao} - P_{alv}$, that depends on the dimensions of the airways, the physical properties of the gas, the flow rate itself, and the flow regime or velocity profile (streamlines) of gas movement. In quiet breathing, the streamlines are parallel and straight (*laminar flow*). The physics of this flow regime is expressed by Poiseuille's Law, which relates the pressure loss between the inlet, P_i, and outlet, P_o, of a cylindrical tube to its length, l, its radius, r, the viscosity of the gas, μ, and the flow rate, $\dot{V}$:

$$P_i - P_o = (8/\pi)\,\mu\,l\,r^{-4}\,\dot{V} \qquad \textbf{(4)}$$

With laminar flow, then, the pressure loss increases directly with the flow rate (Eq. 4 and the *solid portion of the curve* in Fig. 4). Under these conditions, the ratio of the

frictional pressure loss to the flow rate, $(P_i - P_o)/\dot{V}$, is a constant, the *flow resistance,* R. This ratio is often expressed as its reciprocal, the *conductance,* G.

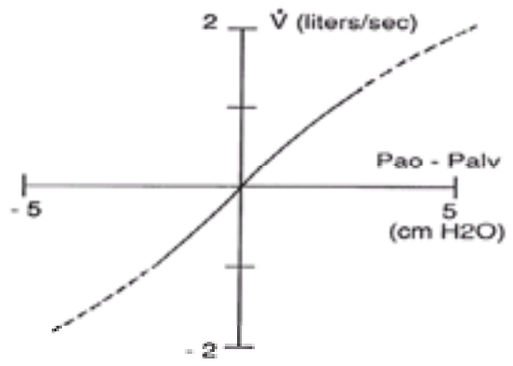

FIG. 4. Expiratory flow as a function of the pressure difference between the airway opening, P_{ao}, and the alveolar gas, P_{alv}, for a given volume. The resistance at a given point on the curve is the inverse slope of a line drawn between the origin and that point. The *solid portion of the curve* is linear, indicating constant airways resistance, consistent with laminar flow, but bends over, indicating higher resistance, at higher inspiratory or expiratory flow rates as turbulent flow begins.

When flows are increased, as during exercise, or when the airways are much narrowed, the streamlines do not remain straight and parallel. Eddies develop; laminar flow becomes *turbulent flow.* The velocity at which this changeover occurs can be predicted by the ratio of the inertial forces to the viscous forces, Reynold's number:

$$N_R = (2\ \rho\ u^2)/(\mu\ u\ r^{-1}) \quad \textbf{(5)}$$

where r is gas density, u is mean velocity, and μ is gas viscosity. The conditions that lead to turbulent flow (N_R 2000) generally do not occur in the distal airways, where the velocity of gas, u, is relatively low. In the proximal airways, however, where u is higher, conditions for a high Reynold's number occur more readily, and flow becomes turbulent when ventilatory rates are high. The pressure loss under a turbulent flow regime is as follows:

$$P_i - P_o = (1/\pi^2)\ f\ l\ r^{-5}\ \dot{V}^2 \quad \textbf{(6)}$$

where f is a friction factor that depends on wall roughness and N_R.

A critical insight from Eq. 4 and Eq. 6 is the importance (fourth and fifth powers!) of airway caliber. This is the basis for the increases in airways resistance seen when the airways are narrowed by mucus, smooth-muscle constriction, or remodeling in asthma, or by reduced tethering of the airways resulting from reduced elastic recoil in emphysema. A second critical insight is the dependence of turbulent flow on the density of the gas, r, rather than on its viscosity, μ, as in laminar flow. This is the basis for the sometimes dramatic clinical reduction in upper airway obstruction caused by local narrowing (tracheal tumor) observed when the low-density gas helium ("heliox") is substituted for the nitrogen in inspired gas.

Resistance in turbulent and orifice flow is higher than in laminar flow and is not constant, but increases with increasing flow and is characterized by curvilinearity of the overall pressure-flow relationship at higher flows (*dashed portion,* Fig. 4). This relationship may be approximated by the empiric Rohrer equation:

$$P_{ao} - P_{alv} = K_1\ \dot{V} + K_2\ \dot{V}^2 \quad \textbf{(7)}$$

where the constant K_1 reflects primarily the behavior under low flow and laminar conditions, and K_2 the additional costs of turbulent flow.

To measure the viscous pressure losses down the airways, it is necessary to know the gas pressure in the alveoli, P_{alv}. This cannot be measured directly in the intact chest, but it can be inferred by body plethysmography. The difference between P_{ao} and P_{alv} divided by the flow rate recorded with a pneumotachograph during a panting maneuver (to open the glottis as much as possible) yields airway resistance, R_{aw}. Another approach is to analyze volume-pressure loops (Fig. 1) and simultaneously measure flow rates; R may be obtained by dividing the width of the loop at a given volume by the difference in flow rates at that volume. A third approach, which may be used to estimate airway resistance in an intubated patient on a mechanical ventilator, takes advantage of the abrupt equilibration of the pressure at the mouth (P_{ao}) with the alveolar gas pressure (P_{alv}) when the distal end of the breathing circuit is briefly occluded at the end of inspiration. The abrupt decrement in pressure observed when the circuit is occluded may be attributed to the flow-related pressure drop along the airways. This observed pressure drop, divided by the preocclusion flow rate, gives R_{aw}.

At the distal end of the conducting airway tree, individual airways are very small and therefore each has a high resistance. Nevertheless, the flow through any one airway is very small because of the very large number of airways arranged in parallel, and consequently, the pressure drop across any one of these airways is quite small. Indeed, the greatest part of the total airway frictional pressure loss is incurred in the upper airways (nose, pharynx, and larynx); the loss is smaller in the trachea and proximal bronchi, and least in the distal airways. The overall airways resistance decreases with increasing lung volume because of the effect of lung recoil on airway caliber. Because their lengths and radii vary nearly as $V_L^{1/3}$, airways resistance, as can be derived after inserting such values in Eq. 4, is inversely related to lung volume. For this reason, R_{aw} is often multiplied by lung volume to obtain *specific airways resistance,* SR_{aw}, a parameter that is nearly independent of the lung volume at which it is measured. Its reciprocal is the *specific airways conductance,* SG_{aw}.

Frictional Pressure Differences Across the Lung Tissues

The solid structures of the respiratory system also incur frictional energy loss during breathing. This is the source of the openness of the very slow loop in Fig. 1. In contrast to the energy loss associated with gas flow in the airways, however, the frictional energy loss across the lung tissue is relatively independent of flow rate. Instead, it is a nearly constant fraction, h, of the tidal volume, V_T, multiplied by the overall tidal pressure excursion, V_T^2/ C_L. The mechanism for this behavior has not as yet been worked out, but there is some appeal in relating the observed energy losses to a parameter h, that is relatively constant, rather than to resistance, a parameter that is an inverse function of frequency and compliance. These tissue frictional losses are small. Nonetheless, in quiet breathing the airway pressure losses are also small, and the tissue frictional losses then represent a large fraction of the total.

Expiratory Flow Limitation

A very different phenomenon supersedes viscoelastic behavior at high rates of ventilation in normal subjects, or at lower rates of ventilation and even at resting ventilation in subjects with obstructive lung disorders. This phenomenon is expiratory flow limitation. Up to a certain relatively modest expiratory effort, flow increases linearly with increasing effort (*solid portion of the lines,* Fig. 4 and Fig. 5). Beyond this effort, however, flow is *effort-independent,* and for a given lung volume, flow does not increase even if more effort is applied (*dashed lines,* Fig. 5).

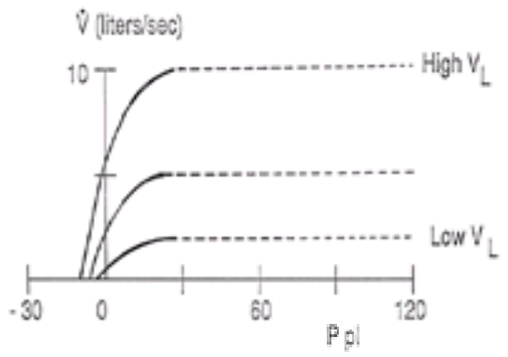

FIG. 5. Expiratory flow as a function of transpulmonary pressure for three different lung volumes. At each lung volume, the relationship is linear at low driving pressures, as in Fig. 4 (*solid portion of each curve*). At relatively modest expiratory efforts, however, flow reaches an absolute maximum; in other words, maximal flow is *effort-independent.* The maximal flow, however, is very much lower at lower lung volumes, showing that maximal flow is *volume-dependent.*

Maximal expiratory flow is also *volume-dependent.* This is readily seen by comparing the three curves in Fig. 5, each of which shows the flow-pressure relationship for a given lung volume. The limiting flow is higher for the higher volumes. This positive volume-dependence is directly demonstrated when maximal expiratory flow is plotted against lung volume (maximal expiratory flow-volume curve, or MEFVC) (Fig. 6).

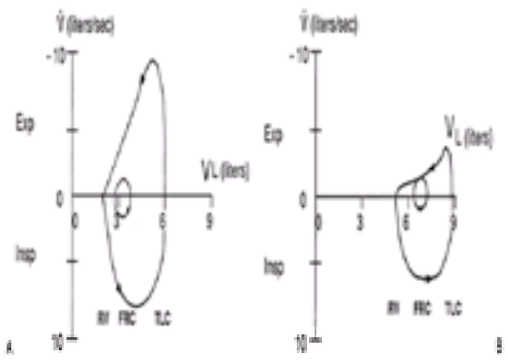

FIG. 6. A: Flow as a function of volume in a normal subject. The *outer loop* shows a forced expiration followed by a forced inspiration. The maneuver starts from a maximal inspiratory position, TLC. The expiratory flow rate peaks when about 20% of the VC has been expired and through the rest of expiration falls inexorably toward zero at maximal expiration, RV. Over this lower 80% of the forced expiratory VC, the curve is effort-independent and is extraordinarily reproducible in an individual *unless* there is a change in airway caliber (e.g., asthma) or lung recoil (e.g., emphysema). Flow during forced inspiration depends on airways resistance and the force/length/velocity properties of the inspiratory muscles. The *inner loop* shows quiet breathing, well within the outer (limiting) loop. As ventilation is increased, the loop increases its vertical dimensions (higher inspiratory and expiratory flows) and usually its horizontal dimensions (increased tidal volume) as well. At high levels of ventilation, however, the loop encounters the expiratory flow limit. Higher flows are then possible only if the curve moves to the right (to higher operating volumes), where the flow limit is higher. **B:** Similar plots in a subject with severe emphysema. Maximal expiratory flow at all volumes is severely decreased. This dynamically increases RV. Furthermore, the loop representing quiet breathing has been forced by the slope of the flow-limiting curve to move to the right. This increases FRC (hyperinflation). TLC is increased mainly because of the loss of elastic recoil. The increase of TLC is typically less than the increase of RV, and therefore the difference between TLC and RV (the VC) is decreased. Maximal *inspiratory* flow is decreased because of higher airways resistance and impaired inspiratory function at high chest wall volumes, but is less pronounced than is the decrease of maximal *expiratory* flow.

The example shown is of a normal subject performing a maximal forced expiratory maneuver followed by a maximal inspiratory maneuver. Having first inspired as deeply as possible, the subject makes a vigorous, sustained expiratory effort. The initial, rising portion of the MEFVC (roughly the first 20% of the VC) varies somewhat with effort, but the rest of expiration is flow-limited (i.e., effort-independent). In this flow-limited region, flow falls progressively during expiration and approaches zero flow at RV. This maximal forced expiratory maneuver has been dubbed an “unnatural act,” because it is not performed except in the laboratory and in certain individuals with severe obstructive lung disease during normal breathing. The concept of flow limitation and its indices, derived from the MEFVC, are useful in understanding and assessing ventilatory limitation and failure in obstructive airways disease.

In obstructive lung disease, maximal expiratory flow is reduced at all lung volumes (Fig. 6B). One consequence ABof this is an increase in the RV. A young, healthy subject can expire down to a statically determined volume at which the elastic recoil of the respiratory system and the available strength of the expiratory muscles are matched but oppositely directed (see above), but in obstructive lung disease the maximal expiratory flow is reduced, preventing the subject from expiring down to the statically determined RV; RV becomes dynamically determined.

With more severe disease, flow limitation may also increase FRC (“hyperinflation”). In the normal subject, quiet breathing follows a small inspiratory-expiratory flow-volume loop contained within the maximal loop. In obstructive lung disease, however, expiratory flow may encounter the flow limit even at rest. Passive expiration then may be interrupted by the next inspiration before the pressure difference across the passive respiratory system reaches zero (Fig. 2). FRC then also becomes dynamically increased above the elastically determined volume. The increase in volume may permit the ventilatory needs to be met, because of the positive volume-dependence of maximal expiratory flow.

One consequence of hyperinflation is elevation of end-expiratory alveolar gas pressure, as can be predicted from Fig. 2. This is readily measured in intubated patients when the airway is momentarily occluded at the end of passive expiration, and it provides a useful indication (“auto-PEEP”) of hyperinflation. With very severe disease, the expiratory flow limitation may be so extreme that resting FRC may end up higher than the premorbid TLC (Fig. 6B)! For hyperinflated patients to increase their ventilation above resting levels, they must breathe at even higher volumes. Although this increase in operating volumes permits a higher level of ventilation, it also impairs inspiratory muscle function by requiring the muscles to operate at shorter lengths and with less favorable mechanical purchase on the chest wall (e.g., flat diaphragm). Ironically, *expiratory* limitation burdens the *inspiratory* muscles! This mechanism (*expiratory* flow limitation ® *increased* operating volumes ® decreased *inspiratory* muscle reserve) is in fact the main cause of exercise limitation, fatigue, and ventilatory failure in acute and chronic obstructive lung diseases. Note that ventilatory capacity in obstructive lung disease is improved by improvement of inspiratory function (e.g., the ability of the chronically hyperinflated patient to inspire to very high lung volumes), and not by strengthening of the expiratory muscles.

It is not useful to think of expiratory flow limitation in terms of a flow resistance. Resistance is the inverse slope of the chord connecting a particular point on the expiratory flow/P_{pl} curve to the zero flow point (Fig. 5). R, as we have seen, is a very useful parameter at lower flows, predicting how much flow can be achieved for a given effort and explaining that prediction in terms of structure and physical properties. All of that significance is lost, however, when excess expiratory pressure is applied to the respiratory system (*dashed portions of the curves,* Fig. 5), and the slope of the chord, R, then varies with the expiratory effort.

The mechanism of expiratory flow limitation involves an interplay between the mechanical properties of the airways, the lung parenchyma, and the characteristics of the respired gas. Consider that in the absence of flow, the airways are effectively distended by lung recoil, $P_{alv} – P_{pl}$. The pressure difference across their walls is the intra-airway pressure, P_{aw}, less the peribronchial pressure, $P_{p\text{-}br}$. P_{aw} is the same as P_{alv} in the absence of flow, and $P_{p\text{-}br}$ is approximately the same as P_{pl}. In expiration, however, P_{aw} is lower than P_{alv} because of frictional viscous losses and the Bernoulli effect. The Bernoulli effect is the lowering of pressure associated with an increase of velocity, and it becomes important in the proximal airways because of convective acceleration, resulting from a substantial increase in the velocity (Dv) of the expired gas as it enters the much smaller net cross-sectional area of the large airways and trachea. A lower intrabronchial pressure produces a lower bronchial transmural pressure difference, which in turn produces a narrower airway, which in turn requires a higher velocity because of convective acceleration, which in turn produces a lower intrabronchial pressure because of the Bernoulli effect. And so on. This cycle of effects has an equilibrium at low expiratory flows solution at all points in the airway. But at some particular higher expiratory flow rate, the cycle of effects reaches the point at some location along the airways at which any higher flow rate would be impossible because it would be incompatible with the airway remaining open! This location is called the aerodynamic “choke point,” and the flow at which it develops is the maximal expiratory flow rate. This maximal flow depends (positively) on three conditions: (1) cross-sectional area and stiffness of the airway at the choke point, (2) elastic recoil (because it provides the driving pressure for flow in the airways upstream of the choke point and because its tethering action increases the

cross-sectional area and stiffness of the airway), and (3) low resistance of the airways upstream of the choke point. The features of expiratory flow limits in health and disease can be understood in this framework. None of these three conditions depends on expiratory effort—hence the *effort-independence* of maximal expiratory flow. The second and third conditions are increased by higher lung volumes—hence the positive *volume-dependence* of maximal flow. Asthma lowers maximal expiratory flow by reducing the caliber of the airways (the first and third mechanisms), and emphysema largely by reducing lung elastic recoil (the second mechanism).

The principles of flow limitation are also relevant to cough. Immediately upstream of the choke point, the airways are dynamically compressed during a cough and the velocity of the air stream is high. As the kinetic energy of the air stream is proportional to the square of its velocity, the energy available to shear mucus from the airway walls is markedly enhanced by this dynamic compression. The choke point moves peripherally as lung volume decreases, and for this reason serial coughs at lower volumes clear progressively more peripheral airways.

DISTRIBUTIONS OF VOLUME AND VENTILATION

The lung parenchyma, consisting largely of interconnected alveolar septa, divides the gas in the human lung into an estimated 400,000,000 gas-exchanging alveolar spaces. What governs the distribution of gas volume within the parenchyma? What mechanisms ensure that inspired gas distributes itself so that there is a reasonable turnover of the resident gas throughout the parenchyma?

Distribution of Volume

The alveolar septa and the alveoli exhibit a degree of variability in size and shape but generally appear to be made of the same structural components. There is no evidence of nonuniformity of elastic properties at a scale larger than about 0.5 cm. Furthermore, at a local level the parenchyma is stable in the sense that one small region is constrained from enlarging or shrinking at the expense of its neighbors. This stability, “mechanical interdependence,” is an inherent property of a network constructed of elastic elements with positive length-tension compliances.

At a regional level, however, there is significant nonuniformity of inflation, primarily because of gravity. The weight of the lung tissue (including blood) makes it sag. As a result, the alveoli in the upper regions are relatively inflated and those in the dependent regions relatively deflated. In the upright position, this gradient of inflation applies from apex to base. In the left lateral decubitus position, it applies from right to left. A vertical gradient of inflation reflects a vertical gradient of elastic tensions, the septal tensions being greater in the upper region from which the lung is “hung” and lesser in the dependent region on which the lung is “sitting.” Although the details of the distribution of pleural pressure remain somewhat controversial, a reasonable starting assumption is that pleural pressure and the associated elastic tensions within the parenchyma maintain a vertical gradient (in centimeters of water per centimeter of vertical distance) equal to lung density (in grams per cubic centimeter), such that the difference in lung recoil between the apex and base of a lung 30 cm in height might be on the order of 6 cm H_2O.

Distribution of Ventilation

In the healthy lung, there is both local and regional nonuniformity of ventilation. At a scale of about 0.5 cm, the nonuniformity of ventilation is modest. At FRC, the variability of the distribution of ventilation has been quantitatively estimated (in terms of the variability of the volume of regions as fractions of their volumes at full expansion) as being on the order of 0.013. The source of the variability presumably is local nonuniformity of elastic tensions. A much greater nonuniformity, however, results from the systematic vertical gradient of ventilation. With quiet breathing in a sitting position, the ventilation of the dependent regions of the lung is about twice that of the apical regions. The generally accepted mechanism for this is that the more distended apical regions of the lung are less compliant than the less distended basilar regions.

Figure 7 shows the specific compliance to be a decreasing function of elastic recoil. Specific compliance is the inverse slope of the $V/P_{el,L}$ curve *divided by V.* It represents the volume change for a given volume of gas rather than for a given anatomic entity, such as an alveolus, and is useful for calculating the fractional turnover of resident gas. Given the assumption that the amplitudes of the pressure swings during the breathing cycle are reasonably uniform, the specific compliance predicts that the turnover of resident alveolar gas volume will be less where the distending pressure is greater, at the apices in the vertical lung, and greater where the distending pressure is very low, in the more dependent regions. An additional nonuniformity of ventilation is seen when portions of lung deflate so far during the breathing cycle that the airways serving them close, trapping gas in the alveolar regions they serve, until a deep inspiration increases the local inflating pressures above the critical opening pressures of the regions.

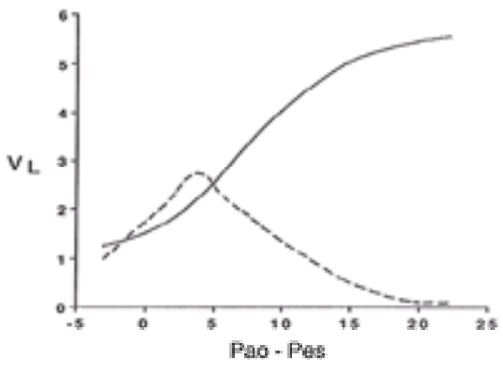

FIG. 7. Regional ventilation depends on regional specific compliance. Lung volume (V_L) (*solid curve*) and specific compliance (SC_L) (*dashed curve*) as functions of lung recoil pressure ($P_{ao} – P_{es}$) obtained during a slow expiration. In the upright chest, the recoil pressure is greater at the apex of the lung ($P_{ao} – P_{es} \sim 8$) than at the base ($P_{ao} – P_{es} \sim 2$). Because SC_L is less at 8 than at 2, the apical region is correspondingly less ventilated.

Finally, viscous properties may cause nonuniformity of ventilation at higher levels of ventilation or with narrowing of the airways. Consider a model in which a number of viscoelastic units ventilate in parallel (e.g., lobes, lobules, or smaller units). Each ventilating unit consists of a flow-resistive element (airway) and an elastic element (distensible parenchyma) in series. The passive emptying of such a unit follows an exponential time course:

$$V = e^{-t/(RC)} \quad \textbf{(8)}$$

where t is the time from the onset of the passive expiration, R is the flow-resistance of the airway of the unit, and C is its compliance. The product, RC, is the *time constant* of the exponential decay and is the time when emptying is 1/e, or about half completed. When regional time constants are short compared with the time of expiration, as they are in the healthy lung during quiet breathing, all units expire to their elastically determined volume. However, when breathing is rapid, and particularly when time constants are longer (higher airway resistance, higher compliance, or both), passive emptying is not completed in all lung units; those units with higher time constants lag behind those with lower time constants. Units with lower time constant are preferentially ventilated.

In disease states, volumes may be very unevenly distributed because of local changes in elastic properties, either from altered connective tissue properties or impaired surfactant. Ventilation may also become unevenly distributed because of uneven time constants, as in asthma, in which the R of small airways is (unevenly) increased, and in emphysema, in which both the R and the C (because of the loss of elastic structure) are increased.

Different patterns of respiratory muscle recruitment may also result in uneven distribution of ventilation, although the effect is small relative to that produced by inequalities of unit time constants. Inhalations deriving from contractions of rib rather diaphragmatic muscle result in preferential distribution of ventilation to the upper lung units, as does active expiration to RV followed by a passive inspiration.

LUNG MECHANICS AND PULMONARY HEMODYNAMICS

Respiratory mechanics directly affect the right ventricular preload, the right ventricular afterload, the left ventricular afterload, and the volume of the intrapulmonary extracapillary vessels. These effects become particularly important during mechanical ventilation.

Lung mechanics affect pulmonary hemodynamics by three distinct mechanisms.

The first mechanism is a consequence of the effects of intrathoracic pressure on right ventricular preload and left ventricular afterload. Intrathoracic pressure varies during spontaneous breathing, voluntary inspiratory or expiratory efforts, and mechanical ventilation. Such changes alter the relationships between the intrathoracic and extrathoracic vascular pressures; in particular, the intravascular pressure gradients at the thoracic inlet and at the level of the diaphragm may be affected. For example, during normal breathing, inspiration *decreases* all intrathoracic pressures relative to extrathoracic pressures. The fall of pressure in the intrathoracic vena cava relative to that in the extrathoracic great veins momentarily aids return of venous blood from the abdomen, head, and limbs. Similarly, the fall of blood pressure in the thoracic aorta relative to that in the arteries of the upper extremities, neck, and abdomen momentarily impedes arterial outflow. A spontaneous inspiration, then, has the effects of momentarily *increasing* right ventricular preload and left ventricular afterload.

Opposite effects occur when the inspiration is passively delivered by mechanical ventilation, because it passively *increases* all intrathoracic pressures relative to extrathoracic pressures. This impedes filling of the right side of the heart and aids emptying of the left side of the heart (i.e., it momentarily *decreases* both the right ventricular preload and the left ventricular afterload). Greater effects are seen when pressure changes affect the full breathing cycle, as in continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP). The increase in intrathoracic pressure under these circumstances is predictably the increase of chest wall volume achieved by the CPAP or PEEP divided by the compliance of the passive chest wall (Fig. 3). Although the changes of pressure may be small, the effects on right ventricular preload may be large, because the right ventricle in diastole is highly compliant. This reduction of right ventricular preload and left ventricular afterload explains the immediate benefit of CPAP or PEEP in acute pulmonary edema, and also the reduction of cardiac output that may ensue when CPAP or PEEP is applied in patients whose intravascular volumes are low or applied pressures are high.

No hemodynamic effects are *directly* attributable to changes of intrathoracic pressure on structures that lie completely *within* the thorax. Consider, as an example, the rise in pulmonary capillary wedge pressure, PCWP, seen when PEEP or CPAP is applied to the airway. The PCWP tracing provides an estimate of left atrial pressure and, in the absence of mitral disease, of left ventricular end-diastolic pressure. The increases of these pressures associated with PEEP or CPAP, however, do not quantitatively reflect increases in the transmural pressure differences across the atrium or ventricle (the measurements with functional meaning because they indicate the degree of filling of the chambers and their compliance) except in the unlikely event that the intrathoracic pressure is unchanged. Fortunately, the relevant transmural pressure differences can be estimated from PCWP – P_{es}.

The second mechanism operates through effects of lung elastic recoil, $P_{alv} - P_{pl}$, on right ventricular afterload. Consider the relationships among the pressures in the alveoli, P_{alv}, the pleural space, P_{pl}, the pericardial space, P_{pc}, and the cavity of the right ventricle, P_{RV}. The contractile tension of the right ventricular myocardium during systole creates a transmural pressure difference between the right ventricular cavity and its pericardial (equivalent of pleural) surface, $P_{RV} - P_{pl}$. Pressure in the right ventricle exceeds that in the pulmonary capillary because of frictional losses, $P_{RV} - P_{pc}$. The distending pressure of the pulmonary capillary must be positive for it to remain open, $P_{pc} - P_{alv}$. Pressure in the alveolus exceeds pleural pressure because of lung elastic recoil, $P_{alv} - P_{pl}$. These serial pressure differences can be related in the algebraic identity as follows:

$$(P_{RV} - P_{pl}) = (P_{RV} - P_{pc}) + (P_{pc} - P_{alv}) + (P_{alv} - P_{pl}) \quad \textbf{(9)}$$

which shows that the right ventricular transmural pressure difference equals the sum of the frictional pressure drop in the pulmonary arteries, the distending pressure of the capillaries, and lung recoil. The latter is generally the largest of the three, and it becomes particularly important when high inflating pressures are imposed by mechanical ventilation.

A third mechanism, probably of little clinical significance other than that it contributes to tamponade physiology, links lung distention to the blood volumes of the intrapulmonary, extra-alveolar arteries and veins. Lung distention *per se* distends all but the smallest intrapulmonary arteries and veins, as was demonstrated in the l920s by C. C. Macklin, who found that positive-pressure inflation of an excised lung paradoxically sucked fluid into these vessels! The explanation of this phenomenon is that these vessels, lying within the bronchovascular compartments, exhibit “mechanical interdependence” with the elastic structure of the surrounding lung. The result of this mechanism is that the volumes of both vascular compartments increase and decrease cyclically as the lung inflates and deflates.

ENERGETICS: WORK RATE AND COSTS OF BREATHING

Spontaneous ventilation reaches its limit and respiratory failure may ensue when respiratory muscles, usually the muscles of inspiration, are overloaded. Up to this point, we have characterized only the *pressure* loads presented by the passive respiratory system. The ability of the muscles to accomplish a given ventilatory task, however, depends not only on the forces they must develop to overcome the pressure loads of the task, but also on the required *velocity* of shortening, on the *duration* of activation, and, most importantly, on their *operating lengths.* These factors may be linked through consideration of the energetics of breathing, first by calculating the *viscoelastic work rate,* which is the rate of *physical* energy required by the passive respiratory system to carry out a given ventilatory task in a given time, and second by measuring the *oxygen consumption,* which is the *chemical* energy actually expended by the muscles in carrying out the task. As the inspiratory muscles are far more critical to ventilation than are the expiratory muscles, we focus on the *inspiratory* work load.

Viscoelastic Work of Breathing

The physical work, W, performed by a muscle in carrying out a given task is the integral of force it develops, F, times the incremental distance it shortens, dl—that is, $\int F\,dl$, or equivalently the integral of pressure times the incremental volume displaced, $\int P\,dV$. The mean inspiratory work *rate,* $\dot{W}_{insp}$, is the work of a single inspiration times the frequency, f. The integral can be depicted graphically (Fig. 8), so that the work performed on the passive respiratory system in a single inspiration is the area between the $V_L/P_{rel,rs}$ curve and the volume axis.

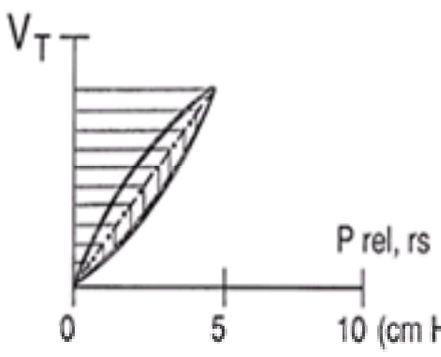

FIG. 8. The pressure difference across the passive respiratory system, $P_{rel,rs}$, as a function of displaced volume, as in Fig. 1. The work of a single inspiration is the integral $\int P_{rel,rs}\,dV$ and can be partitioned into elastic (*horizontal shading*) and viscous (*vertical shading*) work with the assumption of linearity of elastic recoil between end-inspiration and end-expiration.

Work performed on the respiratory system can be partitioned into two components. That expended on the lung can be distinguished from that expended on the chest wall by integrating the transpulmonary pressure difference, $P_L = P_{ao} - P_{es}$ (lung component), and the pressure difference across the chest wall, $P_{rel,cw} = P_{es} - P_{bs}$ (chest wall component). Work can be further partitioned between elastic and viscous sources based on the assumption that the elastic component (Fig. 9) is linear between the end-inspiratory and end-expiratory points. A line drawn between these two points separates the work expended to overcome elastic forces (*horizontal shading*) from that expended to overcome the viscous forces (*vertical shading*).

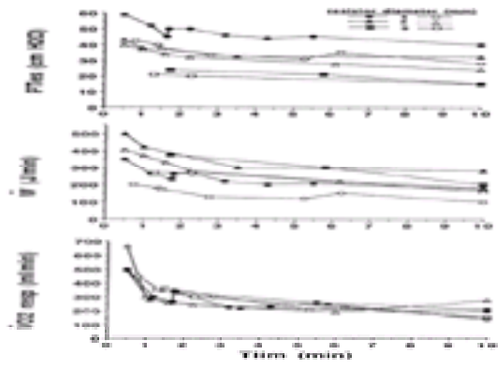

FIG. 9. Endurance in a variety of strenuous ventilatory tasks. A normal subject was assigned a variety of tasks, each of which entailed breathing an assigned tidal volume at an assigned frequency from spontaneous or increased FRC (*closed and open symbols*), through a range of inspiratory resistors (*circles, triangles, squares*), until he could no longer maintain the task. **A:** Plot of the esophageal pressure-time product, PT_{es}, against time to task failure, T_{lim}. **B:** Data replotted to show the work rate, $\dot{W}$. **C:** Data replotted to show the incremental oxygen consumption incurred in carrying out the assigned task. The ability of the inspiratory muscles to sustain a specific ventilatory task is reduced as the pressure, flow, duty cycle, or lung volume is increased. There are trade-offs among the four variables such that, for example, the same time to task failure, T_{lim}, is seen in high-pressure, low-flow tasks and low-pressure, high-flow tasks. Neither pressure nor work rate of an imposed breathing task predicts endurance well when volume or flow is varied. The incremental oxygen cost of the task is the best predictor.

The effects of increasing ventilation, of changing the pattern of breathing, or of changes in the mechanical properties of the respiratory system can be analyzed graphically or mathematically. Graphically, the elastic work of a single inspiration (area) is increased when tidal volume, V_T, is increased (extending the line representing the elastic component), when compliance, C_{rs}, is decreased (lowering the slope of the V/P_L curve), or when there is hyperinflation (sliding the operating volumes up the elastic line), and the elastic work rate is that area times the frequency, f. Mathematically, these relationships can be expressed in the following equation:

$$\dot{W}_{el} = (V_T/C_{rs})\,(V_T/2 + \Delta FRC)\,f \qquad \textbf{(10)}$$

where DFRC is the increment above FRC determined elastically, and $\dot{W}_{el}$ is the rate of elastic work performed.

Graphically, the viscous work is increased when the volume-pressure loop is widened by increase of inspiratory flow, $\dot{V}$, or resistance, R_{rs}. Mathematically, these effects on viscous work rate can be seen from the following relationship:

$$\dot{W}_{res} = (\pi^2/4)\,R_{rs}\,V_T^2\,f^2 \qquad \textbf{(11)}$$

where $\dot{W}_{res}$ is the rate of resistive work performed.

Note the interactions between frequency, tidal volume, and ventilation. For example, at a given ventilation, an increase in frequency requires a decrease in tidal volume. These changes have opposing effects on work rate. More rapid, shallower breaths increase overall ventilation for a given alveolar ventilation, increasing the inspiratory flow rates, $\dot{V}$, and therefore the viscous load, but decreasing the elastic load. The net effect on $\dot{W}$ is relatively small over the usual breathing rates, but the effect may become significant at very high or very low frequencies. Usually with increases in ventilation, both frequency and tidal volume increase and $\dot{W}$ increases on both counts. Finally, the work of decompressing intrathoracic gas during inspiration against airway resistance can also be calculated; it can become significant when inspiratory resistance is high, as in asthma.

Energy Costs of Breathing

More relevant to the ability of the respiratory muscles to accomplish a given ventilatory task is the (metabolic) energy cost of that task, and this may differ substantially from the energy actually converted into viscoelastic work. First, it is possible for metabolic costs to be considerable even when no viscoelastic work is accomplished, as during inspiratory effort against a closed glottis, in which chemical energy (adenosine triphosphate) is expended but no work is done. Second, the purpose of muscular contraction is to displace the chest wall against a pressure load, accomplished by shortening of the muscle against a force load. However, the displacement and pressure effected by a given muscle depend on its mechanical coupling to the respiratory system and on the coordination of its contraction with the contraction of the other respiratory muscles. For these reasons, the viscoelastic work of a particular breathing task may be a very misleading index of the difficulty of actually accomplishing the task. Furthermore, the ability of a muscle to develop force depends on its length. For this reason, inspiratory muscles are weak at high lung volumes and cannot perform as they can at lower lung volumes. These three conditions (expenditure of energy without accomplishing work, operating at unfavorable mechanical advantage or with suboptimal coordination, and operating at unfavorable sarcomere lengths) particularly impair inspiratory muscle function at high lung volumes.

The energy costs of a breathing task turn out to be a much better predictor of the ability of the respiratory muscles to perform a task than is the viscoelastic work. Time to task failure has been studied for a variety of sustained tasks. It is shortened by tasks in which inspiration is elastically loaded, resistively loaded, or performed at increased lung volumes. The incremental energy cost (oxygen consumption) is not simply related to the physical work accomplished (viscoelastic work rate in the loaded breathing task); the efficiency of the system is variable among different tasks. Oxygen consumption has been found to be the parameter that best predicts the time to task failure (Fig. 9). This suggests that the limit to sustainable performance of the respiratory muscles is the rate at which they can aerobically generate adenosine triphosphate. This in turn depends on the pattern of pressure and flow loads rather than the external work accomplished. More critically, it depends on the operating lung volume, which is so critical to respiratory failure and to the ability of a hyperinflated patient to be weaned from mechanical ventilation.

INTRODUCTION

The human respiratory tract is a complex organ system specialized for exchange of gases between environmental air and blood circulating through the pulmonary vascular bed. The respiratory system also performs a spectrum of important nonrespiratory functions (Table 1). Certain of these lung functions, such as speech, heat and water conservation, host defense, and filtration of systemic blood, are a consequence of unique anatomic features of the respiratory system. Functional diversity of the lungs also arises from a heterogeneous population of constituent cells that participate in water and electrolyte transfer, air space defense, local neuroendocrine regulation, xenobiotic metabolism, and excretion of volatile substances. This chapter reviews the nonrespiratory functions of human respiratory tract cell populations as they relate to morphologic organization within functionally distinct compartments, including the conducting airways, alveolar region, and vascular structures. The important role of the lung in host defense is reviewed elsewhere in this volume; therefore, only a summary table of lung host defenses is provided for reference (Table 2).

Speech
Heat and water conservation
Electrolyte transport
Host defense
Neuroendocrine secretion
Xenobiotic metabolism
Surfactant synthesis and turnover
Antioxidant defense
Excretion of volatile substances
Filtration
Hemofluidity

TABLE 1. *Nonrespiratory functions of the lung*

Irritant reflexes
Cough
Sneeze
Bronchoconstriction
Mechanical barriers
Nasal vibrissae
Nasal turbinates
Nasopharyngeal and oropharyngeal walls
Airway carinae
Lymphoid tissues
Waldeyer's tonsillar ring surrounding orifice to lower airways
Bronchus-associated lymphoid tissue (BALT)
Mucociliary escalator
Humoral immunity
IgA—predominant in upper airways
IgG—predominant in lower airways
IgM and IgE also present
Cellular defenses
Lymphocytes—individual or aggregates
Natural killer cells
Macrophages—intravascular, interstitial, or alveolar
Polymorphonuclear leukocytes

FUNCTIONS RELATED TO CONDUCTING AIRWAYS

Speech

Speech and language are uniquely human characteristics generated by coordinated activity of the cerebral cortex, the brain stem respiratory drive center, and structural components of the upper airway. Phonation, or creation of sound, results from purposeful expiration of air through the vocal cords located within the larynx. Changes in the pitch of sound emitted by the larynx are achieved by stretching or relaxing the vocal cords and by altering the shape and mass of vocal cord edges. Resonance is added by several structures, including the mouth, nose and paranasal sinuses, pharynx, and chest cavity. Final articulation of sound into language is accomplished with the lips, tongue, and soft palate.

Heat and Water Conservation

During normal spontaneous respiration, inspired air is fully saturated with water vapor at body temperature (Fig. 1). Incoming ambient air is warmed by conduction and convection as it passes through the nasopharynx and tracheobronchial tree. As inspired air is warmed, it is also humidified by evaporation of water from the airway lining. Evaporation of water from the mucosal surface during inspiration transfers thermal energy to the passing air stream and results in net cooling of the airway surface.

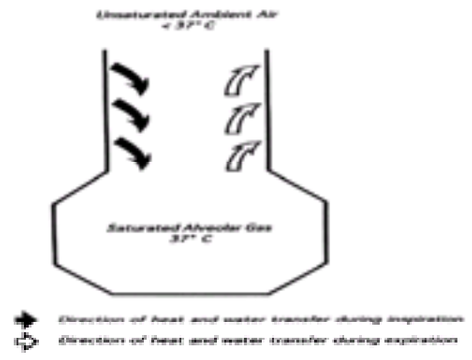

FIG. 1. Countercurrent heat and water exchange in conducting airways.

During expiration, temperature and vapor pressure gradients are reversed, and air loses thermal energy to the cooler airway surface. As air cools during expiration, its ability to hold water decreases, and water condenses along the airway surface. Countercurrent exchange of heat and water during normal tidal respiration allows conditioning of inspired air while thermal energy and water are conserved during expiration. Under normal circumstances, tidal respiration results in a net loss of only about 250 mL of water and 350 kcal of heat from the airways in a 24-hr period.

Countercurrent heat and water exchange is influenced by environmental factors and air flow velocity. Net transfer of heat and water depend on temperature and vapor pressure gradients between the airway surface and passing air stream. Low environmental temperatures increase convective cooling of the airway surface; low humidity enhances evaporative cooling of the airways. The additional heat and water required to condition inspired air raise caloric requirements in cold climates.

Transfer of heat and water from the mucosal surface to inspired air is also related to linear velocity of air flow. Higher flow velocities are associated with lower rates of heat and water transfer to the air stream during inspiration and reduced condensation during expiration. Increases in ventilation during physical activity or other stresses thereby augment the net loss of heat and water from the mucosal surface.

Temperature of the internal milieu can also affect net heat and water transfer. The reduction in temperature gradient between air leaving the lungs and the mucosal surface that occurs at elevated body temperatures facilitates water loss. Net water loss in the setting of fever or physical exertion may actually serve as a mechanism for temperature regulation. The respiratory tract has a major role in temperature control in fur-bearing animals; however, it is not thought to affect core temperature regulation significantly in humans under normal circumstances.

Airway heat and water exchange may have important clinical implications in asthmatic patients, in whom airway cooling caused by low ambient temperatures or increased minute ventilation may provoke bronchospasm. Bronchoconstriction in cooler environments may result from acute stimulation of thermally sensitive body surface and mucosal receptors; however, airway constriction in some asthmatic patients may outlast the duration of thermal receptor stimulation. In this setting, bronchoconstriction is thought to relate to enhanced heat and water loss from the mucosal surface. Ambient temperature-induced bronchoconstriction may be mimicked in asthmatic subjects by increasing minute ventilation at any level of ambient temperature and humidity.

Heat and water exchange in the conducting airways may affect the mucociliary transport mechanism. Effective ciliary action depends on the volume and composition of the overlying mucus layer. Although characteristics of this fluid layer are largely determined by active ion transport across the epithelium and by autonomic control of submucosal gland secretion, evaporative losses and thermally regulated secretion and reabsorption may also contribute to fluid characteristics at the mucosal surface.

Electrolyte Transport

Airway epithelial cells actively transport electrolytes between the airway lumen and the interstitial compartment of the alveolar wall (Fig. 2). Water absorption passively follows net Na^+ transfer from the mucosal surface to the interstitial compartment. In contrast, net fluid secretion is a function of active epithelial cell Cl^- transport from the interstitium to the airway lumen; water passively follows Cl^- movement into the lumen. The balance between Na^+ absorption and Cl^- secretion, and hence net water movement, depends on airway region, pharmacologic intervention, and neurohumoral influences.

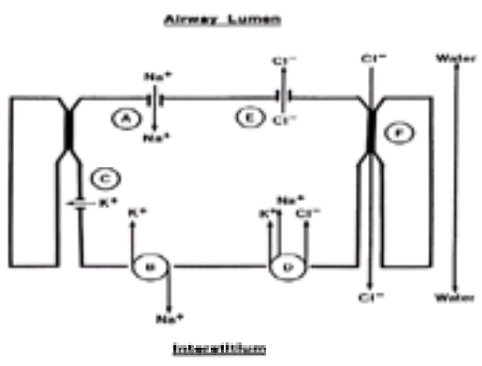

FIG. 2. Electrolyte transport by lung epithelial cells. Na^+ moves passively from the airway lumen into the epithelial cell through a selective Na^+ channel (**A**) down an electrochemical gradient. Na^+, K^+-ATPase (**B**) located in basolateral membranes actively pumps Na^+ from the cell into the interstitium in exchange for K^+, thereby maintaining an intracellular Na^+ concentration that favors passive Na^+ diffusion from the lumen. The accumulation of K^+ within the cell creates an electrochemical disequilibrium that favors passive movement of K^+ out of the cell through basolateral K^+ channels (**C**). Movement of K^+ into the interstitial compartment maintains an intracellular electrochemical gradient that is favorable for Na^+ entry and Cl^- secretion. Cl^- enters the cell from the interstitial space on the Cl^--Na^+-K^+ cotransporter (**D**). Cl^- is then secreted by passive movement down an electrochemical gradient through selective apical membrane Cl^- channels (**E**). Under normal basal conditions, Na^+ is absorbed from the lumen down its electrochemical gradient. Cl^- and water are passively absorbed through a permeable paracellular pathway (**F**) secondary to net Na^+ movement toward the interstitium. Water secretion occurs when the electrochemical gradient favors Cl^- movement into the airway lumen. Cl^- secretion requires activation of apical Cl^- channels.

The predominant direction of fluid movement under basal conditions is from airway lumen to interstitium. Fluid accumulates in the proximal airways as secretions converge from distal regions of greater cross-sectional area via mucociliary transport. Fluid homeostasis is maintained primarily by absorption of Na^+ from the airway lumen down an electrochemical gradient. Cl^- and water follow Na^+ through permeable paracellular pathways. Net Cl^- secretion by epithelial cells is unusual under basal circumstances. However, inhibition of Na^+ absorption, with amiloride, for example, may shift the electrochemical gradient in favor of Cl^- secretion. Furthermore, Cl^- secretion may be stimulated by several neurohumoral agents. Prostaglandins E_2 and F_{2a}, b-adrenergic agents, leukotrienes, adenosine, vasoactive intestinal peptide (VIP), and bradykinin stimulate epithelial Cl^- and water secretion; these mediators activate intracellular second messengers (cAMP, diacylglycerol, Ca^{2+}) that in turn activate apical Cl^- channels and lead to net water secretion.

As previously noted, effective mucociliary clearance depends on mucosal epithelial cell electrolyte and fluid transport. Mucociliary transport forms an important defense against foreign material that comes in contact with the mucosal surface of the airway. The fluid component of the mucociliary transport system is produced by secretory epithelial cells and submucosal glands. Two layers of fluid cover the airway mucosa (Fig. 3). A thin, watery sol layer of low viscosity is in direct contact with epithelial cells and allows free movement of cilia. A slightly thicker and more viscous gel layer rests above the sol layer and traps particulate matter for removal by rhythmic ciliary beating. The sol layer is produced by secretory epithelial cells, whereas the more viscous gel layer arises from submucosal glands.

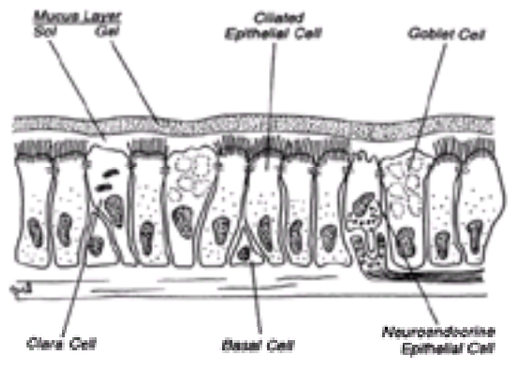

FIG. 3. Histology of conducting airway epithelium.

Epithelial secretory cells of the conducting airways are generally of three varieties. Goblet cells produce a complex mixture of glycoprotein, lipid, immunoglobulin, salt, and water. Serous epithelial cells contribute neutral glycoproteins, lysozyme, and an epithelial transport component of IgA to the sol layer. Clara cells are nonciliated epithelial cells found in highest density in the bronchioles. These cells demonstrate secretory granules containing lipid, protein, and neutral glycoprotein. It has been suggested that Clara cells secrete the hypophase of the surfactant layer.

The clinical impact of epithelial secretory function is demonstrated in cystic fibrosis. In cystic fibrosis, abnormally increased epithelial Na^+ absorption and decreased Cl^- secretion result in relatively dehydrated mucus and defective mucociliary transport. As a result, individuals with cystic fibrosis frequently have severe respiratory infections.

Metabolism

Epithelial cells of the conducting airways are generally metabolically active cells engaged in production of mucoid secretions, electrolyte transport, and xenobiotic metabolism. Synthesis and release of soluble mediators, such as the eicosanoids prostacyclin (PGI_2) and PGE_2, have been reported. Lung epithelial cells demonstrate antioxidant defense mechanisms against free radical oxygen species that may arise from endogenous oxidative metabolism; high concentrations of inspired oxygen, ozone, or airborne chemicals; and circulating xenobiotic compounds.

Xenobiotic Metabolism

Xenobiotic metabolism is largely a function of the liver; however, the presence of xenobiotic metabolizing enzymes in the human lung is well documented. These pathways generally involve both metabolic (phase I) and conjugative (phase II) reactions. Phase I reactions include oxidation, reduction, or hydrolysis; they generate metabolites that may or may not retain pharmacologic activity of the original xenobiotic. Oxidative reactions most often involve metabolism via the cytochrome P_{450} enzyme system. Phase II reactions involve glucuronidation, sulfation, acetylation, or conjugation with glutathione or amino acids. These reactions render the parent xenobiotic, or its metabolite, water-soluble and devoid of pharmacologic activity.

Relatively low concentrations of several xenobiotic deactivating enzymes have been identified in the lung (Table 3). The fact that the distribution of xenobiotic metabolizing enzymes is limited to Clara cells and type II alveolar epithelial cells may account for the relatively low levels of these enzymes in the lung as a whole. Cytochrome P_{450} mono-oxygenase activity has been localized within Clara cells of the conducting airways. Other phase I enzymes, including ethoxycoumarin-*O*-de-ethylase, a microsomal enzyme that catalyzes *O*-demethylation, and epoxide hydrolase, which catalyzes hydrolysis of epoxides arising from oxidative metabolism, have been identified in the lung. Their cellular distribution is less well defined. Activity of several conjugative enzymes has also been demonstrated in the lung; these enzymes include glutathione-*S*-transferases, acetyltransferase, and sulfotransferases.

	Lung	Liver	Intestine	Kidney
Phase I activity				
ECOD	1.0	20.6	0.5	1.2
mEH	0.1	2.1	<0.1	<0.1
Phase II activity				
GST	0.1	0.2	0.1	0.2
AT	0.1	0.7	0.3	0.2
P-ST	<0.1	0.1	<0.1	<0.1

ECOD, ethoxycoumarin-*O*-de-ethylase; mEH, microsomal epoxide hydrolase; GST, glutathione-*S*-transferases; AT, acetyltransferases; P-ST, phenol sulfotransferases.

[a] The table shows relative activities of five enzymes in lung, liver, intestine, and kidney. All activities, which are expressed relative to ECOD in lung, were derived from data presented by Krishna and Klotz.

TABLE 3. *Relative activities of deactivating enzymes in major organ systems*[a]

Many circulating basic lipophilic amines undergo first-pass retention in the lung as a result of endothelial metabolism. Significant first-pass removal has been demonstrated for propranolol, meperidine, fentanyl, and sufentanil, as examples. Retention and extraction of drugs is a function of diffusion or active transport of the substance into the intracellular compartment, followed by enzymatic modification. First-pass retention appears to be a partially saturable phenomenon, whereas overall extraction occurs independently of substance concentration.

Antioxidant Defense

By virtue of its large surface area that is continuously exposed to environmental air, the respiratory epithelium is at risk for damage caused by free radical oxygen metabolites. Generation of free radicals from exogenous sources may be achieved by direct interaction between inhaled agents and epithelial cells, and indirectly via activation of airway inflammatory cells that generate large quantities of reactive oxygen species. Endogenous oxidative metabolism also generates oxygen-derived free radical species that may interact with cell membrane phospholipid moieties and glycoproteins and thereby disrupt their structural integrity. Reaction of oxygen-derived free radicals with cellular components is thought to contribute to the pathogenesis of many disease processes, including bronchopulmonary dysplasia, asthma, emphysema, pulmonary fibrosis, and ARDS (adult respiratory disease syndrome).

The most biologically active oxygen species include superoxide, hydrogen peroxide, hydroxyl radical, and nitric oxide, although several other species have been identified. Superoxide is generated as a by-product of mitochondrial respiration or by interaction of microsomal and nuclear membrane cytochromes with oxygen; it subsequently spontaneously dismutates or is scavenged by superoxide dismutase. Hydrogen peroxide is formed indirectly from enzymatic and nonenzymatic dismutation of superoxide or directly by a cytoplasmic reaction catalyzed by xanthine oxidase. Hydrogen peroxide decomposes into water and oxygen in the presence of catalase. Hydrogen peroxide and alkylhydroperoxides are also scavenged by glutathione redox reactions. Superoxide and hydrogen peroxide react to generate hydroxyl radicals. Hydroxyl radicals also arise from Haber-Weiss and Fenton reactions, which are catalyzed by trace levels of transition metals such as Fe^{2+}. Nitric oxide is formed from the terminal guanidine nitrogen atom of L-arginine by NADPH-dependent oxidation; the reaction is catalyzed by nitric oxide synthase. Although nitric oxide has become well-known for its favorable vasodilatory properties, it can react with superoxide to form peroxynitrite, which degenerates into other very potent mediators of oxidant injury. Free radicals may be released into the extracellular environment if they are produced in quantities that exceed intracellular scavenging mechanisms.

Lung antioxidant defense mechanisms protect airway epithelial and other cell types from harmful effects of reactive oxygen species generated by endogenous metabolism and inhaled chemicals. The major intracellular defense mechanisms against reactive oxygen species include superoxide dismutase, catalase, and glutathione redox enzymes. Different cell populations within the lung vary in their resistance to oxidative injury. Although knowledge of antioxidant enzyme distribution in the human respiratory tract is limited, most antioxidant enzymes in the respiratory tract appear to be localized in the airways. Lower relative concentrations of mitochondrial superoxide dismutase and catalase are present in the bronchial epithelium. Extracellular superoxide dismutase is found in high concentrations in areas

rich in type I collagen, in connective tissues surrounding smooth muscle, and in the junctions between epithelial cells. Antioxidant enzymes that have been identified in other cell populations of the lung are discussed below with other functions involving those cell types.

Neuroendocrine Function

Cells with neuroendocrine characteristics have been identified in the respiratory tract of humans and several other animals. Sensitive immunocytochemical and radiolabeling techniques have localized a wide variety of peptide mediators in the lung (Table 4). Although many of these mediators have been localized in association with autonomic nerve fibers, the present discussion is limited to their association with neuroendocrine epithelial cells and pulmonary vascular endothelial cells.

Peptides associated with parasympathetic nerves
Vasoactive intestinal peptide (VIP)
Peptide histidine isoleucine (PHI)
Galanin
Peptides associated with sympathetic nerves
Neuropeptide Y (NPY)
Peptides associated with sensory nerves
Calcitonin gene-related peptide (CGRP)
Substance P
Peptides associated with endocrine cells
Calcitonin gene-related peptide
Calcitonin
Gastrin-releasing peptide or bombesin (GRP)
Endothelin
Enkephalin
Serotonin (5-HT)
Somatostatin
Cholecystokinin
Substance P
Human chorionic gonadotropin (HCG)
Pancreatic secretory trypsin inhibitor
Pituitary adenylate cyclase-activating peptide
Peptides associated with pulmonary endothelium
Prostacyclin
Endothelial-derived relaxant factor (EDRF/nitric oxide)
Acetylcholine
Endothelin
Peptide associated with large pulmonary vessels
Atrial natriuretic peptide (ANP)

TABLE 4. *Peptide mediators identified within the lung*

Neuroendocrine Epithelial Cells

Epithelial cells that produce peptide mediators have been identified throughout the tracheobronchial tree. These neuroendocrine epithelial cells are demonstrated with silver impregnation staining or antibodies to general endocrine markers, such as chromogranin. Neuroendocrine epithelial cells of the airways share many characteristics with APUD (amine precursor uptake and decarboxylation) cells of the diffuse neuroendocrine system. In humans, pulmonary neuroendocrine epithelial cells are identified by expression of peptide mediators, such as gastrin-releasing peptide (bombesin) and serotonin. In human fetal bronchi, neuroendocrine epithelial cells appear as early as at 8 weeks' gestation and may be involved in regulation of normal lung development. Peptides are expressed in a differential pattern during human airway development. Gastrin-releasing peptide is the primary peptide produced during early human fetal development, whereas calcitonin predominates later in development.

Limited evidence suggests that tracheobronchial neuroendocrine epithelial cells communicate with nonadrenergic, noncholinergic neurons located within the airways. The significance of this communication is unclear. Large numbers of neuroendocrine epithelial cells develop in the airways of animals subjected to experimental hypoxia and in humans who live at high altitudes. From these observations, it has been postulated that neuroendocrine epithelial cells serve a chemosensitive function and relay information about air oxygen content to the central nervous system.

FUNCTIONS RELATED TO THE ALVEOLAR SPACE

Metabolism

The alveolar surface is lined by two distinct populations of epithelial cells (Fig. 4). Type I alveolar epithelial cells are thin, flattened cells that cover approximately 95% of the alveolar surface; they are thought to be relatively quiescent metabolically and form the epithelial surface of the gas diffusion barrier. Type II alveolar cells, in contrast, are cuboidal, metabolically active epithelial cells that cover the remainder of the alveolar surface.

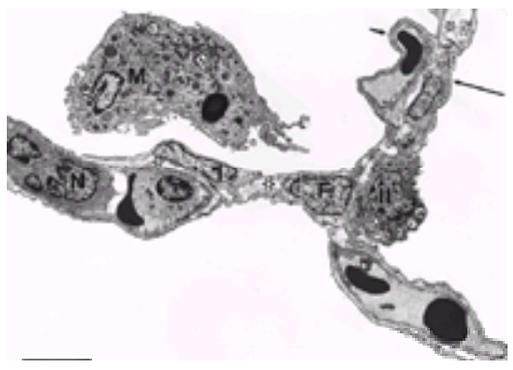

FIG. 4. Morphology of alveolar septum from a normal human lung. *M,* macrophage; *I,* type I alveolar epithelial cell; *II,* type II alveolar epithelial cell; *F,* interstitial fibroblast; *N,* intravascular neutrophil. *Bar* = 5 µm. Note the relatively thin air-blood barrier (*short arrow*) along at least one side of most capillaries. In the region of the *small arrow,* the thickness of the air-blood barrier is less than 0.5 µm. The diameter of the alveolar capillaries is less than 5 µm in most regions. The thick portions of the alveolar septal blood-gas barrier (*long arrow*) commonly range from 3 to 5 µm in thickness and contain connective tissues (*asterisk*) and fibroblasts within the interstitium.

Type II alveolar epithelial cells are the source of pulmonary surfactant, as discussed below. They also demonstrate a capacity for xenobiotic metabolism, as well as enzyme activities that protect against oxidant stress. Type II cells secrete soluble factors that act locally to modulate functions of other lung cells, such as fibroblasts. These regulatory mediators may be important in the coordination of normal lung development, as well as in repair of a damaged alveolar region. Among soluble factors produced by type II cells are several eicosanoids (PGI_2, PGE_2, TXB_2, LTB_4, and LTC_4). The functions of type II cell-derived eicosanoids are poorly defined but may be important in regulation of regional blood flow and ventilation-perfusion matching.

Several investigators have shown that type II alveolar cells synthesize and secrete extracellular matrix components in vitro. Moreover, cultured type II cells participate in the turnover of their underlying substratum. It has been postulated that type II cell matrix synthesis and turnover may be important in repairing damaged substratum such that it will support restoration of differentiated alveolar epithelial cell function.

Surfactant Turnover

Pulmonary surfactant is a complex lipoprotein substance forming a thin fluid film over the alveolar surface. Surfactant is a heterogeneous substance composed of lipid (primarily phospholipid) and specific surfactant-associated proteins (SP-A, SP-B, SP-C, and SP-D). Surfactant is best known for its role in lowering surface tension at the alveolar air-liquid interface; more recent evidence suggests that surfactant is also important in host defense against invading organisms, and that it contains antioxidant enzyme activity.

Type II alveolar epithelial cells synthesize and secrete the lipid and apoprotein components (SP-A, SP-B, SP-C, and SP-D), as demonstrated schematically in Fig. 5. Surfactant is stored in cytoplasmic lamellar bodies that fuse with the cell membrane to release surfactant components into the alveolar space by exocytosis. Surfactant secretion is regulated by soluble mediators, such as glucocorticoids and b-adrenergic agonists, as well as by intracellular second messenger signals generated by mechanical strain in the type II cell.

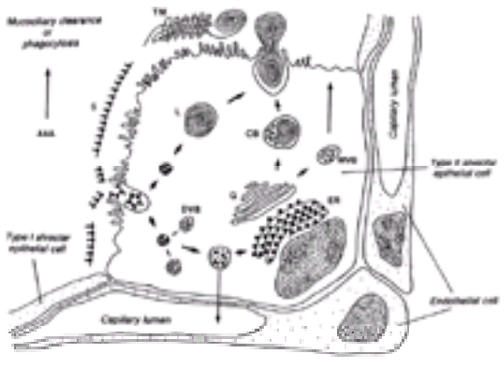

FIG. 5. Pathways of blood coagulation. Surfactant phospholipid and apoproteins are synthesized in the endoplasmic reticulum (*ER*). Phospholipid components are released from the Golgi (*G*) as lamellar bodies (*L*) or combination bodies (*CB*) containing both phospholipid and apoprotein moieties. Surfactant apoproteins may also be released from the Golgi packaged as multivesicular bodies (*MVB*). Lamellar bodies are secreted from the type II alveolar epithelial cell by exocytosis. Surfactant apoproteins A, B, and C are thought to be secreted with lamellar body phospholipids; it has also been suggested that surfactant apoprotein A may be secreted directly from multivesicular bodies. Following exocytosis, the lamellar body uncoils into a lattice structure designated as tubular myelin (*TM*), which subsequently forms the phospholipid-rich surfactant monolayer (*S*) at the air-liquid interface. Surfactant components are cleared from the alveolar space by several mechanisms. A small amount of surfactant may be removed by mucociliary clearance or alveolar macrophage phagocytosis. The type II cell actively clears surfactant components by endocytosis. Some surfactant that has undergone endocytosis is recycled directly into lamellar bodies and resecreted; other surfactant components are metabolized by enzymes contained within dense microvesicular bodies (*DVB*). Metabolized surfactant components may then be recycled for synthesis of new surfactant or released into the circulation for elimination.

Following secretion, surfactant components transform into a three-dimensional, latticelike structure, tubular myelin. Tubular myelin is thought to be a precursor to the surface tension-lowering film of dipalmitoylphosphatidylcholine. Alveolar surfactant is in a constant state of flux; it turns over every 5 to 10 hrs. The quantity of surfactant in the alveolar space is adjusted with changes in alveolar volume, so that an adequate reduction in surface tension is provided at all times. Adjustments in the surfactant pool occur rapidly; alveolar surfactant can increase by 60% during exercise and quickly return to pre-exercise levels with rest.

Clearance of surfactant from the alveolus may involve uptake and resecretion, degradation and incorporation into new surfactant, or complete removal from the surfactant pool. Turnover studies *in vivo* demonstrate that surfactant components are internalized by type II cells and resecreted. Other investigations suggest that surfactant is degraded by type II cells, alveolar macrophages, or within the surfactant fluid layer, and its degradation products are incorporated into newly synthesized surfactant components. Removal of surfactant from the lung may also occur by movement up the mucociliary escalator and swallowing, transfer across the alveolar endothelial-epithelial barrier into the lymph and blood, or degradation and transfer of breakdown products to other organs.

Excretion of Volatile Substances

The importance of human lung in excretion is readily demonstrated by its ability to eliminate the equivalent of more than 10,000 mEq of carbonic acid each day. Details of this important respiratory function have been discussed elsewhere in this volume. Several nonrespiratory metabolites that are volatile at body temperature are also excreted from the alveolar surface. A large number of volatile compounds arise from normal endogenous metabolism; they may also arise from pathologic metabolic pathways characteristic of certain disease states. Measurement of volatile substances in expired air can provide useful diagnostic information relating to abnormal metabolic processes or ingestion of toxic substances. Measurement of breath alcohol concentration, for instance, is used commonly to determine the degree of intoxication.

More than 300 volatile organic compounds have been detected in exhaled air from humans. Most of these substances are hydrocarbons that are either aliphatic (alkanes, alkenes, alkynes) or aromatic (benzene) in nature. The source of exhaled hydrocarbons is often uncertain. A significant number of aliphatic and aromatic hydrocarbons are detectable in expired air by virtue of their prevalence in ambient air. Cigarette smoking is a source of hydrocarbons such as ethene, propene, and propane. A variety of normal and pathophysiologic metabolic processes give rise to volatile carbohydrates that may be excreted from the lung. Hydrocarbons are primarily eliminated by cytochrome P_{450} metabolism in the liver; a smaller number are excreted as volatile gas from the alveolar surface. Lung hydrocarbon excretion assumes a more important role in conditions associated with decreased hepatic cytochrome P_{450} activity.

Certain volatile constituents of exhaled air reflect specific underlying disorders of metabolism. For instance, elevated breath levels of isoprene have been reported in hypercholesterolemia. Isoprene is a breakdown product of dimethylallylpyrophosphate and thereby is linked to the synthesis of the cholesterol precursor, mevalonic acid. The presence of acetone in exhaled breath during ketoacidosis is a well-known phenomenon. Limited glucose availability in conditions such as diabetes mellitus and starvation results in increased mobilization and oxidation of fatty acids. In turn, the production of acetoacetate, acetone, and/or b-hydroxybutyrate increases, and consequently acetone can be detected in urine and exhaled breath. Methylmercaptan, a derivative of methionine metabolism, is excreted from the alveolar surface in hepatic failure and imparts a distinctive odor (fetor hepatis) to exhaled air.

Measurement of breath hydrogen concentration has been employed as an indicator of carbohydrate malabsorption; bacterial breakdown of unabsorbed carbohydrate in the intestine releases hydrogen. Methane is also released by bacterial metabolism in the intestine in some individuals. Furthermore, bacteria in the intestinal tract of methane excretors may convert hydrogen to methane. Combined measurement of breath hydrogen and methane levels has been advocated as a useful indicator of carbohydrate malabsorption in methane excretors.

A large group of volatile hydrocarbons is generated by oxygen radical-induced peroxidation of cellular lipids and proteins. Free radicals generated by ionizing radiation, chemical exposure, physical stress, and other factors may overwhelm endogenous antioxidant defenses and react with polyunsaturated fatty acids and cell glycoproteins to disrupt cell membranes and other structures. The major end products of lipid peroxidation in humans are ethane (arising from degradation of the 3-carbon family of polyunsaturated fatty acids, e.g., linolenic acid) and pentane (arising from degradation of the 6-carbon family of polyunsaturated fatty acids, e.g., linoleic acid and arachidonic acid). Aldehydes and ketones (acetaldehyde, propanal, pentanal, hexanal, and acetone among others) also arise from n-3 and n-6 polyunsaturated fatty acid metabolism and are detectable in human breath. Several investigations have produced data that suggest measurement of breath ethane and pentane concentrations is a useful noninvasive means of evaluating lipid peroxidation in humans.

Lipid peroxidation has been implicated in the pathobiology of aging and a multitude of other pathophysiologic processes. Measurement of breath hydrocarbon levels may have diagnostic potential in disease processes that involve lipid peroxidation. In fact, elevated breath levels of hydrocarbons have been reported after acute myocardial infarction, in relation to lung malignancy, in cirrhosis, and in neurologic illnesses, including multiple sclerosis and schizophrenia.

FUNCTIONS RELATED TO THE VASCULAR COMPARTMENT

Filtration

The pulmonary capillary bed serves as a filter that detains formed blood elements and particulate matter larger than the average capillary diameter of 8 to 10 µm. Pulmonary arterioles may remove larger particles as they taper distally into the capillary network. Filtration in the lung protects other, more sensitive organs, such as the brain and heart, from disabling, or even fatal, effects of particulate embolism.

The lungs commonly remove thrombi that migrate from the peripheral venous circulation. Most of these thrombi are small and do not significantly compromise gas exchange function of the lung. Pulmonary thromboembolism has been identified in as many as two thirds of consecutive patients undergoing autopsy. These observations may provide an underestimate of the true incidence of pulmonary thromboembolism, as intrinsic thrombolysis may remove clot in many instances.

Filtration of cellular elements in the lung may provide a mechanism for modifying the cellular composition of circulating blood. Studies of venous and arterial blood demonstrate higher numbers of megakaryocytes in venous blood and greater numbers of platelets in arterial blood. These findings suggest that megakaryocytes released from the bone marrow are detained and fragmented in the pulmonary circulation. Autopsy observations confirm the presence of significant numbers of megakaryocytes within the lung.

Both white and red blood cells are removed from circulating blood as it traverses the lungs. Lymphocytes and leukocytes may be detained in the pulmonary vascular bed. Limited evidence from transfusion of leukemic blood suggests that the lungs may serve to maintain a preset level of circulating leukocytes. The lung also removes

damaged or lysed erythrocytes.

The lung traps a number of other physiologic emboli, including air, fat, bone marrow, and fragments of placental tissue or amniotic fluid during pregnancy. Malignant cells that have migrated from other tissues may be captured by the lung and establish pulmonary metastases. Infectious organisms can also migrate from other sites and establish infection in the lung. Pulmonary complications of infectious emboli most commonly result from tricuspid or pulmonic valve endocarditis. Foreign materials, such as talc, may be filtered from the venous circulation in intravenous drug users.

Although gas exchange can be disrupted by detention of certain blood particulates, embolic events are often physiologically insignificant or completely reversible if limited to the lung. Enzymatic destruction or phagocytosis of particulate material in lung may prevent fatal embolic events in more sensitive organs, such as the brain.

Metabolism

The pulmonary vascular endothelium forms an expansive blood-tissue barrier that is exposed to the entire volume of cardiac output and, thereby, is uniquely positioned for metabolic functions. Products of endothelial metabolism can be released directly into the circulation; moreover, a number of circulating peptide mediators, lipids, and nucleotides undergo processing by pulmonary endothelial cells (Table 5).

Substances metabolized after endothelial uptake
Serotonin
Prostaglandins E and F
Leukotrienes
Norepinephrine
Substances metabolized at the endothelial surface
Bradykinin
Angiotensin
Adenine nucleotides

TABLE 5. *Vascular endothelial metabolism in the lung*

Several peptide mediators arise from pulmonary vascular structures. Atrial natriuretic peptide (ANP) is produced, stored, and released from specialized myocardial cells that extend into the pulmonary veins. ANP mediates pulmonary blood vessel and airway smooth muscle relaxation. Pulmonary vascular endothelium produces a number of vasoactive and bronchoactive mediators. Prostacyclin and endothelial-derived relaxant factor (EDRF/nitric oxide) have vasodilator properties, whereas endothelin produces vasoconstriction and bronchoconstriction. Endothelin has been shown to have trophic effects on smooth muscle cells and fibroblasts that may be important in repair of damaged lung.

Some circulating substances are processed by lung endothelial cells after being transported from the circulation to the intracellular compartment. The best-known example of intracellular metabolism of circulating compounds is serotonin. Serotonin, or 5-hydroxytryptamine (5-HT), is primarily synthesized from tryptophan in endocrine cells of the gastrointestinal tract. 5-HT serves as a central nervous system neurotransmitter; its release from circulating platelets promotes platelet aggregation. After secretion by the gastrointestinal tract, 5-HT is taken up and stored by nerve endings and platelets, or removed from the circulation by liver and lung.

The lungs remove serotonin from the circulation by a sodium-dependent, carrier-mediated process. After 5-HT is taken up by endothelial cells, it is rapidly metabolized by monoamine oxidase and aldehyde dehydrogenase to physiologically inactive 5-hydroxyindole acetic acid (5-HIAA). Elevated urinary excretion of 5-HIAA is noted in patients with carcinoid syndrome, a neoplasm of endocrine argentaffin cells (APUD cells) characterized by oversecretion of 5-HT. Pulmonary endothelial cells also remove norepinephrine and prostaglandins of the E and F series from the circulation via an active transport process.

Metabolic processing of other substances occurs at the cell surface without intracellular uptake. Perhaps the best-known example of a substance that undergoes metabolism at the cell surface is angiotensin. Angiotensin-converting enzyme, a carboxypeptidase, activates the vasoconstrictor, angiotensin II, from a decapeptide precursor molecule, angiotensin I. Angiotensin I is produced by the enzymatic action of renin on circulating angiotensinogen secreted by the liver. Bradykinin and adenine nucleotides also are inactivated at the pulmonary endothelial cell surface.

Hemofluidity

Normal respiratory functions of the lung depend on continuous blood flow through the pulmonary vascular bed. The entire cardiac output passes through the pulmonary vascular system, making these vessels vulnerable to damage by circulating organisms, toxins, and embolic material. Whereas injured pulmonary vessels may provide a nidus for bleeding or clot formation, intrinsic mechanisms that determine hemostasis and anticoagulation are modulated by the pulmonary vascular endothelium.

Clotting results from the generation of thrombin by either intrinsic or extrinsic pathways of coagulation (Fig. 6). The intrinsic pathway is initiated by interaction between clotting factors and injured vessel wall or platelets; activation of the extrinsic pathway requires release of lipoprotein activity (tissue factor) from damaged tissue. Coagulation by either pathway involves controlled interaction of several clotting factors that converge with the activation of factor X. Activated factor X catalyzes the conversion of prothrombin to thrombin; thrombin in turn cleaves soluble fibrinogen to create a meshwork of insoluble fibrin strands. Platelets and red cells are trapped among the fibrin strands to form a stable clot. In addition to cleaving fibrinogen to fibrin, thrombin also cleaves factor XIII to stabilize the fibrin clot.

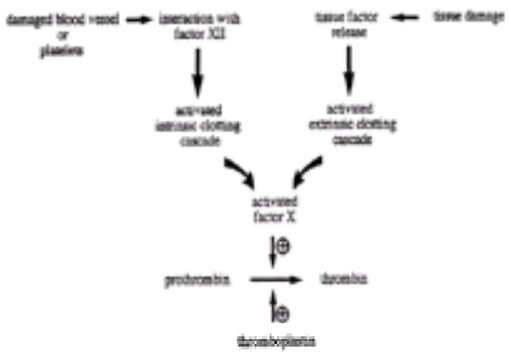

FIG. 6. Schematic representation of surfactant turnover.

Generation of thrombin in the lung is also mediated by thromboplastin. Thromboplastin is a phosphatide-protein complex, found in abundance in the lung, that augments conversion of prothrombin to thrombin.

Thrombin is involved in limitation, as well as initiation, of clot formation (Fig. 7). Thrombin interacts with the endothelium via thrombomodulin to activate protein C, which inhibits clotting factors V and VIII and activates fibrinolysis. In addition to activating protein C, thrombin also initiates release of plasminogen activator from endothelial cells. Plasminogen activator in turn cleaves circulating plasminogen to plasmin, which digests fibrin. The vascular endothelium can also bind and inactivate thrombin; furthermore, it can modify coagulation by releasing the vasodilator prostacyclin in response to thrombin.

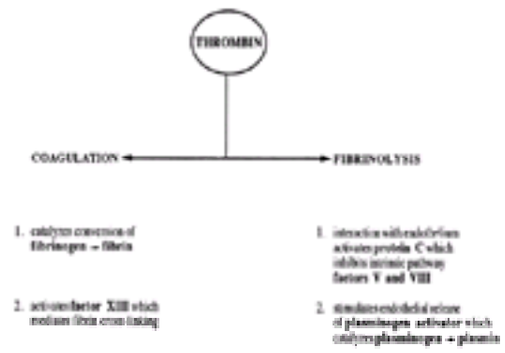

FIG. 7. Modulation of clotting and fibrinolysis by thrombin-dependent mechanisms.

CONCLUSION

Although the respiratory system is specialized for gas exchange, it also performs many important nonrespiratory functions. The functional diversity of the lung arises from its unique organization of heterogeneous constituent cells into branching airways ending in an expansive gas exchange surface intimately surrounded by an extensive capillary network through which the entire cardiac output flows. Structural features of the conducting airway system provide important functions in nonrespiratory activities such as speech, heat and water conservation, and host defense against inhaled foreign material or organisms. Cells of the conducting airways, alveolar region, and pulmonary vascular system participate in many nonrespiratory functions, including electrolyte and water transport, xenobiotic metabolism, antioxidant defense, surfactant production and turnover, neuroendocrine secretion, excretion of volatile substances, and maintenance of hemofluidity. Many nonrespiratory activities of the lung serve to maintain the gas exchange integrity of the respiratory system. Other nonrespiratory activities are important in maintaining physiologic homeostasis overall.

INTRODUCTION

The worldwide poliomyelitis epidemic in the 1950s affected millions of people. The polio virus targeted many motor neuron pools, amongst which were those in charge of ventilation control causing, in many cases, clinical ventilatory failure. An ingenious, albeit palliative, answer to this type of ventilatory failure was the development of the iron lung, an external negative pressure ventilator that saved the lives of countless patients infected during the epidemic. The purpose of assisted ventilation was not to restore the function of the motor neurons, but to take over the work of the failing muscles. Even though polio is now very infrequent in the developed parts of the world, the use of ventilators has increased and the machines have evolved in sophistication and capability. Close to half of all patients admitted to intensive care units require mechanically assisted ventilatory support. Almost all the ventilatory support currently provided uses positive rather than negative pressure, but the overall aims and principles remain the same: to replace the flailing chest. This book has several chapters devoted to mechanical ventilation. In this introduction we point out how, under a variety of clinical conditions, the ventilatory control lapses, and muscles fail to ventilate the lungs, whose final result is ventilatory failure with hypoxia and, frequently, hypercapnia.

Basically, ventilation depends upon the ability of the respiratory pump to move air in and out of the gas exchange portion of the lung. The respiratory muscles serve as the vital link between the different components of the pump: the respiratory centers, the conducting nerves and, ultimately, the lung itself.

The respiratory muscles contract during the breathing cycle, thereby changing the anatomical configurations of the chest wall by displacing its components, so that air can move in and out of the lungs. This chapter systematically analyzes the overall anatomical and physiological arrangements of the respiratory muscles. It specifically addresses the clinical application of these concepts, and familiarizes the reader with the different clinical conditions that are described in other portions of this textbook.

ANATOMICAL CONSIDERATIONS

There are many muscles that participate in ventilation, and they can be divided into those that are inspiratory in action and those that, by their anatomical arrangement, are predominantly expiratory in function. In turn, the inspiratory muscles are divided into ones that actively contribute to inspiratory pressure generation during regular tidal breathing (the so-called primary muscles of respiration) and the accessory muscles, which are activated to participate in ventilation under conditions of increased ventilatory demands.

There are also muscles that participate in breathing whose function is not primarily to displace the ribcage or abdomen. These muscles, located in the upper airways, act to prevent the collapse of the conduits and, in this way, facilitate airflow. The pharyngeal constrictor muscles, genioglossus, and neck strap muscles all increase patency of the pharynx, while the laryngeal abductor muscles open the vocal cords. The activation of these muscles must be synchronized, and actually precede the contraction of the inspiratory muscles.

The diaphragm is the most important muscle of inspiration. As shown in Figure 1, it has a central noncontractile tendon, from which muscles fibers radiate down and outwards to fit into the lower ribcage, and in the first 3 lumbar vertebrae. During contraction, it assists lung inflation through three mechanisms. The diaphragm uses the abdomen as a fulcrum against which it leans, thereby expanding the rib cage. During contraction, the diaphragm also helps inflation because of the cephalocaudal orientation of its fibers, and the curvature of its shape. This anatomical arrangement will expand the ribcage as the fibers shorten. The curvature of the diaphragm approximates the shape of a hemisphere with a radius r. Laplace's law for a sphere states that P = 2T/r, where P is the pressure inside the sphere, and T is the tension in the wall. If T is maintained constant and the diaphragm flattens, its curvature will decrease, r will increase and, by definition, P must decrease. Finally, the diaphragm transmits the increase in abdominal pressure during contraction to the rib cage, through its zone of apposition. This action also has an expansive action on the ribcage.

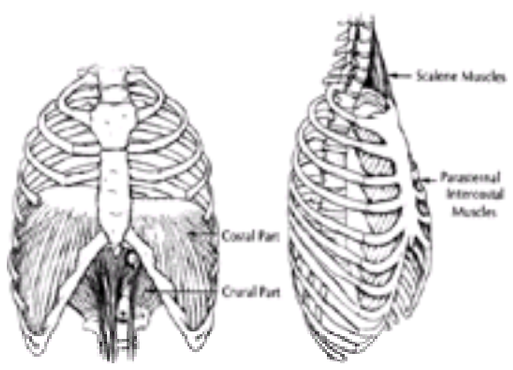

FIG. 1. The left panel shows the human diaphragm in situ at the full expiratory position. Notice the non-contractile central tendon, the radical cephalocaudal orientation of its fibers, and how it is opposed the inner aspect of the lower ribcage. The right panel shows the parasternal intercostal and scalene muscles. Only the left scalene muscles are shown, to illustrate their origin on the spine and their insertion on the first rib.

Patients with COPD characteristically develop lung hyperinflation, causing an increase in the resting volume of the ribcage. It is believed that hyperinflation reduces diaphragmatic strength by shortening of the diaphragmatic fibers, which places the muscle at a suboptimal point on its length tension curve. However, recent studies have demonstrated that when diaphragmatic fibers are experimentally shortened, the muscles adapt by dropping sarcomeres and achieving a new optimal length, so that each bundle is capable of generating its maximal tension for that new length. It can therefore be implied that the decreased diaphragmatic pressure generating capacity in COPD patients is either due to anatomical and mechanical derangement, or to contractile dysfunction, and not to simple length-tension changes.

The other primary inspiratory muscles (some of them also shown in Fig. 1) are the external intercostals, the parasternal part of the internal intercostals, the triangularis sterni and the scalene. They are activated during tidal breathing in normal individuals, but significantly increase their participation in ventilation during increased ventilatory demand. They play a particularly important role in diseases characterized by hyperinflation such as in COPD because they undergo less anatomic shortening, and therefore operate at a lesser mechanical disadvantage than the diaphragm. On the other hand, the true “accessory muscles”, i.e. the sternomastoid, subclavian, pectoralis minor and major, serratus anterior, upper and lower trapezius, and latissimus dorsi, which are usually inactive during normal breathing may

become increasingly important under special circumstances, like in strenuous exercise and in cases of severe ventilatory load. They are also active in patients with severe COPD.

There are other muscles that are not thought to be respiratory in nature such as the muscles of the shoulder girdle. These muscles have dual actions that include fixing the upper ribcage, partaking in upper torso positioning and elevating the upper extremity. They may also exert a pulling action on the rib cage, when they contract and are fixed at their extrathoracic anchoring point. Because of this, patients with severe COPD will often find relief to their dyspnea when they lean on a surface and fix their shoulder girdle.

The respiratory muscles have functions other than breathing. They also participate in very complex functions, like speaking and singing. This requires the simultaneous activation of the inspiratory and expiratory muscles. In other instances synchronous expulsive maneuvers will be needed to achieve other functions such as sneezing, vomiting, and defecating. They may also need to act in concert to facilitate parturition and micturition. A unique aspect of to the respiratory system is the sneezing and coughing reflex. These maneuvers require an initial deep inspiratory effort, followed by the closure of the glottis and a forceful contraction of the diaphragm and the abdominal muscles. When the upper airways are suddenly opened, the increased intra-abdominal pressure results in an explosive expiratory effort. This sudden increase in peak flow helps clear airways, and is very important for the management of secretions. Conditions that result in impaired coughing frequently results in the accumulation of secretions in the lungs, leading to development of atelectasis.

Physiologic Principles

There are two basic principles that control the behavior of muscles when subjected to physiologic stimuli. They are applicable to muscles in general and also include the respiratory muscles. The first is the relationship between the length of a muscle and its capacity to generate force (Fig. 2). The muscle generates more force as it lengthens until it reaches an optimal length. Stretching the muscle beyond that point is associated with decreased strength, until the muscle fibre brakes. More importantly, as the resting length of a muscle shortens (which occurs in diseases that cause lung hyperinflation) the force generating capacity for a given electrical stimuli decreases. In the case of the respiratory muscles, if a similar pressure is required to maintain ventilation then the only possible compensatory mechanism is the recruitment of more muscle fibers, i.e. increasing the motor output of the central nervous system, and then increase the firing rate to the muscle.

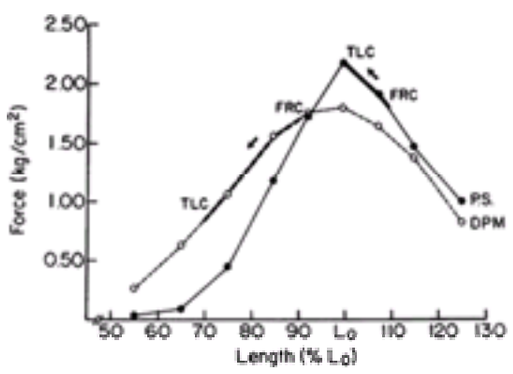

FIG. 2. The relationship between contractile force(kg/cm2) and resting length (%lo) for isolated, perfused strips of canine diaphragm (DPM) and parasternal (PS). Contractile force of both muscles is greatest at optimum resting length(LO). In situ, at functional residual capacity (FRC), the diaphragm is shorter and the parasternal muscles are longer than Lo, and loses force generating capacity. In contrast, the parasternal muscles shorten less. Towards their Lo, and gain force generating capacity. (Reproduced from Farkas G et al. J Appl Physiol 1985;59:528).

The second principle is that of the inverse relationship between the velocity of muscle contraction, and force generation capacity (Fig. 3). As the velocity of contraction increases (as in increased respiratory rate), the capacity to generate forces decreases. Although of limited clinical importance because of the usually relatively low speed of contraction of the respiratory muscles, it may become important at very fast breathing rates, or in patients whose respiratory ailment is associated with very short inspiratory times. Under resting breathing conditions the velocity of contraction and the inspiratory muscle force generated is about 5% of their maximal capacity. Up to 50% of maximal force or velocity can be sustained for prolonged periods of time (hrs).

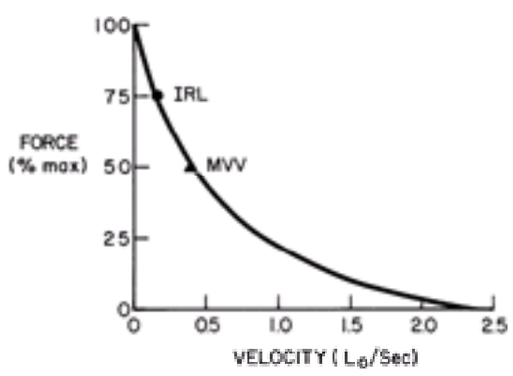

FIG. 3. Idealized representation of the relationship between contractile force(% of maximum) and velocity of shortening (Lo/s) of the human diaphragm. Maximum shortening velocity, measured in vitro, is about 2.5 Lo/s. The points identified as IRL and MVV are estimates of the shortening velocity when measured through a resistance (IRL) and during unencumbered maximal voluntary ventilation (MVV). As shortening velocity increase, force output falls. Force output during the MVV maneuver is estimated to be half that during the maximal static contraction of the diaphragm (Reproduced from Fishman A (ED), Update: Pulmonary diseases and disorders. New York : McGraw-Hill, 1992:88).

Skeletal Muscle Cell Types

Skeletal muscles are composed of different types of muscle fibers. Based upon histochemical staining they have been divided into types I, IIa, and IIb. Type I fibers have a high oxidative capacity and a low concentration of glycolytic enzymes. When activated, they develop a slow rise in force. Physiologically, they are the first to be recruited during muscle activation, because they generate low levels of force and are fatigue resistant. Type IIb fibers which have a low oxidative capacity and a high concentration of glycolytic enzymes, are the last to be recruited, and generate the optimal level of force quickly and may also fatigue rapidly. Type IIa has moderate enzyme concentrations, and is intermediate with respect to fatigability. The diaphragm is composed of approximately 50% Type I and 50% type II fibers, enabling it to withstand the enduring work it has to perform over an individual's lifetime. These properties of the skeletal muscle bear an important relevance to their response to training. In the case of the respiratory muscles, an increasing number of motor units are recruited with increased ventilatory loads, with the type I, IIa, and IIb fibers being recruited in a sequential fashion.

The effects of training on fiber composition vary, depending on the method of training utilized. Endurance training increases the myoglobin content, the capillary density, the mitochondrial density, and the oxidative enzyme capacity of type I fibers. In contrast, strength training increases fiber size (i.e. muscle hypertrophy); with little or no effect on enzyme concentration. Animal studies using biopsy specimens of the ventilatory muscles before and after different forms of training have shown the aforementioned training effects of the diaphragm and other inspiratory muscles. It is now becoming evident that these are a continuum on the fiber composition of type II cells, rather than two distant groups.

METABOLIC AND ENERGY DEMANDS OF THE RESPIRATORY MUSCLES

The concept that muscles behave in the same way as mechanical devices do by consuming energy and producing work, both of which are measurable, was developed in the early part of the twentieth century. Skeletal muscle efficiency was, in fact, reported to be about 25%, while respiratory muscle efficiency was noted to vary from 2% to 24%. The idea that a lack of energy supply, manifested in the form of insufficient oxygen and substrate, result in muscle failure is also well established. Because of these assertions, the role of blood perfusion has been widely explored; hyperpnea is equated to an increase in the blood flow of the diaphragm, as well as other

respiratory muscles. Blood flow to the diaphragm, increases by up to 260 mL/100gr min in maximally exercised ponies. This value which is similar to other skeletal muscles, is achieved by dilatation of the diaphragm vasculature.

Blood flow to the diaphragm has been studied during phrenic nerve stimulation. As opposed to limb muscles, where the duty cycle is relatively constant, the respiratory muscle's duty cycle can vary. The duty cycle is considered to be important because during contraction, the blood flow is either partially or completely interrupted, with flow restitution occurring during the relaxation phase. The first comprehensive study quantifying the relationship between diaphragmatic blood flow (Qdi) and the duty cycle was published by Bellemare et. al. In that study perfusion was related to the product of Pdi multiplied by the duty cycle. The mathematical product was called the tension (or pressure) time index, and has been very useful for defining the physiological behavior of the loaded diaphragm. The authors described a parabolic relation between TTdi and Qdi. Diaphragmatic perfusion rises up to a TTdi value of .20, then declines. Post contraction hyperpnea begins to increase, which is suggestive of blood flow limitation (Fig. 4). Earlier studies have, in fact, shown that the endurance time of the diaphragm when breathing against resistance was also related to the product of force developed and the duty cycle, and that time to task failure was predictable. If breathing was held at a TTdi of .20 or lower, that time is about one hour. In contrast, time to task failure will be about 15 min at TTdi of 0.30. Interestingly, a much higher Pdi (70% of Pdi max) can be also be sustained for 1h, provided that the duty cycle in decreased to .30, which gives more perfusion time (TTdi remains at 0.21). The effect of high tension is offset by the shorter duty cycle. The concept of a pressure threshold is, in reality, valid only if Ti/Ttot is 0.40 -0.45. A duty cycle of 0.30 is common among severe COPD patients. The concept of a threshold TTdi, below which task failure does not develop, and above which it will eventually occur, was proposed by Bellemare and Grassino and is graphically shown in Fig. 5. It should be noted that these results apply to the prevailing experimental conditions from which the data was obtained (constant perfusion pressure and square pressure wave). Regardless of the conditions, the results emphasize the relevance of blood perfusion to the maintenance of diaphragm contractility.

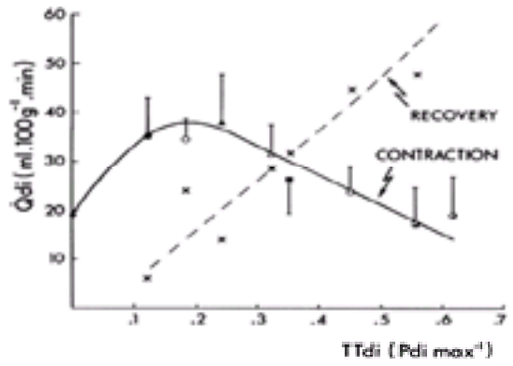

FIG. 4. Relationship between the diaphragmatic blood flow (Qdi) and the Tension Time index (Ttdi). Resting breathing values are the first point to the left. All subsequent data points were obtained with higher inspiratory resistances until a steady state was reached; bilateral phrenic stimulation was used. Peak values of Qdi were obtained at a Ttdi of .15 to .20. Higher Ttdi resulted in decreased flows. The dashed line represents the values of a post-stimulation Qdi. It increases linearly with the amount of Ttdi achieved by stimulation. This is an expression of O2 debt incurred.

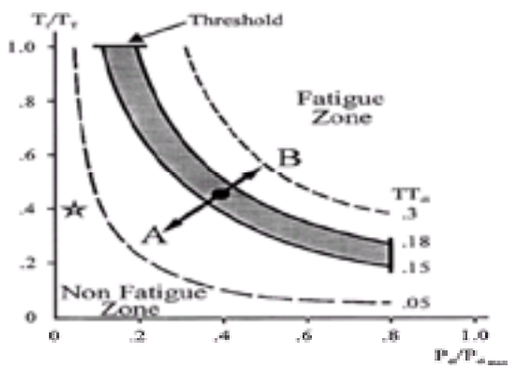

FIG. 5. The Tension Time (or Pressure Time) Index. It is the product of the inspiratory time expressed as a percentage of the total duration of the breathing cycle (Ti/Ttot), multiplied by the Pdi/Pdi max. (Mean trandiaphragmatic pressure developed expressed as a percentage of the Pdi maximal). Each point on the diagram defines a unique breathing pattern. Threshold: all breathing patterns in this zone can be sustained for 45 min or longer in normal human subjects breathing against inspiratory levels (Ttdi of .15 to .20). Fatigue zone: breathing patterns in this zone will result in a failure to sustain the pressure in less than 45 minutes. Muscle fatigue was the main cause of failure in the well motivated subjects. The main mechanism was insufficient blood flow as shown in fig. A. The fatigue threshold can be achieved at smaller Ttdi (arrow A) if the mean blood pressure is lower than normal. The threshold can be higher (B0 if the tension is higher (hyperfusion). The star in this figure is the Ttdi of a normal subject breathing at rest. The Ttdi in normal subjects exercising at 80% of their VO2 max is about .15, but the mechanisms of fatigue may be more complex than in resistive breathing.

Respiratory muscle endurance can be shorter or longer (for a given TTdi), depending on perfusion pressure. If perfusion pressure is increased, endurance is prolonged. In shock, TTdi task failure develops at a TTdi lower than 0.15 to 0.20. Respiratory rate can also affect respiratory muscle perfusion. Faster frequencies increase Qdi for a given TTdi, since Qdi is linearly related to the respiratory muscle's oxygen consumption in normal humans. Other conditions may also influence diaphragmatic perfusion. For example, hypoxemia also increases blood to the diaphragm. The aforementioned mechanisms seem to be adaptive in COPD, where both a fast respiratory rate and a lower tidal volume (faster, shallow breathing) may help preserve muscle performance.

The cellular mechanisms through which blood flow regulates muscle contractibility are not only related to the delivery of oxygen and other substrates, but also to the washout of the catabolites. Limitations of the aerobic metabolism lead to a dependence on creatinine kinase and myokinase for ATP synthesis from ADP only, with the accumulations of Pi and H^+, both of which are deleterious to muscle contractibility.

NEURAL CONTROL AND COORDINATION

The diaphragm and the other respiratory muscles are controlled by central motor neurons which normally maintain rhythmic breathing. The muscles of the upper airways are innervated by lower cranial nerves (ninth, tenth, eleventh and twelfth). The innervation of the other muscles depend on their anatomical location, and in descending order include: the sternocleidomastoid supplied by the spinal accessory nerve (eleventh cranial nerve) with roots from cervical 1 and 2 levels, the diaphragm, supplied by the phrenic nerves with roots from C3 to C5, the parasternal intercostal, supplied by the intercostal nerves. The abdominal muscles, which are mainly expiratory in action, are supplied by motorneurons arising from T8 to L2 levels.

It is evident that given the wide array of neurons that may participate in ventilation, a great degree of coordination is needed to maintain efficient and appropriate ventilation. Unique to the respiratory system is the fact that the natural rhythmic automatic breathing can be voluntarily overridden by the cortex. The system usually functions smoothly, because during quiet breathing we use primarily the diaphragm, the scalene, and some intercostals. With increased ventilatory loads, “accessory muscles” increase their participation in ventilation. Apart from their potential role in respiration, some of these muscles participate in other functions. For example, the upper torso and shoulder girdle muscles assist in positioning the upper extremities, abdominal muscles help with speech, defecation and parturition. Therefore, in situations where these muscles are being used for nonventilatory work, it is important that they maintain a high degree of coordination. When incoordination occurs, either because of an increased load or because of competing control integration, the resulting dysfunction can compromise the patient with underlying lung disease. It has been shown that when patients with severe COPD perform unsupported arm exercise, they develop early thoracoabdominal dyscoordination and fatigue. This type of exercise causes dyssynchrony between the rib cage the and diaphragm-abdomen, because of the competing output of the centers controlling respiratory and tonic activities of the accessory ventilatory muscles and the diaphragm.

Clinical evaluation of Respiratory Muscle Function

The most frequent symptom of respiratory muscle dysfunction is dyspnea. This symptom can be described with different degrees of exercise in many different conditions, including heart conditions. Indeed, dyspnea, which is caused by respiratory muscle dysfunction, is frequently confused with heart ailments. Characteristically, patients with diaphragmatic dysfunction will complain of dyspnea when supine (like cardiac patients), and sometimes have extensive workup

including catheterization, before the exact nature of the problem is elucidated. Patients with bilateral diaphragmatic paralysis report an immediate onset of dyspnea when supine as opposed to patients with heart failure who will complain of dyspnea after a variable time in the supine position. A physical exam can help sort out the nature of the problem. Measurement of the breathing frequency is helpful, because patients with respiratory muscle dysfunction will breathe at a faster rate. Similarly, the patients will adopt a shallow breathing pattern, irrespective of the reason of the muscle dysfunction. Close observation may reveal use of the accessory muscle, and paradoxical inward retraction of the abdomen during inspiration, because the diaphragm is unable to generate pressure to displace the abdominal wall.

Under certain circumstances special considerations apply. In patients with central nervous depression (drug overdoses), the breathing pattern tends to be shallow and slow irrespective of the degree of ventilatory failure. Likewise, patients with hypothyroidism can develop slow shallow breathing which will reverse with thyroid replacement. Patients with severe COPD will not develop the very fast rate seen in patients with interstitial lung disease because of the expiratory obstruction to airflow which tends to prolong the expiratory phase. On the other hand those patients will ineffectively contract the diaphragm and this will retract the lower ribcage (Hoover's sign). They will also contract the abdominal muscles during expiration. This pattern can be easily detected on the physical exam in the most severe cases but not be quite so visible in the milder stages.

During the evaluation, it may be helpful to induce coughing as patients with global respiratory muscle weakness will not be able to generate effective cough. A summary symptoms and signs, and their correlates to disease states and mechanisms is shown in Table 1.

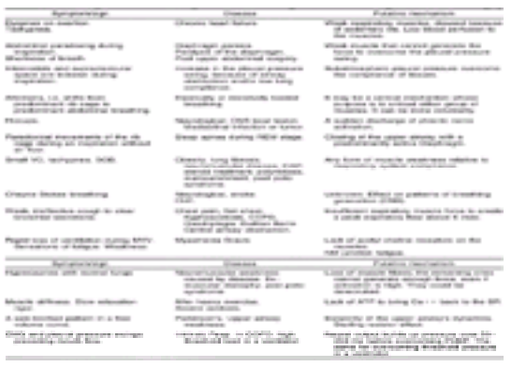

TABLE 1. *Clinical evaluation of respiratory muscle dysfunction*

Laboratory Evaluation of Respiratory Muscle Function

The most accurate source of information on respiratory muscle function is provided by measuring muscle specific physiological properties, like their level of neural activation, force generation, operational length, velocity of shortening, electrophysiological properties, and pattern of recruitment.

In practice, evaluation of the collective function of all the inspiratory and expiratory muscles is the most convenient way for their clinical assessment. It is remarkable that the lung volume-intrathoracic pressure relationship of all the muscles forming the chest wall strongly resembles the force-length characteristic function of a single skeletal muscle fiber. It is, in fact, near functional residual capacity that all inspiratory muscles combined are at their optimal length, and provide the highest intrathoracic inspiratory force. In contrast, all the expiratory muscles develop their maximal force near total lung capacity, where their length is optimal. Their force decreases as lung volume decreases.

The causes of respiratory muscle dysfunction can be found within the neuromuscular activation pathway, as shown in Fig. 6. Upon nerve stimulation, acetylcholine (Ach) is liberated at the neuromuscular junction, where it binds to Ach receptors postsynaptically, thereby causing changes in the muscle fiber membrane potential, and leading to the propagation of membrane depolarization along the surface of the fiber, a signal that is clinically measurable as the electromyogram (EMG). This depolarization also travels towards the center of the muscle fiber via the transversal tubules, which triggers the release of Ca^{++} ions from the sarcoplasmic reticulum into the cytoplasm. In the presence of ATP, CA^{++} links to troponin and triggers the sliding of myosin on actin, thereby generating force (clinically measured as intrathoracic pressure) and velocity of shortening (estimated by mouth flow). The magnitude of intrathoracic pressure developed depends on the initial degree of overlapping between thick and thin filaments within the muscle sarcomere. The magnitude of the shortening depends on the load the muscle encounters, as well as on the number of muscle fibers recruited, and the motorneurones firing rate. The overall degree of muscle activation can be estimated from the recorded EMG signal. Appropriate analysis of the signal, such as the root mean square value (RMS), can be used to quantify muscle activation.

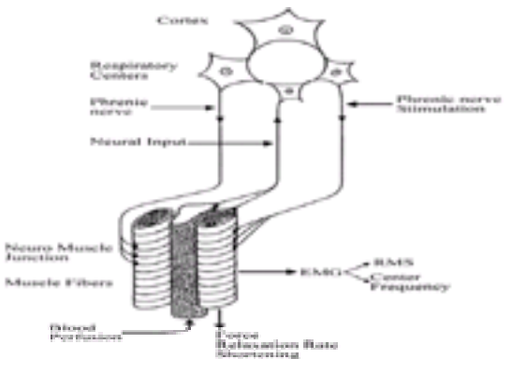

FIG. 6. The diagram shows the different levels of central control of breathing, the afferent and efferent neural pathways. Muscle failure or fatigue can happen A) at the central level (i.e. derecruitment) because of nerve lesions. B) At the nuero muscular junction (transmission failure) C) at the fiber level, being caused by insufficient perfusion, leading to excitation failure or contraction failure . On the right side, there are indications about how to test failure, a maximal phrenic stimulation, which can increase the max. Voluntary force, is an indication of Central Fatigue . EMG Centroid Frequency is an indicator of the muscle membranes conduction velocity. EMG Root Mean Square is an indicator of activation levels reached at the muscle cell. Force is the final mechanical output. Relaxation rate is an index of sarcomere function. Spontaneous shortening is an index of the respiratory center output and muscle force for a given breath.

The ultimate consequence of respiratory muscle dysfunction is ventilatory failure. There are several pathways that can lead to ventilatory failure. One is a lack of central drive (usually due to an overdose of neural depressants such as barbiturates or opiates). This results in lack of muscle activation, and overall hypoventilation. Another path is an alteration in the natural inactivation of acetylcholine or its rate of liberation. This also leads to hypoventilation due, to failure at the neuro muscular junction (myasthenia gravis, curare or curare like muscle relaxants). If respiratory muscle activation occurs, the muscle may still fail to generate adequate pressure through failure of the excitation contraction coupling mechanism. This is a complex step. Dysfunction can happen when the membrane Na^{+}/K^{+} channels are blocked, when lactic acid or inorganic phosphates accumulate in muscle fibers, or when CA^{++} does not recycle fast enough in and out of the sarcoplasmic reticulum.
Excitation-contraction coupling failure leads to loss of muscle force in spite of neuronal activation. This step can be assessed in several ways:

1)Loss of force upon maximal stimulation of the phrenic nerve, which then reverses with muscle rest (fatigue),
2)a slowing down of the relaxation rate of the diaphragm (measured as the rate of decay of transdiaphragmatic pressure), and
3)a change in the central frequency of the power spectrum of the EMG signal.

This is an indicator of the membrane's reduction in the velocity of conduction of myopotentials. A final pathway relates to phenomena independent of adequate intrinsic muscle function. It may be that the activation and contraction are normal, but the muscles are highly preloaded (COPD, obesity, ribcage deformity, interstitial lung disease), so an inordinate amount of muscle force is used to overcome the load before air actually moves onto the lung. Clinical observation of how the chest wall moves, measurements of ribcage and abdomen movements or relative changes in the simultaneously determined pleural (esophageal) and abdominal (gastric) pressures swings may help define the degree of respiratory muscle dysfunction.

Respiratory Muscle Strength

The oldest, simplest and most useful test of respiratory muscle strength is the maximal inspiratory (PI max) and expiratory (PEmax) pressures. There is a significant literature reporting values in normal subjects, patients with COPD, lung fibrosis, and obesity. There are acceptable instruments and techniques adaptable to clinical practice. The pressures are measured during maximal static efforts against a partially closed airway. A small airleak is created during the efforts, in order to avoid the suction effect of the mouth muscles if the glottis is allowed to close. The test has also been expanded to determine mouth pressure over a range of lung volumes over the vital capacity. Like many tests in pulmonary research, the maximal PI and PE are dependent on subject's cooperation, and the value obtained may underestimate the true strength of the respiratory muscles. Nevertheless, there are several practical uses for the measurement of PI max. Its serial evaluation over time can provide insight as to the progression or regression of muscle weakness (as in Guillain-Landry-Barrett syndrome, and weaning from mechanical ventilation) or fatigue. Patients with a maximal inspiratory force of <25 cmH_2O are at high risk of developing ventilatory failure. Similarly, maximal expiratory force of <30 cmH_2O at FRC is seen in patients with ineffective cough, which forecasts an accumulation of bronchial secretions and possible atelectasis, pneumonia and ventilatory failure.

Knowledge of the pressure swing required to sustain ventilation and the value of maximal inspiratory pressure (PImax) allows the calculation of the “force reserve” (Fig. 7). Pressure swings of higher than 50% of maximal inspiratory pressure are associated with rapid (within 15 min) fatigue and task failure. This may occur during some clinical conditions, and could be a reason for ventilatory failure.

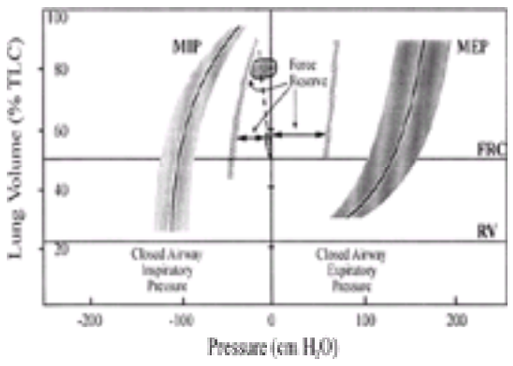

FIG. 7. Force reserve: the values of the MIP (Maximal Inspiratory Pressure) or PI max measured at the mouth against an occluded airway and MEP (pressure at the mouth during a maximal expiratory effort) or PE max. On the ordinate is lung volume, expressed as a percentage of total lung capacity. Predicted MIP-MEP values are shown in the shade areas. The dotted area represents pressures of about 40% of max, levels beyond which a sustains breathing pattern will result in failure. The dashed line is the elastic recoil of the lungs. The loop at FRC is the plural pressure swing required during resting breathing. Notice the margin of force reserve . The upper loop simulated the COPD patient. Hyperinflation and COPD result in lower forces and higher resistances decreasing considerably the force reserve margin.

The direct measurement of PI and PE max can be complemented by the determination of the force exerted by the elastic recoil of the lungs and the chest wall. At FRC, the outward recoil of the chest wall and the inward recoil of the lung are balanced, so the PI and PE max represent the true force of the respiratory muscles. At total lung capacity and residual volume, the values of PI are under or overestimated by about 25%. At TLC, PI max at the mouth is in fact 0, because the muscles have to overcome the elastic recoil of the lungs and the chest wall, which is approximately 30 cmH_2O. Intrathoracic pressure measured with an esophageal balloon would provides the correct value of the respiratory muscle force.

Maximal Transdiaphragmatic Pressure (Pdi)

This test requires the simultaneous measurement of esophageal (to represent pleural) and gastric (to represent abdominal) pressure, using balloon catheters placed in the mid-esophagus and in the stomach, respectively. Pdi is calculated as the difference between Pga and Pes, measured at isotime during a maximal voluntary effort. Pdi can also be estimated by using the difference between Pga and occluded mouth pressure (P mouth). The pressure needed to overcome elastic recoil of the lungs is added to mouth pressure (–5 cms H_2O at FRC and –25 cmH_2O at TLC in normals). The measurement of PdI max is performed while maintaining a small air leak, whose purpose is to help keep the glottis open. With all its caveats, Pdi max is the best index of intramuscular tension and the pressure developed across the diaphragm. There should be a negative pressure in the thorax with simultaneous positive pressure in the abdomen. Pdi should be recorded at known lung volume, keeping the chest wall configuration constant. Values from normal subjects and patients with different lung diseases, as well as details about the technique, have been published. There is considerable variability in the Pdi values obtained in humans, depending on the technique and the subject's capacity to complete the maneuvers. At Pdi values higher than 50% of maximum, blood flow is interrupted altogether. Blood flow is, however, partially reestablished during expiration. This physiological phenomenon is the basis for the explanation about how fatigue develops while breathing against high inspiratory resistance. A Pdi max value higher than 100 cmH_2O is not associated with muscle weakness, and cannot be the cause of ventilatory failure. A low Pdi max value can, however, be the consequence of many different factors, such as a lack of muscle mass, malnutrition, neurological disorder, neuromuscular junction disorder, and intrinsic muscle disease.

Another method of measuring the pressure generating capacity of the diaphragm is the so-called Sniff Test. This test is done by having the person perform a brisk maximal voluntary inspiratory effort through one of the nostrils. The pressure is measured at the nostril or the mouth. The major advantage of this test is that it can be successfully completed by most people with very little training, and it can be easier to perform than a Pdi max maneuver. Its main disadvantage is that it is a dynamic maneuver, where force is affected by the velocity and degree of muscle shortening. This tends to underestimate the value of the force, with respect to those obtained during static maneuvers. A sniff pressure value higher than 80 cmH_2O is likely to represent a good force, and respiratory muscle weakness is unlikely to be present. Low sniff pressure values provide less certainty regarding the presence of weakness. This test is being perfected and, as more experience is gained, it might be better standardized.

Phrenic Nerve Stimulation Techniques

This consists of supramaximal bilateral stimulation of the phrenic nerves at the neck using surface electrodes, resulting in a single brisk diaphragmatic contraction (twitch) pressure. Esophageal and gastric pressures are measured simultaneously with the double balloon technique. This allows the determination of Pdi. Adequate stimulation can be achieved with the use of an electric current, or through magnetic depolarization coils. The former stimulates the phrenic nerves specifically, while the latter is more likely to stimulate several nerve groups as the coils are relatively large. This problem may be solved with the development of smaller coils. Magnetic phrenic nerve stimulation can be done in either the sitting or supine position, and does not require abdominal binding. Cervical magnetic stimulation allows for prospective studies of the respiratory muscles of supine patients. It is nevertheless important to note that magnetic stimulation can interfere with the function of pacemakers and should never be used in patients with these devices in place.

Electrical stimulation should be done in the sitting position, with control of the diaphragm's compound muscle action potential, in order to achieve “supramaximal” nerve stimulus. Changes in the distance between the electrode and the nerve can change the stimulating current intensity, and thereby influence the test's outcome. In some instances, wires have been implanted close to the nerve and left in place to repeat the test, as well as document the changes in force as a function of time. Cutaneous stimulation can be painful, can cause ballistic movement of the arm and is difficult to perform in obese persons. There are numerous studies that provide comparative values from normals and patients with lung disease. The electrically induced twitch pressure values range from 25 to 35 cmH_2O, whereas they range from 30 to 35 cmH_2O for magnetic stimulation. Measurement of the time interval from nerve stimulation until the beginning of the action potential (CMAP) provides the phrenic nerve velocity of conduction. Absence of CMAP indicates phrenic nerve transection, or neuro muscle junction failure.

Respiratory Muscle Endurance

These are important and relevant tests of respiratory muscle function. This should provide more relevant information than tests of respiratory muscle force. There are a few techniques that have both broad acceptance and recognized clinical value; these results are shown in Fig. 8. The first one is the measurement of endurance while breathing at high levels of ventilation. Under these conditions, the respiratory muscles develop high velocity of shortening at relatively low forces, as seen in bicycle exercise. Maximal voluntary ventilation (MVV) is sustainable for about 10 to 15 sec by a normal subject. At this point ventilation decreases, because tidal volume and breathing frequency cannot be sustained. This is fatigue of the respiratory muscles. Maximal voluntary sustainable ventilation is about 50% to 60% of the MVV in normal subjects. It is also the level of VE observed during heavy aerobic exercise (competitive cross country skiing, and marathon running). Maximal sustainable ventilation for 1 to 2 hrs is not a practical clinical test, but has been used in research. Shorter versions using step increases of 10% in the VE every three minutes,

starting at 20% of maximum MVV, and going on until the subject cannot sustain the load, have proven to be useful. In patients with airflow limitations, the load increase is limited by the airflow limitation and progressive hyperinflation, which leads to chest wall configuration changes and muscle shortening. Similarly, its applicability for other patients with different respiratory diseases is limited.

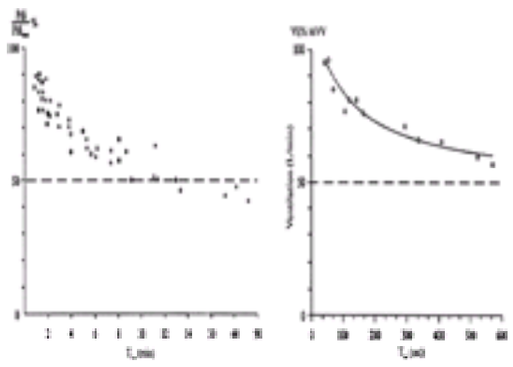

FIG. 8. Left Panel: Time to task failure (time limit) of the inspiratory muscle during resistive breathing in normal subjects. A Pdi of about 50% of max. Can be sustained for about 1h. Right Panel: Time to task failure (Time limit) of the various levels of voluntary ventilation (expressed as a percentage of maximal voluntary ventilation). Ventilation of about 55% max can be sustained for about 10 min or longer. This test was extended to 1 h. In subsequent studies. Sustainable ventilation value is about 50-60% of MVV.

Evaluation of Endurance While Breathing Against Inspiratory Loads

Under these conditions, the respiratory muscles develop high force and slow velocity of shortening. In essence, the subject tested has to breathe against an inspiratory threshold load, which must be overcome before air can flow into the lungs. Mouth flow can be maintained at comparable value, despite the range of load. The load is increased periodically (i.e: every 3 minutes), until the subject cannot overcome it, and consequentially has to stop the test. The highest load value tolerated for a total period (3 minutes, in this case) is then recorded. This test has gained some acceptance, but requires some learning before it yields reproducible results. In the initial reported tests, the breathing pattern was controlled. Subsequent tests conducted in COPD patients resulted in varying breathing patterns, because the patients adopted different breathing strategies when faced with the load. To avoid the influence of force and timing, the pressure time index, or breathing pattern, can be monitored during the test.

One of the most widely accepted methods of measuring respiratory muscle endurance consists of letting the subjects or patients breathe at a level that is a known fraction of the maximal force (PI max). For example, beginning at 30% of PI max, while keeping the CO2 constant. The load is then increased every 2 minutes by 10%, until the person can no longer sustain the pressure for a full period (2 minutes, in this case). The value of the load causing task failure or the tension time index value achieved at that time, can be used to quantify endurance.

Electrophysiological Evaluation of Respiratory Muscles

The EMG is the electrical signal recorded during muscle activation. The muscle is activated by the depolarization and repolarization of the muscle membrane, caused by neural stimulation at a rate of 5 to 50 pulses/sec. If the phrenic nerve is electrically stimulated with a short pulse (0.2 msc), it induces a biphasic muscle action potential on the diaphragm. This can be measured at the surface of the thorax with two electrodes placed along the diaphragm. This is called the compound muscle action potential. During voluntary contractions, motor units are recruited and the firing rate increases resulting, in increasing force production. The spatial and temporal summation of individual motor unit action potentials generate the interference pattern signal. As mentioned previously, the signal can be analyzed by calculating the root mean square (RMS or time domain analysis), which is then expressed as a percentage of a maximal RMS value previously obtained by sustaining an active TLC. Either the RMS peak value (at the end of each inspiration), or the average RMS during a breath is reported. This signal is proportional to the number of fibers recruited, as well as the frequency of motor unit firing rate. RMS is also proportional to muscle force for any given muscle length.

Another form of EMG analysis is to calculate the power spectrum in the frequency domain. This EMG domain is measured in periods (windows) of 20 to 200 msc, where heart PQRST signals are excluded (gated). The index Pdi/RMSdi is an expression of diaphragm effectiveness, because it provides an indirect indication of the ability of the muscle to convert an electrical signal into force. This index is low at FRC (lengthened muscle), and high at TLC (shortened muscle). The power spectrum can be quantified by calculating its moments, one of which is the center frequency. Values of center frequency have been shown to be related to the velocity of propagation of the potential along the membrane. When the EMG of the crural diaphragm is measured with a 10 mm bipolar esophageal electrode, the normal value for CF is 100 ± 4 Hz. During fatigue, CF progressively decreases to values around 60 Hz, at which point it tends to stabilize. A decrease of 15% to 20% of the resting CF is thought to represent a value associated with the development of fatigue. Center frequency returns to baseline values within 5 min after withdrawing the load. Experimental evidence obtained in animals shows that fatiguing loads sustained for periods close to 2 hrs considerably prolongs the recovery time of the center frequency, which can now take several hours. Under these conditions, there is evidence of membrane injury and sarcomere disruption. Whether this occurs in humans is unknown, but is theoretically possible. Muscle injury can explain the prolonged recovery of force observed in some cases of respiratory muscle fatigue.

Electromyographic quality recording of the diaphragm has recently been standardized by Sinderby et. al. It is expected that the standardization of methods and automatization of data recording and analysis will allow for a wider applicability of this important signal. Fig. 9 shows an example of uncoordinated EMG RMS (the patient's neural drive) while ventilated in the assist mode.

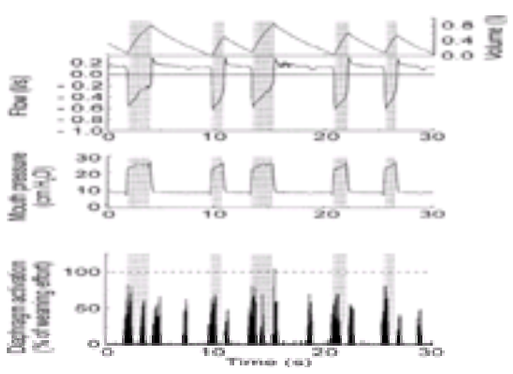

FIG. 9. Neuro mechanical coupling: The panels show 30 seconds of breathing in a patient ventilated on the demand mode. The top panel shows tidal volume and flow, indices of mechanical performance. The lower panel shows the firing of the diaphragm (EMG s RMS from the crural portion). Notice the discrepancy in breathing frequency between the ventilator (10 / min) and patient (30 / min). A considerable number of inspiratory efforts are out of phase with the ventilator. The middle panel shows the simultaneously monitored airway pressure.

Evaluation of Respiratory Muscle Coordination

The use of respiratory inductance plethysmography bands or magnetometers on the ribcage and abdomen, is a noninvasive tool that allows simultaneous recording of the volume displacement of each of the two compartments. Plotting each signal against the other (Konno-Mead plots) provides qualitative and quantitative evaluation of respiratory muscle coordination. Normally, inspiration increases the diameter of both the ribcage and abdomen. Simultaneous calibration against a known lung volume (spirometer) allows for the continuous noninvasive evaluation of tidal volume, and course of breathing. It is very useful because it can help monitor occurrence of apnea, hyperpnea, irregular, and rapid shallow patterns of breathing. Dyssynchronous and paradoxical thoracoabdominal movements can be identified under a variety of experimental and clinical conditions as shown in Figure 10. When well calibrated, tidal volume and minute ventilation can be measured within 5% to 10% of the values obtained via measurements at the mouth. Time based recording of EMG, pressure swings, thoracoabdominal displacements, and airflow allows inferences about the time course of muscle recruitment and their interaction. Application of these techniques to real clinical situations will provide us with a better understanding of

the respiratory system, and its behavior during different conditions, such as patient ventilator interaction, prediction of weaning failure, and the complex interrelation between sleep and respiration.

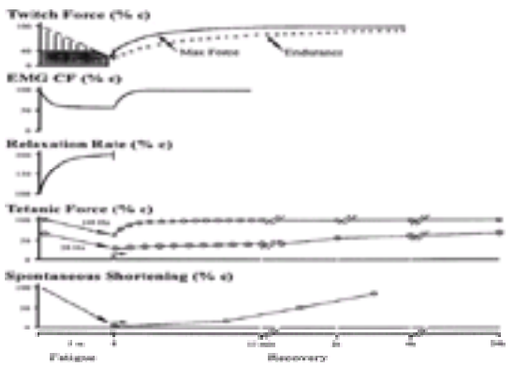

FIG. 10. Time course of various parameters during an isometric contractions held at 40% of maximal force (task) until failure. Panel from the top: Maximal force: voluntary contraction is held at 40% of the force obtained during maximal voluntary effort or during maximal electrical supramaximal pulses of the nerve. The vertical lines are pressure swings obtained by electrical stimulation, showing a progressive loss of maximal force. Task failure occurs when maximal force is equal to task force. The time elapsed from the start until task failure is known as the time limit, or endurance. The exercise is defined as a fatiguing task, because there was loss of maximal force. Regaining the ability to develop maximal force takes a few minutes. Regaining the ability to perform the same task again, however, takes hours. This panel shows the time course of the central frequency (CF) of the EMG obtained via surface electrodes and Fast Fourier transforms in the same exercise. Decay of CF is fast, and is a forewarning of task failure. This parameter is an expression of membrane potential conduction velocity. Relaxation rate shows the time course of relaxation time (if the contraction if interrupted). Control values are the same as in a rested muscle. This parameter is linked to a failure at the sarcomere level, mainly related to calcium coupling and release from troponin. Tetanic force shows the decrease in force during an electrical stimulation at 100Hz or 20Hz, and its ensuing rate of recovery. Recovery from fatigue is faster when the muscle is probed with 100Hz than with 20Hz; the former is proposed to be caused by conduction mechanisms, while the latter is done by contraction mechanisms. Spontaneous shortening of the diaphragm before (100%) and after task failure, and time of recovery.

Respiratory Muscle Fatigue

Definitions

It is now widely accepted that sustained muscular activity causes a reduction in the maximal force (or velocity of shortening of the muscle). The causes are many, and can concurrently develop from the motor cortex to the sarcomere microfibers. Loss of the capacity to generate maximal force due to exertion, recoverable during rest, is defined as *muscle fatigue.* Since the concept of fatigue is a temporary loss of force, maximal force must be measured two or more times during the trial period. *Task failure* is defined as the inability of the muscle to continue to perform a given prefixed target (work, force, tidal volume, ventilation). Although fatigue precedes task failure, task failure does not necessarily follow fatigue. Task failure of the respiratory muscles occurs when they lose the capacity to generate the force required to sustain normal alveolar ventilation. Muscle injury can be defined as a structural change in the sarcolemma or sarcoplasm, and is usually induced by fatiguing contractions, sustained for long periods of time (several hours), as may happen to the respiratory muscles during airway obstruction. Recovery from injury takes several days, giving place to muscular remodeling where, in addition to muscle repair, there are changes in the quality of the muscle's structural or contractile proteins. Muscle weakness is a permanent loss of force, regardless of its origin.

Mechanisms of Respiratory Muscle Fatigue and the Rationale for Diagnostic Tests

Breathing tasks that are “sustainable” will be held mainly by recruitment of fatigue resistant fibers (type I), requiring oxygen to generate ATP. By themselves, type I fibers will not generate more than 30% of the maximal force, but will be able to sustain force for prolonged periods of time. High force (about 40%–50% of max) limits muscle perfusion and may deprive all cells of adequate oxygen supplies and catabolite removal. Low force will allow adequate perfusion of type I fibers, which are fatigue resistant and sustain breathing for life. The chemical composition of the muscles' interstitial space (e.g. K^+ concentration, low pH) provides neural feedback to the respiratory center.

Fatigue, which can be thought of as a regulatory mechanism through which a temporary hypoventilation is allowed to avoid muscle injury, may happen at the central level by derecruitment of fibers, at the neuro muscular junction (failure of transmission), and at the muscle levels (failure of the membrane to conduct potentials, or sarcomere to shorten or relax). Muscle force is the conventional parameter used to determine the level of muscle activity, and is dependent on length and the velocity of shortening. We can now measure parameters other than force that are known to change as fatigue develops. The challenge is to determine how they contribute or how they are related to force, and how they can be used as diagnostic tools for muscle dysfunction.

Figure 10 shows the parameters that help evaluate neuro muscular function and the techniques available for measuring fatigue. A nerve stimulation test can be performed by giving short pulses (.2 msec) of electrical or magnetic currents applied to the nerves during contraction (upper pannel). The resulting twitch force produces a maximal muscle force output. A decrease in twitch force is an indication of muscle fatigue. Presence of twitch force while the muscle is developing maximal voluntary effort is an indication of “central” fatigue or submaximal activation. Techniques for stimulating abdominal muscles through percutaneous low dorsal nerve stimulation is now under development.

Partial mechanisms of muscle fiber function relevant to fatigue can be monitored by several other techniques Membrane excitability due to changes in the sarcolemma polarity induced by nerve stimulation can be measured using the EMG. When the index force/RMS decreases during sustained contractions at constant length, it is an indication of failure of the muscle contraction mechanism, relative to the neural command (fatigue). The frequency domain analysis of EMG provides information about the velocity of propagation of potentials along the fibers, through calculation of the frequency power spectrum. Fatiguing muscle fibers while exerting high force shows a shift towards an increased power in the low frequency component of the spectrum. Membrane excitation is a relevant function because it is the key mechanism to liberate Ca^{++} from the sarcoplasmic reticulum, which is necessary to induce contraction of the sarcomere.

Shifts in the frequency power spectrum occur early in a fatiguing contraction (within a minute of loading), and may serve as a marker for the prediction of task failure (second panel). Fatigue is not, however, the only factor that changes the velocity of propagation of potentials. An alternative to measuring EMG generated by voluntary contraction is to measure the compound muscle action potential resulting from a single .2ms electrical stimulation given to the nerve of a relaxed muscle. Here, all fibers are recruited at once resulting in a biphasic potential, the length and shape of which permits to distinguish neuro muscular abnormalities and/or fatigue.

Velocity of muscle contraction. Once the muscle contracts, its velocity of shortening and velocity of relaxation have been used as an expression of the sarcomere function. Inadequate Ca^{++} binding to and release from troponin (mainly due to lack of ATP) results in a slowing of the sarcomere velocity of relaxation (the muscle becomes stiffer during fatigue). The relaxation rate of the diaphragm during fatiguing contractions is slower than in the fresh diaphragms of normal subjects. When the muscle is subjected to fatiguing contractions, changes in relaxation rates are seen well before task failure occurs, and so the test can be used to herald task failure. Figure 10 also shows the time course of recovery of after low and high frequency stimulation.

Muscle Metabolism

Muscle biopsies and nuclear magnetic resonance spectroscopy (NMR) are the techniques most frequently used to monitor metabolic changes in the contracting muscle. While these techniques have been of great value to study limb muscles, their use in respiratory muscles is much more limited. Phosphorous was the earliest and most frequently used atom to measure high energy phosphates (ATP, ADP, P2r or Ph). The carbon atom (CMRS) has been used to label substrates such as glucose, acetate and pyruvate.

The use of atoms of sodium and potassium (Na^+ and K^+ MRS) permits the monitoring of the intracellular ionic compositions, both of which have great significance in the propagation of membrane potential, and intracellular and extracellular water movement in muscle tissue. Cine MRI is a recent technological development, which has been applied to visualize dynamic internal events such as the beating of the heart or displacement of the diaphragm. Intense muscle exercise results in an accumulation of Pi and an increase in H^+, both affecting pH and the enzyme's capacity to generate ATP. Metabolic changes leading to muscle fatigue may soon be amenable to *in vivo* measurements.

Documentation of Respiratory Muscle Fatigue in Human Subjects. Some of the experimental studies of respiratory muscle fatigue were, in reality, measurements of the total duration during which a given force could be sustained, i.e. time to task failure, or endurance. Once task failure is established, we can assert that fatigue preceded (fatiguing contraction pattern). The evolution of maximal force as a function of time has been well documented in fatiguing contractions. Two major types of tasks have been used to elicit fatigue of the respiratory muscles: a) breathing against high inspiratory (or expiratory) resistance, and b) performing maximal voluntary ventilation under isocapnic conditions (Fig. 7). The resistive breathing protocol consists of setting a target Pdi, duty cycle, and frequency of breathing, or mouth pressure. The target is held until failure; with PaCO2 remaining at a normal level. Fewer studies offered breathing resistance without instructions about how to breathe (i.e. the subject chooses his/her own pattern of breathing). Under these conditions, PaCO2 tended to increase or decrease; in general, it increases considerably when resistances are high, and decreased when resistances were low. Overall, the results of resistive breathing experiments have shown that a pressure swing of about 50% of maximum force sustained at a duty cycle of .4 could be endured for one hour or longer. A few studies have evaluated fatigue in accessory respiratory muscles or abdominal muscles. Task failure was well documented, and we can therefore infer that fatigue did occur. In resistive breathing, the pattern of contraction consists of slow velocity, high force, small shortening, and high intramuscular pressure. Presence of muscle fatigue has been documented by measuring the force frequency curves in the diaphragm before and after task failure. All have shown decreases in maximal pressure following resistive breathing which ended in task failure. It is possible to conclude that fatigue of the respiratory muscles in human subjects does happen during experimental loaded breathing.

The model of fatigue caused by inspiratory resistance breathing may apply to some clinical conditions like heavy snoring or sleep apnea, where peak plural pressures of 40 to 60 cm H_2O have been reported. Such conditions are, however, prevalent for short periods (minutes), followed by unloading (airway opening), and are not expected to cause fatigue.

Expiratory resistive breathing was shown to result in fatigue of abdominal muscles, and can happen in severe expiratory airway disease. Patients with COPD represent a unique situation. Their mean Pdi swing is in the range of 10 to 15cm H_2O (rest), and can increase to 20 cm during exercise; these values are close to 50% of their maximum. It is well documented that high intramuscular tension limits muscle blood perfusion leading to failure. In COPD it is likely that the relatively low Pdi measured may underestimate the intramuscular tension, since the flat diaphragm is far less effective in developing intrathoracic pressure, due to a defective coupling with the rib cage. It is not known if diaphragm perfusion is impaired in COPD. There are, in fact, studies that report a lack of increase in diaphragm perfusion in animals whose lungs were hyperinflated via PEEP: despite a threefold increase in work of breathing and pressure time index. It is known that the degree of activation of the diaphragm in COPD during resting breathing is about three times higher than in normal subjects. Recent studies show that activation of the diaphragm in COPD can rise to 85% of maximal during moderate exercise, and support the hypothesis of a high intramuscular tension in the diaphragm, which is not evident from Pdi measurements.

The second method used to induce respiratory muscle fatigue is to ask normal subjects to sustain the maximal voluntary ventilation (MVV) as long as they can, which is usually a very short period of time (about 30 sec.). Normal subjects can sustain a VE of about 55%-60% of their MVV for periods of 20 min or longer. Such levels of ventilation are seen in aerobic sports such as the marathon, skiing, and biking. During MVV the muscles contract at high speed, relatively low force, and undergo large changes in length with every breath.

In order to measure fatigue of the diaphragm at high levels of minute ventilation, the Pdi generated has been measured by applying a single electrical pulse and short trend stimulations of 10 and 20 Hz. to the phrenic nerves of normal subjects before and after exercise at 85% or 95% of their VO2 max (ventilation in the range of 80 and 120 L/min, respectively). A decrease in the value of the Pdi twitch, volitional Pdi max, and a reduction in the relaxation rate was observed during the test exercising at 95% of VO2 max. No difference was found after exercising at 85% VO2 max. Studies of Pdi max following a marathon run resulted in decreases in volitional Pdi max. It is therefore reasonable to assume that fatigue of the diaphragm develops when VE is held at 50% to 60% levels of MVV or higher. This is of relevance in sports medicine, where the limitations of body performance can be attributed to limitations in ventilation. Fatigue of the respiratory muscle in aerobic exercise may be a more relevant issue in well trained athletes than in sedentary people.

In summary, the loss of force of the respiratory muscles leading to fatigue does happen in human subjects. This becomes evident when subjects are sustaining either 50% of their maximal force or 50% of their maximal voluntary ventilation. Losses in force at lower rates have not been well documented. The monitoring of parameters showing more subtle evidence of muscle dysfunction than a loss of maximal force during loading in both normal and diseased subjects remains an exiting challenge.

Respiratory Muscles Training

In patients with COPD, as the diaphragm becomes functionally impaired, the accessory muscle contribution to ventilation progressively increases. Patients with symptomatic lung disease like COPD are limited in their capacity to exercise, because of dyspnea. Evidence suggests that the dyspnea relates more to respiratory control and muscle function than to airflow obstruction. As the ratio between the pressure needed to ventilate and the maximal pressure that the muscles can generate (Pdi/Pdimax or PI/PImax) increases, there is a proportional increase in dyspnea. Dyspnea also increases with increases in the duration of the contraction (Ti/Ttot) cycle and respiratory frequency. Because these factors have been shown to correlate with EMG evidence of respiratory muscle fatigue, changes in any of them may help explain the observed increase or decrease in exercise performance after training.

Based upon these principles one may postulate the following treatment goals:

1)Decrease in inspiratory force,
2)Shortening of inspiratory time,
3)Increases in maximal inspiratory pressures,
4)Decrease in respiratory frequency, and
5)Improved coordination among the different respiratory muscles.

Data suggests that it is primarily through the last three mechanisms that systematic training in COPD may result in improved exercise endurance.

Exercise Conditioning

Lower Extremity Exercise

Patients with underlying lung disease are restricted in their ability to perform exercise. This leads to a progressive reduction in their physical activity. This, in turn, deconditions the muscles further, perpetuating physical inactivity and a sedentary lifestyle. This is depicted as the downward spiral of patients with COPD. A major goal of exercise training in pulmonary rehabilitation is to interrupt the downward spiral by enabling patients to tolerate a higher level of activity. It is clear that exercise conditioning improves exercise endurance.

In the mostly uncontrolled studies that have evaluated the effect of rehabilitation on exercise performance, the results are clear. Most patients included had moderate to severe airway obstruction with hypoxemia, without carbon dioxide retention. In most studies, the subjects exercised an average of 3 days per week for a total duration of 6 weeks. Walking, with or without treadmill and bicycle ergometry, were the more commonly used exercise modalities. Irrespective of the training mode, exercise endurance increased, without measurable changes in pulmonary function. In none of these studies were ventilatory muscles adequately studied, but the lack of change in vital capacity or lung volume suggest minimal if any effect of general exercise on respiratory muscle function.

Data obtained from several randomized studies with control groups in patients with underlying COPD is now available. The results revealed a significant increase in the 12-minute walking test and peak oxygen uptake with important decreases in the perception of dyspnea and improvement in health related qality of life. Based upon a review of the existing literature, increased VO_2 following exercise training as demonstrated in a few studies, can be interpreted as an enhanced physiological response to exercise. Some studies have demonstrated a decrease in the heart rate, VCO_2, and VE following exercise training. Recent data suggest that the changes are due to true physiological changes, because there have been documented increases in the enzyme content of the mitochondria of peripheral muscle biopsy in trained patients. On the other hand, most evidence indicate that ventilatory muscle function per se is not significantly affected by aerobic leg exercise, although this hypothesis has not been well studied.

Arm Exercise Conditioning

It has been demonstrated that eight weeks of 3 times weekly unsupported arm exercise results in a significant decrease in VE, VO_2 and VCO_2 for simple arm elevation. Several studies have looked at both arm and leg training, and have demonstrated improved task specific performance. Although theoretically possible, arm training has not resulted in significant changes in respiratory muscle function. Its beneficial effects are probably related to the decreased ventilatory demands, because the “efficiency” of the shoulder girdle and arm muscles improve with the training.

Methods of Specific Respiratory Muscle Training

As discussed above, whole body exercise fails to improve ventilatory muscle endurance in patients with COPD, whereas normal subjects and patients with cystic fibrosis may increase ventilatory muscle strength with intense aerobic exercise. It is possible that the levels of ventilation achieved during exercise in COPD is inadequate to generate the appropriate increase in ventilatory endurance. Since reduced inspiratory muscle strength is evident in patients with COPD, considerable efforts have been made to define the role of respiratory muscle training in these patients.

Training has been achieved using two different strategies: strength training and endurance training.

Strength Training. This is achieved through the application of a high intensity low frequency stimulus. This is done by performing repeated inspiratory effort maneuvers against a closed glottis or shutter. Studies have determined an increase in PImax with respiratory muscle strength training. In one study, the Pi max increased by 53% in patients with COPD after 5 weeks of training. Another demonstrated a 50% increase in PImax in 9 patients after 4 weeks of training. The extent to which strength training contributes to clinical improvement is debatable, but it is not unreasonable to assume that some of the observed benefits reported after respiratory muscle endurance training may relate to the increased strength achieved.

Endurance Training. Achieved through the application of low intensity, high frequency stimulus, the following three methodologies have been explored: flow resistive loading, threshold loading and ventilatory isocapnic hyperpnea.

Flow Resistive Loading: The goal is achieved by having the patient breathe through orifices of progressively smaller diameters. Although it is tempting to attribute the ability to breathe through smaller orifices as improved endurance, this may very well just represent an adaptive breathing strategy. It has, indeed, been shown in patients that just by changing the breathing pattern to one of slow long breaths, there was an improvement in resistive breathing endurance, despite the use of a smaller orifice.

In studies where attention was given to the breathing pattern, the results have been encouraging. One first group demonstrated improved ventilatory muscle strength, endurance and exercise capacity in COPD patients who underwent ventilatory muscle training in addition to rehabilitation versus rehabilitation alone. Another study demonstrated improved respiratory muscle strength and endurance in a treated group, as compared to controls. The treatment group reached progressively higher target pressures, whereas the control group breathed through an unloaded system. It is of interest that a significant reduction of dyspnea was observed in the treatment group.

Threshold Loading: The principle of this training mode is to ensure an adequate inspired pressure to ensure training independent of inspiratory flow rate. The results of the controlled studies that have evaluated threashold load training, have shown an increase in respiratory muscle strength, increased endurance to a ventilatory load and a decrease in dyspnea during this maneuver. Those studies which evaluated other important outcomes, such as health related quality of life and exercise capacity, unfortunately demonstrated only minimal improvements. In conclusion, although threshold loading improves ventilatory muscle strength and endurance for resistive breathing; it also seems to decrease dyspnea with exercise, there are minimal systemic benefits from these changes. Other outcomes have not been examined, and require further studies.

Ventilatory Isocapnic Hyperpnea: In this form of training, the patient maintains a high level of minute ventilation for 10 to 15 minutes 2 or 3 times daily while CO_2 is kept constant. This concept simulates whole body exercise such as running, by subjecting the diaphragm and other inspiratory muscles to low tension, high levels of repetitive activity. The level of hyperpnea is measured as the maximum sustained ventilatory capacity (MSVC), defined as the maximum level of ventilation that can be sustained under isocapnic conditions for 15 minutes. The few studies that used this training mode showed that muscle endurance improved in the range of 20% to 50%. Controlled studies by 2 groups have demonstrated that although MSVC improves in COPD patients trained for 6 weeks, exercise endurance is no better than the control groups. Because it is difficult to implement and with no demonstrable change in outcomes other than the improved respiratory muscle endurance, isocapneic hyperventilation is not used as a from of ventilatory muscle training.

Breathing Retraining. There are other less conventional forms of training that are open to critical review, but are conceptually solid and may offer new avenues of treatment. Patients with COPD manifest a higher ventilatory drive than normal patients. In fact, patients on mechanical ventilation who cannot wean have a higher ventilatory drive than those patients who successfully wean. If we could decrease this drive, it would become possible to decrease the consequences of such a high drive: increased work of breathing, respiratory rate and perhaps dyspnea. Although it is scant, there is some available data that supports the study and application of these therapeutic tools.

Feedback: In a recent study, 40 patients were evaluated after at least 7 days of mechanical ventilation. They were randomized to conventional weaning or weaning with the use of electromyographic feedback training using the frontalis signal as an indication of tension and to induce relaxation. They also used the surface EMG of intercostals and diaphragm as indicators of respiratory muscle activity. Using feedback signals to encourage relaxation and larger tidal volumes, there were differences between treated and untreated patients. The results indicate a reduction in mean ventilator days for the biofeedback group. Tidal volume and mean inspiratory flow increased significantly for this group. The increase was also significant when corrected by diaphragmatic EMG amplitude. This was interpreted as improved diaphragmatic efficiency. The authors concluded that breathing retraining resulted in a more efficient breathing pattern which, in turn, decreased dyspnea and anxiety, and allowed for quicker weaning time in the treated patients.

Postural Changes: It is known that musculoskeletal tone and contraction may be determined by habitual positioning. Over the last few years, increasing attention has been given to the voluntary inhibition of those patterns. This has been particularly useful for artists. A recent study demonstrated improved peak expiratory flow rate, maximal voluntary ventilation and maximal inspiratory and expiratory pressures in normal subjects who underwent lessons in proprioceptive musculoskeletal education, compared to controls. This method has not, per-se, been systematically evaluated in patients with lung disease, but breathing retraining (pursed lip breathing and diaphragmatic breathing) constitutes a form of therapy that resembles the above discussed techniques.

Pursed Lip Breathing: Indeed, pursed lip breathing results in a slowing of the breathing rate with increases in tidal volume. PLB will result in a shift in the pattern of recruitment of the ventilatory muscles from one that is predominantly diaphragmatic to one that recruits more the accessory muscles of the ribcage and abdominal muscles of exhalation. Perhaps this shift may contribute to the relief dyspnea that has been reported by patients when this breathing technique is adopted. Patients on ventilators cannot purse lip breath, but it has been shown that the administration of respiratory retard, or PEEP, improves oxygenation, decreases respiratory rate, augments ventilation, and improves work of breathing in weaning patients. Pursed lip prevalence in COPD is related to the degree of airway obstruction.

CONCLUSION

Over the last two decades, numerous studies of ventilatory muscle training on patients with chronic airflow limitations have been reported. Uniformly, they indicate that VMT results in either increased strength or endurance for the specific task for which they were trained. Several questions have been answered regarding the acceptable methods of training. However, based upon the existing literature, we still cannot recommend routine ventilatory muscle training to all patients with COPD, since there is limited evidence that it improves outcomes such as quality of life, or activities of daily living. Future research will attempt to evaluate the role of VMT as an adjunct to other well proven training strategies, such as aerobic leg training. The scientific evaluation of less accepted techniques, such as breathing retraining, yoga, and biofeedback deserve interest and efforts.

Surgery and Respiratory Muscle Function

By removing the most abnormal emphysematous lung and decreasing resting lung volume, lung pneumoplasty allows the respiratory muscles and especifically the diaphragm to regain length and/or mechanical coupling advantage. Recent data shows improved respiratory muscle performance at rest and during exercise and decreased dyspnea. The latter may happen because of a reduction in the neural drive, as overall mechanics and impedance improve after LVR. As more experience is gained with this procedure, it will become a therapeutic option for selected patients with severe COPD.

CHAPTER

7 Molecular Biology of Lung Disease

N. Tony Eissa · Shan C. Chu · Joel Moss

N. T. Eissa, S. C. Chu, and J. Moss: Pulmonary-Critical Care Medicine Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland 20892.

INTRODUCTION

In the past two decades, the techniques of molecular biology have been used increasingly, not only in basic science but also in clinical research. Today, clinicians, including specialists in pulmonary medicine, are confronted frequently with reports of studies in which the techniques of molecular biology are employed. This chapter is intended to help readers understand the information and techniques that are the basis of molecular biology. The concepts of genomic deoxyribonucleic acid (DNA), primary messenger ribonucleic acid (pre-mRNA) processing, including alternative splicing, and translation of mRNA into protein are introduced first. The common techniques of molecular biology are presented next, followed by examples of recent advances in pulmonary research in which these techniques have been used.

BASIC CONCEPTS

Genomic DNA

The nucleus of each normal human somatic cell contains 46 chromosomes—44 somatic chromosomes and two sex chromosomes, which are either XX in a female or XY in a male. Each chromosome contains a single, linear, compacted, double-stranded DNA molecule, which is the genetic material, plus associated proteins, such as histones. The structure of DNA consists of two long complementary polynucleotide chains that wind around each other to form a double helix. The basic building block of the polynucleotide chain is a mononucleotide, comprised of a phosphate group, a sugar ring (deoxyribose), and a base moiety, either a purine (adenine, *A,* or guanine, *G*) or a pyrimidine (cytosine, *C,* or thymine, *T*). The backbone of the helix consists of deoxyribose-phosphate groups. Except at the 5' end of the DNA strand, each phosphate group forms a 5'-3' phosphodiester bond between the fifth carbon of one deoxyribose ring and the third carbon of the adjacent deoxyribose ring. The nucleotide base (G, A, T, or C) attached to each deoxyribose moiety is in the center of helix, oriented perpendicularly to its axis. The two strands of the DNA helix are held together by hydrogen bonds between complementary base pairs (two bonds between adenine and thymine, three between guanine and cytosine). The strands are antiparallel, one running in the 5' to 3' direction and the other in the 3' to 5' direction. Because adenine pairs only with thymine and guanine only with cytosine, the sequence of nucleotides in one strand of the double helix determines the sequence of the other.

The complete DNA sequence, comprising the total genetic information carried on all chromosomes in a cell, is called *genomic DNA.* It is estimated that haploid human genomic DNA contains 3 x 10^9 base pairs (bp), representing 100,000 to 500,000 genes. A gene, which consists of the entire DNA sequence necessary for the synthesis of a functional polypeptide or RNA molecule, such as transfer RNA (tRNA) or ribosomal RNA (rRNA), is the smallest functional physical unit of inheritance. A gene contains not only the nucleotides that encode the amino acids of a protein (coding sequences) or the sequence of a functional RNA, but also all the other DNA sequences needed to produce the primary RNA transcript (Fig. 1). In the eukaryotic genome, critical noncoding sequences include (1) transcription regulatory sequences with promoter, promoter-proximal elements, and enhancers, (2) a sequence at the 3' end of a gene that signals the position for 3' cleavage and polyadenylation, and (3) intervening sequences (introns) that are later removed by splicing of primary RNA transcripts.

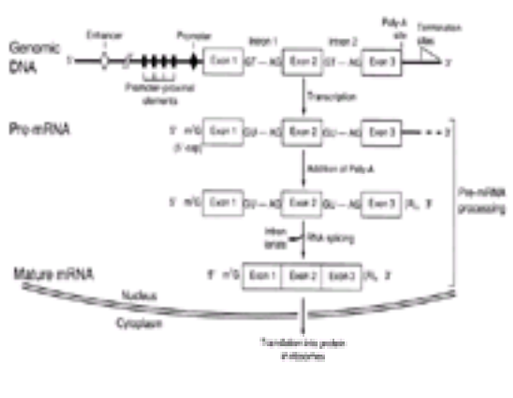

FIG. 1. Gene expression in mammals. Shown at the top is the basic structure of a gene in genomic DNA. Exons (sequences preserved in the mature mRNA), introns (intervening noncoding sequences), and important elements of gene regulation, including the promoter, promoter-proximal elements, enhancer, poly(A) site, and the universally conserved dinucleotides (GU and AG) at the 5' and 3' ends of each intron, are indicated. The gene is first transcribed into pre-mRNA transcripts. After several steps of pre-mRNA processing, including 5' capping with 7-methylguanylate (m^7G), polyadenylation at the 3' end, and RNA splicing to excise introns and ligate exons, mature mRNA is ready to be transported to the cytoplasm for translation into protein in ribosomes. See text for details.

The promoter contains a sequence that determines the site of transcription initiation by an RNA polymerase. Promoter-proximal elements, usually adjacent to the promoter, bind specific factors (transcription factors) to regulate the rate of transcription of the gene into pre-mRNA. An enhancer consists of sequence, located either upstream or downstream at a distance from the transcription initiation site, that can increase or decrease the rate of transcription of the gene by binding to a specific factor(s).

Primary Messenger RNA Processing and Alternative Splicing

Although the genetic information is stored in DNA in the nucleus, the protein (gene product) is synthesized on ribosomes in the cytoplasm. The mRNA, an edited copy of the gene, carries the genetic information from the nucleus to the cytoplasm. The structure of RNA is slightly different from that of DNA, in that uracil replaces thymine

and ribose replaces deoxyribose.

As the first step in transferring genetic information from DNA to protein in eukaryotic cells, a protein-encoding gene is transcribed by RNA polymerase II into pre-mRNA (Fig. 1). The pre-mRNA includes exons (sequences preserved in the mature mRNA) and introns (intervening sequences). RNA polymerase II initiates transcription at the first nucleotide of the first exon (the transcription initiation site) of a gene and stops at any one of multiple sites 0.5 to 2 kilobases (kb) downstream from the 3' end of the last exon (termination sites). To yield a functional mature mRNA, the pre-mRNA undergoes several processing steps in the nucleus, including capping at the 5' end, cleavage and polyadenylation at the 3' end, and ligation of exons with concomitant excision of introns (RNA splicing). Shortly after transcription of pre-mRNA begins, the 5' end of the newly formed RNA is capped with 7-methylguanylate. In addition, in vertebrate cells, the 2' hydroxyls of the ribose of the first and second nucleotides at the 5' end are methylated. This 5' cap facilitates ribosome binding to RNA and increases the efficiency of translation of mRNA into protein. At the 3' end, an endonuclease cleaves the pre-mRNA at the 3' end of the last exon [poly(A) site], usually 10 to 30 bp downstream from the poly(A) signal, which often includes an AAUAAA sequence. Then, a sequence of 100 to 250 adenylate residues [poly(A) tail] is added by a polymerase. Finally, introns are excised by RNA splicing before the mature mRNA is transported to the cytoplasm, where it can be translated.

Pre-mRNA splicing is a tightly regulated process in which introns must be accurately and efficiently removed and exons spliced together to yield mature mRNA. In each mammalian intron, the nucleotides GT are at the 5' end and AG at the 3' end. Important *cis*-acting elements are required for accurate and efficient splicing, including highly conserved consensus sequences at the 5' and 3' splice sites. In addition, many *trans*-acting elements are involved in forming the complex spliceosome for pre-mRNA splicing. These include small nuclear ribonucleoproteins (snRNPs) U1, U2, U4, U5, and U6, and many non-snRNP factors. During pre-mRNA splicing, the 5' splice junction is cleaved first, and the most 5' nucleotide of the intron (G) is joined in a 2'-5' phosphodiester bond to a specific point nucleotide (A) to generate a lariat intermediate. Then, cleavage at the 3' splice junction releases the lariat intron and the two exons are ligated. Mature mRNA is formed in this manner, ready to be transported to the cytoplasm for translation.

Different exons in a given pre-mRNA can be included in the final mature mRNA. This is termed *alternative splicing,* which greatly increases the diversity of proteins that can be derived from a single pre-mRNA. Alternative splicing usually is regulated in a tissue- or development-specific manner. For example, fibronectin (a large extracellular matrix protein) mRNA in fibroblasts contains EIIIA and EIIIB exons, whereas the fibronectin mRNA in hepatocytes does not. Alternative splicing can occur because of differences in sequences at critical splice sites. For example, there is a variable in-frame skipping of exon 9 in cystic fibrosis transmembrane conductance regulator (CFTR) mRNA transcripts. From 0%–92% of CFTR mRNA transcripts in the respiratory epithelium may have a deletion of exon 9 sequences (exon 9^-). This is mainly because of differences among individuals in the length of a polythymidine tract close to the 3' splice site of exon 9. An inverse relationship exists between the length of the polythymidine tract (5T, 7T, or 9T) and the proportion of exon 9^- CFTR mRNA transcripts in respiratory epithelium.

Protein Synthesis: Translation of mRNA into Protein

In the cytoplasm, protein synthesis occurs on ribosomes, where the nucleic acid sequence of mRNA (A, U, G, C) is translated into an amino acid sequence to form a polypeptide by the combined action of tRNAs and ribosomes. From the starting point of translation of mRNA, each triplet of bases forms a “codon” that specifies which amino acid is to be incorporated into the growing polypeptide chain by interaction with a specific tRNA, which contains a unique complementary three-base “anticodon.” There are 64 (4^3) possible codons. Of these, 61 are used to specify 20 different amino acids, and three are stop signals to indicate the end of a polypeptide chain. With the exception of methionine and tryptophan, each amino acid is encoded by more than one codon. Remarkably, every cell of every organism, from bacteria to humans, uses the same three-base genetic code to designate the amino acid that is to be incorporated into the growing polypeptide chain. Ribosomes consisting of rRNAs and many associated ribosomal proteins provide binding sites for all the accessory molecules of protein synthesis. Ribosomes and bound tRNAs move along an mRNA transcript to translate its genetic information into a protein.

COMMON TECHNIQUES OF MOLECULAR BIOLOGY

Isolation of Samples

The lung provides the molecular biologist with a relatively convenient source of samples for evaluation of gene expression and function. Whereas obtaining tissue samples from most organs may require a surgical procedure, the lung is readily accessible via fiberoptic bronchoscopy, which is a less invasive procedure. During bronchoscopy, sampling of respiratory epithelium is performed by brushing with a cytology brush, whereas bronchoalveolar lavage (BAL) allows sampling of the epithelial lining fluid and inflammatory cells in the bronchoalveolar space. Evaluation of sputum or cells from the lining of the nasal passages may be accomplished without bronchoscopy.

Sputum

Sputum can yield information about the cellular and biochemical composition of the lung. Expectorated sputum can be collected easily and analyzed repeatedly. Induction of sputum by inhalation of hypertonic saline aerosol has been used successfully to diagnose lung infections (e.g., *Pneumocystis carinii* pneumonia in patients infected with HIV). Analysis of the cellular constituents of sputum has been used as a less invasive method than bronchoscopy to evaluate and monitor airway inflammation in asthmatic patients. Sputum consists of soluble (SSP) and gel (SGP) phases, which can be separated by centrifugation. Like BAL fluid, SSP can be analyzed to give information about exudation of plasma protein into the airway lumen of patients with lung disease. The amount of protein in SSP is reported to be elevated in several lung diseases, including asthma, chronic bronchitis, and cystic fibrosis (CF), and is reduced by therapy. To assess proteins in SGP, it is necessary to solubilize the SGP with dithiothreitol, a reducing agent that cleaves disulfide bridges in the mucin molecules. Analysis of proteins in sputum with specific antibodies is a valuable tool for studying inflammatory processes in the lung. Analysis of sputum from patients with CF revealed the presence of excess DNA from desquamated epithelial cells, neutrophils, and eosinophils, resulting in increased viscosity and impaired clearance and thereby playing a significant role in airway disease in these patients. This finding led to the development of a specific therapy using recombinant human deoxyribonuclease I, an enzyme that acts as a “molecular scissors” to cleave DNA in purulent lung secretions, making them easier to expectorate.

Bronchoalveolar Lavage

BAL is an invaluable means of evaluating inflammatory and immune processes in the lung. Lavage recovers cells resident in the bronchoalveolar space; these can be used for a variety of morphologic and functional studies after separation from fluid by simple centrifugation. A sample of cells is evaluated by light microscopy for total cell number, differential cell count, cell morphology, and the presence of any abnormal substances (e.g., asbestos bodies). In normal subjects, lavage yields macrophages (90%), lymphocytes (10%), and <1% neutrophils, eosinophils, and/or basophils. A high lymphocyte count is frequently found in hypersensitivity pneumonitis and sarcoidosis. Elevated numbers of neutrophils are common in CF, idiopathic pulmonary fibrosis (IPF), connective tissue disorders, and adult respiratory distress syndrome.

Depending on the cells needed, an array of techniques can be used to isolate specific types of cells from lavage fluids for further characterization. These techniques include the following: adherence to plastic, band-density-gradient centrifugation, and the use of cell-specific antibodies immobilized on the surface of superparamagnetic microspheres (Dynabeads). Dynabeads coated with a specific ligand can be added to a heterogeneous suspension to bind the desired target molecule, forming a complex that is removed from the suspension using a magnet. This technology allows for further subdivision of cell populations (e.g., separation of lymphocytes into B cells and T cells and further categorization of T cells into $CD4^+$ and $CD8^+$ populations). In sarcoidosis, for instance, the lymphocytes in BAL fluid are predominantly $CD4^+$, whereas $CD8^+$ T lymphocytes predominate in hypersensitivity pneumonitis.

Inflammatory cells from BAL fluid can also be evaluated for gene expression at the mRNA or protein level or for the presence of a specific DNA sequence. As gene expression can be altered when cells are removed from the body, it is important that they be processed promptly. When the cells are lysed, released RNases and proteases degrade RNA and proteins, respectively. Cells should be lysed, therefore, in a “protective buffer” appropriate for their intended use. Cells destined for RNA analysis should be handled in an RNase-free environment and lysed in a buffer containing guanidium thiocyanate, a powerful inactivator of RNases. Cells processed for protein analysis need to be lysed in the presence of antiproteases. An alternative approach is to freeze cells as a pellet to be thawed in a specific buffer, depending on the intended use. The latter approach, however, carries a risk for degradation if samples are accidentally thawed.

It may be important to define changes in gene expression in cells after their removal to an *ex vivo* environment. This can be done by maintaining the isolated cells in culture while the desired studies are performed. For instance, one may ask whether bronchial epithelial cells continue to express high levels of inducible nitric oxide synthase after their removal from the lung.

Evaluation of proteins, cytokines, and other mediators in BAL fluid can yield useful information regarding the inflammatory status of the lung. Results of analysis of BAL fluid are usually expressed relative to the volume of epithelial lining fluid. The latter is estimated by comparing concentrations of urea in samples of lavage fluid and plasma obtained simultaneously.

Brushing Techniques

Brushing of the nose and/or main bronchi is useful to obtain samples of respiratory epithelium. Nasal epithelial cells are obtained from the inferior turbinate under direct visualization using a cytology brush. Bronchial epithelial cells are obtained from the trachea and main bronchi during bronchoscopy using a cytology brush. Samples obtained by brushing can be processed in a fashion similar to that described for lavage cells.

Blood

Genomic DNA, purified from blood cells, can be used to correlate pulmonary findings with genetic information (e.g., polymorphism in a specific gene to be related to airway hyperreactivity). It is often useful to compare levels of a component in sputum or lavage fluid with systemic levels in plasma or serum. In addition, estimation of quantities of epithelial lining fluid requires that levels of urea in BAL fluid be compared with levels of urea simultaneously measured in plasma.

Polymerase Chain Reaction

The polymerase chain reaction (PCR) has revolutionized molecular genetic analysis by allowing the exponential amplification of DNA. PCR can produce an enormous number of copies of a single DNA molecule, enough DNA for most molecular biology procedures. DNA polymerase, the enzyme that normally is responsible for DNA replication, is used to synthesize a complementary strand of DNA with the four nucleotides as substrates and a single DNA strand as a template. Because DNA polymerase is not able to initiate DNA synthesis *de novo,* PCR requires a short piece of complementary polynucleotide that acts as a primer. PCR, therefore, mimics the in vivo process of DNA replication.

The particular sequence of DNA to be amplified is defined by a specific pair of DNA primers. The latter are added, in excess, to a tube that contains a mixture of all four deoxynucleotide precursors, the DNA to be amplified, and DNA polymerase. The mixture is heated to 95°C to denature the template DNA (denaturing step). At this temperature, double-stranded DNA molecules separate, forming single strands that become templates for the production of copies with the primers and DNA polymerase. The temperature is then lowered to allow primers to anneal to the complementary sequences in the DNA molecules (annealing step), generating the primed templates for DNA polymerase. This annealing temperature is a key variable in determining the specificity of the PCR and differs depending on the sequence of the primers. The temperature is then raised to 72°C, the optimal temperature for activity of heat-stable *Taq* DNA polymerase, which was isolated from bacteria that live in thermal springs. The temperature is held at 72°C, allowing DNA synthesis to proceed (extension step). At the end of this period, the temperature is raised again to 95°C, so that double-stranded DNA (the original strand and the newly synthesized complementary strand) separates. These single strands become templates for another round of DNA synthesis, and the cycle of denaturation, annealing of primers, and synthesis of new strands by DNA polymerase is repeated for 20 to 50 cycles. PCR does not require a highly purified DNA as a template and can therefore be performed directly on cell lysates from virtually any source.

"RNA" Polymerase Chain Reaction (Reverse Transcription-Polymerase Chain Reaction)

The adaptation of PCR for the analysis of specific mRNA molecules provided a breakthrough. In this technique, short oligonucleotides are annealed to mRNA to act as primers for reverse transcriptase. This enzyme, isolated from certain RNA viruses, uses RNA as a template to synthesize a complementary DNA (cDNA) strand, which then becomes a template for PCR amplification. The exquisite sensitivity of this simple modification of PCR makes possible the detection and sequence analysis of mRNAs that are extremely rare. Because RNA must be reverse transcribed to cDNA before amplification can take place, this technique has become widely known as *reverse transcription-polymerase chain reaction* (*RT-PCR*). Given the proclivity of enzymatic amplification to reveal rare molecules, one must consider whether the amplified products arise from RNA or from contaminating DNA. Whenever possible, PCR primers should be chosen from different exons. Inadvertent amplification of DNA can then be recognized by the size of the products resulting from amplification of the intervening introns. It may be avoided by enzymatic treatment of samples with DNase before RT-PCR. DNA amplification may also be detected by amplification of a control sample without prior reverse transcriptase treatment.

"Hot-Start" Polymerase Chain Reaction

The specificity of PCR can be further enhanced using the "hot-start" technique, which minimizes nonspecific binding of primer to template during preparation of PCR reactions at room temperature. All reagents except one (usually DNA polymerase) are mixed and kept at 70° to 95°C. Just before cycling, the missing component is added to initiate the reaction at the elevated temperature. The method can be automated by interposing a physical barrier of wax between the reaction mixture and the component to be added last. Mixing occurs only at high temperature, when the wax melts. A recent innovation is the use of a neutralizing monoclonal antibody to block DNA polymerase activity during the mixing of PCR components. When the temperature is raised above 70°C during the first PCR cycle, the enzyme-antibody complex dissociates, the antibody is inactivated, and the DNA polymerase becomes active. Typical applications of hot-start PCR include reactions involving complex genomic or cDNA templates, very-low-copy-number targets, "multiplex" PCR (i.e., multiple primer pairs in the same tube), and "long" PCR (see below).

"Touchdown" Polymerase Chain Reaction

"Touchdown" PCR involves gradually decreasing the annealing temperature (e.g., by 1°C every other cycle) to a "touchdown" annealing temperature, which is then used for approximately 10 cycles. The approach takes advantage of the exponential nature of PCR to favor products resulting from correct matches between primers and template rather than incorrect intermediates. In the above example, a difference of 1°C between specific and spurious annealing temperatures will give a twofold difference in favor of the specific product per cycle.

"High-Fidelity" Polymerase Chain Reaction

DNA replication in vivo is extraordinarily accurate. Most bacterial DNA polymerases possess an exonucleolytic activity that scrutinizes DNA synthesis and removes mismatched nucleotides. *Taq* polymerase, however, does not have this "proofreading" capability and incorporates one incorrect nucleotide per approximately every 2 x 10^4 nucleotides. When an exact sequence is required, such as when PCR is being used for cloning, high-fidelity enzymes with "proofreading" exonuclease activity are required (e.g., *Pfu* polymerase, which has an error rate of one per approximately 2 x 10^6 nucleotides).

"Long" Polymerase Chain Reaction

This is one of the most important recent advances in PCR technology and is likely to have revolutionary effects on molecular biology. Until recently, it has been difficult to amplify more than 5 kb of DNA, probably because of premature termination of synthesis at sites of mismatched base pairs. Although DNA polymerases with "proofreading" exonuclease activity can remove mismatches and extend the chain, they can not overcome this length limitation, probably because their exonuclease activity eventually degrades the PCR primers. The solution was to use a mixture of *Taq* polymerase and a small amount of polymerase that possesses a "proofreading" exonuclease activity. Evidently, very little exonuclease activity is sufficient for removal of the mismatches, permitting the predominant polymerase activity to complete strand synthesis. The capability of "long" PCR to amplify DNA sequences of up to 42 kb will make it possible for the speed and simplicity of PCR to facilitate and complement many techniques in molecular genetics.

Rapid Amplification of cDNA Ends

Conventional approaches to the characterization and sequencing of mRNA rely on the preparation and screening of a cDNA library. Frequent problems, however, include loss of rare messages during library preparation and failure to produce complete cDNA molecules because of premature termination of reverse transcription. Rapid amplification of cDNA ends (RACE) offers an opportunity to isolate a message of interest directly by amplification of full-length mRNA. Unlike conventional PCR, which requires knowledge of the sequences flanking the region of interest to design PCR primers, an anchored PCR can be performed when only a small amount of sequence information is available (40 to 50 nucleotides). Amplification is carried out between a defined site (known sequence) and unknown sequences at either the 3' or 5' end of the mRNA. 3' RACE takes advantage of the natural poly(A)$^+$ tail present in virtually every mRNA. In this procedure, mRNAs are converted to cDNA using reverse transcriptase with an oligo(dT) adapter primer. Specific cDNA is then directly amplified by PCR using a gene-specific primer that anneals to the region of known sequence and an adapter primer that targets the poly(A) tail region. 5' RACE uses a sequence-specific primer to initiate the synthesis of the cDNA strand. By means of terminal transferase, cDNA is modified by the addition of a poly(A) tail to flank the 5' end. PCR amplification is then carried out with a sequence-specific primer and an oligo(dT) primer complementary to the newly synthesized tail. Reamplification using a second, internal (nested) sequence-specific primer greatly reduces spurious amplification products. It is advisable to monitor PCR products by Southern blot hybridization using a specific oligomer, to confirm that the desired product has been amplified. After amplification, 5' and 3' RACE products can be combined by ligation to produce an intact, full-length cDNA that can be sequenced directly or cloned into an appropriate vector for further analysis.

Limitations of Polymerase Chain Reaction

The great sensitivity of PCR, although a major advantage, is also its major limitation. Because of the enormous amplification attainable by PCR, small amounts of DNA contamination, either from previous PCR amplification, positive control templates, or samples with large amounts of DNA, can result in product formation even in the absence of added template DNA. Aerosol droplets from a pipette tip may contain amplifiable molecules after prior handling of a positive sample. The use of dedicated equipment and pipette tips with hydrophobic filters is recommended to minimize the incidence of false-positives. All reaction mixtures should be prepared in an area separate from that where PCR products are analyzed. Irradiation of PCR solutions with ultraviolet (254 nm) light before adding DNA template "sterilizes" or renders nonamplifiable any contaminant DNA by causing thymine dimers to form. Another approach is to use uridine triphosphate (UTP) instead of deoxythymidine in the PCR reaction mixture and include the enzyme uracil-*N*-glycosylase (UNG). UNG will degrade any DNA from a former PCR because it contains UTP. UNG is then inactivated by the high temperature initiating the new PCR, so that desired products of the amplification can accumulate.

A second limitation that poses a major hurdle to the concept of quantitative PCR stems from the nonlinear nature of the amplification process. Because of the exponential nature of PCR, an early error can be amplified exponentially and in an unpredictable manner, preventing accurate quantitative results. Two approaches can circumvent this problem: (1) During reverse transcription of mRNA, a known quantity of synthetic mRNA, which can be easily differentiated from the endogenous message, is added, and the two cDNAs are amplified simultaneously in the same reaction mixture with the same sets of primers. The amplified unknown is then compared with the amplified standards. (2) During PCR amplification, a known amount of modified cDNA is added to the PCR medium to compete with the target sequence for the same primers. If the competitor were present at the same concentration as the unknown, both DNAs would be amplified to the same extent. By using several different percentages of the competing DNA, the amount of endogenous DNA can be estimated.

Differential Gene Expression

Paramount to understanding the molecular biology of lung disease is a knowledge of genes that are differentially expressed during physiologic and pathologic processes. Differentially expressed genes can be identified by detecting differences in levels of mRNAs in different types of cells or under different conditions in the same cell. This may be important, for example, to an investigator who would like to identify genes involved in the pathogenesis of IPF. After a group of patients fitting the diagnostic criteria and a group of normal subjects to be used as controls have been screened, and with the knowledge that the alveolar macrophage is important in the pathogenesis of this disease, samples may be obtained by BAL from both groups. Differential cDNA library screening, subtracted cDNA libraries, or PCR-based differential display can be used to identify genes expressed differently in alveolar macrophages from the two groups.

Differential Screening

Differential screening allows a gene-by-gene comparison of mRNA populations in the two samples. For this purpose, a cDNA library is prepared using mRNA isolated from the alveolar macrophages of patients with IPF, plated on agar, and transferred to duplicate sets of filters. Filter A is hybridized to a cDNA probe prepared from alveolar macrophage mRNA of normal subjects. Filter B is hybridized to a cDNA probe prepared in a similar fashion from alveolar macrophage mRNA of patients with IPF. Unlike Southern or Northern hybridization, differential screening must be performed under conditions of limiting (rather than excess) probe to detect differences in the concentrations of mRNA from the two populations. cDNA clones (as plaques) that demonstrate different levels of hybridization with the two probes represent mRNAs that are differentially expressed and can be isolated and screened to confirm their differential expression. This method is straightforward and works well for genes that are highly expressed. It is difficult, however, to isolate mRNAs of low abundance, because of variable signal intensity and relatively high background. The use of subtracted libraries and/or subtracted probes improves the chances of cloning rare cDNAs (see below).

Subtractive Hybridization

Subtractive cloning can be used to construct a cDNA library that is enriched in transcripts of genes specifically expressed in cells of patients with IPF. Single-stranded cDNA is synthesized using mRNA from these cells and then hybridized to an excess of biotinylated mRNA from cells of normal subjects. The cDNA sequences representing mRNAs expressed in normal cells will hybridize, whereas those unique to the cells of patients with IPF will remain single-stranded. By adding streptavidin, a protein that binds to biotin, the biotinylated sequences and cDNA hybridized to them can be removed. Nonbiotinylated single-stranded cDNAs from patients with IPF remaining in the solution can then be used to create a subtracted cDNA library enriched in clones that are unique to patients with IPF. This library is then screened using a probe made from RNA of normal subjects. To enhance specificity, a subtracted probe can be used. Subtracted cDNA probes can be prepared using the same principle as for subtracted cDNA libraries. A major problem with subtracted libraries is the very small number of colonies sometimes obtained, in part as a result of the loss of mRNA during the two or more rounds of hybridization that may be needed to remove shared sequences. This can be overcome by using PCR amplification of both the original and the subtracted DNAs. With very limited amounts of starting RNA, multiple rounds of subtraction and amplification may be needed.

Differential Display Reverse Transcription-Polymerase Chain Reaction

Differential display combines the power of PCR amplification and the high resolution of polyacrylamide gel electrophoresis. Each RNA is transcribed to a cDNA by means of a set of four oligo(dT) primers that anneals to the poly(A) tails, each with an anchored two bases at the 3' end, $T_{12}XA$, $T_{12}XC$, $T_{12}XG$ and $T_{12}XT$ (where X is a degenerate mixture of A, G, and C). Each degenerate anchored oligo(dT) primer will, in theory, reverse transcribe one fourth of the total mRNA population. In combination with a set of 5' random 10-mer oligonucleotide primers, which should anneal to arbitrary subsets of mRNA present in the cell, the cDNA population is amplified by PCR. Each of the random 10-mers anneals to a complementary sequence located at a different distance from the 3' terminus, yielding PCR products of different sizes. By varying primer combinations, most of the RNA species in a cell can be represented. PCR reaction products (labeled with a radioactive isotope, such as sulfur 35 or phosphorus 33, or fluorescein) are separated by electrophoresis in a polyacrylamide gel for side-by-side comparison of RNA samples from different cells, allowing recognition of differentially expressed genes. Differential expression is detected by inspection of autoradiograms to identify bands present in only one group, such as patients with IPF. Fluorescent products can be analyzed using an automated DNA sequencer. Although band intensity may correlate with mRNA abundance, the method is not believed to be quantitative.

Further analysis of differentially displayed sequences requires excision of the band from the gel and elution of the DNA, followed by repeated amplification and gel purification. The DNA is then subcloned, so that it can be sequenced and used to make probes for analysis of Northern blots. High-efficiency cloning can be carried out by taking advantage of the single additional A residues at the 3' ends of PCR products; single T residues are added at the 3' ends of a vector to facilitate ligation to the PCR product (TA cloning). The chosen DNA is then directly used as a probe in Northern blot analysis, utilizing the pools of mRNA from the two groups to confirm differential expression and provide information about the molecular weight of the identified transcripts. Once differential expression of a band is confirmed and sequence is known, it should be determined whether the sequence is part of a true open reading frame (i.e., encodes a protein sequence). The identified sequence can be compared with a gene database to determine if it is part of a novel gene and if it bears sequence similarities to other gene families, which may provide clues to function. The same cDNA can then be used to obtain a full-length clone of the novel gene by screening a cDNA library.

Although differential display provides a rather simple and rapid way of identifying differentially expressed genes, several problems are inherent to the technique. Because of its great sensitivity, it can potentially detect a very large number of genes. Screening and confirmation of differential expression of all these could be very time-consuming. Differential amplification, display, and confirmation should therefore be carried out with multiple identical samples before proceeding. Every experiment requires appropriate controls (e.g., samples without reverse transcriptase paired with reverse transcribed PCR samples to detect amplification of products from contaminating DNA not removed by DNase treatment of RNA samples), as well as confirmation of differential expression by Northern analysis before further cloning or sequencing procedures.

Screening for Members of Common Family Genes

The methods considered above illustrate a rather random approach to identifying novel genes. This may not always be the best strategy. When looking for related genes, which presumes prior knowledge of amino acid sequence of the proteins analogous to the one that is sought, degenerate pools of oligonucleotide primers can be designed for PCR amplification, usually performed at a low annealing temperature to permit several possible mismatches. This, however, can result in an enormous number of irrelevant PCR products. If enough sequence is known, it is advisable to screen PCR products by hybridization with a specific probe before further analysis. An alternative approach is to use a degenerate oligonucleotide probe to screen a cDNA library for the desired gene. For instance, a conserved sequence of seven or more contiguous amino acids provides enough information to design a degenerate oligonucleotide probe to select and clone cDNAs encoding related proteins. If the sequence of another conserved region of the desired gene is known, screening can be simplified by using a second probe to evaluate clones positive on initial screening.

Screening for a Specific Protein or Specific Function

If the nucleotide sequence is not known, functional assays or specific antibodies that recognize the desired gene product can be used. This is accomplished by constructing and screening an expression library of cDNAs with an open reading frame that encodes the desired protein fused to a bacterial protein inserted adjacent to bacterial promoters. Fusion proteins may be more stable than native proteins in bacteria and are therefore likely to yield more product. The cDNA library is screened by incubation with an antibody specific for the protein of interest (primary antibody); then, following removal of unbound antibody, a second antibody is added to react with

the primary antibody. The second antibody can be labeled with radioactive isotope, coupled to biotin, or conjugated with an enzyme such as alkaline phosphatase; each provides a means to detect the clone expressing the desired protein. The clone is then isolated and the cDNA sequence determined. Similar principles apply in screening with a functional assay (e.g., ADP-ribosyltransferase activity) instead of antibodies.

Identifying a Protein by Western Blotting

Western blotting is a simple, sensitive, and powerful method for immunologic detection of particular proteins of interest in a complex mixture of proteins. This commonly used technique combines the resolving power of gel electrophoresis, the specificity of antibodies, and the sensitivity of enzyme assays. Proteins are first denatured in the presence of sodium dodecyl sulfate and separated according to molecular weight by polyacrylamide gel electrophoresis. Then, an electric field is applied to drive the separated protein molecules out of the gel and onto a paper-thin nitrocellulose membrane or its equivalent, where they are immobilized. In the second step, the specific protein of interest is identified by soaking the membrane in a solution containing an antibody (primary antibody) specific for that protein (antigen). Then, the antibody bound to the antigen is reacted with a second antibody, which is covalently linked to alkaline phosphatase or horseradish peroxidase. After washing the membrane, the enzyme linked to the second antibody is detected by reaction with a chromogenic substrate to yield a visible product or with a substrate that yields a luminescent product, which can be detected by autoradiography. Alternatively, the antigen-antibody complex can be detected using protein A labeled with iodine 125, which binds to the antibody.

RECENT ADVANCES IN PULMONARY RESEARCH

Polymerase Chain Reaction in the Diagnosis of Pulmonary Infections

Standard diagnostic procedures for pulmonary infections are based on the ability to grow organisms in culture or to detect their presence in serum using antibodies. These tests can be relatively insensitive and time-consuming. Because of its high sensitivity, PCR may facilitate the early diagnosis of many infectious diseases.

Mycobacterium tuberculosis *Infection*

The diagnosis of *M. tuberculosis* infection requires growth of organisms in culture, a procedure that takes several weeks. More rapid diagnosis of pulmonary tuberculosis can be made by detection of acid-fast organisms in sputum smears. The results of smears are positive, however, in only 50%–75% of cases. Prompt and sensitive diagnosis by PCR is feasible using specific primers for a sequence within a gene that is highly conserved in all mycobacterial species. The amplified fragment is then hybridized with species-specific oligonucleotide probes to identify the specific strain. As few as 10 bacilli in 10^6 cells can be detected by PCR, which has also been used to identify *M. tuberculosis* in blood samples. With the inherent potential for false-positives owing to its great sensitivity, positive PCR results must be interpreted in conjunction with clinical information. In contrast, a negative PCR result rules out the diagnosis. Although at present PCR has not totally replaced established procedures for the diagnosis of *M. tuberculosis* infection, it may be particularly useful in certain categories of patients. In a patient with negative smear results and positive culture results, PCR could provide an early diagnosis on which to base initial therapy. In addition, by the amplification of bacterial DNA sequences that contain mutations associated with antibiotic resistance, PCR may play an important role in the rapid identification of multidrug-resistant strains of *M. tuberculosis.* PCR may be used to diagnose primary tuberculosis in children, which is sometimes difficult to diagnose by conventional means. The results of direct examination of sputum or gastric aspirates are usually negative, and the results of culture are positive in only 20% of cases. Tuberculin skin tests are difficult to interpret in children who are immunosuppressed or have received Calmette-Guérin vaccination. *M. tuberculosis* has been detected by PCR in gastric aspirates from many children with primary tuberculosis and cultures negative for bacteria.

Cytomegalovirus Pneumonitis

The diagnosis of cytomegalovirus (CMV) pneumonitis in immunocompromised patients may be difficult, because of its clinical similarity to diffuse lung injury of other causes. Immunofluorescent staining of alveolar macrophages and epithelial cells for CMV antigens with specific monoclonal antibodies has been used, in combination with clinical findings, to make the diagnosis. PCR provides a very sensitive assay for the detection of CMV in bronchoalveolar lavage fluid. For rapid diagnosis of CMV infection, the combination of PCR and immunofluorescence is an optimal strategy that provides almost 100% sensitivity and specificity. PCR is also useful as a rapid assay to exclude the diagnosis of CMV pneumonitis. In addition, detection of CMV in blood by PCR has been used to predict in which patients CMV pneumonitis is likely to develop or, after completion of initial therapy, which patients are likely to relapse.

Pneumocystis carinii *Pneumonia*

PCR is a highly sensitive technique for the identification of *P. carinii* in BAL fluid or induced sputum; it detects the gene that encodes the mitochondrial rRNA of *P. carinii.* Diagnostic PCR is more sensitive for detecting *P. carinii* than are traditional silver staining and immunofluorescent procedures. The specificity of PCR detection can be enhanced by hybridizing PCR products to specific oligonucleotide probes on Southern blots. Detection by PCR of *P. carinii* in serum has been proposed as a simple test for the diagnosis of disseminated pneumocystosis.

Other Pulmonary Infections

Candida albicans, Mycoplasma pneumoniae, Bordetella pertussis, Aspergillus fumigatus, Legionella pneumophila, respiratory syncytial virus, and influenza virus are examples of other organisms that have been identified using PCR.

Latent Infections

In several studies, the results of PCR in diagnosis of *Mycoplasma* infections were discordant with serologic findings, consistent with the observation that *Mycoplasma* can persist in tissues long after clinical disease has resolved. Although PCR can be useful for detection of persisting sequences of an infectious agent, the clinical interpretation of the finding depends on establishing whether it represents continuing or latent infection. There are situations, however, in which the mere presence of the sequences in a host may have important clinical implications, as in the case of gene therapy protocols utilizing adenovirus (AV) vectors in the lung. In this approach, the normal gene is directly delivered to the respiratory epithelium using AV vectors that have been rendered replication-defective by deletion of a region, E1a, that is critical for viral replication. There is the possibility, however, of a replication-defective AV vector replicating as a result of recombination or complementation with viral E1a sequences present in the host cells from prior infections. Using specific primers to amplify E1a by PCR and evaluating PCR products with a probe specific for that region, it is possible to identify individuals who harbor that viral sequence in their cells. Special precautions in these individuals may be warranted, such as frequent monitoring for evidence of viral replication.

Gene Therapy

Gene therapy is a medical intervention designed to alter the genetic program of cells with therapeutic intent. The goal is to modify specific cells to express, temporarily or permanently, a specific set of new genetic information in a fashion that will be beneficial in the treatment of hereditary or acquired disease. There are two basic strategies of gene therapy. First, cells may be genetically modified ex vivo for subsequent implantation in the host target tissue or organ. This can be carried out using either autologous cells derived from the intended recipient of the therapy or cells from other individuals or species. Alternatively, cells may be modified in vivo. Viral or nonviral vectors can be used for gene therapy (Table 1).

Method	Applicability		Integration
	In vivo	Ex vivo	
Viral			
Retrovirus	+	+++	yes
Adenovirus	+++	+	no
Adeno-associated virus	+++	++	yes
Herpes virus	+++	+	no
Other viruses (e.g., vaccinia)	+++	+	no
Nonviral			
Naked plasmid	+++	+	no
Liposome-plasmid complex	+++	+	no
Ligand-plasmid complex	+++	+	no
Particle bombardment	++	++	?
Combination system			
Co-internalization	+++	+	no

+++, High applicability; ++, medium applicability; +, low applicability; ?, integration results not definitive.

Vectors

Retrovirus (RV) is an RNA virus that enters the cell through specific viral receptors on the cell surface. Once inside the cell, RNA is converted to DNA by the reverse transcriptase activity of the virus itself. The double-stranded DNA provirus is then randomly integrated into the host genome, if the cell is actively dividing. In most RV vectors, the *gag, pol,* and *env* genes are replaced with the gene of interest, so that vectors are capable of entering cells and inserting the new genes into the genomes but cannot direct cells to produce infectious RVs. Theoretically, the newly integrated exogenous gene will be passed on to progeny of the cell when it divides. RV is, thus far, the most widely used vector in gene transfer protocols approved by the Recombinant DNA Advisory Committee (RAC) of the National Institutes of Health. A major disadvantage of RV as a vector for use in vivo, however, is that it cannot be used to express genes in nondividing cells.

The AV vector is more efficient than RV for in vivo gene therapy. AV is a double-stranded DNA virus that provides several major advantages. Replication of host cells is not required for expression of a gene transferred by AV, and there is no known association of human malignancies with AV infection despite its high incidence. In most AV vectors currently used, the E1 region, which is important for viral replication, is deleted. Disadvantages of the AV vector are that (1) many AV genes included in the presently used vectors induce an immune reaction, and (2) gene expression is not stable, as the vector does not integrate into the host genome.

Adeno-associated virus (AAV) is a 4.7-kb, single-stranded DNA virus of the parvovirus family. The AAV genome consists of two genes, *rep* and *cap,* flanked by inverted terminal repeats that serve as signals for origin of DNA replication and packaging. AAV is nonpathogenic and appears not to alter the clinical course of AV infection. AAV cannot naturally replicate and requires coinfection with AV or herpesvirus, which provide helper functions. AAV has the ability to integrate into the DNA of nondividing cells. In the absence of helper virus, AAV infection results in high-frequency, stable DNA integration, usually into a specific site on human chromosome 19 at q13.4. In AAV vectors, the *rep* and *env* genes are usually deleted and replaced with the gene of interest to minimize the possibility of inducing immunity by the expression of viral genes. AAV can be produced to titers of $>10^{10}$ plaque-forming units (pfu) per milliliter. All these features make AAV vectors attractive for human gene therapy. Their disadvantages, however, include the inability to accommodate large genes (packaging limit of 4.5 kb) and the potential risk for contamination by helper viruses, as production of AAV vector requires coinfection with AV or herpesvirus.

Liposomes

Liposome-plasmid complexes are the most frequently used nonviral vectors for human gene therapy. Liposomes are lipid model membranes that can form a complex with DNA and facilitate its transfer into cells, probably through nonspecific fusion of the liposome-plasmid complex with cell membranes.

Gene Transfer Protocols

To date, >100 human gene transfer protocols have been approved by RAC. Of these, 18 are aimed at treating individuals with lung diseases: 13 for CF, one for a_1-antitrypsin deficiency, and four for primary lung cancer (Table 2).

Disease	Gene	Vector	Tissue transduced	Number[b]
Hereditary				
Cystic fibrosis	CFTR	Adenovirus	Nasal and respiratory epithelium	4
	CFTR	Adenovirus	Nasal epithelium and/or maxillary sinus	3
	CFTR	Adenovirus	Respiratory epithelium	2
	CFTR	Adeno-associated virus	Nasal and respiratory epithelium	1
	CFTR	Adeno-associated virus	Maxillary sinus	1
	CFTR	Liposome-plasmid complex	Nasal epithelium	2
a_1-Antitrypsin deficiency	a_1-AT	Liposome-plasmid complex	Nasal and respiratory epithelium	1
Lung cancer				
Non–small-cell lung cancer	p53	Retrovirus	Tumor	1
	K-*ras* (AS)			
	p53	Adenovirus	Tumor	1
Small-cell lung cancer	IL-2	Liposome-plasmid complex	Skin	1
Adenocarcinoma	CEA	Vaccinia virus	Skin	1

CFTR, cystic fibrosis transmembrane conductance regulator; a_1-AT, a_1-antitrypsin; p53, p53 tumor suppressor gene; K-*ras* (AS), antisense sequence of K-*ras* oncogene; IL-2, interleukin-2; CEA, carcinoembryonic antigen.
[a]Only protocols approved by the Recombinant DNA Advisory Committee (RAC) of the National Institutes of Health by December 1995 are included.
[b]Number of protocols approved.

TABLE 2. *Summary of approved protocols for gene therapy of human lung diseases*[a]

For CF, AV vectors are used in nine protocols, AAV vectors in two, and liposome-plasmid complexes in two. In five protocols, vectors are delivered to both nasal epithelium and lung respiratory epithelium, in two to respiratory epithelium only, and in six to nasal and/or maxillary sinus epithelium. In twelve protocols, the vector is instilled in the lung via bronchoscopy or delivered to the nasal and/or maxillary sinus epithelium through a rhinoscope or catheter under direct visualization. In one protocol, the AV vector is administered by aerosol to the lung.

It has been observed that about 30% of adenocarcinomas of the lung have a mutated K-*ras* oncogene, and 50% of non–small-cell lung cancers have mutations or deletions of the p53 tumor-suppressor gene. In two protocols for lung cancer, an RV or AV vector containing wild-type p53 cDNA (for tumors with mutated or deleted p53) or antisense K-*ras* (for tumors with mutated K-*ras*) is injected into a residual endobronchial lesion of non–small-cell lung cancer. Immunotherapy was proposed in two other protocols. In one protocol, intradermal injection of recombinant carcinoembryonic antigen (CEA) vaccinia virus is followed by subcutaneous injection of CEA peptide to induce a host immune response. In the other, autologous tumor cells, irradiated to prevent proliferation, are transduced ex vivo with a liposome-plasmid complex containing an interleukin-2 cDNA and then injected subcutaneously.

Of protocols for gene therapy of human lung diseases, data from four studies of patients with CF have been reported in detail. An AV vector was used in three and a liposome-plasmid complex in one. In all studies, successful gene transfer to a small fraction (<1%–14%) of nasal or respiratory epithelial cells was demonstrated, and CFTR protein or mRNA was detected for at least 9 days. In three studies, two with AV vectors and one with a liposome-plasmid complex, partial correction of abnormalities of potential difference across nasal epithelium was noted. One controlled study using an AV vector, however, failed to demonstrate correction of functional defects in nasal epithelium. In one study, the AV vector caused the level of interleukin-6 in serum to increase, and pneumonia developed in one person who received 2×10^9 pfu of AV vector into a large airway. Parameters of pulmonary function and chest roentgenographic and computed tomographic findings in this patient returned to baseline after 1 month.

Although the technologies are still far from ideal, data relevant to human gene therapy are encouraging; after further refinement, it seems likely that gene therapy will become an increasingly useful therapeutic option.

Transgenic Mouse Model

Transgenic mice have recently been used as models for the study of many human diseases, not only because mice are relatively closely related to the human species but also because their genetic manipulation and propagation are relatively rapid.

Transgenic mice are produced by the permanent alteration of a small part of the genome, which is achieved by at least two different strategies. In the first, a cloned DNA construct is delivered into the male pronucleus of the newly fertilized mouse egg by microinjection. The introduced foreign DNA randomly integrates into the mouse genome, without preference for a particular chromosomal location, and the injected eggs are implanted into a foster mother. Of the 10%–30% of those that develop to term, up to 40% may contain integrated foreign DNA. They are heterozygous and can be bred to homozygosity. Mice that carry the foreign gene are termed *transgenic,* and the integrated DNA is the transgene. Because the foreign DNA is randomly integrated into the mouse genome, there are several potential problems, such as insertion of the transgene into an essential gene or differential expression of the transgene resulting from differences in sites of integration or differences in the number of gene copies introduced.

In contrast to random integration of transgenes, the second strategy modifies a selected gene at a precise location within the genome of a mouse embryonic stem (ES) cell by homologous recombination. Mouse ES cells are derived from the inner cell mass, which corresponds to the future embryo, of a mouse blastocyst. Under suitable culture conditions, the ES cells can proliferate in vitro, remain undifferentiated, and be subcultured repeatedly. Usually, ES cells are grown on a monolayer of fibroblasts that have been treated so that they cannot divide. A cloned DNA construct is then delivered into the ES cells by electroporation. The foreign DNA becomes integrated into the homologous gene locus of the mouse genome by homologous recombination and disrupts or mutates the endogenous gene. ES cells with integrated

foreign DNA can be identified by PCR and/or Southern analysis. They can be positively and/or negatively selected, taking advantage of properties of specific, simultaneously introduced genes. Recombinant ES cells are then microinjected into blastocysts derived from mice with a coat color different from that of the donor of ES cells and implanted in a foster mother. From the coat color of the chimeric offspring, the contribution of recombinant ES cells can be easily evaluated.

Examples of transgenic mouse models for human pulmonary diseases are described below.

Idiopathic Pulmonary Fibrosis

Tumor necrosis factor-a (TNF-a) produces both fibrogenic and inflammatory effects. Expresssion of TNF-a mRNA and protein is increased in type II pneumocytes of individuals with IPF. Surfactant protein C (SP-C) is synthesized and secreted by type II pneumocytes. By microinjecting a construct containing a mouse TNF-a gene, including the entire 3' untranslated region directed by a 3.7-kb fragment of the 5'-flanking region of the human SP-C gene (SP-C/TNF-a), into the male pronucleus of mouse fertilized eggs, Miyazaki et al. generated transgenic mice with elevated expression of TNF-a in alveolar epithelium, mainly in type II pneumocytes. Five of thirteen founder mice died at birth or after 1 month with severe lung lesions. Surviving mice transmitted a pulmonary disease to their offspring, the severity of which was correlated with levels of TNF-a mRNA in the lung. At 1 to 2 months of age, leukocytic alveolitis, with a predominance of T lymphocytes, was extensive within the interlobular septa, beneath the pleurae, and around extra-alveolar small vessels. The extent of fibrosis was minimal at this stage. However, at 6 months of age, the alveolar septa were markedly thickened, resulting in large part from the accumulation of desmin-containing fibroblasts. Alveolar spaces were enlarged and contained desquamated epithelial cells. Alveolar surfaces were lined by hyperplastic type II pneumocytes. Increased levels of vascular cell adhesion molecule-1 (VCAM-1) mRNA, enlargement of the endothelial cytoplasm, and increased platelet trapping in alveolar capillaries were also observed. In general, the numerous pulmonary lesions in the SP-C/TNF-a mice were very similar to those in individuals with IPF.

Transgenic mice in which human transforming growth factor-a (hTGF-a) was expressed under the control of a 3.7-kb fragment of the 5'-flanking region of the human SP-C gene also exhibited pulmonary fibrosis. The fibrosis was prominent in subpleural, peribronchiolar, peribronchial, and perihilar regions. There was, however, no apparent fibrosis or thickening of the alveolar interstitium. The severity of fibrosis differed with the founder line and the abundance of transgene product in the lungs. In addition, greater than normal mitotic activity and numbers of epidermal growth factor (EGF) receptors in the interstitial cells of the fibrotic lesions were observed. These findings support the hypothesis that hTGF-a produced by respiratory epithelial cells stimulates the growth of mesenchymal components of the lung.

These kinds of transgenic mice provide valuable models for evaluating the molecular mechanisms that contribute to the pathogenesis of pulmonary fibrosis and for testing therapeutic strategies in vivo.

Pulmonary Alveolar Proteinosis

Granulocyte-macrophage colony-stimulating factor (GM-CSF), a 23-kd (kilodalton) glycoprotein, stimulates the proliferation of hematopoietic progenitor cells, as well as their differentiation to monocytes/macrophages, neutrophils, and eosinophils. To delineate the *in vivo* function of GM-CSF, Dranoff et al. generated mice carrying a null allele of the GM-CSF gene by homologous recombination in embryonic stem cells. Unexpectedly, the homozygous transgenic mice had normal numbers of peripheral bloods cells, bone marrow progenitors, and tissue hematopoietic populations, including splenic dendritic cells. However, in all homozygous mutant mice, but not in heterozygous or wild-type mice, a progressive accumulation of surfactant lipids and proteins developed in the alveolar space, characteristic of human pulmonary alveolar proteinosis. In mutant mice, levels of surfactant proteins SP-A, SP-B, and SP-C were markedly increased in BAL fluid, although the abundance of surfactant mRNA was indistinguishable from that in wild-type mice. Moreover, the alveolar macrophages of mice deficient in GM-CSF were filled with surfactant protein and lipid, although no accumulation of SP-A was observed in type II pneumocytes. It appeared that alveolar macrophages were defective in processing pulmonary surfactants, as a result of the absence of GM-CSF in the mutant mice, leading to pulmonary alveolar proteinosis. In addition, extensive pulmonary lymphoid hyperplasia surrounding the airways and veins, developed in mutant mice, which could have been the result of an excessive response to otherwise innocuous inhaled antigens.

ACKNOWLEDGMENT

We thank Dr. Martha Vaughan and Dr. Vincent C. Manganiello for critical reviews of the manuscript.

CHAPTER

8 Pulmonary Imaging

Daniel R. Gale · M. Elon Gale

D. R. Gale and M. E. Gale: Department of Radiology, Veterans Affairs Medical Center, Boston, Massachusetts 02130.

INTRODUCTION

Despite the introduction of many technologically advanced imaging modalities, a conventional chest radiograph remains the initial, and sometimes only, diagnostic image necessary to evaluate patients with suspected chest abnormalities. Typically, observations derived from chest radiography, in combination with the clinical history, suggest at least a differential, if not a definitive, diagnosis. Only after complete characterization and assessment of a chest radiographic abnormality are additional diagnostic imaging studies indicated; these can range from low-technology examinations, such as decubitus chest radiographs, to sophisticated technologic examinations, such as computed tomography (CT), magnetic resonance imaging (MRI), nuclear imaging, pulmonary and bronchial artery angiography, and ultrasonography. At this time, the most important of these additional diagnostic imaging studies is CT of the chest. Chest CT has done more to revolutionize the radiologic evaluation and subsequent care of patients with thoracic abnormalities than any other radiographic technique since the invention of conventional chest x-ray imaging.

In addition to conventional radiography and CT, three other broad categories of radiographic examinations can potentially be used to evaluate chest abnormalities. These include angiography, nuclear imaging, and MRI. Although much less frequently performed than chest radiography or CT, these other examinations listed are essential tools in the diagnosis and management of patients with specific medical problems, such as hemoptysis, pulmonary embolus, or brachial plexus involvement by neoplasm. It is now routine practice to use images for accurate staging of a thoracic neoplasm, percutaneous biopsy of a mediastinal mass, drainage of a collection of fluid, or quick assessment of the response of a chest abnormality to therapy. The older imaging techniques (plain tomography and bronchography) have generally been supplanted by one of these newer techniques that in conjunction with other procedures, such as fiberoptic bronchoscopy, provide more reliable anatomic and physiologic information with less patient discomfort. Ideally, the pulmonologist and the radiologist should work together to plan a cost-effective diagnostic and therapeutic imaging workup.

In this chapter, the relevant technical principles of common radiologic examinations are described, and the clinical indications, advantages, and limitations of each examination type are reviewed. A comprehensive review of the myriad diagnostic and interpretative findings found on routine chest radiography or the more specialized examinations is beyond the scope of this chapter; however, clinically pertinent signs are illustrated. A systematic, simplified approach to interpreting any imaging study and organizing a relevant differential diagnosis is presented at the conclusion of the chapter.

STANDARD PLANE CHEST RADIOGRAPHY

Radiographic Technique

Two distinct radiographic techniques are used to obtain a conventional chest radiograph (posteranterior and lateral); the high-kilovoltage (>100 kV) and low-kilovoltage (<90 kV) techniques. The principal advantage of the high-kilovoltage technique is better display of the lung parenchyma without interference from overlying ribs, clavicles, or heart. The principal advantage of the low-kilovoltage technique is the enhancement of the contrast between pulmonary vessels and parenchyma and the identification of calcium. Pulmonary nodules are more easily detected on high-kilovoltage films (100 to 130 kV).

The standard chest radiograph is taken at full inspiration with the patient approximately 72 inches from the plane of the x-ray film. This minimizes geometric magnification of the heart and enhances visualization of the pulmonary vasculature. The optimal density of a conventional posteroanterior or lateral chest x-ray film is a matter of individual preference. In general, the mediastinal structures should be easily discernible from the lung parenchyma and the bones. The intervertebral disk spaces and ribs should be identifiable on a routine posteroanterior film, but not at the expense of an optimal view of the lung parenchyma.

After conventional chest radiographs, portable chest radiographs are the next most frequently used radiographic examination of the chest. No commonly accepted standards or techniques are available for performing portable chest radiographs, as they are for standard posteroanterior and lateral chest radiographs. Further, these films are obtained in the anteroposterior direction, so that magnification artifacts occur. Consequently, the quality and reproducibility of a portable chest x-ray film is extremely variable. The rates for repeated portable chest radiographs are two to four times greater than those for repeated conventional radiographs. Portable chest x-ray films are often obtained in the sickest and most unstable patients. The variabilities of exposure, penetration, and positioning make interpretation of these films more problematic. Standard protocols that maximize consistent and reproducible high-quality portable films should be used.

The most commonly employed portable chest x-ray technique uses manually selected low kilovoltages and exposure times, without a grid. This technique results in portable films of relatively high contrast that are often degraded by scatter radiation. The mediastinal structures or lung parenchyma may not be optimally visualized because the films are either underexposed or overexposed. Overexposure may be done intentionally, to improve visualization of a monitoring line or tube. However, this is an unnecessary practice that contributes to poor overall film quality.

Portable chest x-ray films should be obtained using a fixed high-kilovoltage technique (approximately 110 kV) with a grid and phototiming. Phototiming devices are unavailable in many hospitals, and manually selected exposure times are then required. The high-kilovoltage technique is preferred because portable films can be produced that consistently approximate the quality of a conventional chest x-ray film. An important added benefit is decreased radiation exposure to the patient and hospital personnel. The decrease in exposure time more than compensates for the higher kilovoltage used.

Indications

The American College of Radiology Thoracic Expert Panel has developed a set of indications for chest films that includes signs and symptoms referable to the pulmonary or cardiovascular systems, suspicion of pulmonary or cardiovascular involvement by systemic or extrathoracic diseases, and monitoring of progression or regression of previously identified thoracic abnormalities. Chest radiographs are generally indicated in individuals presenting with the following symptoms: hoarseness, dyspnea, productive or nonproductive cough, hemoptysis, or pleuritic pain (Fig. 1). These symptoms suggest abnormalities in the following anatomic structures: trachea and small and large airways (Fig. 2); lung parenchyma; pleural space; mediastinum, including the heart; and the bony thorax. All these structures may be visualized on a high-quality chest radiograph.

FIG. 1. A: Classic radiographic findings of left lower lobe collapse. These include volume loss (demonstrated by a shift of the mediastinum, heart, and trachea to the left), a triangular opacity in a retrocardiac location (*black arrowheads*), and silhouetting of the medial portions of the left hemidiaphragm. Only the lateral portion of the hemidiaphragm (*black arrows*) is delineated. **B:** In a radiograph obtained after chest physical therapy, the left lower lobe collapse has resolved. The shift of the mediastinum and the triangular retrocardiac opacity are no longer present. The left hemidiaphragm is identified medially.

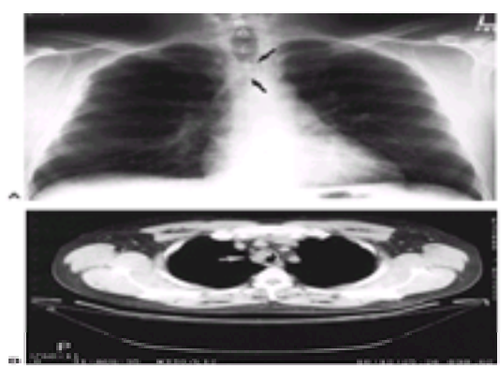

FIG. 2. A: Chest radiograph demonstrating a subtle mass (*black arrows*) projecting into the tracheal air column. **B:** Chest CT confirms the presence of a large fungating mass (*white arrowhead*) within the trachea. The vast majority of tracheal neoplasms are either of squamous cell or minor salivary gland origin. The pathologic specimen revealed adenoid cystic carcinoma.

Routine/Screening Radiography

The utility of chest radiography in routine, periodic, or screening situations (e.g., routine, daily portable chest radiographs in the intensive care unit setting, periodic screening chest films in asymptomatic ambulatory patients, and screening chest radiographs in asymptomatic HIV-infected adults) remains controversial. Routine/screening radiography may be indicated in high-risk populations, but they have not been found to be of use even in the prospective evaluation of persons who smoke, who have a higher risk for the development of lung carcinoma. Chest radiographs that were formerly taken routinely in various clinical situations but are no longer indicated include routine prenatal chest radiographs, routine admission chest radiographs of asymptomatic individuals, routine chest radiographs of geriatric patients in long-term facilities or of patients in psychiatric facilities, periodic examinations unrelated to occupational exposures, mandated chest radiographs for detection of tuberculosis as a condition of initial or continuing employment, and routine preoperative radiographs of patients under the age of 20. Lateral projections should be eliminated from the routine screening examination in patients between the ages of 20 and 39 years.

Portable Radiography

Portable chest radiographs should be routinely obtained in critically ill patients in the intensive care unit setting, as they have been shown to demonstrate unexpected findings or provide an indication for altering therapy in 37%–65% of a population of intubated patients. The American College of Radiology Expert Panel agrees with this opinion and has stated that daily, portable chest radiographs are indicated in patients who are receiving mechanical ventilation, who have acute cardiopulmonary problems to assess lung water, or in whom a new monitoring device or tube has been placed (Fig. 3). Portable chest radiography is indicated only during the initial evaluation of patients who receive just cardiac monitoring.

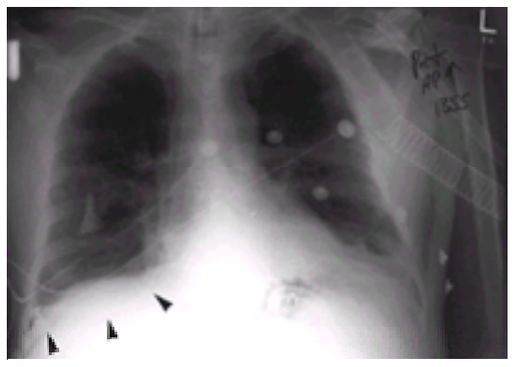

FIG. 3. A portable chest film demonstrating abnormal placement of a nasogastric tube (*black arrowheads*) into the right costophrenic angle. Feeding tubes are much more likely than nasogastric tubes to be inappropriately placed, because they are smaller in diameter and composed of more pliable material.

In settings other than the intensive care unit, the most frequent indications for portable chest radiographs include assessment of a nonambulatory patient for pneumonia or congestive heart failure, or following placement of a monitoring device (Fig. 3). Because of the limitations of the portable technique, it may be difficult to identify or distinguish between atelectasis, pneumonia, adult respiratory distress syndrome (ARDS), pleural effusions, and typical or atypical cardiogenic or noncardiogenic edema.

Utility of the Baseline (Old) Chest Radiograph

A baseline or old chest x-ray film is one of the most important resources in the diagnostic process for two reasons. First, it serves as a baseline examination with which comparisons may be made, so that detection of changes is possible. Second, with the aid of an old film, an assessment of the relative acuity or chronicity of an

observation is possible; this is an invaluable aid in the development of a differential diagnosis. Old films should be obtained for comparison whenever possible. Costs are minimized because the need for additional imaging is reduced, and quality of care is improved because the evaluation is expedited.

Decubitus and Oblique Films

On occasion, decubitus and oblique chest views may be indicated to answer or clarify specific diagnostic questions raised by interpretation of the initial chest radiograph. Decubitus views can delineate the presence and quantity of a free-flowing pleural effusion before performance of a diagnostic or therapeutic thoracentesis. Views are obtained with the patient lying in a recumbent position; each hemithorax should be alternatively visualized in the dependent position. An important advantage of obtaining bilateral decubitus views is that as fluid shifts, the underlying lung parenchyma can more adequately be evaluated for potential abnormalities that may have been hidden by the pleural fluid. In unusual circumstances, a decubitus view of the chest can demonstrate a tiny pneumothorax not necessarily seen on an expiratory upright chest film.

Oblique films of the chest, obtained by rotating the patient with respect to the film, are used to ascertain whether an opacity in the lung represents a parenchymal abnormality versus an overlap of bronchial vascular markings or an abnormality originating in the ribs. These views are usually requested by a radiologist when the level of suspicion is not particularly high that an abnormality seen on a chest x-ray film represents a true parenchymal abnormality or when the availability of CT scanning is limited. Oblique chest radiographs have been used to improve the identification, documentation, and characterization of pleural abnormalities, such as pleural plaques; these functions have now largely been replaced by CT scanning, diagnostic ultrasonography, and MRI.

Rib films, also obtained with the patient positioned obliquely with respect to the film, differ from oblique chest films in that the radiographic techniques used for a rib series are designed to improve the identification of bone abnormalities, such as fractures and metastatic disease, at the expense of visualization of lung parenchyma.

Apical Lordotic Films

Apical lordotic views, obtained with patient standing erect and the x-ray film angled 15° cephalad to the chest, are of limited utility. These views, along with apical kyphotic views, were previously used to improve visualization of the lung apices, thoracic inlet, and superior mediastinum. However, these views rarely provide sufficient additional information to make a diagnosis unequivocal. Questionable parenchymal, thoracic inlet, or mediastinal abnormalities that previously were evaluated by apical lordotic views should now be imaged with chest CT or MRI.

Chest Fluoroscopy

The utilization of chest fluoroscopy has declined in the evaluation of thoracic abnormalities with the advent of chest CT. Unlike routine chest radiography, fluoroscopy of the chest is usually performed at about 70 kV. The low-kilovoltage technique enhances the ability to detect calcium within a thoracic lesion. Current indications for chest fluoroscopy include diagnosis of diaphragmatic paralysis; discrimation between a possible rib or pleural abnormality and a parenchymal lung abnormality (pleural plaques versus a pleura-associated small parenchymal lung nodule); guidance of needle placement during percutaneous needle biopsies of lung, pleural, rib, and mediastinal masses and during percutaneous drainage of fluid collections within the chest; and guidance of bronchoscope and needle placement and confirmation of correct positioning before transbronchoscopic biopsy.

Digital Chest Radiography

The ability to acquire and display radiographs, including chest films, in a digital format should improve efficiency and decrease radiation exposure to patients and medical personnel. This technique is now becoming widely available.

COMPUTED TOMOGRAPHY

CT scans of the chest have two very significant advantages over routine chest radiographs: superior contrast sensitivity, which aids in differentiating fat, water, air, and calcium; and the ability to display cross-sectional anatomy, thereby eliminating superimposition of adjacent anatomic structures. Although images are usually obtained and displayed in a transverse fashion, multiplanar displays now allow sagittal and/or coronal reconstructions. With the advent of spiral CT scans, three-dimensional displays and holographic images may be obtained. All reconstructed display formats are designed to aid in the presentation of complex anatomic relationships. Decreased spatial resolution is the one significant disadvantage of CT in comparison with conventional chest radiography. The identification of small pulmonary nodules is easier on a chest CT scan, not because spatial resolution is enhanced, but rather because contrast sensitivity is enhanced between essentially black normal lung parenchyma and the soft-tissue density characteristic of pulmonary nodules, and also because relevant anatomy is displayed without superimposition of normal structures.

Technique

CT scans are usually obtained at end-inspiration with the patient lying supine. Two basic designs of commercial CT scanners are currently available. In one design, the x-ray tube and detectors rotate simultaneously around the patient, and in the other, the detector wing is stationary and the x-ray tube rotates. Either design produces high-quality images. Routine scanning of the chest is usually done in 8- to 10-mm-thick slices obtained contiguously from the lung apex to base through the diaphragm; the adrenal glands are often imaged as well. This basic scanning protocol may be modified depending on the specific clinical problem.

In general, the use of intravenous contrast material should be limited to evaluations in which vascular lesions (pulmonary arteriovenous malformation, pseudoaneurysm) are suspected, or in which precise vascular anatomy is needed (invasion of a pulmonary artery by a lung neoplasm). Intravenous contrast material can also be used to resolve a central lung mass from associated lung collapse or to identify a pleural effusion as transudative or exudative.

Indications

A compete list of indications for chest CT are too numerous to review here. Some of the more common indications are staging of common primary malignancies of the thorax (bronchogenic carcinoma, esophageal carcinoma); staging of intrathoracic lymphoma; evaluation of suspected vascular abnormalities (arteriovenous malformation, venous varices, pseudoaneurysms, aneurysms with or without dissection); and evaluation or staging of extrapulmonary processes, which include the following:

1. Pleural lesions (mesothelioma) (Fig. 4)

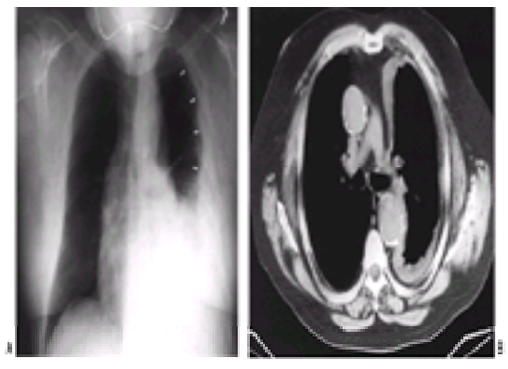

FIG. 4. A: A chest radiograph reveals a blunted costophrenic angle with a lobular configuration (*white arrowheads*) along the lateral pleural surface. This is atypical for a simple transudative pleural effusion, which would exhibit a smooth interface between the lung and pleura and not surround the entire lung. The chest radiographic appearance is very suggestive of a mesothelioma, which was confirmed on chest CT. **B:** A single image from a chest CT scan shows an encased left lung with associated contraction of the hemithorax.

2. Rib lesions (primary bone tumor, Ewing's sarcoma)
3. Pleural space processes (empyema)
4. Lesions of the chest wall

5. Diaphragmatic lesions (diaphragmatic hernias, congenital or posttraumatic)
6. Abnormalities arising from hilar and mediastinal structures, including thymic neoplasms (thymolipoma, thymoma); esophageal abnormalities (duplication cysts); pericardial or cardiac abnormalities (pericardial effusions, pericardial cysts); tracheal neoplasms (primary squamous cell carcinoma, salivary gland tumors); mediastinal or hilar adenopathy; and neoplasms originating in or invading the mediastinum (germ cell tumors, goiter)
7. Malignant neoplasms with a propensity to metastasize to the lung (melanoma, renal cell carcinoma)

Chest CT may also be indicated to characterize more completely an abnormality of uncertain etiology detected on a chest radiograph (Fig. 5).

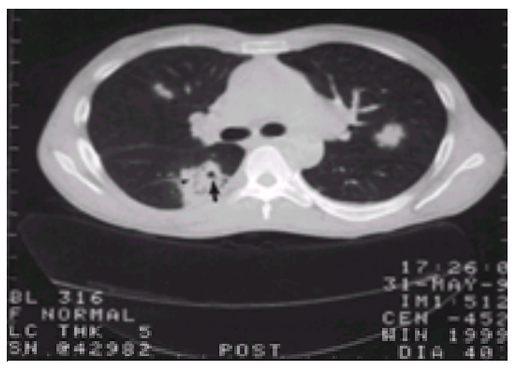

FIG. 5. Chest CT reveals three poorly defined nodular infiltrates. In one of the nodular opacities, air bronchograms (*black arrowhead*) and cavitation (*black arrow*) are visible. The differential diagnosis is broad and includes a diverse clinical conditions such as non-Hodgkins lymphoma, bronchoalveolar cell carcinoma, and Wegner's granulomatosis. With an appropriate clinical history (e.g., a patient with fever and a new systolic murmur), the differential diagnosis is narrowed to septic emboli.

High-resolution chest CT scans employ a modification of the standard acquisition and display protocol to produce thin-section (1.0 to 1.5 mm) cuts that enhance the spatial resolution of lung parenchyma. Edges are sharper and scan times are shorter with this technique. High-resolution CT can detect abnormal lung when the findings on chest x-ray film and conventional CT scan are normal. This modality is used in the evaluation of early interstitial lung disease; active disease is characterized by ground-glass opacities and interstitial or air space nodules, and inactive disease is characterized by scarring. Biopsy specimens can be obtained from areas of lung that appear active on high-resolution CT, or such areas can be followed during therapy.

In the appropriate clinical setting, certain specific diagnoses may be made by high-resolution CT without need of lung biopsy. The entities most confidently diagnosed by high-resolution CT include lymphangiomyomatosis, histiocytosis X, lymphangitic carcinomatosis, sarcoidosis, silicosis, and idiopathic pulmonary fibrosis.

Helical CT scanning is an important recent technologic innovation in which the patient is continuously fed through the scanner gantry as the x-ray images are being taken. This technique generates volumetric information that can be displayed in a conventional axial plane or in a variety of orthogonal planes. Helical CT offers three significant advantages over conventional scans. First, scan times are reduced to 30 to 60 seconds, which increases productivity. Second, less intravenous contrast is required to achieve high-quality scans, and misregistration artifacts are significantly reduced. Third, multiplanar reformation is possible with less degradation of the image. Clinically, helical CT scanning enhances detection and quantification of suspected pulmonary nodules in comparison with conventional CT scans. Vascular imaging is vastly improved, so that helical CT can replace angiography in the evaluation of aortic dissection and trauma and may eventually replace coronary angiography and pulmonary arteriography. Multiplanar reformatting has been used to display complex mediastinal and tracheobronchial anatomy.

NUCLEAR IMAGING OF THE THORAX

Nuclear imaging of the thorax is performed for a variety of clinical indications. The most common and important use of nuclear imaging is in the workup of suspected pulmonary embolus (ventilation-perfusion scans).

Technique

Technetium 99m is the most commonly used radionuclide in diagnostic imaging because it has no particulate emission, has a relatively short half-life (6 hours), and emits almost entirely 40-keV (kiloelectron volt) photons. This makes it a relatively ideal nuclear imaging agent. After intravenous administration, the relevant organ or organs are imaged with a gamma camera. The gamma camera measures the number of photons emitted by the radionuclide and displays these counts as dots; the intensity of the display (number of dots) is proportional to the amount of activity.

The choice of the particular radionuclide or radiopharmaceutical to be used for a particular study is guided by pharmacologic considerations. For example, the radionuclide xenon 133 gas is used almost exclusively for lung ventilation studies because it is not soluble in blood, whereas the radiopharmaceutical agent Tc 99 microaggregated albumin (MAA) is used for multiple indications, but primarily to detect pulmonary emboli or right-to-left shunting. It is extremely soluble in blood and does not appear in exhaled gas.

Pulmonary Embolus

Both ventilation and perfusion nuclear scans are required to assess the likelihood of pulmonary embolism. For these studies, to assess pulmonary ventilation and perfusion simultaneously, a radionuclide is inhaled (xenon 133 gas) and a radiopharmaceutical agent (Tc 99 MAA) is injected intravenously. Images obtained during inhalation, steady-state breathing, and exhalation provide information about regional and overall ventilatory dynamics. Radiolabeled aerosols are sometimes used instead of radioactive gases. Studies using these radioactive aerosols are technically more difficult to perform and may not detect small ventilation defects, but they do provide the important advantage of providing images in views corresponding to the perfusion abnormalities.

The majority of Tc 99 MAA particles injected to assess perfusion are in the 10- to 30-µm range; they mix in the right atrium and ventricle. The particles then enter the pulmonary circulation and become trapped in the pulmonary capillary vascular bed. Because of the relatively small numbers of particles compared with the number of pulmonary capillaries, further vascular obstruction does not occur. Nevertheless, in patients with known pulmonary hypertension or suspected right-to-left shunts, the quantity of Tc 99 MAA injected is usually reduced.

At this time, ventilation and perfusion images are interpreted using criteria and guidelines developed from the Prospective Investigation of Pulmonary Embolus Diagnosis (PIOPED) study. Small but important modifications and refinements to the criteria have been recently made. The size and number of matched and mismatched defects, relative to the concurrent chest x-ray image, are assessed to determine the relative probability of pulmonary embolus. Scans are rated as highly probable for the diagnosis, of intermediate, low, or very low probability, or normal. In the revised PIOPED criteria, four categories have been arbitrarily assigned numeric values: high (80%–100%, probable for the diagnosis), intermediate (20%–79%), low (<19%), and normal. A normal ventilation-perfusion scan essentially rules out the diagnosis of pulmonary embolus.

The classic nuclear imaging characteristics of pulmonary embolus are a high-probability ventilation-perfusion scan, defined as a normal ventilation scan with multiple peripheral perfusion defects corresponding to lobar or segmental anatomy, and a normal chest radiograph. High-probability ventilation-perfusion scans have a specificity for pulmonary embolus of approximately 97%, but a low sensitivity. Only about 41% of the patients demonstrated to have pulmonary embolus by angiography also have a high-probability ventilation-perfusion scan. Angiography studies have shown that a clinically high index of suspicion for pulmonary embolus and a high-probability ventilation-perfusion scan strongly correlate with the presence of pulmonary embolus, and likewise a clinically low index of suspicion for pulmonary embolus and a low-probability ventilation-perfusion scan correlate strongly with the absence of pulmonary embolus.

Other Indications

Perfusion lung scans are also used preoperatively to estimate the amount of lung function that will remain in patients with poor lung function after lobectomy or pneumonectomy (Chapter 13) and to detect and quantify right-to-left shunting (hepatopulmonary syndrome). To document right-to-left shunting, images of the brain or kidney are usually obtained to identify the abnormal location of radioactivity and document the arteriovenous shunt. By measuring the amount of activity in these organs and comparing it with the amount of activity in the lungs, the percentage of shunting can be calculated.

Nuclear imaging may also be used to evaluate occult or suspected pulmonary infection, to assess hilar and mediastinal adenopathy secondary to metastatic disease or lymphoma, and to detect inflammation in the lung parenchyma secondary to adverse drug reactions or alveolitis. Gallium 67 can detect lung injury caused by drugs such as bleomycin before any abnormality can be visualized on chest x-ray films; it can also detect occult lymphoma in mediastinal lymph nodes that appear to be of normal size on CT and occult infections of the interstitium, such as *Pneumocystis* infection. Gallium 67 scanning has been used in conjunction with determination of angiotensin-converting enzyme (ACE) levels to estimate the degree of activity of pulmonary sarcoidosis.

Gallium 67 and thallium 201 scans in combination have been shown to be extremely useful in distinguishing between Kaposi's sarcoma, mycobacterial infection, and lymphoma. This is a common problem in patients with the acquired immune deficiency syndrome (AIDS). Matched patterns of uptake on gallium 67 and thallium 201 scans are suggestive of non-Hodgkin's lymphoma, whereas a gallium-negative and thallium-positive pattern indicates Kaposi's sarcoma. Finally, a gallium-positive and thallium-negative scan is highly suggestive of mycobacterial infection, although other granulomatous infections, such as cryptococcosis, histoplasmosis, or coccidioidomycosis, cannot be completely ruled out by this technique.

PULMONARY ANGIOGRAPHY

Angiography is the least frequently used radiographic study to investigate chest abnormalities. Nevertheless, it is an important diagnostic and potentially therapeutic tool used in the evaluation of specific pulmonary abnormalities.

Technique

Access to the arterial or venous system is gained by catheterization through the groin or upper extremity using the Seldinger technique or one of its variations. Contrast material is injected into the vascular system and rapid-sequence films are obtained. Angiography is associated with low rates of complications, which may be categorized as systemic, local, or catheter-related occurrences.

Systemic complications include the development of contrast-induced nephropathy or severe allergic reaction with cardiovascular collapse. Examples of local complications related to the puncture site are development of a groin hematoma or a pseudoaneurysm. Examples of catheter-related complications are distal embolization or intimal dissection. Before any interventional procedure is undertaken, the relative benefits versus risks need to be understood clearly by the radiologist, referring clinician, and patient. To prevent complications and assess risk, a complete history should be taken (diabetes, contrast allergy, previous bleeding diathesis), and the coagulation status (platelet count, prothrombin time, partial thromboplastin time) and serum creatinine level should be determined before the procedure is performed.

Indications

Pulmonary arteriography is the most common angiographic procedure involving the thorax and is usually performed to rule out pulmonary embolus. Pulmonary angiography is also indicated in the assessment of chronic thromboembolic disease as a suspected cause of pulmonary hypertension, and as part of the evaluation of small pulmonary arteriovenous malformations. Large malformations are more easily diagnosed using contrast-enhanced chest CT.

In the workup of pulmonary embolus, pulmonary arteriography is almost always preceded by ventilationperfusion scanning. Abnormal findings on the scan can be used to guide the subsequent catheterization of the pulmonary arteries. If the ventilation-perfusion scan demonstrates a segmental defect in the left lower lobe, then the left lower lobe pulmonary artery is catheterized first so as to expedite the diagnosis and obviate the need for additional angiographic runs. However, negative results from the study of the left lower lobe pulmonary artery do not in turn obviate the need to image the entire pulmonary arterial system, as pulmonary emboli do not necessarily correspond to defects observed on a ventilation-perfusion scan.

The classic angiographic findings of pulmonary embolic disease include intraluminal filling defects and abrupt arterial cutoffs (Fig. 6). Because intraluminal clot begins to dissolve after 24 hours and 80% of the clot has lysed by 7 days, pulmonary arteriography should be performed as close in time to the suspected clinical event as possible.

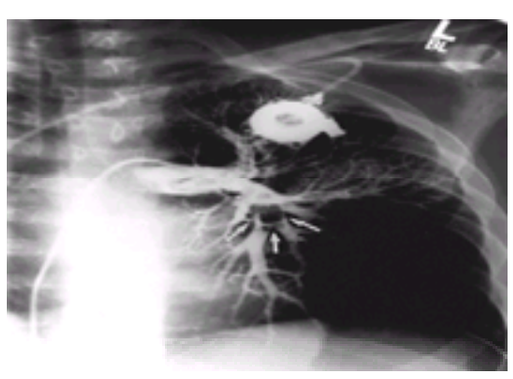

FIG. 6. Pulmonary arteriogram illustrating multiple pulmonary emboli. A large filling defect (*white arrows*), clot, is depicted in the left lower lobe pulmonary artery. Anticoagulation therapy does not immediately take effect to prevent the formation of additional emboli. The indications for fibrinolytic therapy are limited in the treatment of pulmonary embolus.

Elevated pulmonary arterial pressure and left bundle branch block are relative contraindications for pulmonary arteriography. An increase in mortality (<0.5%) is associated with right ventricular end-diastolic pressures of >20 mm Hg, and a left bundle branch block may progress to complete heart block during the procedure. These relative contraindications can be addressed by modifying the angiographic technique and placing a temporary transvenous pacing wire.

Angiography is also used to evaluate the systemic circulation, the thoracic aorta (thoracic aortography), and the bronchial circulation (Fig. 7). The indications for thoracic aortography vary from institution to institution, but generally the procedure is performed to evaluate the possibility of thoracic aortic aneurysm, thoracic aortic dissection, and traumatic injury to the thoracic aorta. At the present time, CT and MRI have begun to replace thoracic aortography for these indications, as they are noninvasive, less labor-intensive, and more cost-effective than angiography. Bronchial arterial arteriography is usually performed to identify the site of bronchial arterial bleeding in patients with life-threatening hemoptysis of known cause who cannot undergo surgical resection (Fig. 8). After identification of the site of bleeding, embolization of the vessel may be performed to reduce hemorrhage. Bronchiectasis, aspergillosis, or cystic fibrosis are the most frequent causes of this type of hemoptysis.

FIG. 7. Thoracic aortogram demonstrating an abnormal collection of contrast (*black arrows*) outside the normal wall of the descending thoracic aorta at the level of the ligament of the ductus arteriosus, diagnostic of an aortic laceration. Aortic lacerations are almost always associated with a deceleration injury, especially in automobile accidents.

FIG. 8. Bronchial arteriogram in a patient with a known mycetoma who presented with severe recurrent hemoptysis. A bronchial artery is cannulated by a catheter (*black arrow*) before embolization. The abnormal vascularity associated with the mycetoma is visualized in the apex of the right lung (*white arrow*).

Venography of the central veins in the chest, such as the superior vena cava, left and right innominate veins, and the azygos vein, is performed rarely. Thrombosis of these vessels, which may be caused by mediastinal neoplasm, mediastinitis, or iatrogenic instrumentation, is more easily investigated noninvasively with either CT or MRI, or an ultrasonographic examination. Occasionally, vascular stents have been deployed in the treatment of superior vena cava syndrome.

MAGNETIC RESONANCE IMAGING

Principle

MRI is a relatively new imaging technique that produces images without the use of ionizing radiation. In an MR image, each voxel is a gray scale representation of the relative intensity of a radio wave signal emanating from tissue that has been perturbed by a characteristic radio frequency (RF pulse). The radio wave signal emanating from each tissue depends on several factors, the most important of which is time. T_1 and T_2 relaxation times originate from this principle. Cardiac gating and suppression of respiratory motion are essential to produce chest images of diagnostic quality. At the time of this writing, poor spatial resolution, respiratory motion, and the lack of sufficient hydrogen protons in lung make MRI of the lung parenchyma impractical for most indications.

Whereas the information in CT scans is acquired in a transverse plane through the chest, MRI is capable of imaging the chest in any plane. Another advantage of MRI in comparison with CT is its ability to identify vascular structures without the use of intravenous iodinated contrast. If contrast is necessary, gadolinium-based contrast agents have a better safety profile than iodinated contrast and can be used to delineate vascular structures. Although neither CT nor MRI can detect neoplastic invasion of tissues at the microscopic level, the superior contrast resolution of MRI offers an advantage in the diagnosis of subtle invasion of fat or soft tissues by tumor.

Current applications of MRI include evaluation of both the central venous and central pulmonary vasculature. Suspected superior vena cava syndrome, resulting from either malignancy or mediastinitis, may be diagnosed using MRI, as can invasion of pulmonary arteries or even the heart by a large central mass. Thoracic aneurysms and pseudoaneurysms, as well as aortic dissections, are readily identified by MRI (Fig. 9). Mediastinal masses, originating from any compartment, may be imaged.

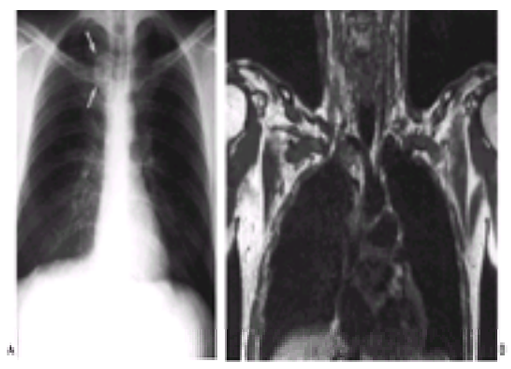

FIG. 9. A: Chest radiograph demonstrating a 2-cm peripherally calcified mass in a right paratracheal location. A vascular origin should be suspected in any chest lesion with peripheral curvilinear calcification. **B:** A coronal MRI displaying a pseudoaneurysm of the right subclavian artery in a patient with a remote history of a penetrating knife wound.

The ability to study anatomic structures in sagittal or coronal planes and the excellent contrast resolution make MRI the modality of choice in the investigation of abnormalities related to the diaphragm, lung apex, chest wall, and mediastinum (Fig. 10). Diaphragmatic abnormalities, such as posttraumatic or congenital hernias, are displayed to advantage. Similarly, abnormalities originating within the lung apex, such as a superior sulcus neoplasm, are optimally staged with MRI as either confined to the thorax or invading the brachial plexus. Chest-wall or mediastinal masses originating in any lung compartment may also be imaged.

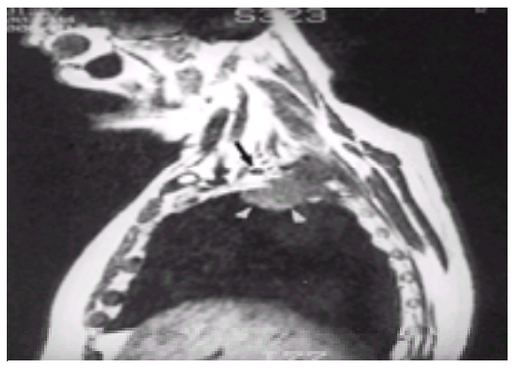

FIG. 10. A superior sulcus neoplasm (*white arrowheads*) extending through the parietal pleura into the supraclavicular fossa is depicted on a sagittal MRI. The cancer spares the subclavian artery (*black arrow*) and brachial plexus, immediately cephalad to the artery.

MRI is also extremely useful in evaluating perihilar and pericardial abnormalities. However, MRI is presently used only as an adjunct to CT in the evaluation of nonvascular abnormalities of the mediastinum and hilar regions, primarily because of expense. Unfortunately, MR signal characteristics cannot reliably distinguish between benign and malignant adenopathy in patients with lung carcinoma. However, residual fibrosis can be distinguished from active neoplastic disease following radiation therapy for lymphoma. Likewise, MRI is capable of distinguishing between rebound thymic hyperplasia and recurrent disease.

INTERVENTIONAL PROCEDURES

Nonangiographic interventional procedures of the chest that require imaging guidance fall into two general categories: percutaneous biopsy (parenchymal lesions, mediastinal masses, or pleural abnormalities) in which either a skinny or cutting needle is used, and percutaneous aspirations and/or drainage of fluid collections located within the pleural space or lung parenchyma and the mediastinum. Imaging guidance for interventional procedures is provided by fluoroscopy, CT, or ultrasonography. The choice of imaging guidance depends on the availability of equipment and the expertise and experience of the operator.

Significant intrathoracic hemorrhage is an avoidable complication associated with interventional procedures. If the number of adequately functioning platelets is >75,000/mm^3 and the INR (International Normalized Ratio) is normal, then the risk for significant hemorrhage is greatly reduced. Patients with known bleeding disorders or abnormal coagulation parameters require a detailed hemostatic evaluation to avoid morbidity associated with these procedures. Also, the needle route should be chosen to avoid larger vessels, such as the internal mammary, intercostal, central hilar, and mediastinal vessels. Significant morbidity has occurred when these vessels have been punctured.

Pneumothorax is the most common complication of percutaneous biopsy of the chest, with a reported rate of 5%–60% of all biopsies (average rate, ~25%–30%). The risk for pneumothorax is related to several factors: the extent of underlying lung disease, especially when adjacent to the lesion from which biopsy samples are being taken (emphysema), and the number of needle passes, especially when passes are made through multiple pleural surfaces or cross a fissure or lung parenchyma during biopsy of the mediastinum.

The percutaneous biopsy route should therefore be planned to avoid crossing multiple pleural surfaces. Up to half the patients who experience a pneumothorax as a result of a percutaneous biopsy require chest tube drainage. A small pneumothorax that does not affect hemodynamics or respiration may be treated with a small catheter and Heimlich valve. If the pneumothorax is large and affects hemodynamics and/or respiration, a large-bore chest tube should be placed.

Frank hemoptysis is almost always self-limiting.

Percutaneous Lung Biosy

Percutaneous lung biopsy has a relatively high safety profile and is usually performed with needles under 19 gauge, although larger needles are required for core biopsies. The diagnostic yield for malignant lesions is approximately 95%. The diagnostic yield is not as high for nonmalignant lesions. The appropriate handling of a specimen is crucial to ensure an accurate diagnosis and requires cooperation between the radiology, laboratory, and clinical services. For example, malignant cytologies are more likely to be obtained from a percutaneous biopsy specimen directly prepared by the cytopathologist or pathologist. Some specimens require special handling (flow cytometry), which necessitates special preparation of the aspirate.

Percutaneous Drainage of Fluid Collections

Although large pleural effusions are usually managed without image-guided drainage procedures, percutaneous drainage of smaller pleural, parenchymal, or mediastinal fluid collections requires imaging for optimal placement of drainage catheters. Small and loculated pleural effusions are most conveniently aspirated under ultrasonic guidance. Uncomplicated empyema is characterized by early clinical presentation, lack of loculations, relatively nonviscous purulent material, and the absence of a thick pleural peel, and may be drained successfully with a percutaneously placed catheter. Postoperative or loculated empyema, or empyema associated with bronchopleural fistula, is less likely to be drained successfully by the percutaneous technique. Fibrinolytic agents have been introduced into the pleural space to aid in the drainage of loculated empyemas. Percutaneous drainage of lung abscesses and mediastinal abscesses has a limited role.

APPROACH TO INTERPRETATION OF RADIOGRAPHIC STUDIES

There are many approaches to the interpretation of a radiographic study. Some approaches are unique to a particular diagnostic imaging modality, and others are unique to a specific clinical problem. The approach to the interpretation of radiographic studies discussed here utilizes a series of simple but informative questions applicable to simple and sophisticated radiologic techniques and most clinical problems. The answers to these questions assist in characterizing an abnormality identified on a radiographic examination and thereby help to build a differential diagnosis. After a radiologic differential diagnosis has been constructed, a clinical decision can be made as to further diagnostic workup.

In the interpretative process, the answers to a set of specific questions that more clearly define the radiologic abnormality can aid in forming a diagnosis. The order in which these questions are asked is not necessarily critical. Although each individual question may seem simple and not likely to elicit important information, the combination of questions and their subsequent answers are extremely enlightening.

An accurate clinical history is a critical component in the diagnostic process of identifying and characterizing an observed radiologic abnormality and developing a differential diagnosis. Whereas a clinical history aids in the interpretation of an examination, the radiologic history (previous film) is also an important tool that improves and contributes to the accuracy of observations. For example, a clinical history of dyspnea, cough, wheezing, pedal edema, and jugular venous distension would suggest the likelihood of finding signs of congestive heart failure on a chest radiograph. Or, a prominent hilum that might otherwise be dismissed as a normal variant would be re-evaluated as a probable mass in the light of an old film showing a normal hilum.

The *temporal history* of the abnormality should be assessed. A widened mediastinum on a chest radiograph has a large differential diagnosis, but knowing the chronicity or acuity of the finding limits the differential diagnosis. A chronically widened superior mediastinum unchanged over many years suggests a benign etiology, such as mediastinal lipomatosis. A newly widened superior mediastinum suggests a more acute process, such as lymphoma or metastatic adenopathy. An acutely widened mediastinum indicates a probable mediastinal hematoma, especially with the confirmatory clinical history of a recent line placement or an automobile accident.

Is the abnormality *solitary, multifocal,* or *diffuse?* For example, a solitary pulmonary nodule on a chest x-ray film has a vast differential diagnosis, but in a specific clinical situation (e.g., in a patient with a long smoking history and occupational exposure to asbestos), a primary lung carcinoma is very likely. However, if subsequent chest CT shows this solitary pulmonary opacity to be one of three pulmonary nodules, the differential diagnosis now suggests metastatic disease to the lung. Similarly, if a follow-up chest radiograph in 3 days demonstrates multiple nodular opacities and cavitation, the differential diagnosis would change again to include multiple septic emboli or granulomatous disease with cavitation.

What is the *density* (composition) of an abnormality? Although the internal composition of a lesion can sometimes be determined on a chest radiograph, chest CT or MRI can accomplish this task more accurately and is therefore indicated for this purpose. Five important internal tissue types may be easily identified on CT or MR scans:

1. Gas (cavitation)
2. Low-density material (lipid) (Fig. 11)

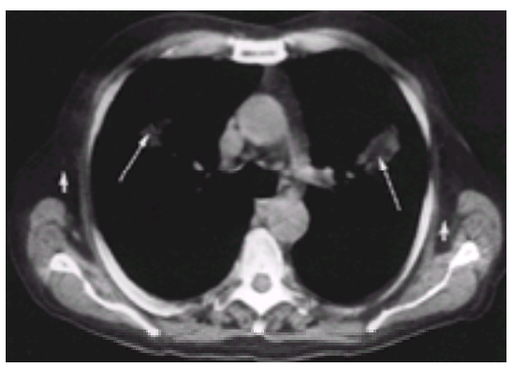

FIG. 11. Chest CT in a patient whose chest radiograph demonstrated multiple, poorly defined nodular opacities that waxed and waned shows bilateral opacities (*long white arrows*) with internal attenuation, similar to that of subcutaneous fat (*short white arrows*). A diagnosis of lipid pneumonia was made.

3. High-density material (hemorrhage)
4. Intermediate-density material (soft tissue)

5. Calcification

A lesion that exhibits *cavitation* may represent a lung abscess, a carcinoma with cavitation, or mycetoma. A lesion that is calcified might represent a calcified granuloma, if located centrally, or a lung carcinoma engulfing an adjacent calcified granuloma, if located eccentrically. A solitary lesion containing material of several types of density by CT suggests a hamartoma.

What are the *shape, size,* and *margins* of the lesion? For example, a defect that conforms to the shape of a segment of lung on a perfusion scan has considerably more significance than a perfusion defect with a shape that is either subsegmental or round in appearance. An earlier principle (solitary vs. multiple) is combined with the principle of shape and size, and the presence of multiple segmental defects on a perfusion lung scan without corresponding matches on a ventilation scan then changes the interpretation of the examination to a high probability for pulmonary embolus.

Similarly, the differential diagnosis for multiple bilateral rounded opacities is vastly different depending on the size of the opacities. When the radiologic differential diagnosis is broad, the clinical history becomes very important. A fine nodular pattern on a chest radiograph in a febrile patient suggests a differential diagnosis that includes fungal, tuberculous, nocardial, and viral infection, whereas in an afebrile patient the differential diagnosis includes sarcoidosis, inhalational disease, metastasis, and less common entities, such as eosinophilic pneumonia (Fig. 12).

FIG. 12. A chest radiograph demonstrating innumerable pulmonary nodules <1 cm in diameter. Some of the nodules are calcified, and in the right upper lobe the nodules are more confluent. This area represents a developing conglomerate mass in a patient with silicosis.

It is also important to determine whether the margins of a lesion are sharply or poorly demarcated. A sharply demarcated lesion suggests encapsulation, whereas indistinct and fuzzy margins suggest a lesion that may be infiltrating into adjacent structures (Fig. 13). For example, multiple bilateral rounded opacities with poorly defined margins on a chest x-ray film suggest a differential diagnosis that includes inflammatory, neoplastic, connective tissue, vascular, occupational, iatrogenic, and idiopathic entities. Additional information, such as whether the opacities wax and wane, occasionally show cavitation, or are associated with febrile episodes, restricts the differential diagnosis to etiologies such as Wegener's or lymphomatoid granulomatosis (Fig. 14). Violation of anatomic boundaries usually suggests an aggressive process, although not necessarily a neoplasm. An abnormality located in the periphery of the lung with evidence of pleural reaction and rib destruction might be caused by actinomycosis rather than carcinoma of the lung.

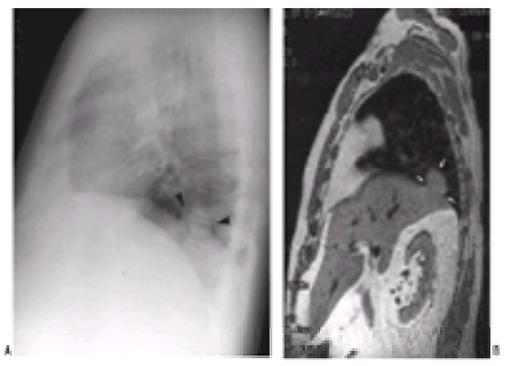

FIG. 13. A: A lateral chest radiograph demonstrating an approximately 2-cm rounded opacity (*black arrowheads*) adjacent to the right hemidiaphragm. Because the inferior margin of the lesion was silhouetted by the diaphragm, it was suspected that the abnormality originated from or below the diaphragm. **B:** A sagittal MRI of the chest shows the liver (*white arrowheads*) herniating through the diaphragm.

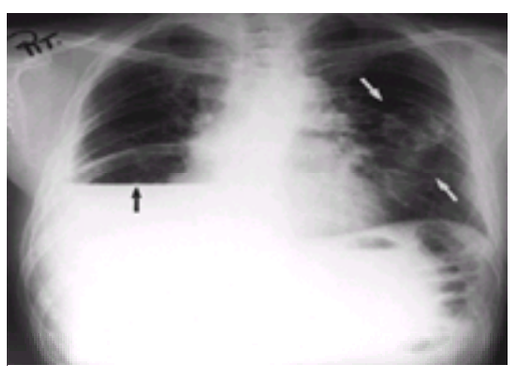

FIG. 14. A postoperative chest radiograph demonstrates an air-fluid level (*black arrow*) in the right pleural space following an open lung biopsy. In the left lung, two cavitary masses (*white arrows*) are identified. The masses, which waxed and waned during a period of months, were pathologically proved to be Wegner's granulomatosis.

From what tissue does the abnormality originate? Specifically, does the lesion arise from the rib or pleura, or from the lung parenchyma, or from within a mediastinal structure? The characteristics of the margin of the lesion also yield important information. For example, a peripherally situated mass forming acute angles with the pleural surface suggests that the mass originates within the lung parenchyma, whereas the same mass forming obtuse angles suggests an origin in the pleura or chest wall.

Sometimes the anatomic location of an abnormality is easily determined from the chest radiograph, as in the case of rib destruction (implying that the abnormality is located in part in the pleural space and also in the chest wall). CT or MRI is usually required to obtain such information (Fig. 15).

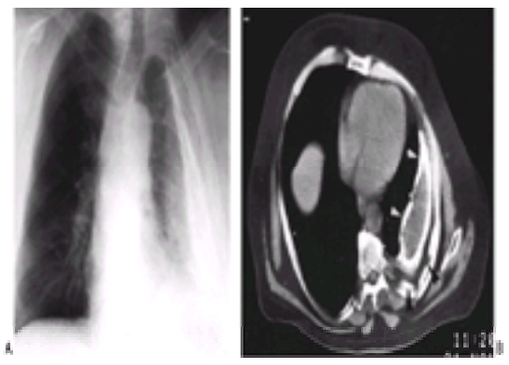

FIG. 15. A: A chest radiograph depicts a relatively small left hemithorax, pleural thickening, and extensive pleural calcification. **B:** Subsequent chest CT reveals calcification of the visceral (*white arrowheads*) and parietal pleura surrounding a high-density pleural effusion. The apparent pleural thickening on the chest radiograph is shown to be extensive subpleural fat (*black arrowheads*). Increased asymmetric subpleural fat associated with a pleural effusion is almost always indicative of an empyema, in this case a tuberculous empyema.

Localizing an abnormality within a specific anatomic compartment is also extremely valuable when constructing a differential diagnosis. For example, if a mediastinal mass can be localized to the posterior mediastinum, or if interstitial lung disease is confined to the lung bases, then the differential diagnosis is further narrowed.

CHAPTER

9 Pulmonary Function Testing

Robert O. Crapo

R. O. Crapo: Department of Medicine, University of Utah School of Medicine, and Pulmonary Laboratory, LDS Hospital, Salt Lake City, Utah 84143.

INTRODUCTION

Pulmonary function tests are widely used to provide objective measures of lung function for (1) detecting and quantifying pulmonary impairment in cardiopulmonary diseases; (2) following the evolution of diseases and monitoring response to therapy; (3) monitoring the effects of environmental, occupational, and drug exposures associated with lung injury; (4) assessing preoperative risk; and (5) assessing disability and impairment. This chapter focuses on the practical pulmonary function tests that are of most use in day-to-day clinical medicine.

The steps in gas exchange from ambient air to cell (Table 1) help put pulmonary function testing in perspective. As respiratory gases move by passive diffusion, optimal concentrations of oxygen (O_2) and carbon dioxide (CO_2) in alveolar gas are necessary to transfer them to and from pulmonary capillary blood. The alveolar environment for gas transfer is established by alveolar ventilation, a function of the bellows action of the lung. Many lung function tests (static lung volumes, spirometry, airways resistance, and respiratory muscle function) characterize the mechanical aspects of the air pump. By themselves, they do not prove that gas exchange is either normal or abnormal. The second step in gas exchange, gas transfer from the alveolar air to blood, is traditionally assessed with carbon monoxide (CO) diffusing capacity (transfer factor) and arterial blood gas measurements. Diffusing capacity is an indirect test, whereas arterial blood gases allow a more direct assessment of O_2 loading and CO_2 removal from blood. Assessing gas transport and gas transfer from blood to cells involves evaluation of arterial and mixed venous blood gases, cardiac output, and end-organ function (usually brain and kidney function). These aspects of gas transfer are usually the focus of the intensive care unit and are not directly assessed in traditional pulmonary function laboratories.

Step	Purpose	Structure(s)	Tests to characterize structure or function
Ventilation	Maintain normal alveolar O_2 and CO_2 pressures (PAO_2 and $PACO_2$)	Air pump (lungs, chest wall, and neuromuscular apparatus)	$PaCO_2$, spirometry, lung volumes, airways resistance, respiratory muscle strength
Gas transfer (lungs)	Transfer of gases between alveolar air and pulmonary capillary blood	Alveolar capillary membrane	Arterial blood gases (PaO_2 and $PaCO_2$), alveolar-arterial PO_2 gradient [$P(A-a)O_2$], oxygen content, carbon monoxide diffusing capacity
Circulation	Delivery of O_2 from the lungs to the systemic capillaries and CO_2 from the systemic capillaries to the lungs	Blood pump (heart and blood)	Heart function (e.g., cardiac output, oxygen content, oxygen delivery)
Gas transfer (periphery)	Transfer of gases between systemic capillaries and metabolizing cells	Systemic capillary membranes and metabolizing cells	Difficult to assess. Tests of end-organ function (e.g., central nervous system and renal function) provide regional information and are the least clinical indicators. Lactic acidosis may occur with tissue hypoxemia but is not a definite indicator of its presence.

TABLE 1. *Gas exchange between the atmosphere and body cells: gas transport system steps*

Control of breathing can be assessed by measuring the ventilatory response to progressive hypercarbia or hypoxemia, but these tests are uncommonly used in clinical practice. The final element in practical lung function testing is measuring cardiac and respiratory responses to exercise. Because exercise stresses the entire heart, lung, and blood system, exercise testing provides an opportunity to tease out the factors leading to dyspnea and impaired exercise capacity. Exercise testing is covered in Chapter 10. Reference sources for exercise are also included in this chapter's reference list.

Lung function tests are different from most other medical tests in that many of them require patients to participate actively and vigorously. Test quality depends on coaching every patient to an acceptable, vigorous effort. My own experience in evaluating pulmonary function laboratories suggests that it is not uncommon to find poor test quality in more than half of the studies at an initial evaluation. It is also not uncommon to see dramatic improvement in test quality after the staff has been trained to recognize quality tests and encouraged to coach more vigorous effort. Even when test quality is carefully controlled, some patients are unable to perform the tests. In a general population study, in which test quality was carefully controlled, Hankinson and colleagues found about 85% of more than 6000 spirometry studies met American Thoracic Society (ATS) standards of quality. Individual pulmonary laboratories can institute quality control measures and, with modest effort, bring their test quality to these standards.

STATIC LUNG VOLUMES

The static lung volume subdivisions, illustrated in Fig. 1, are grouped into volumes and capacities. Volumes, the primary subdivisions, cannot be subdivided. Capacities contain two or more volumes and, therefore, can be subdivided. Total lung capacity (TLC), the volume of air in the lungs at the end of a maximal inspiration, is attained when maximal inspiratory muscle force is counterbalanced by the recoil forces of the lung and chest wall. The maximal volume of air that can be exhaled after a maximal inhalation is vital capacity (VC). Vital capacity can be measured with either an inspiratory or an expiratory maneuver and with either an unforced, slow exhalation (SVC) or a nearly maximally forced maneuver (FVC). The volume of air remaining in the lungs after a maximal exhalation is residual volume (RV). RV is determined by the balance of the forces tending to reduce lung volume (maximal expiratory muscle force and inward lung recoil) against the force tending to increase lung volume (outward recoil of the chest wall). Tidal volume (V_T) is the volume of air moved with each breath during normal breathing. Functional residual capacity (FRC) is usually defined as the volume of air in the lungs at the end of a quiet, relaxed exhalation, although it is sometimes used to indicate the volume of air in the lungs at the end of a tidal breath regardless of whether exhalation is active or passive. Inspiratory capacity (IC) is the maximal volume of air that can be inhaled from

FRC. Expiratory reserve volume (ERV) is the maximal volume of air that can be exhaled from FRC. IC and ERV have little role in diagnostic testing, although ERV is the most commonly reduced lung volume in the morbidly obese.

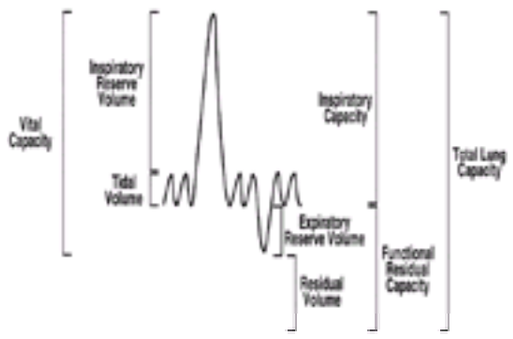

FIG. 1. Lung volumes and capacities. Volumes cannot be subdivided. Capacities contain two or more volumes. (Reproduced with permission from Aldose MD. Practical aspects of pulmonary function testing. In: Baum GL, Wolinsky E, eds. *Textbook of Pulmonary Diseases.* Boston: Little, Brown; 1993.)

The displaceable lung volumes—those that can be inhaled and exhaled from the mouth—are measured with a spirometer. Two types of spirometer are schematically illustrated and described in Fig. 2. The parameters measurable with a spirometer are vital capacity, tidal volume, inspiratory capacity, and expiratory reserve volume (Fig. 1). The remaining volumes and capacities contain residual volume, which cannot be measured with a spirometer. Plethysmographic, gas dilution, and radiographic techniques each measure one of the capacities that contains residual volume. Once measured, this capacity can be combined with the appropriate displaceable volumes to calculate all the remaining lung volumes and capacities. The following descriptions are brief overviews. The reader is directed to the reference list for more detailed descriptions of the tests and how they are performed.

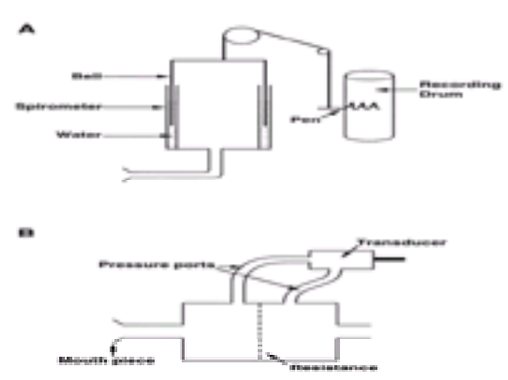

FIG. 2. Two types of spirometers. **A:** Volume-based spirometer that uses water as a seal. Air blown into the spirometer causes the bell to rise, inscribing the height of a cylinder and, therefore, volume. Time is also recorded to allow measurement of volumes as a function of time. As volume is the primary measurement, flows are derived by differentiating the volume-time information. **B:** Flow-based spirometer. Air is blown across a resistor; differential pressures measured across the resistor are related to flow. As flow (volume/time) is the primary measurement, it must be integrated to get volumes. (Reproduced with permission from Aldose MD. Practical aspects of pulmonary function testing. In: Baum GL, Wolinsky E, eds. *Textbook of Pulmonary Diseases.* Boston: Little, Brown; 1993.)

Gas Dilution Techniques

Gas dilution techniques measure the gas volume in the lungs that communicates via the airways. Although the techniques vary in details, all use a mass balance approach to calculate lung volume. The most common approach is schematically illustrated in Fig. 3. The patient is allowed to breathe from a known volume and concentration of a relatively insoluble and inert tracer gas [e.g., helium (He)]. Mixing is allowed to occur for a variable length of time, and the final mixed concentration of tracer gas is measured. A mass balance equation uses the initial volume and tracer gas concentration and the final tracer gas concentration to calculate the volume present in the patient's lungs at the moment tracer gas breathing began. The assumptions that the tracer gas is relatively insoluble and inert and is well mixed in lung air are critical. Use of a relatively soluble gas would cause lung volumes to be overestimated; incomplete gas mixing would cause them to be underestimated. In the case of the He rebreathing method, the patient quietly rebreathes from the test circuit for 4 to 7 min, with occasional deep breaths, until gas measurements demonstrate the concentration of He in the circuit is stable, indicating complete mixing in lung air. The long rebreathing time (up to 7 min) allows complete mixing of He in the circuit, but it also means that CO_2 has to be removed from and O_2 added to the circuit to ensure patient safety and comfort.

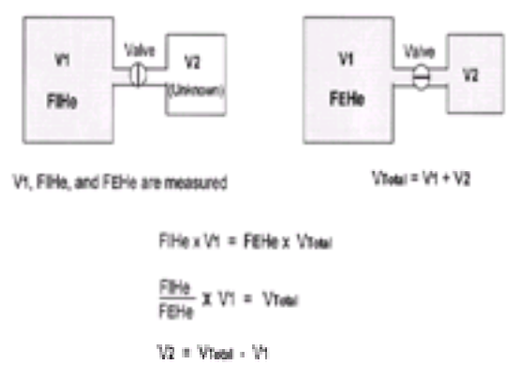

FIG. 3. Schematic illustration of the basic theory of gas dilution measurement of lung volume. Air in a subject's lungs is allowed to come into equilibrium with a known mass of a relatively insoluble and inert gas, such as He. Initial volume (V_1) and He concentration (F_IHe) are known. The diluted, final He concentration (F_EHe) is used to calculate the unknown volume (V_2).

A gas dilution measurement of TLC (usually reported as alveolar volume, or V_A) accompanies every measurement of the single-breath CO diffusing capacity test. In this test, subjects inhale a VC-sized volume of gas that contains about 10% He, 0.3% CO, and 17%–21% O_2, hold their breath for 10 sec, and then exhale. An alveolar gas sample is analyzed to get the diluted alveolar He concentration. The assumption that He is completely mixed during the 10-sec breath-hold is reasonably acceptable in healthy individuals; for healthy people, TLC is only minimally underestimated compared with the multibreath technique. In patients with airway obstruction, mixing becomes less complete as obstruction worsens, and TLC is progressively underestimated. Therefore, in patients with airway obstruction, the single-breath technique has little utility as a technique for measuring TLC.

Nitrogen (N_2) washout techniques also use a mass balance approach to estimate TLC. In the multibreath N_2 washout method, the subject begins breathing 100% O_2 at FRC. O_2 is breathed until N_2 is displaced from the lungs, and the mass of displaced N_2 is measured. FRC is calculated assuming (1) that the mass of displaced N_2 is equal to the mass of N_2 in the lungs at the beginning of the test, and (2) that the initial concentration of N_2 in the lungs was 80%. TLC is estimated as FRC + IC (Fig. 1). N_2 washout techniques also underestimate TLC when airway obstruction is present.

Plethysmography

Plethysmography is used to measure lung volumes and airway resistances. For lung volumes, plethysmography measures the compressible gas volume in the chest using Boyle's Law: the product of gas volume and pressure is a constant ($V_1 \times P_1 = k$) when temperature is held constant. The test is performed by having the patient sit in a sealed box and pant gently against a closed shutter located at the mouth. During the inspiratory phase of the panting maneuver, the thoracic volume increases, slightly decompressing the volume of air in the lungs while compressing the air in the box. In the expiratory phase of the panting maneuver, thoracic gas volume decreases slightly, compressing the air in the lungs and decompressing box air. By Boyle's Law,

$$V_1 \times P_1 = V_2 \times P_2$$

The initial pressure and volume at FRC (the beginning volume before panting) are P_1 and V_1. Pressure and volume at the end of the inspiratory phase of the pant are P_2 and V_2, which can be rewritten as $(P_1 + DP) \times (V_1 + DV)$. P_1 and DP are measured at the mouth, assuming that mouth pressure is equal to alveolar pressure, and DV is measured using the change in box pressure. The equation can then be solved for V_1.

Body plethysmography is still considered the “gold standard” of techniques used to measure static lung volumes. It is, however, sensitive to technical and procedural errors and, like all other lung volume techniques, requires exquisite attention to quality control. For example, the assumption that mouth pressure equals box pressures tends to fail when panting frequency exceeds one pant/sec, because there is inadequate time for the pressure changes at the mouth to equilibrate with alveolar pressure. This is a particular problem in patients with airway obstruction, in whom rapid panting causes a significant overestimation of TLC.

When plethysmographic and single-breath gas dilution measurements of TLC are made during the same test session, the difference between the two ($TLC_{PL} – TLC_{GAS}$) can be used as an estimate of the poorly ventilated gas volume in the lungs, commonly referred to as trapped gas. The volume of trapped gas is increased in the presence of airway obstruction.

Radiographic Total Lung Capacity

TLC can also be estimated from standard posteroanterior and lateral chest radiographs. A radiographic TLC measurement starts with a calculation of total intrathoracic gas volume, from which estimated volumes for the mediastinum, heart, blood, and diaphragm are subtracted. Several studies show excellent correlation between radiographic TLC and plethysmographic TLC in healthy individuals and those with airway obstruction. The advantages of radiographic measurement of TLC are that the methodology is simple, requires no special equipment, and takes little time. However, chest radiographs solely for measuring TLC cannot be justified, even though the radiation exposure is small. Luckily, chest radiographs are often available because they are commonly included in evaluations for respiratory diseases. In addition, the radiographic method can be used to re-create a history of TLC. Old chest radiographs often provide the only source of lung volume information from a patient's past. They can provide evidence of change in a patient whose loss of lung volume would otherwise not have been detectable. This advantage is being compromised by the current trend to destroy radiographs earlier.

The radiographic TLC method has not yet been proved accurate in patients with interstitial lung diseases, and test variability is larger than for other methods. Chest structures are magnified slightly on chest radiographs. Published methods usually use a magnification factor based on a target-film distance of 72 inches (183 cm). For other target-film distances, the magnification factors differ and must be computed by the reader.

Pathophysiologic Correlates with Lung Volumes

The three basic patterns of lung volumes illustrated in Fig. 4 are normal, overinflation (too large), and restriction (too small). In the normal pattern, TLC, VC, and RV fall within a reference range based on healthy people. RV in the young constitutes about 25% of TLC, and FRC about 40%. With aging, lung recoil decreases causing a slight shift in the pattern of air flow toward one of obstruction. With aging, TLC remains essentially unchanged, RV increases, and FRC either increases slightly or does not change. RV increases with aging primarily because the slight shift toward an obstructive pattern makes it impossible for a true expiratory plateau to be reached and RV becomes a dynamic measurement, dependent on expiratory time.

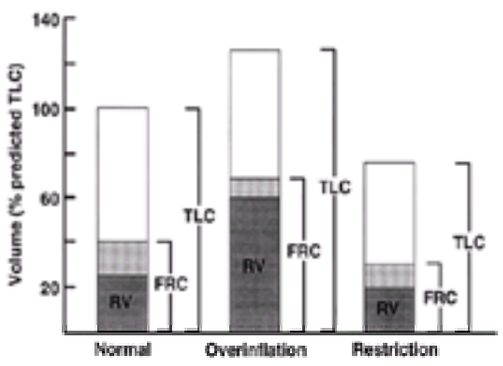

FIG. 4. The three basic lung volume patterns: normal, overinflation (too large), and restriction (too small). (Reproduced with permission from Aldose MD. Practical aspects of pulmonary function testing. In: Baum GL, Wolinsky E, eds. *Textbook of Pulmonary Diseases.* Boston: Little, Brown; 1993.)

Diseases that alter the elastic properties of either the chest wall or lungs may alter lung volumes. Diseases such as emphysema reduce lung recoil and may cause TLC, FRC, and RV to be increased, even when minimal airflow obstruction is present. In emphysema, airway obstruction commonly accompanies decreased lung recoil, and both contribute to overinflation. Mechanically, airway obstruction leads to the initiation of inspiration before expiration is complete; overinflation follows. The process is exacerbated when respiratory rate increases, causing expiratory time to be shortened. Asthma is a classic illustration of a disease with overinflation secondary to airflow obstruction. There is also evidence in asthma that inspiratory muscle activity persists throughout expiration, contributing to overinflation.

Overinflation is primarily determined by an elevated TLC. Other patterns may be used to suggest the presence of overinflation, but one should be cautious in calling overinflation when TLC is within the normal range. The suggestive patterns are an elevated RV or the presence of significant gas trapping.

Lung volumes may be reduced (restriction) in any disease process that increases lung recoil (e.g., pulmonary fibrosis), compresses the lungs (pleural effusion), decreases chest wall compliance (kyphoscoliosis, morbid obesity), alters the shape of the chest (kyphoscoliosis), or decreases respiratory muscle function (neuromuscular diseases, diaphragmatic paralysis).

TLC is also the primary variable used to determine the presence of restriction. Technically, the presence of restriction can be determined only by a reduction in TLC. From a practical standpoint, however, a reduced VC in the absence of airway obstruction has proved to be an excellent predictor of restriction and is an inexpensive, simple parameter to monitor change in patients with restrictive diseases. When both TLC and VC are measured and one is low and the other normal, decisions to classify the presence of restriction should default to TLC. The default to TLC assumes there is no evidence that TLC is underestimated because of technical problems.

DYNAMIC TESTS OF LUNG FUNCTION

Spirometry

Spirometry, which can include both quiet and forced VC maneuvers, is the most common and useful of the lung function tests. Its clinical utility has been proved extensively, it is the least expensive test to perform, and it should be the test most widely available in doctors' offices, clinics, and hospitals. The FVC test is performed by having a patient inhale to TLC and then make a maximally forced exhalation into a spirometer. Classically, exhaled volume is measured as a function of time. Flow may also be measured and displayed as a function of exhaled volume. The three primary spirometric indices in the forced test are FVC, forced expiratory volume in 1 second (FEV_1), and their ratio, FEV_1/FVC. Numerous other spirometric measures are available, but their clinical utility is less well established. Typical volume-time and

flow-volume spirographic displays for a healthy individual are shown in Fig. 5.

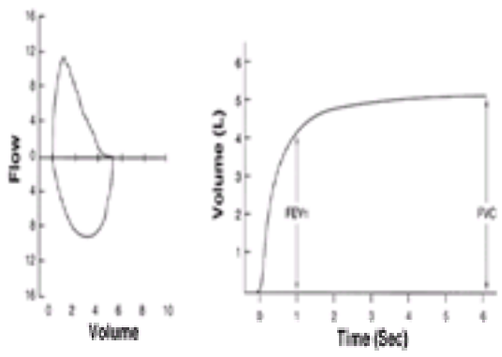

FIG. 5. Spirogram of acceptable quality in a healthy 54-year-old man. In the flow-volume display, markers of good quality include a quick start with a rapid rise in expiratory flow, a well-defined peak flow, the absence of a cough or hesitation in the early portion of the spirogram, and an exhalation that exceeds 6 seconds. The slight tail at the end of exhalation and the continued increase in volume even after 6 seconds of exhalation (volume-time tracing) reflect normal age-related changes.

Test quality depends on achieving a maximal inhalation, a nearly maximal effort during the initial few seconds of exhalation, and a complete exhalation. A complete exhalation is indicated by a plateau in the volume-time tracing; a minimum expiratory time of 6 sec is recommended. A plateau is rarely reached in individuals with airflow obstruction or in healthy older people who have reduced airflow at low lung volumes because of the normal age-related loss of lung recoil. Because expiratory flow never truly reaches a plateau in these individuals, VC increases and FEV_1/VC falls with increased expiratory time. The effect of expiratory time on the FEV_1/VC ratio is minimized if expiratory time lasts at least 10 seconds or if SVC is used rather than FVC.

Syncope may occur, even in healthy subjects, when maximal expiratory force is exerted throughout the entire maneuver. Recent evidence suggests that spirogram quality is not be altered if patients are allowed to reduce their expiratory effort after about 3 seconds and continue to exhale without squeezing hard.

Detailed standards for quality control published by the ATS and the European Respiratory Society (ERS) are outlined in Fig. 6. The first step is to acquire a spirometer that has been demonstrated to meet accuracy standards. Although this statement seems flagrantly obvious, a study of more than 50 instruments on the market in the early 1980s found that only about half met ATS accuracy standards. The problems have largely been corrected, and most but not all commercially marketed spirometers now meet accuracy standards. Care should still be taken to be certain of the accuracy of a spirometer before purchase. Once in use, spirometers need regular quality control checks to ensure proper performance. Such checks are especially important after an instrument has been serviced or upgraded.

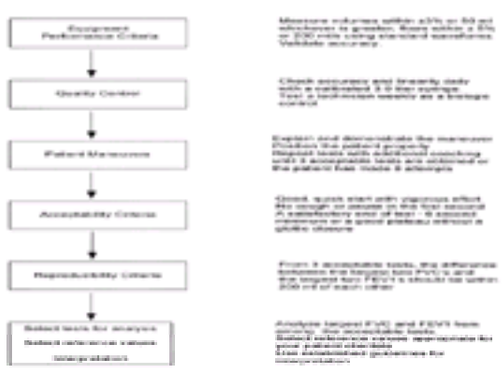

FIG. 6. Summary of ATS recommended steps to assure good-quality spirometric measurements. The same steps can be modified slightly to ensure good quality of all other pulmonary function tests. (Modified and reproduced with permission from Crapo RO, Chair. Standardization of spirometry: 1994 update. Official statement of the ATS. *Am J Respir Crit Care Med* 1995;152:1107–1136).

As instrumentation has improved, the major quality issues now have to do with how the tests are performed. Test quality includes acceptability criteria for each effort and reproducibility criteria for the series of tests performed (Fig. 6). Current standards require that at least three acceptable quality spirograms be obtained. The reproducibility criteria are then applied to the acceptable spirograms to ensure that the data are representative of the patient (Fig. 6). If spirograms of acceptable quality do not meet reproducibility criteria, the patient should be asked to perform the test again. If both the acceptability and reproducibility criteria are not met in eight tries, it is unlikely that they will be with further tests, and the study may be terminated. Efforts to improve the procedural aspects of spirometry include immediate computerized analysis of each test waveform with feedback to the technician about test quality, often with a statement about how to correct problems. Computer displays have also been created to help motivate patients to make good efforts.

Acceptability and reproducibility criteria are ideal targets for the quality of test performance. Even suboptimal tests may provide some useful information, and patient data should not be discarded only because of failure to meet acceptability and reproducibility criteria. The best data available should be submitted for interpretation, and the interpretation should deal with the limitations. Often, partial information can be gleaned from a less-than-optimal test. For example, a test with completely inadequate initial effort still may yield a VC if a reasonable end of test is achieved. Failure to meet acceptability criteria in an individual test occurs for a variety of reasons, including inability or unwillingness of a patient to perform the test, even with vigorous coaching. Failure to meet reproducibility criteria in an individual test may also indicate the presence of hyperreactive airways. Frequent test failures in a laboratory indicate the presence of quality control problems.

Most quality issues are the responsibility of the laboratory and its director, but clinicians who use pulmonary function tests in their medical practice should be able to recognize good-quality tests as well as various disease patterns. Spirograms should be analyzed for quality by visually inspecting both flow-volume and volume-time displays. Typical good-quality spirograms along with several faulty spirogram patterns are illustrated in Fig. 5, Fig. 7, and Fig. 8.

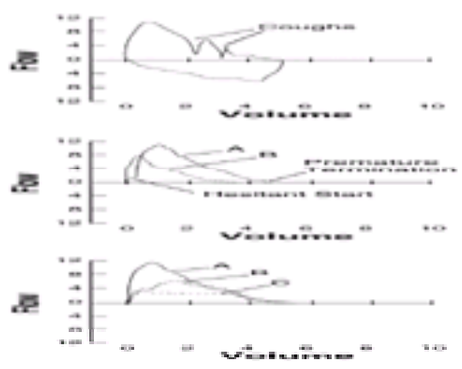

FIG. 7. Several types of faulty spirograms. **Top panel:** Multiple coughs begin early in exhalation (before 1 second). Coughs are characterized by sudden falls in flow followed by quick restoration of flow. Early coughs may cause FEV_1 to be underestimated. **Middle panel:** A hesitant start (waveform A) could cause FEV_1 to be overestimated, and a premature termination of exhalation would cause FVC to be underestimated. Waveform B, from the same patient, illustrates an inadequate inhalation followed by a good expiratory effort. Alone, the curve would be graded acceptable; it is unacceptable when compared with waveform A. **Bottom panel:** Nonreproducible tracings. Waveform A is an acceptable tracing. Waveforms B and C show two different but submaximal initial efforts. FEV_1 may be underestimated with the submaximal efforts; FVC may be acceptable in all tracings depending on the presence of an adequate inhalation and end of test.

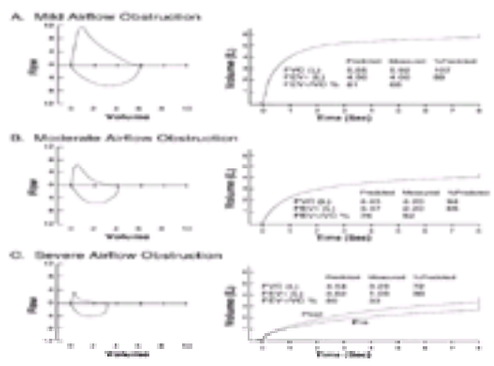

FIG. 8. Typical spirograms for mild, moderate, and severe airway obstruction. Note that with increasing obstruction, the flow-volume tracings show increasing concavity toward the horizontal axis. The *bottom panel* contains prebronchodilator and postbronchodilator tracings, illustrating a good response to administration of an inhaled bronchodilator.

Full spirometry should include both FVC (forced) and SVC (unforced) maneuvers. SVC is often larger than FVC, especially in older persons and those with airway obstruction, in whom the forced maneuver effectively causes some air trapping. If the unforced maneuver is excessively slow, VC will be underestimated. The largest VC found during testing, whether from the forced or the unforced maneuver, should be used to calculate the FEV_1/VC ratio.

For studies that meet acceptability and reproducibility standards, the next question is choosing which measurements to use for interpretation. In general, selecting only from acceptable tests, the largest FVC, FEV_1, and peak flow are used for interpretative purposes; they need not come from the same trial. If midflows (e.g., $FEF_{25\%-75\%}$) or instantaneous flows (e.g., $V_{max50\%}$) are used for interpretation, they should be selected from the single, acceptable-quality spirogram that has the largest sum of FVC and FEV_1. Average ($FEF_{25\%-75\%}$) and instantaneous flow ($V_{max50\%}$) variables should be used only to assist in decision making when the primary indices (FVC, FEV_1, FEV_1/VC) are close to the lower limits of their normal ranges. Average and instantaneous flows have limited clinical utility and are not discussed further here.

Pathophysiologic Correlations with Spirometry

From a diagnostic standpoint, spirometry is used only to classify patients as having one of three patterns: normal, airflow obstruction, and restriction. Specific diagnoses cannot be made with spirometry alone; spirometry patterns must be interpreted according to the clinical questions being asked. The interpretation of spirometry is discussed in detail in the section below on interpretation.

Maximum Voluntary Ventilation

Maximum voluntary ventilation (MVV) is the maximum amount of air that a person can exhale while breathing as fast and deep as possible with vigorous coaching. It is measured over 12 to 15 sec and expressed as L/min at BTPS (body temperature, ambient pressure, and saturated with water vapor) conditions. Test duration is short, because people cannot sustain the MVV maneuver much beyond 15 sec. It is often estimated rather than measured by multiplying the FEV_1 by 35 or the $FEV_{0.75}$ by 40. An optimal test is somewhat hard to describe, because V_T decreases as respiratory rate increases. As a general rule, the peak MVV in healthy subjects occurs at a respiratory rate close to 100 breaths/min with a V_T about 35% of VC. There is, however, not much variation in MVV for respiratory frequencies from 70 to 120/min.

The MVV is a nonspecific test. Reductions in MVV occur in the presence of airway obstruction and chest restriction associated with neuromuscular diseases, loss of coordination, and diminished cognitive function. It may also be reduced because the subject is unwilling to work maximally during the test, as may occur in elderly patients, those with chronic illness, and individuals for whom a poor test result promises secondary gain. Because it is so nonspecific, the clinical utility of MVV is limited. One could, however, argue that the nonspecific nature of the test might also be an advantage in some instances. Reductions in MVV correlate well with postoperative risks for respiratory complications and with dyspnea from any cause. If measured MVV is significantly below calculated MVV, one can tentatively speculate that nonpulmonary factors are involved in the reduction.

The MVV is often used in exercise studies to estimate ventilatory reserve. The common practice of using an estimated MVV for this purpose is problematic, because the normal between-individual variation in measured MVV is large and because there are so many variables besides FEV_1 that affect MVV.

Peak Expiratory Flow and Peak Flow Meters

Peak expiratory flow (PEF) is the maximum flow achieved during an FVC maneuver. It occurs very early in the FVC maneuver (usually within the first 0.2 sec if the maneuver is well performed). This places the measurement in the most effort-dependent portion of the FVC maneuver. Thus, PEF is significantly more effort-dependent than FEV_1, and of less clinical utility from that aspect. The value of PEF in clinical medicine derives from the availability of small, easily portable, highly reproducible, inexpensive peak flow meters. The meters are acceptably accurate but are less accurate than good spirometers. Reproducibility is excellent for individual PEF meters, but there is less reproducibility between meters and there can be marked differences among different PEF meter models. The low cost and reproducibility of PEF meters makes them a practical monitoring device for patients with asthma. Because asthma symptoms and physical findings are imperfect indicators of the severity of asthma, the addition of a relatively inexpensive, objective assessment of lung function is attractive. Monitoring information from PEF meters is of two basic types: (1) trending over days to months, and (2) trending across a day. Increased variability across a day (>20%) indicates airway hyperreactivity and may be an indication of diminished asthma control or a reaction to a provocative stimulus (asthma trigger). At the present time, PEF meters should not be used diagnostically to define normal or abnormal function, because there are no reference values that are applicable to all PEF meter models.

Peak flow meters can be used to track response to medication, monitor the course of asthma, and quantify the effects of exposures to potential triggers or other environmental factors. In numerous national and international guidelines, peak flow meters are used to structure individualized asthma management plans. In the midst of all the enthusiasm for PEF meters, a small note of caution must be sounded. At present, the role of PEF meters in the management of asthma is largely based on reasonable suppositions; there is little science to document exactly what their benefits are and who should be using them.

Bronchodilator Administration and Testing

In patients with airway obstruction, it is common practice to perform spirometry before and after the administration of an inhaled, rapidly acting b_2-selective agonist. The test is performed by obtaining baseline spirometry, administering the bronchodilator medication, waiting a brief period (usually about 15 min), and then repeating the spirometry. The 15-min wait is conservative; some studies suggest 5 min is enough. The test is best performed with a spirometer but can be done with a peak flow meter. An improvement in FEV_1 of 12% and 200 mL is considered an unequivocally positive response. There is, however, some controversy on how to calculate the percentage of change. The ATS statement calculates it as percentage of change from the baseline study, and the ERS publication as a percentage of the reference value for FEV_1. An increase in peak flow of 60 L/min is considered a positive response.

A positive response is considered strong evidence that the patient will benefit from bronchodilator therapy. The converse, however, is not true. The absence of a bronchodilator response in a single laboratory setting does not predict whether bronchodilator therapy will benefit an individual patient. The laboratory outcome can be affected by several technical issues, including the dose and method of administration of the bronchodilator, the wait time, and the quality of the spirogram efforts. In addition, patient response is variable from one day to the next and may vary with the choice of b-adrenergic agonist. Finally, the obstructive effect of mucous plugging and mucosal edema might be large enough to mask a smooth muscle response to bronchodilator medication. Often, a several-week trial of regular bronchodilator therapy is required to decide whether a patient is benefitting or not. The decision to use bronchodilator medication in a patient is therefore a clinical decision. Bronchodilator response in a laboratory setting contributes to the decision but should not be the sole determinant.

Bronchial Reactivity Testing

Airway hyperresponsiveness, an index of the degree of airway narrowing on exposure to provocative stimuli, is one of the primary characteristics of asthma. On average, the airways of asthmatic patients are far more sensitive to provocative stimuli than those of nonasthmatic subjects. Airway hyperreactivity can usually be

suggested by simple tests, such as documenting a response to a bronchodilator or documenting excessive variation in peak flow during a day (most nonasthmatic subjects have a within-day variation in peak flow of <20%). Specific tests measuring response to provocative stimuli are, however, sometimes needed to document the presence of airway hyperresponsiveness.

Two broad categories of stimuli are used to provoke airway narrowing: (1) exposure to aeroallergens like ragweed antigen or chemicals like toluene diisocyanate (specific stimuli), or (2) exposure to methacholine, histamine, exercise, hyperventilation, or cold dry air (nonspecific stimuli). However, the bronchoconstrictive response will vary with the individual stimulus regardless of category.

The most common nonspecific bronchoprovocation test uses methacholine, a parasympathomimetic analogue of acetylcholine, as the bronchoconstricting agent. Methacholine chloride is prepared in several dilutions and administered as a nebulized aerosol in progressively increasing doses. The test begins with baseline measurements of FEV_1 and/or airway resistance. If airway resistance is measured, changes are usually expressed as specific conductance (1/resistance/thoracic gas volume). A second set of measurements follows administration of the diluent alone. Each methacholine dose is followed, after a brief wait, by measurement of FEV_1. A response is considered positive if a sustained 20% fall (calculated from the postdiluent value) in FEV_1 is observed within the prescribed dosage schedule (Fig. 9). The dose of methacholine that elicits a 20% fall in FEV_1 is designated as the PC_{20}, the provocative concentration that causes a 20% fall in FEV_1. As the study is performed in steps, the PC_{20} is calculated either mathematically or graphically from the stepwise changes in FEV_1 (Fig. 9). The response is a continuum; the lower the PC_{20}, the more reactive the airways. Most asthmatic patients have a PC_{20} of £8 mg/mL. If specific conductance is used as the measure of response, a positive response is indicated by a 35% fall (PC_{35}) during the test. Methacholine challenge testing deals with complex issues and requires rigid standardization to ensure that proper doses of active drug are administered on a proper schedule, that timing of spirometry relative to the dose is controlled, and that spirometry quality and patient safety are properly addressed. Details of these issues and protocols are provided in articles in the reference list. Standard protocols for methacholine challenge that include seven dosage steps are time-consuming; abbreviated protocols with fewer steps have been found to produce acceptable results for clinical testing.

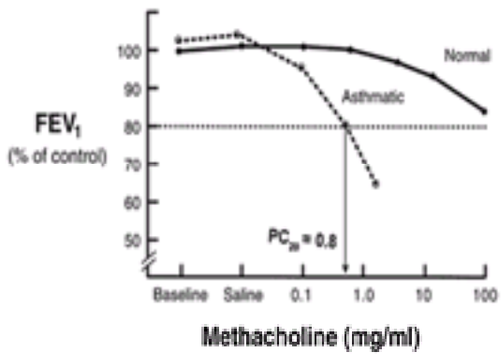

FIG. 9. Graphic display of normal and asthmatic responses to a methacholine challenge test. FEV_1 expressed as a percentage of the control (diluent value) is graphed against the methacholine dose. The point at which the fall in FEV_1 exceeds 20% is used to calculate the provocative concentration, PC_{20}. (Figure courtesy of Charles Irvin, Ph.D.)

Methacholine challenge studies are common in research protocols involving asthma because they allow bronchial hyperreactivity to be quantified and monitored. In most clinical settings, it is not necessary to document or quantify airway hyperreactivity with formal challenge tests. However, when the diagnosis of asthma is uncertain, bronchoprovocation studies may be clinically useful, as in a patient who has normal spirometry results but also has chest symptoms, such as cough or chest tightness, that suggest asthma. A positive methacholine challenge test result in this setting is highly suggestive of asthma. Clinical monitoring airway hyperreactivity during therapy as a means of quantifying response to treatment is controversial. Currently, such monitoring would be indicated only in selected patients under special circumstances.

Methacholine challenge testing is a safe procedure, but when methacholine is administered in large doses to asthmatic patients it can provoke severe attacks. Excessive salivation, abdominal cramping, diarrhea, and sweating can occur if the systemic dose is excessive. Atropine is a specific antidote. Contraindications and precautions are well described in standard references. Bronchoprovocation with sensitizing agents like antigens or occupational sensitizers is associated with higher risks, and more caution is warranted. Testing with sensitizing agents should be limited to laboratories specializing in such studies.

Exercise Bronchoprovocation

Exercise provokes bronchospasm in 60%–90% of asthmatics. The level of ventilation obtained during exercise is probably the most important determinant of this response to exercise. For testing outside a laboratory, a fall in FEV_1 of 15% or more in response to modest amounts of exercise (achieving ventilation at 40%–50% of predicted MVV) is considered a positive test result. With formal testing in a laboratory, a 10% fall in FEV_1 with exercise may be significant. Standardized protocols are available.

DIFFUSION

After arterial blood gas measurement, the most common test of gas transfer across the lungs is the CO diffusing capacity (D_LCO), also called *transfer factor* (T_LCO). The test measures the rate of transfer of CO from the lungs to the blood. Units of measurement are expressed in two ways. In North America, D_LCO is expressed as mL CO/min/mmHg driving pressure; in Europe, T_LCO is expressed as mmol CO/min/kPa. CO, rather than O_2, is used as the gas of interest because in the lungs it behaves similarly to O_2, with the advantage that D_LCO can be measured, whereas D_LO_2 cannot. The pathway for the movement of CO or O_2 from alveolus to hemoglobin (Hb) molecule is illustrated in Fig. 10. Diffusion across the alveolar-capillary membrane is only a small portion of the pathway. In fact, accumulating evidence suggests that mixing within the red cell and the chemical reaction rate are far more important limiting factors in healthy individuals than is diffusion across the alveolar-capillary membrane. This supports the European community's decision to describe the test as transfer factor rather than diffusing capacity.

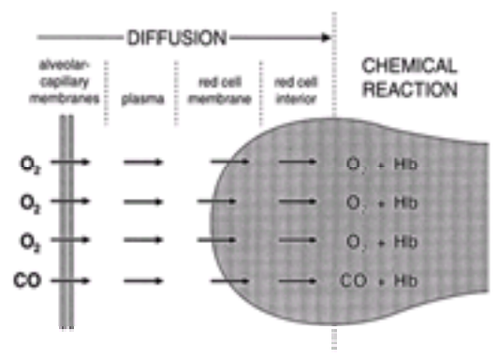

FIG. 10. The diffusion pathway for O_2. Pathway lengths in this figure do not reflect true pathway distances. The pathway is identical for CO, the gas used in the diffusing capacity test. O_2 and CO move across the alveolar-capillary membrane, traverse a very thin plasma layer, cross the red cell membrane, diffuse within the red cell interior, and chemically react, binding with Hb. O_2 and CO compete for the same binding sites on the Hb molecule (Reproduced with permission from Forster RE, DuBois AB, Brisco WA, Fisher AB. *The Lung: Physiologic Basis of Pulmonary Function Tests.* 3rd ed. Chicago: Year Book; 1986).

Diffusing capacity can be measured with single-breath, steady-state, and rebreathing techniques. The single-breath technique is by far the most common, best-standardized, and readily available technique. It also is the method on which most of our clinical information relating D_LCO to disease states is based. The

single-breath test is performed as follows: The patient exhales to RV, a valve is opened, and the patient inhales to full VC the test gas, which in addition to N_2 contains 0.3% CO, an inert, insoluble tracer gas (e.g., He), and 18%–21% O_2. The patient relaxes into a breath-hold at TLC for 10 sec and then exhales rapidly. An alveolar sample is collected for analysis after anatomic and mechanical dead space is flushed out by exhaled air. The test is safe and easy to perform. Details of the technique and the computations involved are well described in current ATS and ERS standards documents.

Several important technical and physiologic issues must be considered to avoid interpretive errors. The first is that the selection of reference values for D_LCO is confounded by the fact that in early studies, D_LCO measured in the same person in different laboratories could vary by as much as 90%. These differences occur because test results are affected by variations in procedural and computational techniques. Although recent testing has demonstrated that standardizing the performance and calculation procedures reduces this large interlaboratory variability, there are still differences of 15%–20% between well-standardized laboratories. Thus, reference data must be carefully selected, or interpretative errors will be frequent.

The remaining issues center on physiologic variables that can influence D_LCO without indicating the presence of an abnormality in lung function. CO competes with O_2 for the same Hb sites, and the number of binding sites available influences D_LCO. Anemia decreases and polycythemia increases D_LCO. Interpreting D_LCO in patients without knowing their Hb concentration is potentially misleading, especially in settings in which Hb is likely to be altered. In patients being monitored for pulmonary injury while receiving chemotherapy, for example, a fall in D_LCO could reflect lung injury, the development of anemia, or both. If carboxyhemoglobin (CoHb) is elevated, as in smokers, the COHb effectively reduces the available binding sites while at the same time creating a small CO back pressure in the plasma. These effects combine to lower D_LCO artifactually about 1% for each 1% increase in COHb. The best (although, not the easiest) method of avoiding problems with COHb is to have patients refrain from smoking overnight before testing. An optimal procedure is to also measure Hb and COHb once during each D_LCO testing session and adjust measured D_LCO accordingly. The small back pressure created by CO is another factor to keep in mind during testing. The test gas itself will raise the COHb level about 0.5% for each trial.

Because CO and O_2 compete for the same Hb binding site, changes in O_2 pressure that give one or the other a competitive advantage also artifactually alter D_LCO. For example, administration of supplemental O_2 increases the inspired O_2 concentration (F_IO_2), gives the advantage to O_2, and lowers D_LCO. As individuals move from sea level to higher altitudes, the decreased barometric pressure lowers F_IO_2 and gives the advantage to CO, causing D_LCO to increase about 0.35% for each decrease of 1 mmHg in alveolar partial pressure of O_2 (P_AO_2). Using a correction factor in the computation or simulating the F_IO_2 at sea level (150 mmHg) by adding O_2 to the test gas mixture will compensate for the effect of altitude.

Pathophysiologic Correlations

Diseases associated with decreased D_LCO include those that (1) reduce lung surface area (emphysema and pulmonary fibrosis), (2) thicken or alter the structural components of the alveolar-capillary membrane (pulmonary fibrosis), or (3) obstruct or obliterate pulmonary capillaries (pulmonary embolism, fibrosis, emphysema, pulmonary hypertension). Although the combination of airway obstruction, overinflation, and a reduced D_LCO are the best physiologic markers for emphysema, this entire constellation of findings does not usually occur until later stages of the disease. Isolated reductions in D_LCO have been reported to be early indicators of the presence of both emphysema and interstitial fibrosis. For example, in one report of patients with dyspnea, normal chest radiographs, and pathologically demonstrated pulmonary fibrosis, a reduced D_LCO was the among the most common functional abnormalities. However, the sensitivity and specificity of an isolated reduction in D_LCO, even in the presence of dyspnea, are still unknown.

Reductions in D_LCO are thought to predict exercise-associated arterial O_2 desaturation. In patients with chronic obstructive lung disease and restrictive lung diseases, D_LCO values that are <50% of predicted have been shown to correlate with exercise hypoxemia. Reports are not entirely consistent, however. One should view the 50% threshold with some suspicion because of the known large interlaboratory variability in percentage of predicted values for D_LCO.

Increases in D_LCO are not commonly encountered clinically. They occur in the presence of polycythemia and with intrapulmonary hemorrhage (e.g., Goodpasture's syndrome). They may also represent a technical problem, as D_LCO can be dramatically increased when an individual continues to try to inhale during the breath-hold part of the test (Mueller maneuver).

RESPIRATORY MUSCLE STRENGTH

Routine pulmonary function tests may be useful in suggesting the presence of respiratory muscle dysfunction. Typically, individuals who cannot generate normal respiratory muscle force have a reduced VC. In patients with bilateral diaphragmatic paralysis, VC is usually smaller in a supine than in an upright position. VC may also be a useful tool to follow patients with respiratory muscle dysfunction. MVV is commonly reduced in the presence of respiratory muscle dysfunction, but its use is limited because so many different factors reduce it.

Overall respiratory muscle strength is usually assessed by measurement of maximum inspiratory (MIP) and expiratory (MEP) pressures at the mouth. These pressures can be easily measured with portable pressure meters in most clinical settings. MIP is usually measured from RV, and MEP from TLC. Patients should be coached to make the maneuver from their lungs and not use their cheek muscles, which can generate falsely high pressures. The measurements are made against a closed valve; a small, 1-mm fixed air leak is introduced to reduce the effect of using the cheek muscles to generate pressure. Mouth pressures well within a normal range (MIP >80 cm H_2O) can be used to exclude clinically significant respiratory muscle weakness. Lower values are more problematic, because they can represent disease or inadequate effort.

In patients for whom measurements of MIP and MEP do not resolve the question being asked, more sophisticated assessment of respiratory muscle function can be performed with measurement of transdiaphragmatic pressures and with nerve stimulation tests. These tests have the disadvantage that they are more technically demanding and therefore are usually limited to specialty laboratories.

Tests of respiratory muscle strength are useful when neurogenic and myopathic processes are known or suspected. They are also useful when diaphragmatic weakness, fatigue, or paralysis are suspected. Diaphragmatic weakness, when severe, can cause dyspnea and tachypnea and can, even when mild, contribute to dyspnea resulting from other disease processes.

TESTS OF ELASTIC PROPERTIES

These tests are used to characterize the elastic properties of the lung and chest wall. They require the measurement of transmural pressures across the lung (lung elastic recoil pressure, or P_{el}) and across the chest wall (chest wall elastic recoil pressure, or P_{th}). The chest wall includes the abdomen. Measurement of these transmural pressures requires estimates of pleural pressure (P_{pl}) and alveolar pressure (P_{alv}). A small esophageal balloon is inserted into the lower third of the esophagus; esophageal pressure is used to approximate pleural pressure. Mouth pressure under static conditions (no air flow in a relaxed patient with an open glottis) is used to approximate alveolar pressure. Under static conditions, esophageal and mouth pressures are measured at several lung volumes between TLC and RV. Curves relating transmural pressures to lung volume (pressure-volume curves) are calculated separately for the lungs and chest wall and for the respiratory system (lung and chest wall combined). Compliance is calculated as change in lung volume divided by change in pressure (DV/DP).

Normal aging and diseases like pulmonary emphysema, which involve disruption of the alveolar walls, are associated with decreased lung recoil pressures for a given lung volume and, consequently, increased lung compliance. Diseases like pulmonary fibrosis increase lung elastic recoil pressures and reduce lung compliance. Aging and chest wall disorders are associated with decreased chest wall compliance.

Although these tests are critical for clarifying the pathophysiology of lung function in various diseases, their clinical utility in routine patient care has never been proved. Interested readers should consult pulmonary physiology texts for further information.

ARTERIAL BLOOD GASES

Thus far, the discussion has been concerned with tests of the mechanical properties of the lung—the bellows action that moves air into and out of the lungs. The mechanical studies, including spirometry, lung volumes, and respiratory muscle testing, characterize the function of the lung but do not provide any estimate of how adequately the lung is performing its primary function. Measurement of arterial blood gases provides direct evidence about the adequacy of gas transfer across the lungs.

It is important to understand both what information is provided by arterial blood gases and what is not. Arterial blood gases define how well the lung is loading O_2 into and removing CO_2 from blood. However, they characterize only the initial steps in the gas transport system (Table 1). They do not allow an overall assessment of the

adequacy of delivery of O_2 to cells or of the adequacy of cellular function.

Blood gas technology is advancing rapidly. Blood gas machines are now highly automated. They calibrate and monitor themselves for errors. They wash and rinse themselves and provide numerous alert messages when conditions are not properly controlled. They measure temperature and barometric pressure and compensate for electrode nonlinearity with empirically derived mathematical algorithms. Because they do so much and the technician needs to do so little, laboratory physicians and technicians may become less knowledgeable about the details of blood gas analysis. The increased accuracy of modern blood gas machines partially compensates for this lack of knowledge while at the same time exacerbating it.

The field of noninvasive monitoring of blood gas parameters is also advancing rapidly. Pulse oximeters are widely used, and other techniques for continuously monitoring blood gas parameters are being developed. In the managed care environment, blood gas analysis, along with most other laboratory measurements, is under increasing scrutiny. Documentation for the efficacy of these measurements is being required.

Details of blood gas measurement and interpretation are available in several of the references listed. Briefly, analysis of arterial blood gases involves three separate issues: (1) acid-base status, (2) ventilation status, and (3) oxygenation status. The importance of the lungs in maintaining acid-base balance is illustrated by the fact that the lungs excrete approximately 13,000 mEq of CO_2 per day. In contrast, the kidneys excrete 40 to 80 mEq of fixed acid per day. In a blood gas report, pH and $PaCO_2$ are the two measured elements relating to acid-base balance. The pH and arterial pressure of CO_2 ($PaCO_2$) are used to calculate bicarbonate concentration using the Henderson-Hasselbalch equation. Calculated bicarbonate may provide quick insight into the metabolic component of acid-base derangements.

The adequacy of ventilation is assessed with the $PaCO_2$, according to Eq. 1:

$$PaCO_2 \propto \frac{\dot{V}CO_2}{\dot{V}_A} \propto \frac{\dot{V}CO_2}{\dot{V}_E - \dot{V}_D} \quad \textbf{(1)}$$

where $\dot{V}CO_2$ is CO_2 production, $\dot{V}_A$ is alveolar ventilation, $\dot{V}_E$ is minute ventilation, and $\dot{V}_D$ is dead space ventilation.

Equation 1 illustrates that $PaCO_2$ is determined by the matching of $\dot{V}_A$ to $\dot{V}CO_2$. An elevated $PaCO_2$ indicates hypoventilation; that is, $\dot{V}_A$ is inadequate relative to $\dot{V}CO_2$. Inadequate $\dot{V}_A$ can occur because $\dot{V}_E$ is reduced and/or $\dot{V}_D$ is increased. If $PaCO_2$ is low, hyperventilation is present. A normal $PaCO_2$ implies adequate matching of $\dot{V}_A$ to $\dot{V}CO_2$, but it is not the sole determinate of the efficiency of ventilation. Efficiency of ventilation must be interpreted in light of the clinical setting, including breathing parameters and $\dot{V}CO_2$. Problems with $\dot{V}CO_2$ can usually be diagnosed simply by looking for markers associated with increased $\dot{V}CO_2$ that may be driving the metabolic processes. In the intensive care unit, these markers include fever and overfeeding with parenteral nutrition. Increases in $\dot{V}CO_2$ are rarely reflected directly as increases in $PaCO_2$ because the ventilatory reserve is so large.

Evaluation of oxygenation parameters includes assessment of the PaO_2 and arterial O_2 content. The PaO_2 provides a valuable—but incomplete—estimate of the adequacy of O_2 loading in the pulmonary capillary blood. It is useful to think of PaO_2 as an intensive rather than a quantitative variable. Although very useful, PaO_2 by itself gives no information about the volume of O_2 contained in the blood (O_2 content). Analyzing both PaO_2 and O_2 content enhances blood gas information.

CO-oximeters are available for accurate measurement of Hb concentration, arterial O_2 saturation (SaO_2), COHb concentration, and methemoglobin (Met-Hb) concentration. Their availability improves the accuracy of estimations of SaO_2 and simplifies the diagnosis of CO poisoning. Blood gas reports should now routinely include a calculation of arterial O_2 content (CaO_2) using CO-oximeter measurements (Eq. 2). Its components include Hb concentration, SaO_2, and the volume of O_2 dissolved in plasma, calculated as $0.0031 \times PaO_2$. The amount of O_2 dissolved in the plasma is trivial compared with the amount bound to Hb in most clinical settings.

$$CaO_2 = 1.39\ Hb \times SaO_2 + 0.0031\ PaO_2 \quad \textbf{(2)}$$

Calculation of the alveolar-to-arterial pressure gradient for O_2, or $P(A\text{-}a)O_2$, when the patient is breathing room air can be useful in separating the physiologic causes of hypoxemia. The method of calculating $P(A\text{-}a)O_2$ is shown in Eq. 3:

$$P(A\text{-}a)O_2 = FIO_2(PB\text{-}47) - PaCO_2\left(FIO_2 + \frac{1\text{-}FIO_2}{R}\right) - PaO_2 \quad \textbf{(3)}$$

where $P(A\text{-}a)O_2$ is the alveolar-to-arterial pressure gradient for O_2, FIO_2 is the inspired O_2 concentration, ($PB - 47$) is the barometric pressure minus water vapor pressure at 37°C, and R is the respiratory quotient (usually assumed to be 0.8). For blood gases obtained at sea level with a patient breathing room air, Eq. 3 can be reduced for rapid clinical use as follows:

$$P(A\text{-}a)O_2 = 150 - 1.2 \times PaCO_2 - PaO_2$$

It is clinically useful to categorize the physiologic causes of hypoxemia. Physiologic causes of hypoxemia are summarized in Table 2, along with corresponding alveolar-to-arterial gradients when appropriate.

Cause	$P(A\text{-}a)O_2$
Low PaO_2	
• Low inspired PO_2, FIO_2 is low Barometric pressure is low	• Normal If inspired PO_2 is incorrectly assumed to be 21%, the A-a gradient may be elevated.
• Hypoventilation (Elevated $PaCO_2$)	• Normal
• V/Q mismatching	• Elevated
• Diffusion impairment	• Elevated Rarely a cause of hypoxemia
• Right-to-left shunting	• Elevated With large shunt, response to oxygen poor
Low oxygen content (CaO_2)	
• Anemia	
• Low SaO_2 Presence of other hemoglobin species, such as COHb or Met-Hb Shift of oxyhemoglobin curve to right	

COHb, carboxyhemoglobin; Met-Hb, methemoglobin; CaO_2, arterial oxygen content; FIO_2, fraction of inspired oxygen; PO_2, partial pressure for oxygen; PaO_2, arterial partial pressure for oxygen; $P(A\text{-}a)O_2$, alveolar-arterial gradient for oxygen; $PaCO_2$, arterial partial pressure for carbon dioxide; V/Q, ventilation/perfusion.

TABLE 2. *Physiologic causes of hypoxemia*

The most common noninvasive measurement of oxygenation status is made by pulse oximetry. Pulse oximeters do not directly measure SaO_2 but relate light absorption across the finger to arterial blood gas data from volunteers in whom arterial blood gases and pulse oximeter light absorption are simultaneously obtained. One side of a pulse oximeter probe contains two light-emitting diodes, each emitting light at a different wavelength (one at about 660 nm and one at about 940 nm). The other side contains a photocell to measure light intensity after light has passed through a finger or ear lobe. A clever variation of Beer's Law (the light absorbed by a solute in a solution is related to the concentration of the solute) is used to estimate SaO_2. Light is absorbed in a pulsatile fashion, increasing with each heartbeat. The assumption is that the increased absorption is caused by arterial blood.

It is important to keep in mind the limitations of pulse oximetry. These include the margin of error, the fact that pulse oximetry does not differentiate between different Hb species, and the effect of substances in the body that may affect light absorption. As a general rule, a single isolated measurement of SaO_2 by pulse oximetry will be within ±4% of the saturation measured in blood directly. Therefore, a pulse oximeter reading of 90% could actually be between 86% and 94%. If the device is being

used to monitor SaO_2 in a single individual, a 2% change is considered significant. As pulse oximetry only uses two wavelengths of light, it cannot distinguish either COHb or Met-Hb. Pulse oximeters measure COHb as if it were oxyhemoglobin. In a patient with CO poisoning, therefore, the low SaO_2 would not show up on a pulse oximeter reading.

Other conditions that may result in misleading readings include presence of dyes (methylene blue), elevated bilirubin, states of low perfusion, anemia, and presence of strong external light sources, which may interfere with absorbance measurement. On occasion, the assumption that the pulsatile waveform marks arterial blood does not hold. For example, in a patient with tricuspid regurgitation and strong venous pulsations, the pulse oximeter cannot separate arterial from venous pulsations, and an erroneous reading may occur.

REFERENCE VALUES AND INTERPRETATION

Background

The first step in interpreting pulmonary function tests is selecting the best possible reference values. For many tests, the selection is made by a laboratory physician, but as equipment moves into offices and clinics, individual clinicians will be called on more and more often to make that choice. Guidelines for selecting reference values are widely available. For pulmonary function tests, the ATS and ERS provide access to appropriate reference values.

Medical decisions are made after comparing clinical observations with one or more sets of reference data. This is not as simple as defining a normal range. Results of clinical tests that fall within a normal range often imply absence or low risk of disease. This may not be correct when the typical representative comparison is made. For example, a cholesterol value may fall well within an average range from a general population sample but indicate increased risk for coronary disease when compared with reference data based on total risk assessment. In pulmonary function testing, the assumption may also be incorrect. For example, an individual who starts out with an FEV_1 that is 110% of the predicted value could suffer a reduction of 25% or more in FEV_1 and still have a value within the normal range. The loss—and thus the underlying disease process—would not be detected by routine lung function testing.

Interpreting lung function tests may also be based on comparisons of observed values with reference value information, including comparisons with recognized disease patterns or values previously measured in the same patient. Using historical lung function data from the same patient neatly eliminates all the between-individual variability that exists in the representative group comparison; changes as small as 5% can be detected. However, it is not practical to perform baseline studies in every patient against the unlikely chance that a pulmonary disease will develop. It is practical, however, to track individual lung function in at-risk populations, such as those in occupations with a known tendency to cause lung injury.

The issues involved in reference value selection and comparison have been the subject of many expert panels and are well described by Solberg (1989) and Grasbeck (1990). The general rules, modified slightly for pulmonary applications, are as follows: (1) The reference population must be clearly defined and described. (2) The patient being examined must resemble the reference study subjects as much as possible in regard to the biologic factors known to contribute to lung function variability. For lung function, these factors are sex, age, height, weight, ethnic group, past and present health, socioeconomic status, and environmental exposures, including cigarette smoke, air pollution, and occupational exposures (Fig. 11). (3) Clinical and reference value measurements should be made with adequately standardized methods and appropriate quality control. Technical variability is reduced when a clinical laboratory makes measurements with the same standardized methods as those used in a reference value study. This last issue is the basis for the development of equipment and procedural standards that have been published by many different respiratory societies.

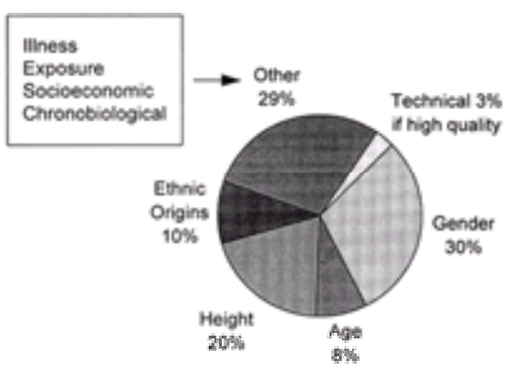

FIG. 11. Schematic illustration of the sources of variability in lung function tests. These sources of variability must be dealt with as part of the performance and interpretation of lung function tests or else the noise encountered in the testing will overwhelm the signal of interest, which in a clinical setting is usually change in lung function with disease. Note that the 3% technical variability assumes high-quality tests. Substandard tests can cause technical variability to exceed all other sources of variability. (Created from data contained in Becklake MR, White N. Sources of variation in spirometric measurements. *Occup Med State of the Art Rev* 1993; 8:241–264.)

Reference data vary depending on the population being sampled, the method of sampling the population, and the methods of analyzing the data. The data may be gathered from a subset of a population sample in a larger epidemiologic study, or it may come from a study specifically designed as a reference value study. Although the optimal method of sampling a population is random sampling, volunteer samples are less expensive and easier to perform and thus more frequently used. Sample size is important. In general, lung function reference studies are better if they include at least 10 subjects of each sex for each decade. The method of analysis also influences reference ranges. In some pulmonary function reference studies, only linear relationships are considered; in others, complex models are used.

Lower Limits for Reference Ranges (Lower Limits of Normal)

Once reference values have been selected, a reference range defines the limits for comparisons. In pulmonary function testing, three sets of limits are commonly used. The most common is also the least desirable. It defines the normal range for FEV_1/VC as >70% or >75% and the normal range for everything else as the predicted value ±20%. This method is popular because of its simplicity, but it is statistically incorrect and should be abandoned. The FEV_1/VC ratio falls with aging, so a fixed ratio to define normal is inappropriate. Using ±20 to define a reference range causes false-negative results in younger and taller patients and false-positive tests in shorter, older patients. It causes large numbers of false-positive errors in the interpretation of midflows and instantaneous flow variables, for which statistically appropriate lower limits of normal approach 50% of the predicted value.

Two statistically acceptable approaches to lower limits of normal are available. One, based on an assumption that the data distribution is Gaussian, uses 95% confidence intervals, usually calculated as 1.645 times the standard error of the estimate in a linear regression equation. The other is based on a calculated lower (or upper) 5th percentile. The percentile calculation is usually based on data expressed as a percentage of the predicted value. Calculation of percentiles avoids the Gaussian distribution assumption. Both are probably acceptable for basic pulmonary function tests that involve FVC and FEV_1. The instantaneous and midflow variables are more likely to have skewed distributions; reference ranges defined with percentiles are preferable for these variables.

Lower limits of normal are variable and should not be treated as arbitrary demarcations. Measured values that lie well within or outside the normal range can be interpreted with confidence. Those that lie close to lower or upper limits should be interpreted with caution. In these borderline cases, clinical information is the best guide to categorizing a test result.

Restricting the Number of Tests Used in an Interpretation

More than 30 parameters can be obtained from spirometry, lung volumes, and diffusing capacity. By chance alone, more than 25% of healthy subjects would have an abnormal result in one or more tests if all 30 were used. The chances for a false-positive test decrease when one is selective about the number of results analyzed. For spirometry, the interpretation should focus on three variables: VC, FEV_1, and FEV_1/VC. For static lung volumes, the interpretation should focus on TLC, and for diffusing capacity, on D_LCO. The other results reported may help make decisions in borderline cases, but clinical data are even more useful in those borderline situations.

General Interpretative Guidelines

Spirometry

A simple algorithm for interpreting spirometry using three variables is outlined in Fig. 12. Obstructive lung diseases are characterized by decreased expiratory flows compared with healthy persons. Early airway obstruction, which begins in the small airways, tends to reduce flows at lower lung volumes. Numerous tests for small-airways disease have been studied. Tests, including closing volume, $V_{max50\%}$, and $FEF_{25\%-75\%}$, tend to correlate well with small-airways disease in groups, but there is still no convincing evidence they can be effectively used in a clinical setting to diagnose the presence of small-airways disease in a given individual. The pattern of reduced air flow at lower lung volumes is also seen as part of normal aging, reflecting the loss of elastic recoil of the lungs with age.

FIG. 12. Simple algorithm for interpretation of spirometry. For simplicity, the severity of restriction based on VC is not diagrammed. Severity of restriction here would use percentage of predicted VC and use a scale similar to that for obstruction. (Adapted from information contained in Becklake MR, Crapo RO, co-chairs. Lung function testing: selection of reference values and interpretative strategies. Official statement of the American Thoracic Society. *Am Rev Respir Dis* 1991;144:1202–1218.)

As airway obstruction worsens, air flow is reduced at higher lung volumes. The flow-volume display shows progressively more concavity toward the horizontal axis; the volume-time curve shows a slowly rising volume even after 6 to 10 sec. The primary marker for the presence of airway obstruction is the FEV_1/VC ratio. Once airway obstruction has been diagnosed on the basis of FEV_1/VC, severity is classified using the FEV_1% (FEV_1 as a percentage of the predicted value) (Fig. 12). The characteristic patterns of severe airway obstruction are illustrated in Fig. 8. All expiratory flows are reduced. With good effort, a well-defined but reduced peak flow is seen, followed by a rapid fall in flow to a very low level. At that point flow decreases almost linearly, and the patient never achieves a true expiratory plateau.

Central airway obstruction has a characteristic pattern, depending on the location of the obstruction (Fig. 13). The classic pattern is not seen, however, until the obstruction is rather advanced. The pattern of central airway obstruction can be replicated by submaximal inspiratory and expiratory efforts. Therefore, vigorous patient effort is especially important when central airway obstruction is suspected.

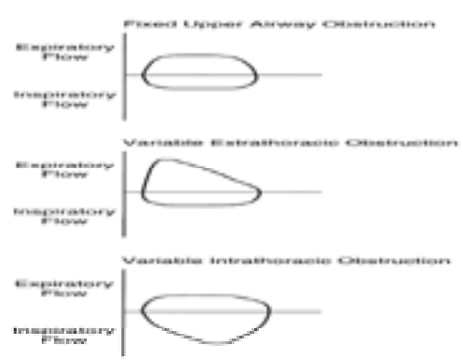

FIG. 13. Central airway obstruction patterns. Three basic forced expiratory flow-volume patterns seen in the presence of at least moderate upper airway obstruction are schematically illustrated. The basic pattern of airflow obstruction in central airways is constant flow over a significant portion of the inhaled and/or exhaled volumes. In fixed central airway obstruction, the pattern does not vary with inspiration or expiration. Variable extrathoracic obstruction is associated with a relatively normal pattern during expiration, as extrathoracic airways widen during exhalation and narrow during inspiration. Conversely, variable intrathoracic obstruction tends to have a more normal pattern during inspiration, as intrathoracic airways tend to widen during inspiration and narrow during expiration. The patterns may also be seen with submaximal effort. The patterns are present to some degree in patients with milder degrees of obstruction but may be more subtle.

Restrictive patterns in spirometry are characterized by a reduced VC in the absence of airway obstruction (FEV_1/VC is normal). Flows taken from a spirogram are typically reduced when restriction is present because of the smaller absolute lung volume, and by themselves they do not indicate the presence of combined obstruction and restriction. Small VCs commonly occur in the presence of obstruction because expiratory time is relatively short. If airway obstruction is present and VC is low, no certain determination of restriction can be made on the basis of spirometry alone. If it is clinically indicated, a measurement of TLC is necessary to confirm the presence of a combined obstructive and restrictive pattern. The presence of restriction can also be determined in most patients who have airway obstruction by simply reviewing the chest radiograph obtained for other clinical reasons.

Static Lung Volumes

The static lung volume variables used for interpretation should be limited to TLC to avoid excessive numbers of false-positive results. Statistically based lower limits of normal should be used. In the classification of restriction, occasionally TLC and VC findings will conflict. If there are no obvious technical problems, TLC should determine the estimation of restriction. The classic pattern of overinflation includes elevations in TLC, FRC, and RV. Increases in FRC and RV may precede increases in TLC, but one should be cautious in using them to diagnose overinflation, because they also increase the risk for false-positive calls. Overinflation can also be recognized in chest radiographs when classic signs are present.

Diffusing Capacity

The primary variable used for interpretation is D_LCO. There is increasing hesitancy to use D_L/V_A in interpretative schemes, largely because it frequently conflicts with D_LCO and the clinical situation. A laboratory can usually categorize D_LCO only as within or outside the reference range. The one pattern of findings that suggests a clinical diagnosis is the combination of airway obstruction, evidence of overinflation, and a low D_LCO (suggesting emphysema). Further interpretation of alterations in D_LCO requires knowledge of the clinical question being asked. A common pattern is to find a reduced D_LCO as the only abnormality in a battery of pulmonary function tests. In the absence of other clinical or functional information, an isolated reduction in D_LCO does not have clinical significance and need not be pursued further.

Changes in Lung Function Measurements with Time

It is difficult to define precisely a significant change with time. A consistent trend in lung function revealed with multiple measurements will define significant change earlier than will two or three measurements. For changes in VC and FEV_1 occurring within a few weeks, a 12% change in healthy subjects and 20% in subjects with obstruction is likely to be significant. Through years, a 15% change (adjusting for age) is probably significant for both. For D_LCO and TLC, within-test and between-test variability are increased, and criteria defining change with time are largely absent. When no trending information is available, I tend to consider changes of >15% as

significant, but do so with some discomfort.

CHAPTER

10 Exercise Testing

Issahar Ben-Dov

I. Ben-Dov: The Pulmonary Institute, Chaim Sheba Medical Center, Sackler Medical School, Tel-Aviv University, Israel.

THE INTEGRATIVE CARDIORESPIRATORY EXERCISE TEST

The essence of clinical integrative cardiorespiratory exercise testing is the ability to assess oxygen uptake ($\dot{V}O_2$) from measurements of ventilation and respired gas concentrations. When considered together, these parameters (ventilation, gas exchange, $\dot{V}O_2$, and others) allow for extended conclusions to be made regarding diverse cardiovascular, respiratory, and metabolic adaptations to the stress of exercise. Normal peak O_2 uptake indicates adequate (although not necessarily optimal) gas transport from the atmosphere to the mitochondria of muscle and effective utilization of molecular O_2 by the cellular enzymatic machinery. Fick's relationship portrays the factors governing O_2 consumption:

$$\dot{V}O_2 = \dot{Q} \times C(a\text{-}\bar{v})O_2 \quad (1)$$

where $\dot{Q}$ is cardiac output, C is content, a denotes arterial blood, and $\bar{v}$ denotes mixed venous blood. The determinants of O_2 uptake, as delineated by Fick's relationship, are presented in Table 1. O_2 utilization depends on a synchronized response of many supporting systems to the metabolic load. However, normal values for peak $\dot{V}O_2$ do not ensure that each element of the O_2 transport chain is normal, as not all are rate-limiting. Exercise capacity can be normal for age despite certain loss of heart, lung, or hemoglobin structure and/or function. On the other hand, when peak $\dot{V}O_2$ is reduced (if this is not caused by poor effort), one (or more) of the components of the O_2 transport/utilization chain is evidently abnormal.

Variable	Determinants
Cardiac output	Heart function, normality of peripheral and pulmonary vascular beds, volume status, blood viscosity, and drugs
Arterial O_2 content	Hemoglobin concentration, P_{50}, poisonous gases (CO), lung function, pulmonary vascular bed, central ventilatory control, and inspired O_2 pressure
Mixed venous O_2 content	Cardiac output, status of peripheral vascular bed and oxidative cellular machinery, including poisonous gases (CO)

P_{50}, oxygen half-saturation pressure of hemoglobin; CO, carbon monoxide.

TABLE 1. *Determinants of O_2 uptake, as described by Fick's relationship*

When exercise capacity is restricted, it is a challenge for the clinical physiologist to identify the organ(s) or system(s) whose malfunction is causing the limitation. This goal is approached by a thorough analysis of the response to exercise, including symptoms, electrocardiographic pattern, blood pressure, ventilation, gas exchange, O_2 uptake, partial pressure of arterial blood gases, and blood pH and lactic acid concentrations. These are assessed at submaximal and/or at the highest tolerable work rate. More than one protocol may be used for exercise testing. In this review, we concentrate (unless otherwise stated) on data collected during incremental maximal studies (on a cycle ergometer or a treadmill). Various aspects of exercise physiology are addressed only briefly, and the reader is referred to recent editions of comprehensive textbooks and review articles for the details of physiology, muscle fiber type, bioenergetics, cardiovascular and ventilatory control issues, and clinical applications. As is discussed later, it is usually possible to differentiate between ventilatory and cardiovascular mechanisms leading to exercise limitation. However, discrimination among potentially limiting constituents within the O_2 transport chain (mainly cardiovascular factors) and between cardiovascular limitation and poor fitness is more subtle (poor fitness may be considered a reversible form of cardiovascular dysfunction).

WHY PERFORM AN INTEGRATIVE EXERCISE STUDY?

Metabolic exercise challenge is not performed to arrive at a specific pathophysiologic diagnosis, even though, on occasion, such diagnosis is feasible (i.e., myocardial ischemia or asthma induced by exercise). Exercise is performed to evaluate how an individual (with normal or diseased organs) adapts to physical stress, and/or to answer specific, quantitative physiologic questions. Examples of such questions are shown in Table 2. They are often difficult or impossible to settle based on resting pulmonary functions or resting hemodynamic data. Marked discrepancy often exists between resting measurements and the actual peak exercise O_2 uptake. For example, in patients with severe heart or lung disease, such as a left ventricular ejection fraction of <20%, or a forced expiratory volume in 1 sec (FEV_1) of <1 L, exercise capacity varies; it may be nearly normal or severely reduced.

1. Is exercise capacity reduced, and if yes, to what extent?
2. Which supporting system is limiting exercise or causing exertional dyspnea?
3. Are gas exchange and arterial blood gases normal during exercise, and if not, what is the extent of the abnormality?
4. What is the metabolic cost ($\dot{V}O_2$) of performing a given work rate task?
5. What is the ventilatory requirement for performing a given work rate task?
6. Is there a clue that suggests the presence of metabolic abnormality or myopathy?
7. Does the exercise intolerance represent a behavioral abnormality or an apparent intolerance is being fabricated for a secondary gain?
8. What is the metabolic level ($\dot{V}O_2$) that a subject can sustain?

TABLE 2. *Examples of questions that can be answered by an integrative cardiorespiratory exercise test*

The pattern of response to the exercise challenge should direct any subsequent diagnostic workup (if needed). At that stage, workup should be targeted to arrive at a specific diagnosis (e.g., pulmonary angiography for an apparent pulmonary embolic disease, or specific muscle enzyme assay for an apparent metabolic myopathy). The algorithms used for interpretation of the exercise data are based on recognition of distinctive patterns. These algorithms are founded on known physiologic principles, but their predictive power in some specific disease categories needs further clarification.

NORMAL AND ABNORMAL CARDIOVASCULAR, VENTILATORY, AND GAS EXCHANGE RESPONSES TO AN INCREMENTAL WORK RATE EXERCISE TEST

Cardiovascular Response

Stroke Volume and Heart Rate

Cardiac output ($\dot{Q}$) increases during exercise as a linear function of the metabolic rate at all levels of fitness. However, heart rate (HR) and stroke volume (SV) react differently. The SV rapidly reaches its highest level at a work rate that is about one third of the maximal. This SV is maintained throughout the range of work rates. In contrast, HR increases linearly with $\dot{V}O_2$ throughout exercise. From rest to peak exercise, SV may double in fit subjects, and HR rises even more.

In heart disease or in unfit subjects (3 weeks of bed rest is sufficient to induce a state of unfitness), SV augmentation during exercise is limited, and SV often actually falls below resting level. In these patients, augmentation of cardiac output is mostly or solely dependent on HR, which is high at rest and rises steeply during exercise. If the chronotropic effect is also depressed, the rise in cardiac output is further limited.

In trained subjects, at rest and at any given work rate, SV is higher, HR is slower, and the slope of the HR response is more shallow. In addition, with training, as $\dot{V}O_2$ rises, the O_2 content of the venous blood ($\bar{v}O_2$) becomes progressively smaller, but maximal HR does not rise. In sedentary subjects, the lowest $\bar{v}O_2$ content, at peak exercise, is 3 to 4 mL/100 mL [$C(a\text{-}\bar{v})O_2$ = 16 to 17 mL/100 mL], whereas in athletes, values for $\bar{v}O_2$ can be lower. SV is augmented as a result of higher venous return during exercise (Starling's effect) and of the inotropic, sympathetic effect. The change in HR is brought about by loss of parasympathetic tone at the low range of work rates and by sympathetic stimulation at the higher range of work rates. If the normal response is inhibited by a negative chronotropic process, a pharmacologic agent (e.g., a beta blocker), or by actual denervation (e.g., heart transplantation), the cardiac output response is delayed or limited.

Augmentation of O_2 consumption during physical activity is supported by a rise of O_2 flux ($\dot{Q}$), but also by augmented extraction of the O_2 stored in the arterial blood, which increases the $C(a\text{-}\bar{v})O_2$. By using Fick's equation and assigning an estimate to these parameters during exercise, we can calculate peak $\dot{V}O_2$ in a subject. Assuming a peak $\dot{Q}$ of 20 L/min and arterial and mixed venous O_2 concentrations of 20 and 2 mL/100 mL, peak $\dot{V}O_2$ = 20 L/min × 0.18 = 3.6 L/min. This level is characteristic for a relatively fit subject.

Peripheral and Pulmonary Vascular Resistance and Blood Pressure

The elevated O_2 flux during exercise is directed preferentially to the muscles (up to 70%–80% at peak exercise) secondary to a marked fall in peripheral vascular resistance in the vascular bed of the active muscles. Local accumulation of active metabolites (including endothelium-derived relaxing factors, i.e., nitric oxide) contribute to selective vasodilation at the metabolically active tissues. Generalized sympathetic stimulation causes vasoconstriction in nonactive vascular beds. If vascular resistance is relatively fixed, as in peripheral vascular disease, the capacity of the muscle to sustain generation of force will be limited. In systemic hypertension, peripheral vascular resistance at rest is elevated and the fall during exercise is also limited. These factors contribute to exercise limitation in hypertensive patients. Pulmonary vascular resistance also falls considerably during exercise. This is brought about by marked recruitment of capillary bed not perfused at rest. However, even in normal subjects, the increment in blood flow exceeds the capacity of the peripheral resistance to fall, and as a result, systemic blood pressure normally rises during exercise. The systolic pressure rises linearly with exercise intensity, but the peak value and the slope increase with age. A level of 200 mmHg is considered normal for systolic pressure at peak exercise. Diastolic pressure rises to a lesser extent, with a maximum of about 90 mmHg. Despite equal augmentation of flow in the two circuits, the mean pulmonary arterial pressure rises during exercise to an absolute value of 15 mmHg, whereas the mean systemic arterial pressure rises 50 mmHg above the resting level. The rise of the pulmonary pressure during exercise becomes marked if pathologic processes affect the pulmonary vascular bed.

Ventilatory Response

Whereas cardiac output for a given $\dot{V}O_2$ is mostly predictable, ventilation can vary markedly, even at similar metabolic rates. Unfortunately, disease processes affecting the lungs or heart are commonly associated with a higher ventilatory demand, thus placing affected patients at further disadvantage.

Factors Affecting Exercise Ventilation

Ventilation is determined by factors described by the following equation:

$$\dot{V}_E = K \times \dot{V}CO_2/PaCO_2 + \dot{V}_D \quad \textbf{(2)}$$

where $\dot{V}_E$ is ventilation, K is a constant, $\dot{V}CO_2$ is CO_2 production, and $\dot{V}_D$ is dead space volume flow (V_D × respiratory rate). The linkage of $\dot{V}CO_2$ and $\dot{V}_D$ to ventilatory demand is clear. These factors represent the metabolic rate and the fraction of wasted ventilation. Ventilation is tightly linked to $\dot{V}CO_2$ rather than to $\dot{V}O_2$. This linkage facilitates the regulation of arterial pH (which changes with fluctuating $PaCO_2$) rather than the regulation of alveolar PO_2 (PAO_2). As the slope of the hemoglobin dissociation curve at nearly normal PaO_2 is shallow, the effect of larger PAO_2 fluctuations on arterial hemoglobin saturation is modest.

The contribution of the third factor, $PaCO_2$, to the ventilatory demand is less clear. For a given metabolic rate, ventilation is higher if resting $PaCO_2$ is lower. This results from the fact that when the concentration of CO_2 in the arterial blood, $PaCO_2$, and hence in the alveolar air, is lower, any ventilated volume eliminates less CO_2 than when CO_2 concentration in the alveolar air is higher. This set-point effect is advantageous to patients with chronic obstructive pulmonary disease (COPD) which is associated with abnormally elevated $PaCO_2$, because the high $PaCO_2$ leads to a reduced ventilatory demand at any given $\dot{V}CO_2$. However, this same set-point effect imposes a larger ventilatory response in healthy or COPD subjects when $PaCO_2$ is low or needs to be lowered, as in chronic metabolic acidosis. As shown by the above relationship (Eq. 2), $\dot{V}_E$ is directly proportional to $\dot{V}CO_2$. Therefore, the higher the $\dot{V}CO_2$, the larger the $\dot{V}_E$ increment for any given decrement of $PaCO_2$. As a result, trained subjects, operating at high metabolic levels, require a progressively larger ventilatory response to compensate for the lactic acidosis produced during

exercise.

The integrated effect of these three factors governing exercise ventilation is illustrated in the four-quadrant graph of Fig. 1. It is shown that ventilation in response to exercise at $\dot{V}O_2$ of 1 L/min can vary markedly. This variation is related to the respiratory exchange ratio (R), the CO_2 set point, and the ratio of dead space to tidal volume (V_D/V_T). It can be as low as 20 L/min or as high as 60 L/min. This relationship illustrates why the ventilatory response during exercise may be markedly increased, even in the absence of intrinsic lung disease. With the exception of V_D/V_T, the factors governing ventilation, $\dot{V}CO_2$ and $PaCO_2$, can be abnormal as a result of metabolic causes, such as metabolic acidosis. Even V_D/V_T can vary without any apparent lung disease, as a consequence of the breathing pattern.

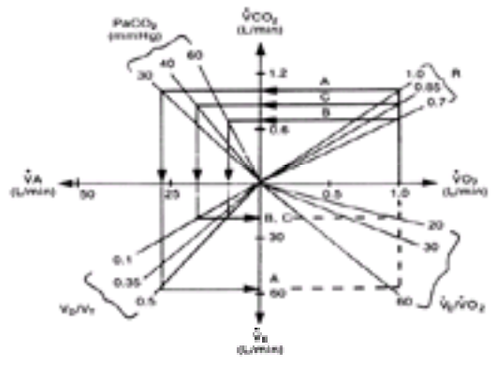

FIG. 1. Schematic representation of the effect of the respiratory exchange ratio (R), the $PaCO_2$ set point, and the dead space fraction of the breath (V_D/V_T) on the ventilatory response to exercise ($\dot{V}_E$) at a metabolic rate of O_2 uptake ($\dot{V}O_2$) of 1.0 L/min. If values for all three determinants are normal [*line B;* the ventilatory equivalent for O_2 ($\dot{V}_E/\dot{V}O_2$)) will be 20], the $\dot{V}_E$ will be 20 L/min. However, if R is elevated, the $PaCO_2$ set point is low (such as if the load is above the subject's anaerobic threshold), and the V_D/V_T is high (*line A*), the ventilatory response will be 60 L/min. [Modified with permission from Whipp BJ. The bioenergetics and gas exchange basis of exercise testing. In: Weisman IM, Zeballos RJ, eds. *Clinical Exercise Testing.* Philadelphia: WB Saunders; 1994 (*Clin Chest Med;* vol 15).]

In addition to these three factors, ventilation is affected by various other stimuli, such as PaO_2, pH, and temperature, and it can be modified voluntarily.

Periodic Breathing in Heart Failure

In patients with advanced failure of the left side of the heart (and rarely in otherwise healthy subjects), breathing is oscillatory, with alternating phases of hyperventilation and hypoventilation; each cycle (peak to peak) lasts up to 1 min. This pattern is more distinct during exercise of low to moderate intensity and is attenuated at high intensity. The oscillations are associated with simultaneous oscillations of O_2 uptake. However, as shown in Fig. 2, the $\dot{V}O_2$ oscillations exceed (in amplitude) and precede (in phase) the ventilatory oscillations. True $\dot{V}O_2$ oscillations must result from oscillatory blood flow, not from oscillatory breathing. Therefore, the coexistence of $\dot{V}O_2$ and $\dot{V}_E$ fluctuations suggests that circulatory oscillations (represented by $\dot{V}O_2$ oscillations) play an important or even a primary role in the induction of ventilatory oscillations.

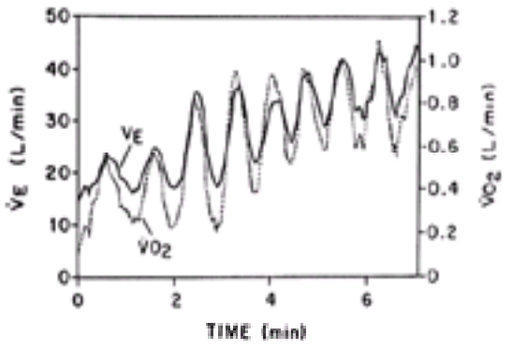

FIG. 2. Ventilation ($\dot{V}_E$) and O_2 uptake ($\dot{V}O_2$) in a subject with heart failure during 2 minutes of rest (time 0 to 2 minutes) and during incremental exercise. Oscillations are present at rest and are augmented as exercise starts. $\dot{V}O_2$ oscillations exceed (in amplitude) and precede (in phase) the $\dot{V}_E$ oscillation. Because hemoglobin is fully saturated, the $\dot{V}_E$ oscillations cannot induce these $\dot{V}O_2$ oscillations. Therefore, pulmonary blood flow must be oscillatory. (Modified with permission from Ben-Dov I, Sietsema KE, Casaburi R, Wasserman K. Evidence that circulatory oscillations accompany ventilatory oscillations during exercise in patients with heart failure. *Am Rev Respir Dis* 1992;145:776–781.)

Pattern of Breathing During Exercise

The ventilatory response is brought about by increasing both the tidal volume (V_T) and the respiratory rate. Normally, at low work rates, the change in V_T predominates. V_T reaches its maximal exercise value, which is about 60% of the vital capacity (VC), and this ratio is unchanged across age groups. V_T at peak exercise is, however, 70% of the inspiratory capacity (IC). Respiratory rate, which rises minimally at low work rates, is the predominant variable at the higher range of work rates above the anaerobic threshold (AT)] and does not reach a plateau during exercise. In disease states, such as COPD, interstitial lung disease, and congestive heart failure, the pattern is similar. However, the contribution of V_T to ventilation is smaller and that of the respiratory rate is larger. In these disease states, the 60% ratio of V_T to VC is maintained, but the ratio of V_T to IC, especially in interstitial lung disease, approaches 100%. The normal and abnormal relationships between V_T, VC, IC, and maximal voluntary ventilation (MVV) in healthy subjects and patients with obstructive and restrictive lung disease are schematically illustrated in Fig. 3.

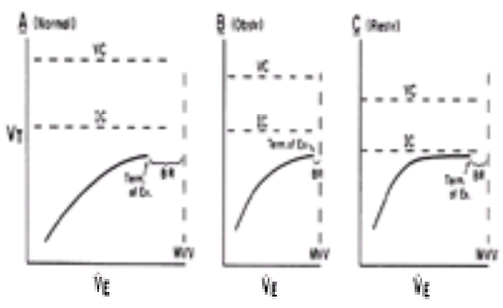

FIG. 3. Tidal volume (V_T) related to the vital capacity (VC), inspiratory capacity (IC), and maximal voluntary ventilation (MVV; *vertical dashed line*), as a function of minute ventilation ($\dot{V}E$), during an incremental exercise. The normal response (**A**), the pattern in obstructive lung disease (**B;** *Obstr*), and the response in restrictive disease (**C;** *Restr*) are shown. V_T as a fraction of the VC is not different. However, in restrictive diseases it approaches the IC at an early stage of exercise. Breathing reserve (BR; MVV minus end-exercise $\dot{V}_E$) is low in B and C. (Modified with permission from Wasserman K, Hansen JE, Sue DY, Whipp BJ, Casaburi R, eds. *Principles of Exercise Testing and Interpretation.* 2nd ed. Philadelphia: Lea & Febiger; 1994.)

When breathing is periodic, as in congestive heart failure, the fluctuations are brought about predominantly by oscillations of the VT. Fluctuations in respiratory rate are smaller in magnitude and are opposite in phase to the fluctuations of VT. Therefore, the respiratory rate fluctuations, if anything, attenuate the amplitude of the $\dot{V}_E$ oscillations.

Gas Exchange During Exercise

Oxygen Cost for Performing Work: Work Efficiency

The O_2 cost for a given increment in work rate is constant. Small, true variations depend on the specific substrate being utilized, and false variations result from differences in motor skills when various tasks are performed. This O_2 cost, which is 10.2 ± 1 mL/min per watt (W) for upright cycling, holds true irrespective of a subject's age, sex, or training status. At high-intensity exercise (above the AT), the contribution of anaerobic metabolism increases. Theoretically therefore, $D\dot{V}O_2$/Dwork rate is expected to be lower. However, it has been found that if the work rate increments are between 10 and 25 W/min, the normal ratio is sustained. Analysis of the position and shape of the $\dot{V}O_2$-work rate relationship is of clinical importance. Upward displacement of the curve is characteristic of situations of high metabolic cost, such as obesity or thyrotoxicosis. The slope of the relationship is apparently normal in these situations, although small differences in the slope (within the normal range) have been suggested, at least in hyperthyroidism (Fig. 4). Flattening of the slope is characteristic of low O_2 availability or utilization. The normal value of 10.2 mL/min/watt translates to muscular work efficiency (for that task) of approximately 30%--that is, the caloric equivalent of the work generated is 30% of the caloric equivalent of the energy consumed, as shown in Eq. 3:

$$\text{Efficiency} = \text{Work Done} \times 100/\text{Energy Cost} \qquad \textbf{(3)}$$

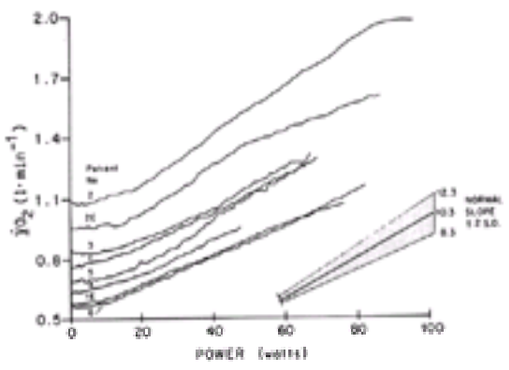

FIG. 4. Relationship of work rate and O_2 uptake in six patients (*1–6*) with hyperthyroidism during an incremental exercise test. Patients 1 and 2 repeated the test at the euthyroid state (*1E* and *2E*). Despite high O_2 uptake during pedaling at 0 W (consistent with hyperthyroidism), the relationship fell within the normal range. The normal range of the slope, 10.2 ± 1 mL/W, is shown by the *dashed area.* In the euthyroid state (*1E* and *2E*), the curves, as expected, are displaced downward. However, the slope is also more shallow relative to the hyperthyroid state (*1* and *2*). This suggests a mild change of work efficiency in hyperthyroidism. (Modified with permission from Ben-Dov I, Sietsema KE, Wasserman K. Oxygen uptake in hyperthyroidism during constant work rate and incremental exercise. *Eur J Appl Physiol* 1991;62:261–267.)

The work done per unit of time is the work rate in watts. Energy cost for that change in watts is actually measured or calculated by multiplying change in watts (above 0 W) by 10 mL of O_2 per minute per watt. To convert the denominator to calories, the caloric value of 1 mL of O_2/min is 5 cal/min. In the numerator, each 4.186 W = 1 cal/sec [1 cal = 4.186 J (joules)], and 1 W is defined as 1 J/sec, so that 1 W = 14 cal/min. For example, if $D\dot{V}O_2$ from 0 to 100 W = 1000 mL of O_2/min, the efficiency can be calculated as follows:

$$\text{Efficiency} = 100 \times \frac{100\ \text{W} \times 14\ \text{cal/min}}{1000\ \text{mL} \times 5\ \text{cal/min}} =$$

$$100 \times \frac{1400}{5000} = 28\%$$

Anaerobic (Lactate) Threshold

At a certain work intensity, usually about 50% of the individual $\dot{V}O_{2max}$, lactic acid starts to accumulate in the muscles and in the blood at a faster rate, and this metabolic level can be detected from measurements of gas exchange. The first gas exchange criterion used for the detection of accumulation of lactic acid is the respiratory exchange ratio (R). This accumulation of lactic acid represents a larger contribution of anaerobic metabolism to the energy utilized, as shown in Fig. 5. The metabolic rate ($\dot{V}O_2$) at which this shift occurs is defined as the anaerobic threshold (AT). The lactic acidosis of exercise is crucial for performing at high work intensities. Acid pH facilitates O_2 dissociation from hemoglobin at low capillary PO_2. This is achieved by inducing a shift to the right of the hemoglobin dissociation curve, thereby allowing higher capillary PO_2 (high driving pressure for diffusion) despite lower O_2 content. The shift towards a larger contribution by anaerobic metabolism could result from a limited O_2 supply to the muscle mitochondria at the AT. However, some authors dispute this. In any case, the accumulation of lactic acid is clearly linked to O_2 supply. Situations in which O_2 supply to the muscles rises (such as breathing a high concentration of O_2 and perhaps training) increase the AT, whereas situations in which O_2 supply falls (anemia, heart failure, low inspired O_2, carboxyhemoglobinemia) reduce the AT.

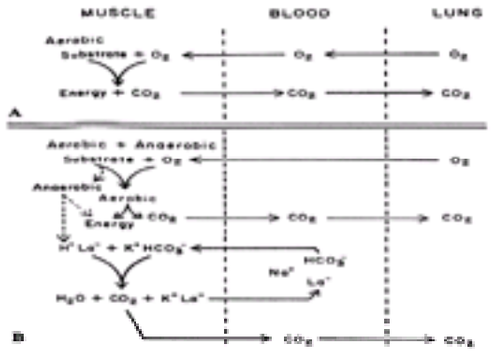

FIG. 5. Aerobic (**A**) and aerobic plus anaerobic (**B**) pathways for energy generation from substrates and molecular O_2. The aerobic pathway produces CO_2 and ATP. The anaerobic pathway produces lactic acid and ATP. The acid is buffered by intracellular bicarbonate ions, a reaction that produces additional CO_2, which is eliminated by ventilation. As lactate accumulates in the cell, part diffuses to the extracellular space and to the blood in exchange for a bicarbonate ion. If the substrate is glucose, 36 ATP molecules are produced by aerobic metabolism, whereas only two ATP molecules are produced by the anaerobic pathway. (Modified with permission from Wasserman K, Hansen JE, Sue DY, Whipp BJ, Casaburi R, eds. *Principles of Exercise Testing and Interpretation.* 2nd ed. Philadelphia: Lea & Febiger; 1994.)

Besides O_2 shortage, other mechanisms have been proposed as explanations for the accumulation of lactic acid. Two alternative mechanisms may account for the lactic acidosis of exercise. The first is the possible role of shifting at the AT to the activation of more glycolytic, type II muscle fibers with lower oxidative capacity. The other is the possible role of rate-limiting mitochondrial oxidative enzymes. There is no evidence, however, that either of these mechanisms is operative. Irrespective of its mechanism, the AT is physiologically important as a metabolic level. It represents the highest work intensity that an individual can endure; higher levels provoke lactic acidosis and rapid fatigue. It also represents the metabolic level above which, even with a constant work rate effort, a steady state for $\dot{V}O_2$ (and for other gas exchange variables) is delayed or not attained.

The AT can reproducibly be determined noninvasively from gas exchange parameters. The criteria used for determination of the AT from an incremental test are summarized in Table 3 and demonstrated in Fig. 6. It has been found that in healthy subjects and in disease states the noninvasive AT corresponds or is close to the AT determined invasively by measuring lactate concentration, lactate-to-pyruvate ratio, blood pH, or blood bicarbonate concentration. If a low normal value for the AT is chosen (e.g., <40% of predicted peak $\dot{V}O_2$), the AT becomes a sensitive index to distinguish normality from various kinds of cardiovascular dysfunction. However, low AT is also found when O_2 flow is reduced, in severe ventilatory diseases, and in deconditioning.

Definition of criterion	Explanations and critique
Slope is steeper for $\dot{V}_E$ and for $\dot{V}CO_2$ response curves.	Reflects excess $\dot{V}CO_2$ and $\dot{V}_E$. The initial small change of the slopes is often obscured. $\dot{V}_E$ is often irregular.
$P_{ET}O_2$ rises while $P_{ET}CO_2$ remains unchanged.	Reflects excess breathing relative to $\dot{V}O_2$. This point is often obscured because of small absolute change of $P_{ET}O_2$ and relatively shallow slope of $P_{ET}CO_2$.
$\dot{V}_E/\dot{V}O_2$ rises while $\dot{V}_E/\dot{V}CO_2$ remains stable.	Ratios between these changes. Using the ratios highlights the turning point.
R ($\dot{V}CO_2/\dot{V}O_2$) rises, usually to > 1. CO_2 approaches the value of $\dot{V}O_2$.	Reflects the excess $\dot{V}CO_2$, but practically often obscured by fluctuations resulting from an irregular $\dot{V}_E$.
V-slope, $\dot{V}CO_2$ starts to accelerate faster relative to $\dot{V}O_2$.	Reflects the excess $\dot{V}CO_2$ above $\dot{V}O_2$. Eliminates the dependency on normal ventilatory response to the acid load (normal ventilatory control and mechanics are not required).

$\dot{V}_E$, minute ventilation; $\dot{V}O_2$, O_2 uptake; $\dot{V}CO_2$, CO_2 production; $P_{ET}O_2$ and $P_{ET}CO_2$, end-tidal pressure of O_2 and CO_2, respectively.

TABLE 3. *Gas exchange criteria for determination of the anaerobic threshold from incremental exercise testing*

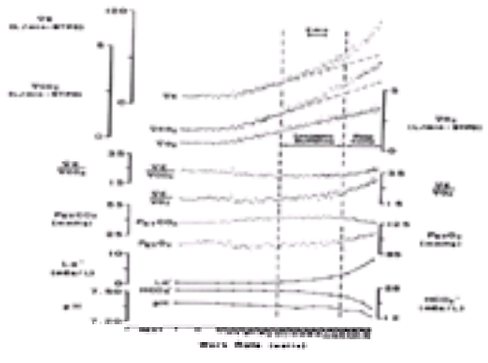

FIG. 6. Parameters used to determine the anaerobic threshold. Gas exchange parameters, lactic acid and bicarbonate concentrations, and blood pH are recorded at rest, during unloaded pedaling, and during an incremental period. The *left vertical dashed line* represents the anaerobic threshold. At this metabolic level, the slopes of the following curves accelerate: lactic acid, $P_{ET}O_2$, ventilatory equivalent for O_2 ($\dot{V}_E/\dot{V}O_2$), O_2 uptake ($\dot{V}O_2$), ventilation ($\dot{V}_E$), and the respiratory exchange ratio (R; not shown). The slopes of the following curves show a fall: pH and bicarbonate. The slopes of the $P_{ET}CO_2$ and the $\dot{V}_E/\dot{V}CO_2$ remain stable at the threshold and change only at a later stage, when respiratory compensation starts. (Modified with permission from Wasserman K, Hansen JE, Sue DY, Whipp BJ, Casaburi R, eds. Principles of Exercise Testing and Interpretation. 2nd ed. Philadelphia: Lea & Febiger; 1994.)

The AT can be determined noninvasively in most normal subjects and in many patients with cardiovascular disease. However, in some normal subjects the data are not discriminative. In moderate to severe COPD, the AT is attained (and can be detected) in approximately two thirds of patients. In general, because of higher noise-to-signal ratio, the lower the peak $\dot{V}O_2$, the less likely it is that a distinct value for the AT can be determined from gas exchange parameters. When the respiratory response is erratic or irregular, as in periodic breathing, it is difficult to discern the AT. However, even in these latter situations, the V-slope method, in which $\dot{V}O_2$ is plotted against $\dot{V}CO_2$, using an appropriate scale (Fig. 7), is often helpful. By this method, determination of the AT is not dependent on ventilation (control or mechanics). In situations in which the AT cannot be detected from gas exchange data, it can be discerned by invasive measurements after plotting $\dot{V}O_2$ against lactate, bicarbonate, or the lactate-to-pyruvate ratio. In rare situations, when an even more sensitive method is needed, O_2 should be plotted against lactate levels using a log scale for both axes. This method enables discrimination between the early and late slopes of lactic acid accumulation, below and above the AT.

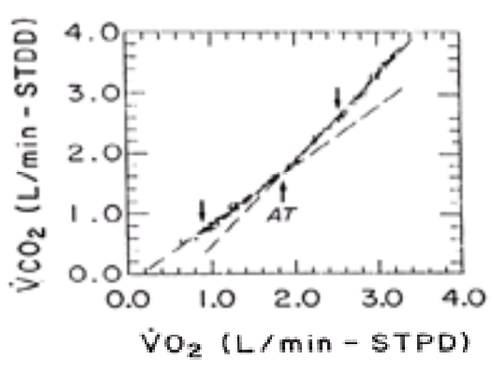

FIG. 7. V-slope method for determination of the anaerobic threshold (AT) from incremental exercise data of a healthy subject. $\dot{V}O_2$ is plotted against $\dot{V}CO_2$. The initial slope of the relationship is linear; at $\dot{V}O_2$ of 1.9 L/min, the slope becomes steeper. The point of deviation of the slope indicates the AT. The *dashed lines* represent the initial and late slopes of the relationship. Determination of AT by this method eliminates dependency on the normality of the ventilatory response. (Modified with permission from Beaver WL, Wasserman K, Whipp BJ. A new method for detecting anaerobic threshold by gas exchange. *J Appl Physiol* 1986;60:2020–2027.)

The kinetics of lactic acid accumulation and wash out at the transition from rest to exercise and during recovery is shown for a representative subject in Fig. 8. If a single blood sample is drawn for peak exercise lactic acid, bicarbonate, or pH change, the levels at 2 to 3 min after exercise are representative of the peak exercise values.

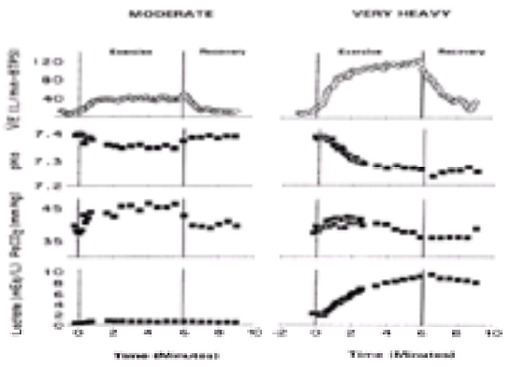

FIG. 8. Ventilation ($\dot{V}_E$), arterial Ph (pHa), arterial PCO2 ($PaCO_2$), and blood lactate in a subject exercising at a constant work rate of moderate intensity (below the anaerobic threshold) and at a constant work rate of very high intensity (close to the highest tolerable level). During the test at moderate intensity, a steady state for $\dot{V}O_2$ during exercise was attained, and lactic acid remained at the resting level. During the test at high intensity, no steady state was attained for the $\dot{V}O_2$ and lactic acid. At the recovery phase, despite a rapid fall of $\dot{V}O_2$, the concentration of lactic acid and the pHa remained at peak exercise levels for at least 2 to 3 minutes. (Modified with permission from Stringer W, Casaburi R, Wasserman K. Acid-base regulation during exercise and recovery in humans. *J Appl Physiol* 1992;72:954–961.)

The AT can be estimated if needed from a constant work rate test, but this demands repetition of the test at several work rates. At a below-AT intensity, a steady-state $\dot{V}O_2$ is maintained. At an intensity above the threshold, a steady state is delayed or not attained. Therefore, if $\dot{V}O_2$ at minute 3 of a constant work rate exercise is subtracted from $\dot{V}O_2$ at minute 6 ($D\dot{V}O_2$), the proximity to the AT can be estimated (Fig. 9). The larger the difference, the farther the metabolic level is above the AT. If the difference is 0, the metabolic level is below (or at) the individual AT. This method of calculating the AT from a constant work rate test is useful in patients with severe exercise limitation or for whom maximal exercise is considered too risky.

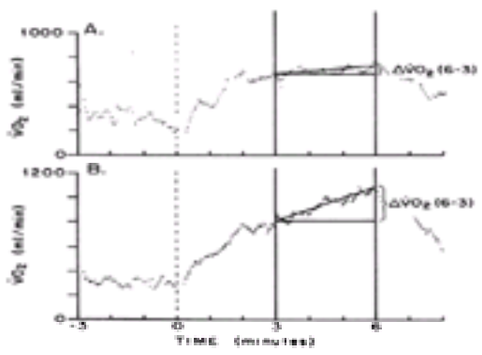

FIG. 9. $\dot{V}O_2$ response to a constant work rate exercise at 25 W (**A**) and 75 W (**B**) of a patient with heart failure. Exercise starts at time 0. The $D\dot{V}O_2$ is calculated from a linear regression of $\dot{V}O_2$ between minutes 3 and 6 of the exercise. In B, the difference is 300 mL. The departure from a steady state for O_2 uptake indicates that this metabolic rate is well above the patient's anaerobic threshold. In A, the difference is 50 mL, indicating that the metabolic rate is just above (or at) the patient's anaerobic threshold. This patient will probably be able to sustain a 25-W task (walking) for long period but will become exhausted after few minutes at a 75-W task. (Modified with permission from Zhang YY, et al. O_2 uptake kinetics in response to exercise: a measure of tissue anaerobiosis in heart failure. *Chest* 1993;103:735–741.)

PARAMETERS USED FOR INTERPRETATION OF EXERCISE DATA

Maximal or Peak O_2 Uptake

Maximal $\dot{V}O_2$ ($\dot{V}O_{2max}$) should be related to the mode of exercise—namely, to the mass of the exercising muscles. $\dot{V}O_{2max}$ is different for running on a treadmill or cycling with the legs than for cycling with the upper extremities. Predicted maximum should be based on ideal body weight for a given height. Otherwise, overweight patients will be expected to achieve unusually high values. In underweight individuals, the height may overestimate muscle mass, and therefore the predicted $\dot{V}O_{2max}$. The maximal $\dot{V}O_2$ is ideally defined as the $\dot{V}O_2$ plateau level (stable $\dot{V}O_2$ despite rising work rate). Our experience has been that true plateau is more often not attained, especially in patients with heart disease. A false plateau is noted when a subject slows the pedaling rate at peak exercise, so that the desired work rate is not maintained. In this situation, the $\dot{V}CO_2$ curve is also relatively flat. If a plateau is not demonstrable, peak $\dot{V}O_2$ rather than $\dot{V}O_{2max}$ should be reported. Peak $\dot{V}O_2$ is meaningful if the patient effort is judged to be adequate and if gas exchange measurements indicate proximity to peak tolerable level (i.e., R >1.2), provided no noncardiovascular mechanism (ventilatory or skeletal) leads to termination of exercise.

Peak Heart Rate and Heart Rate Reserve

HR rises linearly with $\dot{V}O_2$. In heart disease, the rise of cardiac output is more dependent on HR. Therefore, the relation of HR to work rate shows upward displacement and/or a steeper slope. However, these characteristics of the curve cannot distinguish between heart disease and situations of low O_2 availability and/or deconditioning.

There are limitations to reliance on the HR response. The maximal HR, even in healthy subjects, can deviate markedly from the predicted mean maximum. Furthermore, in patients with heart failure, the predicted maximal HR is typically not attained, and the deviation from the predicted peak value is larger for the more disabled, as shown in Fig. 10. Likewise, HR response can be attenuated by chronotropic dysfunction (ischemia) or by commonly used medications.

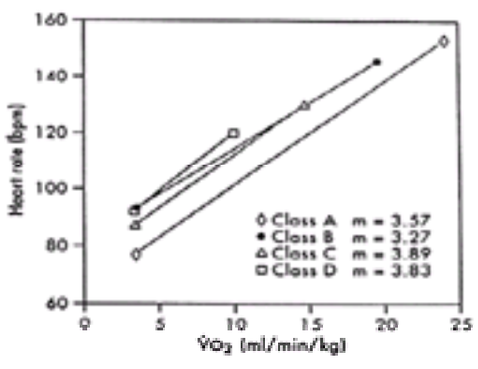

FIG. 10. The response of heart rate (mean) as a function of O_2 uptake ($\dot{V}O_2$) for patients with heart failure of the four functional classes. The higher the functional class, the higher the heart rate at peak exercise. The ability of the sicker patients to increase heart rate (and cardiac output) is more limited. (Modified with permission from Weber KT, et al. *Cardiopulmonary Exercise Testing: Physiological Principles and Clinical Applications.* Philadelphia: WB Saunders; 1986.)

Oxygen Pulse

O_2 pulse, the volume of O_2 extracted (or loaded) during one heart beat, is calculated from Fick's relationship ($\dot{V}O_2 = \dot{Q} \times C(a\text{-}\bar{v})O_2$; Eq. 1) by dividing both sides of the equation by HR:

$$\dot{V}O_2/HR = O_2\ Pulse = SV \times C(a\text{-}\bar{v})O_2 \quad \textbf{(4)}$$

where SV is stroke volume.

The O_2 pulse depends on the product of SV and the $C(a\text{-}\bar{v})O_2$. Therefore, quantitative assessment of each of these from the O_2 pulse is possible only when the other variable is of a relatively constant value. SV is relatively constant at high levels of exercise or during exercise in the supine position, whereas $\bar{v}O_2$ is temporarily relatively constant (if $\dot{V}O_2$ is measured breath by breath) early in the transition from rest to exercise, when the venous effluent from the exercising muscles has not reached the lung. During this phase, most of the change of pulmonary arterial hemoglobin O_2 saturation is caused by the rise in pulmonary blood flow. Close to peak exercise, when O_2 extraction is near the maximum, $\bar{v}O_2$ is also relatively constant.

O_2 pulse can be reduced in any situation in which $\dot{V}O_2$ is reduced—heart disease, peripheral vascular disease, anemia, and other situations leading to reduced O_2 content or reduced O_2 utilization (including deconditioning).

Ventilatory Equivalents for Oxygen and Carbon Dioxide and the Dead Space-Tidal Volume Ratio

The ventilatory equivalents can be considered as markers of ventilatory efficiency, because they represent the ventilatory demand at a given metabolic rate. Relative to rest, the values of the ventilatory equivalents decline at low- to moderate-intensity exercise, probably because of more optimal matching of ventilation to perfusion. The lowest values are reached around the AT. Above this metabolic rate, the ventilatory equivalents for O_2 and CO_2 diverge. Initially, when excess CO_2 is produced from buffered, newly formed lactic acid, the ventilatory equivalent for O_2 rises. Later, after a short isocapnic period, the ventilatory equivalent for CO_2 also rises, as a result of compensatory hyperventilation (Fig. 6).

The values of the ventilatory equivalents depend on various factors linking ventilation to its metabolic regulators (Eq. 2). The equivalents can also change in response to hyperventilation, either voluntary or secondary to anxiety or discomfort. When the ventilatory equivalents at a given exercise intensity are abnormally elevated, the simultaneous presence of a high $PaCO_2$ indicates (and a high $P_{ET}CO_2$ may suggest) that the abnormality is the result of intrinsic lung disease (poor distribution of ventilation, high $\dot{V}/\dot{Q}$ areas, or an increased dead space). The pattern of change of the ventilatory equivalents during incremental exercise in healthy subjects and in patients with obstructive and restrictive lung disease is schematically shown in Fig. 11. The ventilatory equivalents therefore contribute to our understanding of the ventilatory requirement. However, these parameters do not accurately reflect the dead space volume of the lung, calculation of which should be based on measurement of arterial PCO_2. The V_D/V_T is calculated as shown in Eq. 5.

$$V_D/V_T = (PaCO_2 - P_{ET}CO_2)/PaCO_2 - V_{DV}/V_T \quad \textbf{(5)}$$

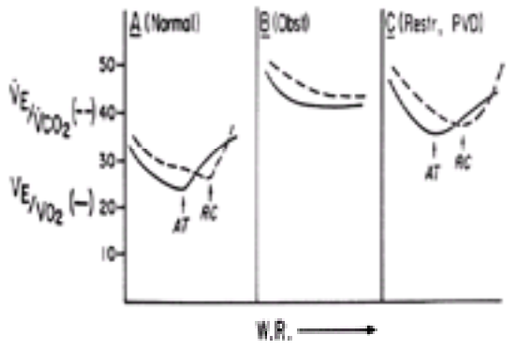

FIG. 11. A: Schematic illustration of the ventilatory equivalents for O_2 ($\dot{V}_E/\dot{V}O_2$) and CO_2 ($\dot{V}_E/\dot{V}CO_2$) as a function of work rate in a normal subject, in obstructive ventilatory (**B**) (*Obst*), restrictive ventilatory (**C**) (*Restr*), and pulmonary vascular disease (*PVD*) states. The anaerobic threshold (AT) at the lowest level of $\dot{V}_E/\dot{V}O_2$ and the respiratory compensation point (RC) at the lowest level of $\dot{V}_E/\dot{V}CO_2$ are marked. The values for the ventilatory equivalents normally fall during light to moderate exercise and rise again when lactic acidosis occurs. **B:** Because of mechanical restraint, the anaerobic threshold is often not attained and/or the respiratory compensation is limited, so that the late rise is not seen. **C:** Pattern is similar, but the absolute values are abnormally elevated. (Modified with permission from Wasserman K, Hansen JE, Sue DY, Whipp BJ, Casaburi R, eds. *Principles of Exercise Testing and Interpretation.* 2nd ed. Philadelphia: Lea & Febiger; 1994.)

where $P_{ET}CO_2$ is end-tidal partial pressure of CO_2 and V_{DV}/V_T is the dead space volume of the breathing valve apparatus. As noted, the breathing valve volume should be taken into account in this calculation.

The specificity of the ventilatory equivalents as markers of certain diagnoses is low, as high values are seen in lung disease, heart disease, pulmonary vascular disease, and metabolic acidosis. The calculated ratio of dead space to tidal volume (V_D/V_T) is more predictive of an intrinsic lung abnormality. However, the V_D/V_T is high when breathing frequency is high, and its sensitivity is limited even in relatively advanced pulmonary vascular disease, which contradicts previous belief that a lack of fall in V_D/V_T during exercise is sensitive and often the sole detectable abnormality in early pulmonary vascular disease, even at a stage in which it cannot be detected by other clinical modes.

PaO_2 and $P(A\text{-}a)O_2$ Difference

PaO_2 in healthy subjects is normal or increased during exercise, but the $P(A\text{-}a)O_2$ difference usually widens. This behavior is also characteristic of situations of low O_2 carrying capacity that are not caused by lung disease, such as anemia, neuromuscular weakness, and unfitness. In obesity, PaO_2 rises and $P(A\text{-}a)O_2$ narrows early during exercise; subsequently, behavior of the parameters is similar to the normal response. Exceptions to these rules occur in the early phase of exercise, when ventilation lags behind $\dot{V}O_2$ rise, and in trained athletes at peak exercise, when PaO_2 can fall. Interestingly, in uncomplicated heart failure, PaO_2 also remains relatively unchanged throughout exercise.

In patients with COPD, exercise PaO_2 may remain unchanged, slightly improve, or fall. In interstitial and pulmonary vascular disease, an exercise-induced fall (often profound) of PaO_2 is more characteristic, and this fall progresses as exercise intensity increases. Exercise desaturation is a consistent finding in the presence of right-to-left intracardiac shunt, and the degree of desaturation is probably proportional to the magnitude of the shunt. The degree of exercise desaturation cannot be accurately predicted from resting data, such as diffusion capacity for carbon monoxide (D_LCO), and needs to be measured directly.

$PaCO_2$ and $P(a\text{-}ET)CO_2$ Difference

In normal subjects exercising at low to moderate intensity, $PaCO_2$ remains at or near the resting level. At higher intensities, $PaCO_2$ progressively falls, as a result of ventilatory compensation for lactic acidosis.

In COPD, $PaCO_2$ may rise slightly during exercise, even in patients in whom the resting value is normal. In interstitial lung disease, $PaCO_2$ is usually normal or slightly reduced.

At rest, the end-tidal partial pressure of CO_2 ($P_{ET}CO_2$) is lower by 2 to 3 mm/Hg than $PaCO_2$, so that the $P(a\text{-}_{ET})CO_2$ is positive. However, during exercise this difference becomes negative. $PaCO_2$ is an average value, measured across several breathing cycles. In contrast, end-tidal partial pressure is obtained during a late stage of a single expiration. During this phase of the breathing cycle, the alveolar partial pressure of CO_2 (P_ACO_2) rises progressively as a result of the CO_2-rich venous blood reaching the lung. As $\dot{V}CO_2$ rises during exercise, P_ACO_2 during expiration rises at a faster rate, allowing the $P_{ET}CO_2$ to surpass the mean $PaCO_2$. In situations in which units of high ventilation-perfusion ratio ($\dot{V}/\dot{Q}$) predominate in the lung (as in pulmonary vascular disease), CO_2 is not being added to the end-tidal gas at a fast rate, and $P(a\text{-}_{ET})CO_2$ remains positive. In the presence of right-to-left shunt, as venous CO_2 is diverted to the arterial side, even less CO_2 is being added to the alveolar gas, and therefore this difference is consistently positive. The magnitude of the difference is proportional to the fraction of shunted blood.

SYSTEMS LIMITING EXERCISE CAPACITY

The concept of the presence of a supporting system that limits exercise needs clarification. Obviously, the output of every system is restricted, and when a system fails to increase its output to a level required to perform a given task, this system restricts the ability to accomplish that task. However, at peak output of a supporting system (i.e., heart or lung), if the neural stimulus to an exercising muscle to generate force persists, the muscle can respond in two ways. It can either maintain (at least temporarily) the peak or close-to-peak output, or it can cease to generate force (i.e., electromechanical dissociation). If in response to inability of the heart to increase the O_2 flux the muscle ceases to generate force, then the heart obviously limits exercise capacity. However, if despite inadequate O_2 flux the muscle maintains (temporarily) maximal or nearly maximal contractions, then the heart does not directly limit exercise capacity. In this latter situation, the restricted function of the heart induces a deviation from homeostasis (i.e., lactic acidosis), which is perceived as a sensation that cannot be endured.

When a certain intensity of this sensation is reached, it leads to voluntary cessation of muscle contraction. In most situations encountered during clinical exercise testing, there is probably no global failure of force generation, but rather a distasteful sensation, resulting from stimuli such as the ventilatory load or acidosis. According to this description, exercise starts and probably ceases voluntarily. Therefore, the question about a system limiting exercise should be modified. The challenge is to identify the system(s) whose capacity is inferior relative to the load, therefore creating discomfort. To avoid such discomfort, the individual prefers to terminate the effort.

A striking demonstration of the role of intensity of symptoms as a determinant of exercise tolerance is provided by a comparison of responses to work between healthy subjects and patients with moderate to severe COPD. In both groups, the median intensity of dyspnea and of perceived leg exertion at peak exercise were similar (approximately 70% of the maximal intensity on the scales used). This intensity of sensation obviously occurred at a lower work intensity in the patients with COPD.

A partial list of disorders that may limit exercise capacity, including pathophysiology and discriminative findings, is shown in Table 4.

TABLE 4. *Pathophysiology and discriminating measurements of some disorders limiting exercise performance(reduced maximum $\dot{V}O_2$)*

Ventilatory Limitation of Exercise

Ventilatory limitation of exercise is defined on the basis of a limited exercise breathing reserve. The maximal output of the respiratory system is the maximal voluntary ventilation (MVV). It is assumed that the maximal output can be accurately measured or estimated. The 10-sec resting MVV maneuver is the favored method. The estimated MVV is obtained by multiplying the measured forced expiratory volume in 1 second (FEV_1) by a factor of between 35 and 40 (estimated MVV = $FEV_1 \times 40$). It is also assumed that this maximal resting ventilation volume is valid for exercise (a disputable assumption). The actual peak exercise ventilation ($\dot{V}_{Emax}$) is then subtracted from the MVV. The closer the $\dot{V}_{Emax}$ is to the MVV, the closer the subject is to the ventilatory limit. A difference of <15 L/min between MVV and $\dot{V}_{Emax}$ (MVV – $\dot{V}_{Emax}$), or a $\dot{V}_{Emax}$-to-MVV ratio of >80% ($\dot{V}_{Emax}$/MVV) has been considered diagnostic for the presence of ventilatory limitation to exercise (Fig. 12).

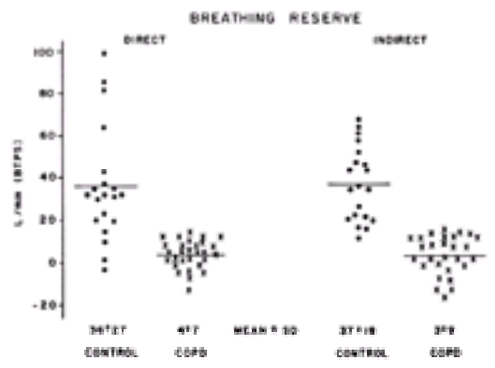

FIG. 12. Breathing reserve (MVV – $\dot{V}_{Emax}$) in patients with COPD and in control subjects. On the *left side,* the MVV was calculated from directly measured MVV. On the *right side,* the MVV was empirically estimated (MVV = $FEV_1 \times 40$). The estimated MVV is slightly higher. In the patients with COPD, the reserve is close to 0, indicating the proximity to the limit of ventilation. Interestingly, the calculated reserve in some patients has a negative value, indicating that breathing during exercise exceeds the resting MVV. (Modified with permission from Wasserman K, Hansen JE, Sue DY, Whipp BJ, Casaburi R, eds. *Principles of Exercise Testing and Interpretation*. 2nd ed. Philadelphia: Lea & Febiger; 1994.)

The same principle of breathing reserve can be applied to every tidal breath during exercise (Fig. 13). If the flow rates during exercise approach (or surpass) the boundary of the maximal resting flow volume loop, then a subject is at or close to the ventilatory limit. If the ratio between peak exercise V_T and IC approaches 1 during exercise, this also represents ventilatory limitation (Fig. 3).

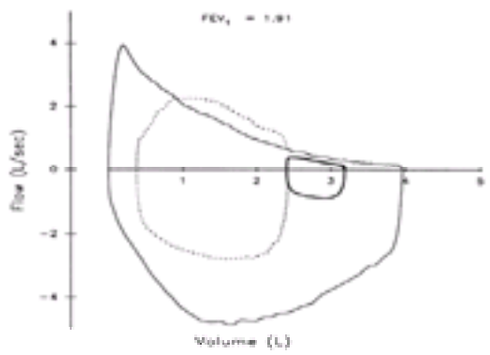

FIG. 13. Schematic representation of resting inspiratory and expiratory maximal flow volume loop (*outer solid line*), resting tidal breathing (*inner solid line*), and breathing at peak exercise (*dashed line*) in a patient with COPD. During exercise (but not at rest), the flow rates surpass the boundary of the resting maximal expiratory curve. In addition, the end-expiratory lung volume has increased about 0.75 L (left shift) during exercise relative to rest. This patient is probably close to or at his ventilatory limit during exercise. [Modified with permission from Gallagher CG. Exercise limitation and clinical exercise testing in chronic obstructive pulmonary disease. In: Weisman IM, Zeballos RJ, eds. *Clinical Exercise Testing.* Philadelphia: WB Saunders; 1994 (*Clin Chest Med;* vol 15).]

Maximal breathing capacity during exercise, however, is not necessarily the same as the resting MVV. There is evidence, at least in COPD, that breathing capacity during exercise often exceeds the resting MVV (Fig. 12), and the calculated reserve may become (absurdly) a negative value. It is likely that in other diseases, such as certain neuromyopathies, and in heart failure, maximal breathing capacity during exercise may be lower than the resting level. Furthermore, when the ventilatory load is profound, subjects often stop exercise because of dyspnea, even before a true physiologic limit has been attained. Factors such as acidosis or hypoxemia enhance the sensation of dyspnea and exaggerate the cessation of effort at a ventilatory level that is lower relative to the resting MVV.

Cardiovascular Limitation to Exercise

In contrast to ventilatory limitation, determination of cardiovascular limitation on the basis of the concept of “cardiac exercise reserve” is difficult to achieve. Measurement (or estimation) of the maximal attainable cardiac output and/or the actual cardiac output at peak exercise is a demanding task. Using the HR reserve (predicted peak exercise HR minus actual peak exercise HR) as a substitute for cardiac output reserve is not practical. Peak HR is highly variable, and many patients with heart disease do not attain the age-predicted maximal HR, as shown in Fig. 10. Therefore, the diagnosis of cardiovascular limitation (in contrast to diagnosis of ventilatory limitation) is indirect and based on the presence of a combination of gas exchange and other criteria that indicate an exhausted O_2 transport/utilization capacity. These criteria are summarized in Table 5. The criteria are not specific for a distinctive type of cardiovascular dysfunction, but they reveal an exhausted O_2 transport capacity. Therefore, situations such as anemia, certain hemoglobinopathies, carbon monoxide poisoning, or even severe arterial hypoxia, produce similar gas exchange abnormalities.

(a)
Chest pain, claudication leg pain or syncope
Ischemic electrocardiographic changes or exercise-induced arrhythmia
Blood pressure fall
High respiratory exchange ratio (R ≥ 1), in the presence of low $\dot{V}O_2$max, especially when $\dot{V}O_2$-WR relationship becomes shallow
Low and flat O_2-pulse-WR relationship
Low HR reserve
Lack of ventilatory limitation (normal or high breathing reserve)
(b)
Tachycardia, steep HR-$\dot{V}O_2$ relationship
Low and relatively shallow O_2-pulse-WR relationship, with rise after exercise
Low $\Delta\dot{V}O_2/\Delta$WR ratio
Early lactic acidosis, low anaerobic threshold
Periodic breathing
Low $\dot{V}O_2$max while breathing reserve is normal or high
Abnormally high blood pressure or limited rise of blood pressure during exercise
Limited HR response

TABLE 5. *Indications that a cardiovascular (or O_2 flow) limitation to exercise (a) is present, or that a cardiovascular abnormality (b) is present*

Different Categories of Cardiovascular Processes Affecting Exercise Capacity

Although many of the gas exchange criteria listed in Table 5 are present in cardiovascular disease of any type (central cardiac, peripheral vascular, or pulmonary vascular disease), certain alterations are more likely to occur with specific abnormalities. For example, exercise desaturation and elevated dead space volume are more likely in pulmonary than in peripheral vascular disease. Elevated ventilatory equivalents are present in failure of the left side of the heart and in pulmonary vascular disease, but are less likely to occur in isolated peripheral vascular disease or anemia. These associated findings are useful to distinguish the specific segment within the cardiovascular circuit that limits exercise.

Clinical Symptoms at Peak Exercise

It is tempting to believe that the subjective complaint at peak exercise is specific for the system leading to exercise limitation. Chest pain, leg pain, fatigue, and lightheadness are suggestive of cardiovascular limitation, whereas shortness of breath suggests ventilatory limitation. However, these symptoms lack specificity and are of low diagnostic value, as the perception of stressful stimuli at peak exercise varies among individuals.

INDICATIONS FOR AN INTEGRATIVE CARDIORESPIRATORY EXERCISE TEST

Exercise study is done primarily to quantitate functional capacity and magnitude of gas exchange abnormalities, and to identify the supporting system(s) limiting exercise. A detailed list of situations in which exercise testing has been recommended, or is potentially valuable, is shown in Table 6. This list includes firmly established indications and also situations in which an exercise test is potentially beneficial, even if its role in these situations has not been systematically evaluated. For exercise to be a useful clinical tool, it should provide sensitive and specific criteria for the diagnosis of diseases, and these should have a high predictive value. However, more remains to be learned concerning the relative merit of various exercise-derived parameters and their combinations. For example, the predictive value of parameters such as low AT or low breathing reserve during exercise (how low is low?) for specific diagnoses (i.e., cardiac or ventilatory limitations) is difficult to ascertain. Because of the lack of widely accepted and easily obtainable measurements (a “gold standard”) for classifying patients according to whether they are limited by cardiac or ventilatory factors, a stringent sensitivity analysis cannot be applied to these exercise-derived gas exchange criteria.

TABLE 6. *Indications for the integrative cardiorespiratory exercise test, and situations in which the testis potentially valuable*

DATA ANALYSIS

Most commercial exercise systems provide options for data averaging and plotting. For general clinical use, eight breaths, or 15- to 30-second averaging, are acceptable. Despite averaging, however, the data are often obscured by oscillatory noise. Unusually deep or shallow breaths, especially when functional residual capacity (FRC) is oscillating or the breathing pattern is periodic, will predictably obscure the real data. Values are chosen from these averaged time plots or from the tabular report after ensuring that no spurious estimates are selected.

Values for $\dot{V}O_2$, HR, O_2 pulse, respiratory exchange ratio, $\dot{V}_E$, work rate, and other parameters are measured at peak exercise. Various parameters, such as the ventilatory equivalents and AT, are determined at certain submaximal exercise levels. The lowest value should preferably be reported for the ventilatory equivalents. Some parameters, such as V_D/V_T and blood gases, are recorded repeatedly during exercise, and others, such as $D\dot{V}O_2$/Dwork rate, are calculated from continuous exercise data. The obtained values are compared with the normal reference values, which should be applicable to the specific population studied, and the percentage deviations from normal means are calculated.

Framework for Interpretation of Cardiorespiratory Exercise Test

Algorithms for interpretation have been published (see Wasserman et al.).

The interpreter should be present during the test. Attention should be paid to patient cooperation—motivation, coordination, and maintenance of the pedaling rate—especially close to peak exercise. Data regarding the course of the test, including symptoms at peak exercise and a note on special events, should be available. Not rarely, a subject stops exercise for a trivial cause (e.g., dry oral mucosa), a situation that does not allow conclusions to be reached regarding the true physiologic maximum. To determine if the measurements are acceptable, it is prudent to allude to the measured metabolic values at rest and during unloaded cycling. Resting $\dot{V}O_2$ should be 200 to 300 mL/min, and R should be 0.8 to 0.9. At unloaded pedaling, $\dot{V}O_2$ roughly doubles (depending on the body weight). $\dot{V}O_2$ at any work rate can be estimated by the following equation:

$$\dot{V}O_2\ (\text{mL/min}) = 5.8 \times \text{weight (kg)} + 10.2 \times \text{work rate (W)} + 151 \quad \textbf{[6]}$$

If a value deviates markedly from the expected, the validity of the data should be questioned. After completion of the test, the following steps are required for data analysis:

1. Assess if exercise capacity, as determined by the $\dot{V}O_{2max}$, is normal. A normal $\dot{V}O_{2max}$ does not in itself indicate normality of either the cardiovascular or ventilatory system. Each or both systems (and others) may be abnormal and yet have sufficient reserve to allow for the age-predicted $\dot{V}O_{2max}$ to be attained. For previously trained subjects, attaining the age-predicted level may actually represent deterioration. Therefore, even if $\dot{V}O_{2max}$ is within the normal range, the cardiovascular and respiratory responses need to be carefully analyzed to prove the normality of the supporting systems.
2. If $\dot{V}O_{2max}$ is reduced, optimal patient cooperation and satisfactory performance of the study should first be ascertained. On occasion, the requested power output is not achieved because of slowing of the pedaling rate at high exercise intensity. This predictably leads to spurious lowering or flattening of the slope of physiologic functions, such as $\dot{V}O_2$ or O_2 pulse. (In this situation, as opposed to true flattening, both $\dot{V}CO_2$ and $\dot{V}O_2$ are level.) The next step is to determine which organ system is limiting exercise, is closer to its maximal capacity, or is inducing the intolerable symptom(s) that are leading to cessation of effort. At first, broad categories, such as respiratory, cardiovascular, metabolic, musculoskeletal, or motivational limitations, should be sought. If breathing reserve is reduced, ventilatory limitation is present. Cardiovascular limitation is suggested by a combination of findings reflecting reduced or exhausted O_2 transport capacity (Table 5). Among these findings, the normality or abnormality of the AT is fundamental. If one system is limiting exercise capacity, it does not mean that the other systems are normal, or even that the other systems are not concomitantly limiting. Cardiovascular and respiratory limitations often coexist at the same metabolic load. On the other hand, when one system is limiting, other supporting systems are not being challenged to their maximal capacity, so that their normality cannot always be ascertained.
3. If exercise capacity is reduced and the major limiting system can be found, the pathophysiology leading to the exercise limitation should be specified. This includes classification according to obstructive versus restrictive lung disease, myocardial (ischemic, valvular, or conductive) versus peripheral or pulmonary vascular disease, or metabolic causes, such as anemia or acidosis. Other contributing factors (especially those that are potentially treatable) to the limitation should be looked for, such as pharmacologic or metabolic causes. This goal is achieved by a detailed analysis of multiple subjective and objective characteristics of the responses, and their comparison with resting subjective and objective data.
4. It should be determined whether information obtained from the exercise test advances understanding of the patient's symptoms, functional capacity, essential diagnostic workup, and treatment plan. The required complementary diagnostic workup or modes of therapy should be arranged for the patient.

After implementation of this sequential analysis, most patients can be assigned either to a normal exercise tolerance group or to one of the broad diagnostic groups of abnormal exercise tolerance. A certain number of patients remain enigmatic. In our experience, a common dilemma is that of the patient with reduced exercise capacity who, by the cited criteria, is classified with the cardiovascular group but for whom static measurements (e.g., echocardiogram) show no resting cardiovascular abnormality. In some of these individuals, the cause is poor fitness. In others, we believe that heart function, even if normal at rest, may be abnormal during exercise. In some patients, especially hypertensive subjects, diastolic dysfunction may be an important cause of exercise limitation. Another problematic group is comprised of patients with known, often advanced, cardiac and/or ventilatory disease who stop exercise before breathing reserve is exhausted or before significant lactic acidosis (a true physiologic limit) is attained. Some of these patients may be restricted by peripheral causes, such as peripheral and/or respiratory muscle weakness.

CHAPTER

11 Diagnostic Procedures Not Involving the Pleura

Austin B. Thompson and Stephen I. Rennard

A. B. Thompson and S. I. Rennard: Section of Pulmonary and Critical Care Medicine, Department of Internal Medicine, University of Nebraska Medical Center, Omaha, Nebraska 68198-5300.

SPUTUM

The examination of sputum for cytologic and microbiologic diagnoses continues to be useful despite well-documented shortcomings. Contamination of sputum with oral contents is problematic for the interpretation of bacteriologic findings. However, it is less of a problem for the diagnosis of endobronchial malignancy or infection with organisms, such as *Pneumocystis carinii,* that are not colonizers of the oropharyngeal mucosa.

For cytologic examination, sputum is best collected early in the morning. There are a number of methods for handling sputum before staining for cytologic diagnosis, but in general, the diagnostic yield of the cytologic examination of sputum ranges from 50%–90%. The diagnostic yield for sputum can be increased by examining multiple specimens; improved recovery rates have been demonstrated for up to five samples. The collection of sputum for examination has the advantage of being noninvasive, and adequate samples can be readily obtained on an outpatient basis with a minimal amount of patient instruction. However, obtaining a positive diagnosis from sputum does not always obviate the need for bronchoscopy. In the case of tumors other than the small-cell type, bronchoscopy is often essential for adequate staging when a patient is being considered for surgery. False-positive results from cytologic examination of the sputum are low, ranging from 1%–3% in most series, and tend to occur when acute inflammation is present.

Cytologic examination of sputum in noninfectious, benign disorders is rarely fruitful. Exceptions include the findings of lipid-laden macrophages, suggestive of aspiration, lipoid pneumonia, or fat embolism, or hemosiderin-laden macrophages, suggestive of intrapulmonary hemorrhage associated with Goodpasture's syndrome, idiopathic pulmonary hemorrhage, or diffuse alveolar hemorrhage as a complication of high-dose chemotherapy.

In infectious diseases, attention to detail in sputum collection is essential. The patient must be encouraged to produce secretions from the tracheobronchial tree rather than saliva. Sputum can be induced by inhalation of an aerosolized solution of saline solution, distilled water, propylene glycol, or sulfur dioxide. In any case, observation by trained personnel can greatly aid in the collection of an adequate specimen. Once the sputum specimen has been obtained from the patient, it should be delivered promptly to the microbiology laboratory if bacterial, mycotic, or viral diseases are suspected. Interpretation of sputum Gram stains requires attention to the clinical presentation. Amplification of DNA by polymerase chain reaction can extend the sensitivity of sputum analysis and has been applied in the detection of tuberculosis and infection with *Chlamydia trachomatis* and HIV-1. For the detection of mycobacteria, three fresh, early-morning specimens give the best yield. Because of the hardiness of these organisms, 24- to 72-hr collections of sputum are useful, especially when sputum production is scant and sputum induction is either not available or ineffective.

Cytologic examination of sputum for offending organisms is most clearly diagnostic when organisms are identified that portend significant lung disease in the clinical setting. Thus, isolation of *P. carinii* in patients with AIDS or *Aspergillus fumigatus* in patients with leukemia are indications for specific therapy. In hosts who are not immunocompromised, sputum findings can be diagnostic of pneumonia when the Gram stain demonstrates predominance of a single organism or cultures yield a pure growth of a pathogen. The utility of sputum cytology for diagnosis of pneumonia is maximized by the use of special stains, such as the Grocott-Gomori silver stain for fungi or *P. carinii,* and the use of immunologic and molecular biologic techniques, such as the direct fluorescent antibody stain or polymerase chain reaction for *Legionella.*

TRANSTRACHEAL ASPIRATION

A major limitation of examination of sputum in infectious diseases is contamination by the oropharyngeal contents. Transtracheal aspiration was introduced as a method for bypassing the oropharynx during collection of tracheobronchial secretions. In this technique, the cricothyroid membrane and overlying skin are anesthetized and a large-bore (14-gauge) needle is passed into the trachea with gentle aspiration of air confirming proper placement. A plastic catheter is threaded caudally, and once it is in place, the needle is withdrawn. A small amount of saline solution is infused through the catheter, causing cough, and the secretions that are produced are aspirated into the catheter. False-negative results in transtracheal aspiration are rare, estimated to be <1%. However, false-positive results, resulting from colonization of the lower respiratory tract in association with chronic bronchitis, cigarette smoking, and chronic diseases, are not uncommon, with estimates of a false-positive rate up to 27%. Even in a young, healthy population, Gram stain of a transtracheal aspirate offers no advantage over sputum Gram stain in the initial management of acute pneumonia. Because of these limitations and rare but severe complications, which include mediastinal and subcutaneous emphysema, hypoxemia with complicating cardiac arrhythmias, and hemorrhage (rarely associated with fatality), transtracheal aspiration is not as widely performed as previously. The development of other diagnostic procedures, including bronchoalveolar lavage (BAL), protected specimen brush catheters, and, when more invasive procedures are clinically justified, transthoracic needle aspiration or video-assisted thorascopic lung biopsy, has provided alternatives to transtracheal aspiration that are safer or yield more useful information.

FLEXIBLE FIBEROPTIC BRONCHOSCOPY

Flexible fiberoptic bronchoscopy was introduced by Dr. Ikeda in the late 1960s. By the mid-1970s, the flexible fiberoptic bronchoscope was widely utilized in the United States, and its clinical applications have continued to expand even as limitations of flexible fiberoptic bronchoscopy have become more fully appreciated.

Flexible fiberoptic bronchoscopy can be readily performed in sedated, spontaneously breathing patients following anesthesia of the upper airway mucosa with topically

applied agents. The tip of the bronchoscope can be passed through the nose or mouth with the patient sitting or supine. Alternatively, bronchoscopy can be performed in previously intubated patients, or intubation can be performed over the bronchoscope. In intubated patients, a size 7.5-French or larger endotracheal tube assures adequate air flow. Instillation of lidocaine through the bronchoscope effectively suppresses cough. Cough and bronchospasm are minimized by pretreatment with inhaled b-agonists. Atropine is also routinely administered before flexible fiberoptic bronchoscopy to diminish airway secretions and prevent vasovagal reactions. To help ensure safety, patients should have intravenous access established before bronchoscopy. Vital signs should be checked on a regular schedule, cardiac rhythm monitored via electrocardiography, and oxygen saturation monitored continuously.

Flexible fiberoptic bronchoscopy is relatively contraindicated in patients with uncorrected coagulopathies, severe airway obstruction, hypoxia or hypercarbia, or cardiac arrhythmias. It is also contraindicated in patients who are uncooperative. Complications of flexible fiberoptic bronchoscopy are rare but potentially include drug reactions, cardiac arrhythmia, hemorrhage, pneumothorax, pneumonia, and exacerbation of airway diseases.

Flexible fiberoptic bronchoscopy has proved to be an invaluable diagnostic technique for endobronchial lesions. The bronchoscope can be used to visualize the airways directly down to the fourth or fifth generation, allowing for precise localization of endobronchial lesions and visual identification of neoplasms, aspirated foreign bodies, and sites of trauma to the airways, such as tracheal lesions caused by prolonged endotracheal intubation or bronchial wall erosions caused by broncholiths.

In the evaluation of hemoptysis, flexible fiberoptic bronchoscopy has been used to localize anatomic sites of bleeding from peripheral lesions and to visualize directly bleeding from lesions in the central airways.

Direct visualization of the airways by flexible fiberoptic bronchoscopy enables identification of characteristic changes associated with acute inflammation, such as mucosal edema, erythema, friability, and secretion of mucus; thus, it can be used to confirm diagnoses associated with acute inflammation, such as pneumonia or acute bronchitis. Likewise, changes typical of chronic bronchitis may be identified, including hyperemia, thinning and striations of the mucosa, and mucosal pits that represent orifices of enlarged submucosal glands.

Direct visualization of endobronchial lesions is very useful for the staging of lung cancer. The extension of a tumor mass into the trachea, onto the carina or within 2 cm of the carina, implies that the tumor cannot be resected without special techniques to reconstruct the trachea.

Flexible fiberoptic bronchoscopy can also be used for follow-up of chemotherapy or radiation therapy of endobronchial lesions. The ability to sample pulmonary lesions, both endobronchial and extrabronchial, via the flexible fiberoptic bronchoscope greatly extends its clinical utility.

ENDOBRONCHIAL BIOPSY

Endobronchial biopsies are performed with forceps introduced through the suction port of a flexible fiberoptic bronchoscope. A number of instruments can be used for endobronchial biopsy. Biopsy forceps are available in various configurations, all of which can provide adequate samples. Preference for forceps configuration is primarily a function of operator training and experience. If the surface of the endobronchial lesion is smooth and firm, the biopsy forceps may, at times, slide off the lesion. This can be prevented by using a “spear” forceps, in which a small knife emerges from the base of the forceps and is encompassed by the forceps. This knife can be plunged into the tumor, anchoring the forceps and allowing biopsy to proceed. If the endobronchial lesion involves an airway wall parallel to the orientation of the bronchoscope, there may not be an adequate surface for the forceps to grab and hold. In this case, a curette designed to flex to 90° can be used to scrape the lesion to obtain a sample for cytologic examination.

The partial occlusion of the suctioning channel by the introduction of the biopsy forceps may limit suctioning of airway secretions, thereby compromising the field of view and increasing the technical difficulty of the biopsy. This problem can be avoided by using a smaller-sized forceps and a larger-sized suctioning channel, or by employing a bronchoscope with two suctioning channels.

Endobronchial biopsies are generally performed following the instillation of lidocaine directly onto the mucosal surface to be sampled. The procedure is typically complicated by small (<5 mL) amounts of bleeding, but with highly vascular lesions, especially endobronchial carcinoid tumors, the resulting bleeding can be massive and life-threatening. Highly vascular endobronchial carcinoid tumors can be recognized by their cherry-red appearance. A flexible fiberoptic bronchoscope should not be used to obtain specimens from endobronchial lesions with this presentation; rather, such lesions should be approached with a rigid bronchoscope and appropriate surgical support.

Endobronchial biopsies have been associated with pneumothorax. However, the incidence of pneumothorax following endobronchial biopsy is exceedingly low and does not justify routine chest roentgenograms following the procedure.

The greatest utility of endobronchial biopsy is in the diagnosis of cancer. Typically, endobronchial malignancies represent bronchogenic carcinoma. However, endobronchial metastases can occur, most frequently from carcinoma of the breast, malignant melanoma, and tumors of the kidney or colon.

Cytologic brushes provide another tool for collection of endobronchial material. Vigorous brushing of the mucosal surface with a stiff brush exfoliates cells that are ideal for cytologic examination. The cytologic brush samples a larger surface area than an endobronchial biopsy forceps. The brush can be used to obtain samples from airways distal to the visual field of the bronchoscope, so that the complications associated with transbronchial biopsy can be avoided (see below). Hemorrhage is rare, but brushing with cytologic brushes is routinely associated with more bleeding than is obtaining samples with a forceps alone. This is especially true if the mucosa is friable, as is often the case when airways inflammation complicates an endobronchial lesion.

The diagnostic yield of direct forceps biopsy of endobronchial lesions is very high. Reported diagnostic yields range from 70%–100%, with most investigators reporting yields of up to 95%. Lesions associated with false-negative results include large necrotic masses from which nondiagnostic, necrotic material is obtained and lesions that are physically difficult to sample because of their shape, surface characteristics, or location.

Brushings also have a high diagnostic yield of up to 93% for directly visualized lesions. However, they do not appear to add significantly to the diagnostic yield of endobronchial forceps biopsy if the lesion is readily visualized. Similarly, cytologic examination of washings gathered through the bronchoscope during the course of the bronchoscopy or expectorated sputum gathered after bronchoscopy has been utilized, but neither of these specimens adds to the diagnostic yield of forceps biopsy.

TRANSBRONCHIAL BIOPSY

Transbronchial biopsy extends the utility of flexible fiberoptic bronchoscopy to include sampling of peripheral masses and pulmonary parenchyma suspected of being diseased or infected. Transbronchial biopsies are performed by extending the biopsy forceps beyond the visual range of the bronchoscope. Patient cooperation is essential. The forceps are opened during deep inhalation and closed during exhalation. This enfolds lung parenchyma into the forceps, increasing the amount of lung parenchyma that is sampled.

The procedure is generally performed under biplanar fluoroscopy to localize sampling of discrete lesions accurately and to prevent extreme peripheral placement of the forceps, which may result in perforation of the lung pleura. Unintentional biopsy of small muscular arteries can lead to bleeding. Instillation of 1 mL of 1:20,000 epinephrine before performing the biopsy and keeping the bronchoscope wedged into the airway at the site of sampling generally controls the bleeding. Thus, it is imperative that the bronchoscope be maintained in a wedged position until hemostasis is ensured. Transbronchial biopsies are also associated with an incidence of pneumothorax as high as 5%. Most of these cases are not serious, but occasionally placement of a chest tube is required.

The diagnostic yield of transbronchial biopsy varies according to the character of the lung lesion being assessed. For peripheral masses, diagnostic yields range from 30%–90%, with a mean of about 60%. Yields have been improved by the use of bronchography to plan the bronchoscopic approach to the peripheral lesion and by the use of bedside cytology with repeated sampling after the procedure. In interstitial lung diseases, transbronchial biopsy can validate clinical diagnoses of sarcoidosis, pulmonary alveolar proteinosis, eosinophilic granuloma, hypersensitivity pneumonitis, and lymphangioleiomyomatosis. Transbronchial biopsies can be diagnostic in each of these diseases because of their distinctive pathologic features. In contrast, transbronchial biopsy is not felt to be diagnostic for idiopathic pulmonary fibrosis or other interstitial pneumonitides. The diagnostic yield for interstitial lung disease has been most extensively studied for sarcoidosis. Sampling errors are minimized by repeated biopsies; for sarcoidosis, four biopsies have been found to produce up to a 90% yield.

Transbronchial biopsy has also been used for the diagnosis of infectious diseases. In most infectious diseases, sampling is best done by BAL (see below), but there are exceptions. The yield of BAL is low in fungal infections, particularly invasive aspergillosis, and such cases should be approached with transbronchial biopsy or transthoracic needle aspiration if clinically feasible. Prophylactic treatment for *P. carinii* in patients with AIDS leads to lower yields with BAL in the diagnosis of *P. carinii*

pneumonia. Yields are increased from 60%–80% by the addition of transbronchial biopsy.

TRANSBRONCHIAL NEEDLE ASPIRATION

A variety of needles have been developed for needle aspiration of lesions via the flexible fiberoptic bronchoscope. The choice depends on operator preference and biopsy site. Steel needles are preferred for transbronchial and transtracheal biopsies, whereas flexible plastic needles are better suited for apical biopsies. Needle aspiration is especially useful for the diagnosis of lesions that lie beyond the visual field of the bronchoscope. The technique has been used to sample paratracheal nodes, mediastinal nodes (especially subcarinal nodes), submucosal lesions, extrabronchial lesions, and peripheral masses. Transbronchial needle aspiration can be used to approach peripheral lesions that are, because of airway anatomy, inaccessible to the transbronchial biopsy forceps.

To sample areas contiguous to the large airways, the needle is advanced under direct visualization to the suspected area and pushed through the airway wall, and suction is then applied to aspirate a specimen for cytologic examination. Following withdrawal of the needle from the bronchoscope, a small amount of saline solution is used to flush the specimen from the needle. To sample peripheral lesions, the needle is advanced under fluoroscopic guidance and plunged transbronchially directly into the lesion. Complications resulting from needle aspiration, which are rare, include pneumothorax and pneumomediastinum with reported rates of <1%.

The diagnostic yield for aspiration of paratracheal and hilar adenopathy, as visualized on chest roentgenograms, is quite high, with a sensitivity of 50% and specificity of 96% in one study. Investigations have suggested that the yield for needle aspiration can be improved by the use of computed tomographic (CT) guidance. The yield for transbronchial needle aspiration of peripheral masses depends on the size of the lesion. The recovery rate is 33% for lesions <2 cm in diameter and 80% for lesions ^{3}2 cm in diameter. Transbronchial needle aspiration may compliment transbronchial biopsy. In cases in which the transbronchial forceps cannot reach the lesion because of anatomic distortion of the airways, a transbronchial needle can be used to penetrate directly into the lesion through the distorted airway. Transbronchial needle aspiration has not been associated with significant complications.

BRONCHOALVEOLAR LAVAGE

Technique

The lower respiratory tract can also be sampled with the technique of BAL. In this method, a sterile isotonic solution is infused through the biopsy port of the bronchoscope. This fluid fills the intraluminal space of the conducting airways and the alveoli, and it can then be recovered by aspiration. Because the fluid mixes with the intraluminal contents, the resulting lavage fluid effectively samples the intraluminal space of the lower respiratory tract.

A large number of variations of the technique have been developed. In general, however, the procedure is done after wedging the bronchoscope in a segmental or subsegmental bronchus. The wedged position allows the lavage fluid to be infused distally in a controlled manner into a single region of the lung, and more or less prevents the fluid from spreading proximally into other lung regions. The fluid most commonly used is sterile normal saline solution. Warming the fluid to body temperature is felt to reduce cough.

The fluid initially infused reaches the intraluminal space of the more proximal conducting airways more effectively than it reaches the more distal alveolar spaces. As a result, the use of small volumes of fluid can provide a sample enriched for bronchial contents. To have an adequate sampling of alveolar contents, a total volume of at least 100 mL is generally recommended. The fluid is infused in aliquots varying in volume from 20 to 60 mL. Reduced volumes have been successfully used in children. Most bronchoscopists aspirate the fluid immediately after infusion, but some investigators allow the fluid to remain for a period of dwell time. The procedure can be repeated in several subsegments if desired.

Complications

Apart from the procedure of flexible fiberoptic bronchoscopy, BAL itself has some associated risks. The most common complication is fever. The syndrome of post-BAL fever typically develops 4 to 6 hours after the procedure, characterized by the sudden onset of rigors, fever, and malaise. Symptoms generally respond promptly to intravenous meperidine (Demerol) and often to oral acetaminophen. The syndrome is self-limited and generally resolves within 24 hrs. Fever after bronchoscopy is not thought to be caused by infection, but rather by the release of endogenous pyrogens. The occurrence of this complication appears to increase with the volume of fluid used. With a 300-mL lavage, the frequency is felt to be 20%–30%.

Infiltrates on chest roentgenogram are also common, occurring in the majority of individuals studied immediately after the procedure. These infiltrates, which presumably represent retained fluid and atelectasis, generally spontaneously resolve within 24 hrs. True infections may also occur following BAL with a frequency of 1/1000 or less. Patients generally have fever, cough, and often pleuritic chest pain 1 to 3 days following the bronchoscopy. Bleeding, pneumothorax, and bronchospasm have been reported but are rare.

Transient declines in both vital capacity and FEV_1 (forced expiratory volume in 1 second) are frequent, and these can be associated with hypoxemia. They generally are limited to about 10% declines in predicted values. Interestingly, BAL in patients with mild asthma appears to be associated with no statistically significant increased risk for decline in lung function in comparison with normal controls, although bronchospasm has been reported as a complication. These transient declines in lung function are not clinically significant in individuals with normal lung function. However, in individuals with severely compromised lung function, BAL can lead to retention of carbon dioxide or precipitate respiratory failure. Should such individuals require BAL, however, the procedure can still be performed. It is recommended that before BAL is performed, such patients undergo intubation with or without the initiation of mechanical ventilation to support ventilation and gas exchange.

Processing Bronchoalveolar Lavage Specimens

The techniques for handling and processing BAL fluids are varied. It is important that each center have a standardized technique to allow valid interpretation of results from lavage performed by different personnel. Close cooperation between clinicians and pathologists is obviously required.

Indications for Bronchoalveolar Lavage

BAL is often the diagnostic modality of choice in evaluating immunocompromised individuals with suspected pneumonia. Because the lavage fluid effectively samples the peripheral intraluminal space, peripheral intraluminal infections can be diagnosed with a high degree of reliability. For example, the diagnostic yield for *P. carinii* pneumonia in untreated patients is felt to be >95%. Viral infections can also be diagnosed reliably. For cytomegalovirus and herpesvirus, pathognomonic cytopathic changes can be recognized cytologically. The sensitivity for detecting viral material can be increased with the use of special techniques, including monoclonal antibodies, cDNA probes, and the polymerase chain reaction. Samples obtained by BAL can also be cultured for viruses, and the cultures can be analyzed using a variety of diagnostic techniques. Monoclonal antibodies can be used to assist in the diagnosis of other infections, including *Legionella* infection, but the yield is greater when this technique is combined with culture methods. The recent introduction of the analysis of BAL fluid with the polymerase chain reaction provides a very sensitive method for the detection of *Legionella, Mycobacterium, Pneumocystis, Chlamydia, Mycoplasma* organisms, and for an increasing number of viruses.

BAL fluid can also be used for the diagnosis of fungal infection, both cytologically and by culture. Because some fungi, particularly *Mucor-Absidia* and to some extent *Aspergillus,* preferentially invade the vascular spaces, the intraluminal sampling technique of BAL may not be as effective. For this reason, the diagnostic yield of BAL in cases of invasive aspergillosis may only be 50%. Negative results, therefore, must be interpreted with caution.

The sensitivity of BAL for the detection of some micro-organisms that are not inevitably associated with disease (e.g., cytomegalovirus and *candida*) creates the problem of distinguishing between infection and colonization. Asymptomatic colonization may precede clinically significant infection in some situations. Thus, although BAL can provide diagnostic information, this information must be used in an appropriate clinical context.

BAL can also provide diagnostic information in individuals who are not immunosuppressed but are suspected of having infections. Not only can unusual organisms be detected, but quantitative cultures can help to confirm the presence of pneumonia when other causes of lower respiratory tract abnormalities are also present. The presence of $>10^5$ organisms on a quantitative BAL culture has a specificity approaching 100% for the diagnosis of bacterial pneumonia. This technique also permits the identification of multiple pathogens, which appear quite frequently in hospital-acquired cases of pneumonia. Quantitative cultures combined with protected BAL, in which a special catheter is used, or with culture of only the last aliquot of fluid infused during BAL appears to have improved specificity. In direct comparisons, the specificity and sensitivity of quantitative BAL appear to be similar to those of the more complex protected brush and protected BAL procedures.

Cytologic examination of BAL fluid for pulmonary malignancy can be performed. Primary and metastatic solid tumors and hematologic malignancies can be readily detected by standard and specialized cytologic techniques. BAL appears to be particularly effective in the diagnosis of lymphangitic carcinomatosis. This is probably because in such cases the tumor involves not only the pulmonary interstitium but also the intraluminal spaces. The diagnostic yield for primary lung cancer by BAL

depends on several factors. Most importantly, the appropriate segment must be washed. Diagnostic yields >50% have been reported. In one large series, BAL was felt to have a superior diagnostic yield when compared with transbronchial biopsy for the diagnosis of peripheral lesions not visualized at bronchoscopy. BAL has also been suggested as one means to follow the effectiveness of chemotherapeutic intervention in patients with lung cancer.

Both routine and special cytologic techniques can be used to diagnose pulmonary malignancies in material obtained by BAL. For example, monoclonal antibodies for specific tumor-associated antigens may be helpful in detecting rare cells and determining the type of malignancy. When routine cytologic analysis is used, however, it is essential that material be interpreted by a skilled cytologist and that appropriate clinical correlations be made. In a number of nonmalignant conditions, abnormal cells can be observed that are confused easily with cancer. Infection, cytotoxic therapy, and severe inflammation may all be associated with a range of atypical cells having an appearance that can vary from mildly metaplastic to closely resembling malignancy. Thus, the diagnosis of pulmonary malignancy based on cytologic material obtained by BAL should be made only in an appropriate clinical setting.

It is possible to use BAL to assess inflammatory processes in the lower respiratory tract, such as interstitial lung diseases and lower airways diseases. The BAL findings are not pathognomonic of any particular interstitial disease, but they may be suggestive. For example, increased numbers of neutrophils in BAL fluid are often seen in idiopathic pulmonary fibrosis, whereas increased numbers of T-helper cells are found in pulmonary sarcoidosis and of T-suppressor cells in hypersensitivity pneumonitis. Thus, the analysis of inflammatory cells obtained by BAL, although not specific, can often be helpful in suggesting a diagnosis.

The intensity of alveolitis, as suggested by BAL, may be helpful in making clinical decisions, such as when to proceed to definitive biopsy procedures or when to initiate or change therapy.

Eosinophilia and increased numbers of mast cells, together with increased levels of eosinophil- and mast cell-derived mediators, are commonly found in the airways of patients with asthma. The presence of these cells and their mediators correlates with hyperresponsiveness and clinical symptoms. Increased airways neutrophilia has been reported by some investigators in asthma and has also been reported in chronic bronchitis. Although patients with airways disease have been studied by BAL, at present this technique should be regarded primarily as a research procedure rather than as a clinical tool.

BAL has also been used to obtain material for the analysis of a large number of chemical components present in the lower respiratory tract. These measurements are mainly research activities without current clinical use.

SCALENE NODE BIOPSY

Pulmonary malignancies as well as inflammatory diseases of the lung spread in a somewhat predictable pattern, based on the lymphatic drainage system. The lymphatics of all the lobes of the right lung drain initially into the lymphatic sump of Borrie, a collection of intrapulmonary lymph nodes lying between the upper lobe bronchus and the bronchus medius. From there, the upper lobe drainage enters the lower paratracheal area in the region of the azygos vein. The middle and lower lobes drain to the subcarinal, pulmonary ligament, and paraesophageal nodes. From these locations, all lobes of the right lung drain to the right scalene area. Both lobes of the left lung drain to the lymphatic sump between the upper and lower lobe bronchi and hence to the subcarinal, pulmonary ligament, and paraesophageal nodes. The upper lobe also drains to nodes in the aortopulmonary window, left paratracheal area, and anterior mediastinum. Approximately 25% of left lower lobe drainage crosses over to the right side, whereas 90% of the left upper lobe drainage stays on the left, eventually reaching the left scalene nodes. However, it is important to remember that these drainage patterns are not absolute, and crossover metastases from either side may occur, probably as a result of obstructed lymphatics.

The procedure of scalene node biopsy is well established and is almost always carried out with local anesthesia. A 5-cm transverse incision is made over the lateral border of the sternocleidomastoid muscle, 2 cm superior and parallel to the clavicle. The fat pad containing lymph nodes, located in the space posterior to the sternocleidomastoid muscle and anterior to the anterior scalene muscle, is removed for microscopic study. The most important structures encountered are the subclavian vein inferiorly, the internal jugular vein and carotid artery medially, and the phrenic nerve lying on the anterior surface of the anterior scalene muscle and on the left side the thoracic duct. The operating time for this procedure is short, and postoperative patient discomfort is minimal.

In patients with lung cancer, biopsy of palpable scalene nodes has a positive diagnostic rate of about 80%. In patients with lung cancer but nonpalpable scalene nodes, the positive diagnostic rate is only about 20%. Scalene node biopsy has been used in nonmalignant disease as well. The biopsy of nonpalpable scalene nodes may offer a positive diagnosis in as many as 80% of patients with sarcoidosis and other granulomatous diseases.

Complications of scalene node biopsy include hematoma, seroma, pneumothorax, infection, air embolism, lymph fistula, hoarseness, phrenic nerve palsy, chylothorax, or a Horner's syndrome. These complications are rare, with a total prevalence of all complications of only 1%–2% and a mortality rate of 0.1%. Prior radiation therapy incorporating the scalene nodes in the field of radiation is a relative contraindication, as the resulting fibrosis complicates surgical dissection and healing and may lower the likelihood of a positive biopsy result.

For suspected malignant intrathoracic disease, most authors would recommend that scalene node biopsy be performed first whenever palpable nodes are present. Scalene nodes positive for malignancy are N3 nodes, indicating a stage of IIIB for lung cancer, considered by most to be beyond curative resection. Routine biopsy of nonpalpable scalene nodes in patients with lung cancer has a low diagnostic yield, especially with peripheral lesions and tumors <3 cm in diameter. Although the matter is controversial, most surgeons would forego scalene node biopsy in these patients and proceed with staging using radiologic imaging and mediastinoscopy when indicated. Used judiciously, scalene node biopsy is a simple, valuable procedure that may obviate the need for more invasive staging or even thoracotomy.

MEDIASTINOSCOPY

Technique and Complications

Mediastinoscopy is a surgical procedure performed under general anesthesia with the neck hyperextended and the head turned to the left. A short (4-cm) transverse incision is made centered just above the suprasternal notch. Once the pretracheal fascia is reached, blunt finger dissection is used to open the relatively bloodless plane of loose areolar tissue just anterior to the trachea. The rigid mediastinoscope is introduced into this plane and is advanced down as far as the carina. In this way, right and left paratracheal nodes, anterior subcarinal nodes, and some proximal right hilar nodes may be visualized and sampled. Access to the left hilum is limited by the aortic arch. In performing this procedure, the surgeon has only monocular vision without depth perception. Expertise is essential, because the pretracheal space entered by the mediastinoscope contains a number of vital structures, including the aortic arch, superior vena cava, brachiocephalic artery, and left atrium. This procedure is relatively brief, and patients require only an overnight hospital stay. Mediastinoscopy requires pliable tissue planes free of adhesions to allow blunt dissection, so that prior mediastinoscopy, other mediastinal surgery, or mediastinal radiation therapy are relative contraindications to this procedure. Prior open heart surgery may fix the mediastinal structures and make mediastinoscopy much more difficult. Superior vena caval obstruction usually causes mediastinal venous engorgement and elevates the risk for bleeding, but it is not an absolute contraindication for mediastinoscopy.

Because the nodes draining the left upper and lower lobes may drain to the subaortic nodes or the anterior mediastinum, they may not be readily accessible to standard cervical mediastinoscopy. To approach these nodes, an extended cervical mediastinoscopy has been described. With this technique, the anterior mediastinum can also be explored through the same neck incision, but this method has not become popular because of its perceived difficulty and higher risks.

Despite the vital structures surrounding the area explored with the mediastinoscope and the limited surgical field, complications from standard cervical mediastinoscopy are infrequent in the hands of an experienced surgeon. The principle risk is hemorrhage from laceration or inadvertent sampling of a blood vessel. Pneumothorax, recurrent laryngeal nerve paralysis, tracheal injury, or wound infection also may occur. The prevalence of all complications is low (1.7%–2.3%), and the rate of emergency thoracotomies required to control serious complications is 0.3%. In two recent clinical series with a combined total of 2259 patients undergoing mediastinoscopy, there were no deaths. A mortality of £1% has been reported in most series.

Indications for Cervical Mediastinoscopy

Cervical mediastinoscopy is primarily indicated to evaluate the status of mediastinal lymph nodes in patients with potentially resectable lung cancer who do not have palpable supraclavicular nodes. The technique also provides a tissue diagnosis for any patient whose primary lesion is not accessible or who is not a candidate for resection because of poor pulmonary function or other medical reasons. The diagnostic yield depends largely on patient selection. When routine mediastinoscopy is performed in all patients with presumed operable carcinoma of the lung, 27%–30% of patients have metastatic disease in the excised nodes. The highest yields have been seen in patients with tumors of the right lung, larger central tumors, and small-cell tumors or adenocarcinomas.

An area of considerable interest has been the role of CT of the chest in staging mediastinal metastases in patients with lung carcinoma. Based on studies of CT scans in normal patients and cadavers, nodes up to 1 cm in diameter are generally considered to be normal. Nodes with a diameter of ³1.5 cm are abnormal, and nodes between 1 and 1.5 cm in diameter are indeterminate or suspect. With these criteria, the sensitivity of CT ranges from as low as 61% up to 95%, and specificity from

50%–94%. Magnetic resonance imaging of the chest has not offered any advantages over CT in the assessment of mediastinal nodes.

Recent studies including exhaustive lymph node dissections and meticulous correlation with CT findings have demonstrated that the sensitivity of CT may not be as high as previously thought. Mediastinal metastases were found involving lymph nodes of <1 cm in diameter in as many as 33% of patients. These nodes would have been classified as normal using the CT criterion for normal size of £1 cm in diameter. Nevertheless, patients with mediastinal micrometastases or minimal N2 disease discovered at the time of thoracotomy have 5-year survival rates of as much as 34% after resection of the tumor and mediastinal metastases followed by postoperative radiation therapy.

CT may be useful in screening for macroscopic metastatic disease indicated by enlarged nodes (>15 mm) or indeterminate nodes (10 to 15 mm) that need to be verified by mediastinoscopy. If CT shows no mediastinal abnormalities and especially if there is a small peripheral lesion, then mediastinoscopy can be bypassed as a surgical staging procedure, and the surgeon can proceed directly to thoracotomy. At thoracotomy, a thorough mediastinal node dissection must be performed in all patients with negative findings at mediastinoscopy or in patients in whom this procedure has not been performed, so as to make an accurate determination of the surgical stage. Meticulous sampling of mediastinal nodes at thoracotomy is also important in all patients with tumors of the left lung, as metastases to some nodal groups may be inaccessible by mediastinoscopy. Thus, a policy of routine mediastinoscopy for all patients is not a reasonable, cost-effective approach in lung cancer.

Mediastinoscopy is also indicated to verify the diagnosis of nonpulmonary malignancies, such as lymphoma, and of granulomatous diseases, such as sarcoidosis, histoplasmosis, and occasionally tuberculosis. The diagnostic yield is high, particularly with CT evidence of mediastinal or hilar adenopathy. Mediastinoscopy is practically 100% accurate in the diagnosis of sarcoidosis in the presence of appropriate CT abnormalities and has become the preferred invasive diagnostic procedure with this disease whenever transbronchoscopic biopsy is unsuccessful and other, more accessible sites are not involved.

Parasternal Anterior Mediastinotomy

Anterior mediastinotomy requires general anesthesia with endotracheal intubation. A short, transverse (“hockey stick”) incision is made over the second or third costal cartilage just adjacent to the sternum on the appropriate side. A segment of cartilage is removed, and through the bed of the resected cartilage an extrapleural plane is bluntly developed toward the hilum of the lung. Use of a headlight and careful retraction allows evaluation of nodes in the anterior mediastinum lying in front of the great vessels, right paratracheal nodes, subaortic nodes on the left, and tracheobronchial angle nodes. Vigorous retraction occasionally permits sampling of paraesophageal nodes, posterior-inferior tracheobronchial nodes, or posterior subcarinal nodes. Entry into the pleural cavity (often done inadvertently) permits direct exposure of hilar masses for biopsy. When the pleura has been entered, a small chest tube is inserted through a separate wound and is left on suction for a short time after wound closure and recovery. Depending on the number of frozen sections obtained and the extent of dissection necessary, most procedures can be completed in a reasonably brief period of time. The in-hospital recovery time is generally 1 to 2 days, depending on whether a chest tube is used or not. Postoperative discomfort is mild but usually greater than that experienced after mediastinoscopy.

Few complications occur with anterior mediastinotomy, although it is more invasive and has a slightly higher complication rate than mediastinoscopy. Bleeding is usually controlled by pressure or suture; if bleeding is severe, the incision can be extended into an anterior thoracotomy for repair of the site of bleeding. Wound infection, pneumothorax from unsuspected pleural entry, pleural effusion, pneumonia, and phrenic nerve damage also have been described. The total rate of all complications is reported at 6.7%–9%, and the mortality rate is 1% or less. Relative contraindications to this procedure include a history of prior median sternotomy or radiation therapy, as adhesions and lack of pliable tissue planes make dissection hazardous through the small mediastinotomy incision.

The indications for anterior mediastinotomy are generally the same as for mediastinoscopy. In patients with nonpalpable supraclavicular nodes who have suspected pulmonary malignancies and evidence of mediastinal adenopathy, anterior mediastinotomy is a good staging alternative to mediastinoscopy. It permits access to nodal areas such as the anterior mediastinum and aortopulmonary window, which are common sites of left lung metastases but are inaccessible by mediastinoscopy. Mediastinotomy is preferred in patients with the superior vena caval syndrome, prior mediastinal radiation therapy, or prior mediastinoscopy. In cases of nonpulmonary neoplasms and inflammatory diseases, mediastinotomy offers the potential for biopsy of enlarged mediastinal nodes seen on CT, and also allows an open lung biopsy to be performed through the same incision should the mediastinal nodes prove nondiagnostic.

Some surgeons prefer anterior mediastinotomy because it provides an open, more accessible surgical field, compared with the limited field provided by mediastinoscopy. However, mediastinoscopy is associated with less morbidity and mortality, a shorter operating time, and less postoperative pain than anterior mediastinotomy. Mediastinotomy and mediastinoscopy can be viewed as complementary rather than competing procedures that have equivalent results in properly selected patients. The procedure to be used is best chosen based on CT and individual patient evaluation, with the goals of minimizing morbidity and maximizing the likelihood of a diagnosis.

PERCUTANEOUS TRANSTHORACIC NEEDLE BIOPSY

Transthoracic needle aspiration or biopsy has several indications, which include the following: (1) diagnosis of parenchymal lung nodules, particularly peripheral lesions, whether solitary or multiple; (2) classification and staging of suspected pulmonary or mediastinal metastasis; (3) diagnosis of suspected infectious diseases (nodules or infiltrates); (4) diagnosis of mediastinal, hilar, and pleural masses; and (5) evaluation of lesions for which bronchoscopic evaluation has failed to provide a definitive diagnosis.

Contraindications include anticoagulation, bleeding dyscrasia, and thrombocytopenia (platelet count <50,000). It is essential that the patient be able to cooperate fully with the procedure. If not, the complication rate rises and adequate specimens may not be obtained. If clinically indicated, coagulation defects can be temporarily corrected, reducing the risk for hemorrhage. Severe chronic obstructive pulmonary disease (COPD) is a relative contraindication. COPD is associated with an increased risk for pneumothorax from percutaneous needle aspiration or biopsy, and such patients are less able to tolerate the effects of a pneumothorax. Other relative contraindications to transthoracic needle aspiration include pulmonary hypertension, positive-pressure mechanical ventilation, and suspected vascular lesions, such as arteriovenous malformations.

Sensitivity of transthoracic needle biopsy ranges from 60%–97%. Diagnostic yield is optimal when adequate samples are provided, and both an experienced surgeon to perform the biopsy and an experienced cytopathologist to interpret the results are required. Transthoracic biopsy of malignant mediastinal and hilar lesions provides an accurate diagnosis in approximately 90% of cases. The positive yield for metastatic pulmonary and mediastinal disease is >80%. Correlation between cytologic and histopathologic diagnoses varies from 77%–82% and depends on sampling error, intraobserver variability in interpretation, and tumor pleomorphism.

Tools and Technique

Several types of needles are available for percutaneous sampling of the lung. These fall into two basic types: aspiration or fine needles and biopsy needles. Aspiration needles for the lung and mediastinum usually range in size from 18 to 23 gauge and are primarily used to aspirate cells for cytologic examination, but they may provide small fragments of tissue for histology as well. Probably the most familiar of the aspiration needles is the Chiba needle, which has a beveled tip angled at 24° and an inner removable stylet. Spinal needles can also be utilized as aspiration needles for the lung and mediastinum. They have a greater bevel angle, possess thicker walls, and hence are stiffer than the Chiba needle.

Biopsy needles also are of two general types: small-gauge biopsy needles and cutting biopsy needles. Small-gauge biopsy needles (e.g., Greene, Turner, Westcott, or Haaga needles) are modified aspiration needles designed to acquire small samples of tissue for histologic examination and preparation of cell blocks. The fine needles are commonly employed for transthoracic needle biopsy of the lung and mediastinum and are superior for obtaining cells for cell block analysis. Cutting needles are designed to obtain adequate amounts of tissue for histology. The sample provided by needle biopsy augments cytologic diagnosis of malignancy, confirming the diagnosis of a specific cell type or supporting a negative cytologic result. However, there is controversy regarding whether histologic sections of tissue obtained with thin needles significantly often lead to a positive diagnostic result when needle cytology specimens have given a negative result. Cutting needles are recommended for the biopsy of an unknown primary or a possible second primary; evaluation of suspected benign disease, especially in the anterior and posterior mediastinum; and for cases in which several passes or prior attempts with an aspiration needle have not revealed a positive cytologic diagnosis. Concerning the question of increased risk for hemorrhage, a recent prospective study demonstrated that the use of large-bore, true-cut needles was not associated with a significantly greater rate of complications than fine-needle aspiration in the evaluation of mediastinal masses, even those situated near major vessels.

Imaging Guidance

Fluoroscopy, CT, and ultrasonography have all proved to be effective guides for transthoracic needle biopsy. Fluoroscopy has the advantages of low cost and relative ease of operation. Lesions that are at least 1.5 to 2 cm in diameter can be adequately visualized by fluoroscopy. Biplanar fluoroscopy is the most precise fluoroscopic technique. CT of the chest should probably be obtained before fluoroscopically guided needle biopsy to ensure that the suspected lesion is not vascular and to localize the lesion in relation to other vital structures, thus helping to design the optimal pathway for the aspiration or biopsy needle. CT-guided transthoracic needle biopsy should be considered for lung and mediastinal lesions that are not well visualized by fluoroscopy because of small size or other reasons. CT-guided imaging is

suggested for lesions between 0.5 and 1.5 cm in diameter that are contiguous to major vascular structures or blebs. CT-guided needle biopsy is limited by the higher cost and longer duration of the procedure.

Complications

The most common complication following transthoracic needle aspiration or biopsy is pneumothorax. The frequency of pneumothorax in most studies ranges from 10%–35% following fluoroscopically guided procedures, and is approximately 37% when CT is the imaging method employed. The increased incidence of pneumothorax in CT-guided needle biopsies is most likely a consequence of the use of this imaging method for more difficult lesions requiring longer biopsy time and multiple passes with the needle. Thoracostomy tubes are required in fewer than half of cases of needle biopsy pneumothorax. In one series of 2421 transthoracic, fine-needle biopsies, a pneumothorax developed in 34% of patients, but only 7.8% required insertion of a thoracostomy tube. Indications for thoracostomy tube treatment of a pneumothorax following biopsy include dyspnea, a pneumothorax >30% in size, or an interval increase in the size of the pneumothorax on repeated x-ray imaging of the chest. A 7-French chest tube with a Heimlich valve is frequently sufficient to treat a pneumothorax following biopsy. Needle size does not appear to affect the incidence of pneumothorax. Factors that do predispose to biopsy-induced pneumothorax include increased number of needle passes, increased depth of the lesion, cavitary lesions, increasing patient age, and the presence of COPD.

Other mild complications include hemoptysis, which occurs in approximately 10% of cases, and subcutaneous emphysema.

Procedure

Transthoracic needle aspiration biopsy is usually an outpatient procedure. Patients who are very anxious may benefit from premedication with short-acting sedatives or benzodiazepines. Atropine has been used to reduce vagal tone and help prevent the possibility of vasovagal reactions. An intravenous line is routinely inserted, and electrocardiogram, arterial saturation, and blood pressure are routinely monitored during and after the procedure. The lesion to be sampled is localized, usually with fluoroscopy, and prior CT radiographs are examined for visualization of the lesion and its relation to vital structures. The patient is placed in the supine, prone, oblique, or lateral decubitus position according to the location of the lesion. The approach for mediastinal and hilar lesions depends on the size and proximity of the lesion to cardiovascular structures. In general, for anterior mediastinal masses, the anterior or parasternal approach is preferred, whereas for posterior mediastinal lesions, a paravertebral approach is often chosen. For biopsy of hilar masses, an anterior or posterior approach is employed, depending on whether the lesion is anterior or posterior to hilar vessels on contrast-enhanced CT of the thorax. Lidocaine (Xylocaine) is used for local anesthesia of the skin, subcutaneous tissue, and parietal pleura. Whenever possible, the needle is advanced over the superior margin of a rib to avoid injury of the intercostal neurovascular bundle. The actual passage of the needle into the lesion should be accomplished during breath-holding at end-expiration. This is particularly important in the biopsy of small nodules.

Techniques have been described that allow for multiple passes of the needle into a suspect lesion without repeated penetration of the pleura. In one method, the coaxial technique, an inner, smaller-gauge needle is used to aspirate samples repeatedly through an outer, larger needle passed just to the outer margin of the lesion. This method can be used with small-gauge biopsy needles and cutting biopsy needles, thereby allowing for histologic as well as cytologic examination. Following the biopsy, some choose to inject 5 to 10 mL of an autologous blood clot to patch the tract of the outer needle. In the second technique (the tandem needle approach), one needle is passed into the lesion to localize or mark the site while the second needle is employed for aspiration and biopsy in tandem to the path of the marker needle. Rapid cytologic processing of the samples can be used both to minimize the number of passes made and to ensure that diagnostic material is obtained. Gram-stained smears and cultures of aspirated materials should be done if indicated. If cores of tissue are obtained, these should be submitted in formalin for histopathologic examination.

A chest radiograph is routinely performed immediately after the procedure, and then 2 to 4 hours later, to detect the presence of a pneumothorax. The patient's vital signs should be monitored after the procedure, and the patient should be observed for symptoms of chest pain, dyspnea, hemoptysis, and cardiovascular instability.

Interpretation and Clinical Application of Results

Difficult clinical decisions must be made when a biopsy result is negative or benign, which occurs in 5%–25% of all transthoracic needle biopsies. Biopsy should be repeated if findings are nonspecific (e.g., inflammation, necrosis, or hemorrhage), as a negative result does not exclude malignancy. Repetition of the procedure with a biopsy needle should be considered if tissue for histology was not obtained, or the surgeon should proceed directly to thoracotomy for a histologic diagnosis. A specifically benign diagnosis, such as hamartoma, granuloma, or infection, is usually reliable. However, if the clinical presentation or radiologic features strongly suggest malignancy, then a thoracotomy should be performed despite specifically benign findings. When the clinical presentation and radiographic features are more consistent with benign disease, the patient can be carefully followed with regular x-ray imaging every 3 months for the first year, then every 4 to 6 months for the second year, and annually thereafter. Subsequent growth of the lesion revealed on chest x-ray films warrants prompt re-evaluation. Conversely, an interval reduction in the size of the suspect lesion lends support to a benign diagnosis, and further observation of the lesion is appropriate.

OPEN LUNG BIOPSY

Technique

When less invasive diagnostic methods fail, or the clinical situation dictates the need for a very rapid definitive diagnosis, open lung biopsy remains the most reliable approach.

Open lung biopsy is performed under general anesthesia with endotracheal intubation. For most diffuse infiltrative or nodular lung disease, a small, 5- to 7-cm incision is made over the fourth or fifth intercostal space anteriorly. The pleural cavity is exposed with a small rib spreader. A portion of the lingula, the anterior portion of the right or left lower lobe, or the right middle lobe is allowed to herniate through the wound. In the inflated state, a transverse or wedge biopsy of lung is excised using lung staplers and is sent fresh for pathologic and bacteriologic examinations. Most importantly, the portion of lung obtained should include adequate amounts of both normal and abnormal tissue. If appropriate, several samples from two lobes may be obtained through the same incision. Lateral and posterior portions of either lung are usually not accessible for biopsy through this anterior incision. A chest tube is left in place in the pleural cavity, usually for 24 to 48 hours. The entire surgical procedure is brief, with minimal blood loss. The small, anterior thoracotomy incision usually does not significantly compromise the mechanics of breathing in a group of patients who usually have serious underlying systemic disease. Localized nodular disease or peripheral nodules, especially in the apical, posterior, and lateral areas of the lung, generally require a more extensive, full posterolateral thoracotomy for access.

Complications

The reported complications from a small diagnostic anterior thoracotomy include bleeding, wound infections, persistent air leak, pneumonia, or any systemic complication of general anesthesia. In a review of 15 clinical series with a total of 2290 open lung biopsies, the overall complication rate was 7.0% and the mortality was 1.8%, usually related to a patient's underlying disease. The yield of specific diagnoses in this large group was 94%. Relative contraindications to open lung biopsy include patient instability, which can usually be improved by judicious medical management, and coagulopathies, which may be corrected in most cases with blood component therapy.

To minimize the morbidity of an open lung biopsy for diffuse infiltrative disease, the lingula or middle lobe is frequently sampled, as these areas allow for the smallest incision and shortest operating times. The question of the representative accuracy of this approach has been answered by a prospective study, which found a 100% histologic correlation of lingular biopsies with open biopsies of other lung segments obtained at the same thoracotomy. Thus, it appears that lingular biopsies are extremely accurate and representative of the pathologic process occurring in diffuse infiltrative lung disease.

Indications

The indications for an open lung biopsy and its sequence in the diagnostic algorithm depend on the pulmonary process and the patient's systemic condition. Of all patients with chronic infiltrative lung disease, transbronchial biopsy can be expected to provide a definitive diagnosis in only approximately 40%. In contrast, open lung biopsy yields a specific diagnosis in approximately 90%. Transbronchial biopsy findings of interstitial pneumonia, chronic inflammation, nonspecific reaction, and fibrosis are generally regarded as nondiagnostic and should lead to open lung biopsy.

In immunosuppressed patients with pulmonary infiltrates, considerable differences of opinion exist regarding the risk-benefit ratio of an open lung biopsy. In some series, open lung biopsy had a very high (97.5%) diagnostic accuracy rate and determined therapy in 45% of patients. However, the mortality in patients whose biopsy findings dictated a change in treatment was not significantly different from that in patients in whom no chae was indicated.

There is much controversy concerning the indications for open lung biopsy in patients with AIDS who have pulmonary infiltrates. In one series, a 70% diagnostic

accuracy rate was found in patients in whom transbronchial biopsy was nondiagnostic. In a later, prospective study of AIDS patients with interstitial infiltrates, combined transbronchial lung biopsy and alveolar lavage gave a diagnostic yield of 85% for infections, comparable with that of open lung biopsy (88%), thereby indicating a minimized need for open lung biopsies. An exception to this is an expected diagnosis of Kaposi's sarcoma, for which open biopsy is more frequently diagnostic.

In general, open lung biopsy is accompanied by low morbidity and low mortality with a high diagnostic yield. In properly selected patients, it should not be unduly delayed to perform other, less productive diagnostic techniques when a definitive tissue diagnosis can be readily and safely obtained. Of critical importance is maximal use of the biopsy specimen, including microbiologic examinations in addition to pathologic study and also including chemical and physical examinations when indicated.

VIDEO-ASSISTED THORACOSCOPIC SURGERY

Thoracoscopy has generated a large amount of interest as a newer approach to lung biopsy. When performed with a rigid scope, classic thoracoscopy was a limited procedure that provided the surgeon with poor visualization and access to intrathoracic structures. Application of video-endoscopic technology and percutaneous methods of dissection and exposure developed for abdominal surgery has resulted in a major advance in the diagnosis and treatment of intrathoracic disease.

Technique

Video-assisted thoracic surgery is performed under general anesthesia using a double-lumen endotracheal tube. The patient is positioned in the lateral decubitus position and the skin is antiseptically prepared and draped as for a standard posterolateral thoracotomy. The ipsilateral lung is collapsed and a 2-cm incision is made in the midaxillary line in the seventh intercostal space. After digital entry and palpation of the pleura surrounding the incision to avoid tearing adhesions, a 10-mm operating port is inserted. The video-telescope is inserted through the port to inspect the intrathoracic contents, and images are projected onto a high-resolution video monitor. One to three operating ports are then inserted through small, separate incisions in the anterior and posterior axillary lines, preferably along a line that can be used for a thoracotomy incision should the need arise. The entrance ports need not be sealed, as in laparoscopy, because carbon dioxide insufflation is not required to maintain an operating field. Through the operating ports the surgeon and assistant may dissect, retract, staple, excise, and digitally palpate the lung and intrathoracic structures. Application of the electrocautery and argon beam electrocoagulator is significant with this method. At the completion of the procedure, one or two small chest tubes are tunneled into the chest and the small thoracoscopy incisions are closed.

The primary reason for the development of thoracoscopy, and now video-assisted thoracic surgical techniques, is to permit invasive intrathoracic diagnostic and therapeutic procedures to be performed with minimal pain and morbidity. Complications of this procedure vary with the actual surgery performed. Pneumothorax, air embolism, bleeding, and inadvertent lung injury are the most common intraoperative complications of the procedure, but these can be controlled easily in most instances with current instrumentation. The results of a large series suggest an overall complication rate of 14% and mortality ranging from 1.5%–9.8%, depending on the underlying clinical condition, indications, and the video-assisted thorascopic surgical procedure performed. Intraoperative complications may lead to urgent thoracotomy in 1%–3% of cases, and patients are draped and prepared for open thoracotomy at the onset of the procedure.

Contraindications to video-assisted thoracic surgery are generally based on limitation of visualization of the intrathoracic space. Absolute contraindications include an obliterated pleural space, an inability to tolerate one-lung anesthesia, the need for high positive-pressure ventilation, and severe chronic or acute respiratory insufficiency, all of which would not allow collapse of the ipsilateral lung for exposure. Thus, when a patient being maintained on a ventilator in the intensive care unit requires open lung biopsy, the standard approach of anterior thoracotomy is generally used. Additionally, the procedure may be ill-advised for patients who have previously undergone thoracoscopy or even tube thoracostomy because of excessive adhesions in the pleural space. The clotting parameters of patients who are receiving anticoagulant medication or who have a coagulopathy must be normalized before video-assisted surgery can be performed.

Indications

The most traditional indication for thoracoscopy is evaluation of pleural effusions and other pleural pathology by visual exploration and directed biopsy. In a series of 102 patients with recurrent pleural effusion in whom all prior studies were nondiagnostic, a definitive diagnosis was obtained in 80.3% with thoracoscopy; there was no procedure-related mortality and a 2% complication rate.

Open lung biopsy an ideal indication for video-assisted surgery. Unlike traditional small anterior thoracotomy and classic lung biopsy, in which sampling is limited, with video-assisted biopsy any segment of any lobe of the lung in which disease has been identified can easily be sampled to make a definitive diagnosis. Small peripheral subpleural lung nodules up to approximately 2 cm in diameter can be resected for diagnosis by means of video-assisted surgery. The expected diagnostic yield with video-assisted open lung biopsy should equal or even exceed that of the standard open procedure. Other specific diagnostic and therapeutic applications of video-assisted thoracic surgery include biopsy of aortopulmonary and other mediastinal nodes; excisional biopsy of a variety of benign and malignant masses of the lung, chest wall, and mediastinum; biopsy and excision of bronchial, pericardial, and mediastinal cysts; evaluation and treatment of recurrent pneumothorax; thoracic sympathectomy; pericardial biopsy and excision; and even lobectomies in selected cases.

Despite the fact that video-assisted thoracic surgery is somewhat more difficult and tedious to perform than surgery done through a traditional open thoracotomy incision, the benefits of lessened postoperative pain, a shortened hospital stay, and quicker recovery have led to increasing use of the technique. As the technology advances, one can expect that the future will bring new diagnostic and therapeutic indications for video-assisted thoracic surgical techniques.

PULMONARY ANGIOSCOPY

Pulmonary vascular diseases present diagnostic dilemmas for which diagnostic and treatment modalities are limited. Direct visualization of vascular structures has been investigated and shows promise for expanding diagnostic capabilities.

The equipment is based on traditional endoscopic designs, except that the fiber bundle is narrow (outer diameter of 2.8 mm) and long (120 cm). Although blood in the peripheral vascular bed and in the very small coronary arterial bed can be flushed from the field of view intraoperatively, visualization in the much larger pulmonary arterial bed is best achieved using an inflatable balloon over the lens to displace blood mechanically from the area to be viewed.

The procedure is very similar to catheterization of the right side of the heart. The angioscope is passed through an introducing catheter, usually in the internal jugular vein, and directed into the right side of the heart and pulmonary arteries using direct visualization and fluoroscopy. The balloon can be inflated or deflated as needed, and distal tip deflection facilitates accurate movement of the angioscope into areas of interest.

Animal studies have established the diagnostic accuracy of angioscopy in detecting acute pulmonary emboli and the hemodynamic safety of the procedure. Safety has been confirmed in subsequent human trials.

To date, angioscopy has been applied to the diagnosis of chronic pulmonary hypertension, particularly to distinguish chronic thromboembolic pulmonary hypertension from other causes of chronic vascular obstruction and hypertension. Chronic thromboembolic pulmonary hypertension was chosen as the initial area of investigation because of significant problems with standard techniques, such as angiography, in establishing the diagnosis or determining operability.

Distinctive endoscopic features of chronic pulmonary emboli can be identified by angioscopy. These include roughening of the intimal lining, presence of bands and webs, irregular vessel contour, vascular obstruction by fibrotic masses of organized emboli, and partial recanalization. Abnormalities associated with other diseases can also be identified, such as atherosclerotic plaques, extrinsic vessel compression, and tumor. Perhaps most importantly, angioscopy has proved useful in determining the proximal extent of the chronic thromboembolic process and is therefore useful in assessing operability, a key issue in this patient population.

With this foundation established in an unusual disease entity, future clinical trials may focus on the more common problem of acute pulmonary emboli, to evaluate the role of angioscopy in relation to lung scanning and angiography. Applications in valvular heart disease will also be an area for future exploration.

CHAPTER

12 Pleural Anatomy, Physiology, and Diagnostic Procedures

Steven A. Sahn

S. A. Sahn: Division of Pulmonary and Critical Care Medicine, Medical University of South Carolina, Charleston, South Carolina 29425.

ANATOMY

The pleural space is real, approximately 10 to 20 μm in width and situated between the mesothelium of the parietal and visceral pleurae. The parietal and visceral pleurae are continuous at the hilum, where they are penetrated by the pulmonary and bronchial vessels and the two main bronchi with their accompanying nerves and lymphatic vessels. The areas of the two pleural surfaces are approximately equal (2000 cm^2 in a person weighing 70 kg) if the interlobar fissures of the visceral pleura and the costophrenic recesses of the parietal pleura are included. Both the visceral and parietal pleurae consist of a single layer of pleomorphic mesothelial cells, a basement membrane, and layers of collagen and elastic tissue in addition to the microvessels and lymphatics.

The mesothelial cells vary in shape from flattened with an elongated nucleus and minimally discernible cytoplasm to cuboidal or columnar with a round nucleus and an indistinct luminal surface. Despite differences in morphology, mesothelial cells remain a single layer at all sites. Mesothelial cells vary in thickness from 1 to 4 μm and in surface diameter from 16 to 40 μm. Mesothelial cells contain surface microvilli that are approximately 0.1 μm in diameter and up to 3 μm in length. The density of microvilli is higher on the visceral than on the parietal mesothelial cells, possibly to trap hyaluronic acid-rich glycoprotein, particularly in the lower portion of the thorax, to decrease friction between the lung and chest wall.

Openings between mesothelial cells, called *stomata,* range in size from 2 to 12 μm and are found only on the parietal pleural surface by scanning electron microscopy. These stomata communicate directly with lymphatic lacunae, the roofs of which contain bundles of collagen. Stomata are the usual exit point for pleural liquid, protein, and cells that are removed from the pleural space.

In humans, the visceral pleura is supplied by branches of the bronchial circulation. The venous return from the subpleural capillaries drains largely into the pulmonary veins. The human parietal pleura is supplied by branches of the arteries that flow to the adjacent chest wall. The costal pleura is supplied by branches of the intercostal and internal mammary arteries; the mediastinal parietal pleura by branches of the bronchial and upper diaphragmatic, internal mammary, and mediastinal arteries; and the apical pleura by branches of the subclavian artery. The venous system of the parietal pleura drains into the bronchial veins. The diaphragmatic pleura is supplied by branches of the internal mammary artery, thoracic and abdominal aorta, and celiac arteries; drainage is into the inferior vena cava and brachiocephalic trunk.

The lymph drainage of the pleural space has a major impact on the accumulation of pleural fluid in normal and disease states. Lymphatic drainage of the pleural space begins at the stomata that are located mainly in the mediastinum caudally and on the intercostal and diaphragmatic pleurae. The stomata connect with lymphatic lacunae situated immediately below the mesothelial layer and appear to be closed at their end by the endothelium of lymphatics to form valves. The lymphatic lacunae drain into larger lymphatic channels that course along the intercostal space and drain into the mediastinum. The origin of lymphatic vessels in the parietal pleura determines the node into which the fluid drains. The pleura of the anterior thoracic wall and anterior portion of the diaphragm drains to the sternal lymph nodes; the middle portion of the diaphragmatic pleura drains to the middle mediastinal lymph nodes; the anterior portion of the diaphragmatic and mediastinal pleura drains into the anterior mediastinal lymph nodes; the posterior portion of the diaphragmatic pleura drains to the posterior mediastinal lymph nodes; and the costal parietal pleura drains to the intercostal lymph nodes. The majority of the visceral pleura drains to the middle mediastinal lymph nodes, whereas the visceral pleural drainage of the lower lobes flows into the posterior mediastinal lymph nodes.

PHYSIOLOGY

Most of what is known about normal pleural fluid turnover is derived from noninvasive studies of pleural fluid formation in the sheep, an animal with a pleural anatomy similar to that of humans. The assumption is made that in the steady-state condition, pleural fluid absorption is equivalent to pleural fluid formation. The normal pleural fluid-to-plasma protein ratio is approximately 0.15, and the pleural fluid volume is about 0.1 to 0.2 mL/kg. Studies from sheep show that pleural fluid is formed at an hourly rate of 0.01 mL/kg, the equivalent of 0.6 mL/h in a 60-kg person.

Pleural fluid is essentially an ultrafiltrate of the systemic pleural microvessels. Because the parietal pleural microvessels are closer to the pleural space than are the visceral pleural microvessels, the interstitial fluid in the parietal pleura moves between mesothelial cells into the pleural space along a pressure gradient; most or all of the interstitial liquid that moves out of the visceral pleural microvessels is removed by lung lymphatics because the fluid would have to travel a greater distance to enter the pleural space. Therefore, in normal humans, the parietal pleura is responsible for most or all pleural fluid formation. Pleural fluid exits the pleural space via the lymphatic stomata of the parietal pleura. Most pleural fluid exits the pleural space by bulk flow, not by diffusion. In addition to the pleural liquid being removed through the stomata, cells and protein exit by this route. The lymphatic flow from the pleural space is influenced by both the contractility of the lymph vessels and respiratory movements. The circulation of fluid in the pleural space enabling liquid to move into stomata may be driven by respiratory movements.

The lymphatic drainage of the pleural space appears to have a large reserve, so that when an abnormal amount of pleural fluid accumulates in disease states, it must represent increased formation, decreased absorption, or both. Most probably both mechanisms contribute to pleural fluid formation. An increase in pleural fluid formation is unlikely to cause a pleural effusion clinically, as the pleural lymphatics have an extensive reserve to handle excess fluid formation. Furthermore, a decrease in pleural fluid absorption is unlikely to cause a pleural effusion clinically because the normal entry rate is slow.

Mechanisms of increased formation of pleural fluid include the following: (1) an increase in microvascular pressure (as occurs in congestive heart failure); (2) a decrease in pleural pressure (as in atelectasis), which decreases the pressure surrounding the nearby microvessels and increases the gradient of pressures driving fluid across the microvascular barrier; and (3) a decrease in plasma oncotic pressure (as in hypoalbuminemia), which increases the forces for filtration until the balance is restored.

When the lymphatic system is involved by disease at any point from the stomata of the parietal pleura to the mediastinal lymph nodes, a decrease in absorption rate can occur. Factors that may affect lymphatic flow include the following: (1) inhibition of lymphatic contractility during infiltration by malignancy or anatomic abnormalities (as in yellow nail syndrome); (2) limitation of respiratory movement (as in lung collapse); (3) blockage of lymphatic stoma by malignancy or fibrin; (4) acute increases in systemic venous pressure; and (5) decreased fluid availability to the stoma after pneumothorax.

Pleural fluid can form when fluid moves across the diaphragm from the peritoneal cavity, either because of congenital diaphragmatic defects or by convection across the two mesothelial layers. Inflammation may also be a factor, as in acute pancreatitis and increased pleural capillary filtration. There is no evidence for the existence of direct lymphatic channels connecting the peritoneal and pleural spaces across the diaphragm. Lastly, mediastinal inflammation, as seen in esophageal sclerotherapy and esophageal perforation, can lead to a pleural effusion. When fluid from a pancreatic pseudocyst or rupture of the thoracic duct (chyle) collects in the mediastinum, a pleural effusion can form when the mediastinal pleura ruptures.

DIAGNOSTIC PROCEDURES

Thoracentesis

Diagnostic Yield

The discovery of a pleural effusion provides an opportunity for the clinician to verify the disease, procedure, or drug that has caused the effusion. With a simple bedside procedure, thoracentesis, the fluid can be rapidly sampled and observed, its constituents observed microscopically, and its contents quantified. A comprehensive and systematic approach to analysis of pleural fluid in conjunction with the clinical presentation should allow the clinician to diagnose the cause of a pleural effusion in 75% of cases. A definitive diagnosis, such as the finding of malignant cells or specific organisms in pleural fluid, can be established in only one of four patients; however, a presumptive diagnosis, based on a clinical impression before thoracentesis, can be substantiated by pleural fluid analysis in an additional 50% of patients. Even with a nondiagnostic thoracentesis, pleural fluid analysis can be useful in excluding other possible causes of a pleural effusion, such as infection. Therefore, in three of four patients the cause of an effusion can be “diagnosed,” and in >90% of patients information relevant to clinical decision making can be gained by pleural fluid analysis.

Indications and Contraindications

When a pleural effusion is suspected on physical examination and confirmed radiographically, a diagnostic thoracentesis should be performed in an attempt to establish the cause of the effusion. If the clinical diagnosis (e.g., uncomplicated congestive heart failure) is secure, it is reasonable to observe the patient's response to therapy and proceed with thoracentesis only when the clinical response is not appropriate. There are no absolute contraindications to diagnostic thoracentesis. Relative contraindications include a bleeding diathesis, anticoagulation, a small volume of pleural fluid, and mechanical ventilation. The needle should never be passed through an area of active skin infection. The patient on mechanical ventilation is not at increased risk for pneumothorax when undergoing thoracentesis, but tension pneumothorax is more likely to develop if the lung is punctured.

Technique

Diagnostic thoracentesis should be a simple and rapid procedure for the operator and impose minimal discomfort on the patient. Patient anxiety can be minimized greatly if the procedure is explained completely at the time informed consent is obtained. It is rarely necessary to administer atropine, narcotics, or sedative drugs for a diagnostic thoracentesis.

The selection of the site for thoracentesis is critical to a successful outcome. A chest radiograph should be available in the procedure room for review before site selection. The physical examination should dictate the precise placement of needle insertion. The site should be one to two interspaces below the level where the percussion note becomes flat and tactile fremitus decreases. With a free-flowing effusion, an area midway between the spine and the posterior axillary line should be selected, as the ribs are easily palpated in this location. When the interspace is selected, the needle should be passed over the superior surface of the rib to avoid possible laceration of the neurovascular bundle, which courses near the inferior rib margin. This is especially applicable in elderly patients, who tend to have tortuous intercostal arteries that may impinge on the intercostal space, so that the risk for laceration is increased. If the fluid is loculated or small, as demonstrated by decubitus radiographs, thoracentesis should be done under ultrasonic guidance. Thoracentesis should be performed with the patient positioned exactly as during ultrasonography.

Good technique minimizes complications. The operator should maintain appropriate sterile technique and clean a wide area around the site selected for needle puncture. A 10% povidone-iodine solution decreases the usual cutaneous bacterial population by 85% for about 1 hour. The quaternary ammonium compounds, such as benzalkonium chloride, have a rapid onset of action, but their activity is antagonized by soaps and tissue constituents, and when these compounds are applied to the skin, they tend to form a film under which bacteria may remain viable. Furthermore, these compounds do not kill spores and require more than 5 minutes to decrease the bacterial population by 50%. The normal pleural space appears to have effective mechanisms for clearing bacteria; however, patients with severe pleural injury or immunosuppression probably are at increased risk for iatrogenic empyema if careful aseptic technique is not maintained.

If the skin, periosteum of the rib, and parietal pleura are properly injected with lidocaine, the patient should have minimal pain, similar to the discomfort associated with venipuncture. When pleural fluid is obtained by aspirating with the syringe containing lidocaine, the syringe and needle should be withdrawn and a 22-gauge needle, 1 1/2 inches long and attached to a 50-mL syringe, should be used along the same tract to obtain fluid for diagnostic evaluation. One milliliter of heparin (1:1000) should be added to prevent clotting of the fluid.

Occasionally the thoracentesis will be “dry.” This may result from the absence of pleural fluid, incorrect needle placement, or a needle of inappropriate length. If air is obtained in the syringe, the lung has been punctured because the needle was placed superiorly to the effusion. If no air, or possibly blood, is obtained, the needle may have been inserted too inferiorly or been too short for an obese patient. If there are no adverse consequences of this misadventure, then appropriate adjustment of the technique usually results in a successful procedure. A longer needle should be used in a patient who is markedly obese.

Fifty milliliters of fluid is all that is necessary for complete pleural fluid analysis. The tests requested should be based on the clinical presentation. It is not clinically efficacious or cost-effective to request an entire battery of pleural fluid tests. It is probably cost-effective and clinically efficacious to order the following tests for all patients who undergo a diagnostic thoracentesis: total protein, lactate dehydrogenase (LDH), nucleated cell count and differential, and either a glucose or pH determination. Concomitant serum protein, LDH, and glucose levels should be measured; arterial pH should be measured if the pleural fluid pH is below 7.30 and acidemia is suspected. The aforementioned tests provide information that allows characterization of the fluid as a transudate or an exudate, narrows the differential diagnosis of an exudate, and indicates the degree of pleural inflammation and the acuteness of pleural injury. Gram, acid-fast bacilli (AFB), and potassium hydroxide (KOH) stains should be performed and pleural fluid cultured when infection is suspected. Pleural fluid cytology should be requested when malignancy is suspected or if an exudate is undiagnosed; lipid studies should be ordered when the fluid is milky, and immunologic studies should be performed if rheumatoid or lupus pleuritis is suspected. Amylase concentration should be measured when pancreatitis, pancreatic pseudocyst, esophageal rupture, or malignancy is considered.

Complications

Complications of diagnostic thoracentesis include pain at the needle insertion site, bleeding (local, intrapleural, or intra-abdominal), pneumothorax, empyema, and spleen or liver puncture. Pneumothorax is the most common clinically important complication of diagnostic thoracentesis and has been reported to occur in up to 10% of patients. The rate of pneumothorax correlates indirectly with operator experience. However, the pneumothorax usually is small and often can be treated expectantly. Liver or spleen puncture tends to occur when the patient is not sitting absolutely upright, because movement toward a recumbent position causes cephalad migration of the abdominal viscera. However, even if the liver or spleen is punctured with a small-bore needle, generally the outcome is favorable if the patient is not receiving anticoagulants and does not have a bleeding diathesis.

Pleural Fluid Analysis

Definitive Diagnosis

There are only a select number of diagnoses or causes of the effusion that can be established definitively by thoracentesis. These include malignancy, empyema, tuberculous pleurisy, fungal infection of the pleural space, lupus pleuritis, chylothorax, urinothorax, esophageal rupture, hemothorax, peritoneal dialysis, and extravascular migration of a central venous catheter (Table 1). Confirming the diagnosis of chylothorax does not establish the cause but provides evidence that the thoracic duct has been violated; lymphoma is the cause in >50% of cases. Esophageal rupture is the single entity associated with a pleural fluid having a high amylase concentration and a pH of <7.00. A pancreatic pleural effusion is associated with a high amylase concentration but the pH is virtually always >7.30. Some malignant pleural effusions have high amylase concentrations and the pH is >7.30 in two thirds of these patients; when the pH is low in malignant effusions, it rarely is <7.05. Empyema, tuberculous pleurisy, rheumatoid disease, and lupus pleuritis can all be associated with a low pleural fluid pH (<7.30), but the pleural fluid amylase concentration is less than the concomitant serum value. With extravascular migration of a central venous catheter, the resultant pleural effusion can be similar to the infusate and may be hemorrhagic and neutrophil-predominant because of trauma and inflammation. The pleural fluid-to-serum glucose ratio is >1.0; however, the pleural fluid glucose level is usually lower than that of the infusate, as glucose is transported rapidly from the pleural space.

Disease	Diagnostic pleural fluid tests
Empyema	Observation (pus, putrid odor); culture
Malignancy	Positive cytology
Lupus pleuritis	LE cells present
Tuberculous pleurisy	Positive AFB stain, culture
Esophageal rupture	High level of salivary amylase; pleural fluid acidosis (pH < 7.00)
Fungal pleurisy	Positive KOH stain, culture
Chylothorax	Triglycerides (>110 mg/dL); lipoprotein electrophoresis positive for chylomicrons
Hemothorax	Hematocrit (pleural fluid/blood ratio >0.5)
Urinothorax	Creatinine (pleural fluid/serum ratio >1.0)
Peritoneal dialysis	Protein (<1 g/dL); glucose (300–400 mg/dL)
Extravascular migration of a central venous catheter	Observation (milky if lipids are infused); glucose pleural fluid/serum >1.0
Rheumatoid pleurisy	Characteristic cytology; pH 7.00; glucose <30 mg/dL; LDH > 1000 IU/L

TABLE 1. *Diagnoses or causes that can be established definitively by pleural fluid analysis*

Diagnostic Clues at the Bedside

Diagnostic clues can be obtained by gross inspection of the pleural fluid as it is being aspirated from the patient's chest (Table 2). A straw-colored fluid is typical of all transudates and minimally inflammatory exudative effusions, such as those seen in early malignancy, tuberculous pleurisy, and yellow nail syndrome. A bloody fluid in the absence of trauma suggests either malignancy, benign asbestos pleural effusion (BAPE), postcardiac injury syndrome (PCIS), or pulmonary infarction. A milky effusion suggests chylothorax but can be caused by a chyliform effusion (a lipid effusion that is not chyle with or without a high cholesterol level) or an empyema. Chylothorax signifies leakage of chyle from the thoracic duct, and the pleural fluid virtually always has a triglyceride concentration of >110 mg/dL; a triglyceride concentration of <50 mg/dL virtually excludes chylothorax. A chyliform effusion occurs in chronic pleural disease and is usually associated with a trapped lung, rheumatoid pleurisy, or tuberculous pleurisy, or is the result of pneumothorax therapy for tuberculosis. The diagnosis of a chyliform (cholesterol) effusion can be established by identifying cholesterol crystals on smears of the sediment; these rhomboid-shaped structures impart a lustrous sheen to the pleural fluid. Some chyliform effusions have high triglyceride levels; to differentiate between a chylothorax and a chyliform effusion that does not demonstrate cholesterol crystals, or if the triglyceride concentration is between 50 and 110 mg/dL, a lipoprotein electrophoresis should be performed to evaluate for the presence of chylomicrons, which are diagnostic for chylothorax.

Feature	Suggested diagnosis
Color	
Pale yellow (straw)	Transudate, some exudates
Red (bloody)	Malignancy, BAPE, PCIS, pulmonary infarction, trauma
White (milky)	Chylothorax or cholesterol effusion
Brown	Long-standing bloody effusion; rupture of amebic liver abscess
Black	Aspergillus
Yellow-green	Rheumatoid pleurisy
Color of enteral tube feeding	Feeding tube has entered pleural space
Color of central venous line infusate	Extravascular catheter migration
Character	
Pus	Empyema
Viscous	Mesothelioma
Debris	Rheumatoid pleurisy
Turbid	Inflammatory exudate or lipid effusion
"Anchovy paste"	Ruptured amebic liver abscess
Odor	
Putrid	Anaerobic empyema
Ammonia	Urinothorax

BAPE, benign asbestos pleural effusion; PCIS, postcardiac injury syndrome.

TABLE 2. *Diagnoses suggested by observations of pleural fluid*

When an amebic liver abscess ruptures into the pleural space, it produces an “anchovy paste”–like pleural aspirate that is a mixture of liver tissue that has undergone cytolysis, small pieces of liver parenchyma, and blood. The effusion is almost always right-sided. Amebae can be demonstrated in pleural fluid in <10% of patients. In patients with rheumatoid pleurisy, the fluid may have a yellowish-green tint or may appear to contain debris that results from exfoliation of necrotic visceral pleural rheumatoid nodules.

When fluid the color of the enteral feeding is aspirated from the pleural space, it confirms that a narrow-bore enteral feeding tube has passed through the tracheobronchial tree and into the pleural space. When the pleural fluid is similar to the infusate in a central venous line, extravascular catheter migration, which is most commonly associated with left-sided catheter placements through the jugular veins, has occurred. A viscous effusion suggests malignant mesothelioma because of the high levels of hyaluronic acid. A putrid odor is diagnostic of an anaerobic empyema, and the smell of ammonia suggests ipsilateral obstruction uropathy producing a urinothorax.

Transudates and Exudates

The characterization of pleural fluid as a transudate or an exudate is the next deductive step in pleural fluid analysis following observation of the aspirate. Transudates, largely because of imbalances in hydrostatic and oncotic pressures in the chest, can also result from movement of fluid from the peritoneal (cirrhosis) or retroperitoneal (urinothorax) spaces, or from iatrogenic causes, such as crystalloid infusion into a central line that has migrated extravascularly. Nevertheless, the diagnostic possibilities with a transudate are limited, and the diagnosis can usually be easily determined from the clinical presentation (Table 3).

Cause	Comment
Effusion virtually always transudative	
Congestive heart failure	Acute diuresis can result in pseudoexudate
Cirrhosis	Rare without clinical ascites
Nephrotic syndrome	Usually subpulmonic and bilateral
Peritoneal dialysis	Massive effusion develops within 48 hours of initiating dialysis
Hypoalbuminemia	Edema fluid rarely isolated to pleural space
Urinothorax	Caused by ipsilateral obstructive uropathy
Atelectasis	Caused by increased intrapleural negative pressure; common in ICU setting
Constrictive pericarditis	Bilateral effusions
Trapped lung	Result of remote inflammation
Superior vena caval obstruction	Caused by acute systemic venous hypertension or acute blockage of thoracic lymph flow
"Classic exudates" that can be transudates	
Malignancy	Caused by early lymphatic obstruction, obstructive atelectasis, or concomitant disease
Pulmonary embolism	Incidence of 23%; caused by atelectasis
Sarcoidosis	Stage II and III disease
Hypothyroid pleural effusion	Transudates secondary to hypothyroid heart disease

TABLE 3. *Causes of transudative pleural effusions*

In contrast, exudative effusions can be caused by a variety of diseases and present more of a diagnostic dilemma. Exudates result primarily from pleural and lung inflammation (pneumonia) or impaired lymphatic drainage of the pleural space (malignancy), and these in turn represent a capillary protein leak or decreased protein removal from the pleural space, respectively. Exudates can also result from the movement of fluid from the peritoneal space, as seen in acute or chronic pancreatis, chylous ascites, and peritoneal carcinomatosis. Disease in virtually any organ can cause exudative pleural effusions through a variety of mechanisms, including infection, malignancy, immunologic responses, lymphatic abnormalities, noninfectious inflammation, iatrogenic causes, and movement from below the diaphragm (Table 4).

TABLE 4. *Causes of exudative pleural effusions*

The most practical method of distinguishing between transudates and exudates is measurement of serum and pleural fluid protein and LDH concentrations. If at least one of the following criteria is met, the fluid is virtually always an exudate, and if none is met, the fluid is virtually always a transudate: (1) pleural fluid protein-to-serum protein ratio of >0.5; (2) pleural fluid LDH-to-serum LDH ratio of >0.6; and (3) pleural fluid LDH >67% of the upper limits of normal for the serum LDH. Recent data using receiver operating characteristics (ROC) analysis suggest that an LDH concentration of 160 IU/L is the ideal cutoff point to separate transudates and exudates. Pleural fluid cholesterol appears to be a relatively good differentiating marker, with a level of 60 mg/dL as a cutoff; virtually all effusions with cholesterol levels of <60 mg/dL are transudative, and up to 10% of exudates have cholesterol levels of <60 mg/dL.

Transudates have characteristic, but not diagnostic, cellular and biochemical characteristics that support their noninflammatory pathogenesis. These effusions are usually straw-colored, nonviscous, and odorless. In approximately 80% of cases, the nucleated cell count is <1000/μL; it is rare to find a transudative effusion with a nucleated cell count of >10,000/μL. Eighty-five percent of transudative effusions have red blood cell counts of up to 10,000/μL, so the clinician cannot conclude that a serosanguinous effusion is not a transudate. Furthermore, serosanguinous transudative effusions do not become pseudoexudates by LDH criteria, possibly because extensive pleural space hemolysis would be required to affect pleural fluid LDH. Transudative effusions, because of their noninflammatory nature, are mononuclear-predominant and composed of lymphocytes, mesothelial cells, and monocytes-macrophages; it is extremely unusual for classic transudates to be neutrophil-predominant, and if found, this should suggest dual diagnoses. A low pleural fluid glucose level is not found in transudative effusions, and the pleural fluid pH is alkaline (with the exception of urinothorax) and exceeds the simultaneously obtained blood pH, usually in the range of 7.45 to 7.55.

In the acute stages of an exudate, the inflammatory response produces pleural fluid with high nucleated cell counts and a predominance of neutrophils. In the subacute or chronic stages, the exudative effusions may have low cell counts of <5000/μL with a predominance of mononuclear cells, usually lymphocytes.

Pleural Fluid Cells

The nucleated cell count in pleural fluid is virtually never diagnostic; however, counts of >50,000/μL usually are found only in parapneumonic effusions, usually empyema. Transudates generally are associated with nucleated cell counts of <1000/μL, and chronic exudates, as in malignancy and tuberculosis, with counts of <5000/μL. Patients with pleural fluid nucleated cell counts of >10,000/μL generally have substantial pleural inflammation, as can occur with pneumonia, pancreatitis, PCIS, and pulmonary infarction. When pleural fluid is grossly purulent, the nucleated cell count often is less than anticipated, because lysis of neutrophils has occurred and the debris from these cells, in addition to fibrin and collagen, causes turbidity and purulence of the fluid.

The timing of thoracentesis in relation to the acute pleural injury determines the predominant cell in the exudate. Acute exudative pleural effusions are neutrophil-predominant. As the time from the acute insult to performance of thoracentesis lengthens, the effusion becomes mononuclear-predominant if pleural injury is not persistent. Diseases in which the patient is examined soon after the onset of symptoms, such as pneumonia, pulmonary embolism, and pancreatitis, usually are associated with neutrophil-predominant effusions.

Pleural fluid lymphocytosis, particularly lymphocyte counts of 85%–90%, suggests tuberculous pleurisy. However, lymphoma, sarcoidosis, and chronic rheumatoid pleurisy should be considered in the proper clinical setting. Carcinomatous pleural effusions have >50% lymphocytes in two thirds of cases. As the aforementioned diseases can be diagnosed by closed pleural biopsy, the presence of an unknown exudate and lymphocytosis is the prime indication for pleural biopsy. Approximately a third of patients with transudative pleural effusions have a predominance of lymphocytes; however, this finding is of no clinical relevance and does not indicate the need for pleural biopsy.

Pleural fluid eosinophilia (>10% of total nucleated cells are eosinophils) suggests a benign, self-limited pleural effusion associated with air or blood in the pleural space. Therefore, it is commonly seen following pleural space hemorrhage, pulmonary infarction, pneumothorax, or BAPE, or after thoracentesis. Pleural fluid eosinophilia is rare but not unknown in tuberculous pleurisy and is unusual with a malignant pleural effusion despite the high incidence of pleural space hemorrhage. When air or blood is not present with pleural fluid eosinophilia, parasitic disease (paragonimiasis, hydatid disease), fungal infection (histoplasmosis), and drugs (dantrolene, nitrofurantoin) should be considered. Approximately one third of eosinophilic pleural effusions are idiopathic; many of these effusions are probably caused by occult pulmonary embolism or BAPE, as these effusions are frequently bloody. Pleural fluid basophilia (>10% of total nucleated cells are basophils) is rare and suggests leukemic involvement of the pleura.

Mesothelial cells are predominant in transudative pleural effusions and are found to a variable degree in exudates. The presence of mesothelial cells in exudates is important, because if >5% of cells are mesothelial cells, tuberculous pleurisy is virtually excluded, and they may be confused with malignant cells. Mesothelial cells are scarce in the pleural space when there is diffuse pleural injury or fibrosis inhibiting exfoliation; this has been noted with empyema, rheumatoid pleurisy, after pleurodesis, and in chronic malignant effusions.

The pleural fluid macrophage has its origin in the circulating blood monocyte. The macrophage appears to modulate pleural injury and is called to the pleural space by pleural fluid neutrophil chemotaxins. The presence of macrophages is of no diagnostic value, but it is important not to confuse these cells with mesothelial cells, as the presence of macrophages does not exclude tuberculous pleurisy.

Finding a large number of plasma cells in pleural fluid suggests multiple myeloma with pleural involvement. A small number of plasma cells is nondiagnostic and has been observed in a spectrum of diseases ranging from congestive heart failure to malignancy.

The presence of blood-tinged pleural fluid is of minimal diagnostic value, as only a few drops of blood in 500 mL of fluid will result in hemorrhagic fluid. Up to 50% of exudates and 10%–15% of transudates may be sanguineous. The finding of more than 100,000 red blood cells per microliter suggests that the exudate is caused by trauma, malignancy, pulmonary embolism, PCIS, or BAPE. In the absence of trauma, malignancy is the most common cause of a frankly bloody pleural effusion. Determining whether the bloody effusion is real or caused by a traumatic thoracentesis frequently poses a dilemma. A traumatic thoracentesis is suggested by nonuniform color during aspiration, clotting of the fluid within several minutes, and the absence of hemosiderin-laden macrophages.

Pleural Fluid Chemistries

A low pleural fluid glucose concentration (<60 mg/dL, or pleural fluid-to-serum ratio of <0.5) narrows the differential diagnosis of the exudate to rheumatoid pleurisy, empyema, malignant effusions, tuberculous pleurisy, lupus pleuritis, and esophageal rupture. The mechanisms responsible for a low pleural fluid glucose concentration include decreased transport of glucose from blood to pleural fluid (malignancy, rheumatoid pleurisy) and increased glucose utilization by constituents of pleural fluid (empyema, malignancy). The lowest glucose concentrations are found in empyema and rheumatoid pleural effusions, with glucose being undetectable at times. In tuberculous pleurisy, lupus pleuritis, and malignancy, the glucose concentration when low is generally in the range of 30 to 55 mg/dL.

A pleural fluid pH of <7.30 with a normal blood pH is found in the same conditions associated with a low pleural fluid glucose concentration. Pleural fluid acidosis has been found with esophageal rupture (pH of 6.00), empyema (5.50–7.29), rheumatoid pleurisy (7.00), malignancy (7.05–7.29), and lupus pleuritis (7.05–7.29). The mechanisms responsible for pleural fluid acidosis are increased acid production by pleural fluid cells and bacteria (empyema), and decreased acid efflux from the pleural space because of pleuritis or pleural fibrosis (malignancy and rheumatoid pleurisy). A low pleural fluid pH has diagnostic, prognostic, and therapeutic implications in malignancy and parapneumonic effusions. In parapneumonic effusions, a pleural fluid pH of <7.10 suggests the need for chest tube drainage. In malignant pleural effusions, a pH value of <7.30 predicts a short survival time, an increased yield on pleural biopsy and cytology, and a poor response to pleurodesis.

An increased pleural fluid amylase concentration (above the upper limits of normal for serum, or a pleural fluid-to-serum ratio of >1.0) indicates one of four diagnostic

possibilities: (1) acute pancreatitis, (2) pancreatic pseudocyst, (3) esophageal rupture, and (4) malignancy.

In addition to fulfilling one of the criteria defining an exudate, a high LDH level (>1000 IU/L) suggests empyema, rheumatoid pleurisy, or paragonimiasis involving the pleural space.

Immunologic Studies

A pleural fluid rheumatoid factor titer of 1:320 or higher is suggestive but not diagnostic of rheumatoid pleurisy. The finding of LE cells in pleural fluid is virtually diagnostic of lupus pleuritis. The likelihood of demonstrating LE cells in pleural fluid appears to be enhanced if the fluid is allowed to remain at room temperature for several hours before it is examined with Wright stain. An antinuclear antibody (ANA) titer of 1:160 or higher or a pleural fluid-to-serum ANA ratio of 1.0 or greater is suggestive but not diagnostic of lupus pleuritis. Pleural fluid complement levels are low in most patients with lupus pleuritis and rheumatoid pleurisy; this is true whether total hemolytic complement or complement components are measured.

Cytology

Cytology is a more sensitive test for the diagnosis of malignant pleural effusions than is percutaneous pleural biopsy, because pleural metastases tend to be focal and the latter is a blind sampling procedure. The yield of cytology increases as the disease becomes more advanced. With improved techniques, the yield from exfoliative cytology now approaches 90%–95%. If the clinician suspects a malignant effusion, several hundred milliliters of fluid should be removed at the initial diagnostic thoracentesis. This maneuver will not improve the yield on the initial study, but if the results are negative, a repeated procedure several days later may provide fluid with fewer degenerative cells and freshly exfoliated malignant cells. If the results of a second cytologic examination several days after the first are negative, a third examination soon after usually is nondiagnostic. Reasons for a true negative cytologic examination include improper handling of the specimen, variance of tumor type, and lack of interest and expertise of the cytopathologist.

Pleural Biopsy

Several techniques for percutaneous pleural biopsy have been available since the 1920s, but not until the 1950s, with the popularization of the Cope and Abrams needles, did routine bedside pleural biopsy become available to the clinician.

Percutaneous pleural biopsy is a simple bedside or outpatient procedure whose main indication is the evaluation of exudative effusions of unknown cause. The two diagnoses most commonly established by pleural biopsy are malignancy and tuberculosis. The diagnosis of rheumatoid pleurisy, fungal pleurisy (coccidioidomycosis, blastomycosis), sarcoidosis, and parasitic diseases, such as echinococcosis) also can be confirmed by pleural biopsy. Culturing *Coccidioides* from pleural tissue appears to be an excellent method of establishing the diagnosis of acute coccidioidal pleural effusion.

Demonstration of free-flowing fluid in the pleural space is imperative if complications are to be minimized. If doubt exists, confirmation before biopsy of fluid location by ultrasonography is recommended. The presence of pleural fluid is not a prerequisite for percutaneous pleural biopsy; if pleural symphysis does not exist, allowing air to enter the pleural space will separate the lung from the chest wall and allow the biopsy to be performed safely. If loculated pleural fluid is present, the biopsy should be done under ultrasonic guidance.

Contraindications to pleural biopsy include (1) pleural symphysis; (2) an uncooperative patient; (3) anticoagulation; (4) a bleeding diathesis, including moderate to severe azotemia, when a normal bleeding time cannot be ensured; (5) empyema; and (6) local cutaneous lesions (herpes zoster, pyoderma).

Technique

Proper positioning of the patient is important for any invasive procedure but particularly for pleural biopsy. The patient should be seated leaning backward in a chair with arms resting against the backrest or on a table to allow optimal patient comfort and ease of access of the operator to the posterior chest wall. Vasovagal episodes during pleural sampling are not uncommon in anxious patients; proper preparation of the patient, adequate local anesthesia, and preoperative administration of atropine virtually eliminate this complication.

A biopsy site should be chosen one to two intercostal spaces below the fluid level demonstrated on physical examination. Appropriate anesthesia of the parietal pleura and periosteum of the rib provides maximal patient comfort and cooperation. A skin incision parallel to the ribs with a No. 11 blade facilitates entrance to the pleural space of the 11-gauge outer cannula just above the superior border of the rib. When the outer cannula enters the pleural space, a characteristic pop is felt. After fluid is aspirated through the trocar, pressure is applied in the direction of the cutting needle, allowing the parietal pleura to be snagged. Several biopsy specimens should be obtained by rotating the trocar and cutting needle to different locations, with care taken to avoid the intercostal neurovascular bundle, which is more likely to be encountered with extreme cephalic or caudal angulation. The tissue is cut from the parietal pleura by advancing with a twisting motion (Cope needle) or rotating the inner cutting needle (Abrams needle). Three to five specimens should be taken from a single site. The pleural tissue should be placed in 10% formaldehyde for histologic examination and in sterile nonbacteriostatic saline solution for culture. If malignancy is the suspected diagnosis, only a single specimen needs to be cultured. If tuberculosis is likely, the specimen should be divided evenly between histology and culture.

Diagnostic Yield

The literature reports a wide range of diagnostic yields, from 30%–70% in patients with malignancy and 60%–95% in patients with tuberculous pleurisy. Patient population, biopsy technique, and the expertise of the operator, pathologist, and microbiology laboratory account for some of the variability. In a compilation of 14 series from the literature inclusive of 2893 pleural biopsies, 51% were nondiagnostic, 245 (75%) of 325 were positive for a confirmed diagnosis of tuberculous pleurisy, and 618 (57%) of 1080 were positive with a known diagnosis of carcinoma.

Sampling error has led to controversy as to the number, location, and sites for percutaneous pleural biopsy. A paucity of data exists regarding an adequate number of individual biopsy specimens to be taken at a single site, yet there is a suggestion that four or more improve the diagnostic yield. The sampling location usually is directed by the fluid level as determined on radiologic and physical examination. Thoracoscopy has demonstrated the nonuniform location of pleural metastasis. The highest yield would be expected from specimens obtained close to the diaphragm and midline, as pleural metastases tend to begin in the former location and spread toward the costal pleura and cephalad. Increasing the number of biopsy sites at one sitting does not appear to increase the diagnostic yield in either tuberculous pleurisy or malignancy. The stage of the malignancy at the time of pleural biopsy appears to be related to the diagnostic yield; more studies are positive in patients with far-advanced disease. The diagnostic yield is also high in patients with malignancy and a low pleural fluid pH (<7.30), as in advanced disease hydrogen ion efflux from the pleural space is impaired by increased tumor bulk and pleural fibrosis.

The primary indication for percutaneous pleural biopsy today is tuberculous pleurisy, as this test provides the highest diagnostic yield. With improvement in cytologic techniques, the yield of pleural fluid exfoliated cytology approaches 95% when the pleura is involved with malignancy; therefore, pleural biopsy rarely adds to the diagnosis. However, there are instances in which results of the cytologic examination are negative and the pleural biopsy findings are positive. Therefore, if findings of the first cytologic examination are negative and malignancy is suspected, a second procedure should include repeated cytologic examination with a single-site percutaneous pleural biopsy.

Complications

Potential complications of closed-chest pleural biopsy cover a spectrum ranging from pain at the needle insertion site to empyema; however, complications are unusual and generally of minimal clinical consequence. Pneumothorax, the most common and potentially important clinical complication, usually is small and is caused by the entrance of air through the needle into the pleural space, not by lung puncture. Small pneumothoraces have been reported in up to 15% of biopsies and usually can be treated expectantly. Site pain (reported incidence of 1%–15%) can be minimized with good technique and local anesthesia. Vasovagal reaction, reported in 1%–5% of patients, can virtually be eliminated with the use of atropine. The remaining complications, including hemothorax, transient fever, tumor seeding, site hematoma, subcutaneous emphysema, air embolism, biopsy of extrapleural tissue (liver and spleen), and empyema, occur in <1% of patients.

Thoracoscopy

Jacobaeus first described an endoscopic approach to serous cavities more than 80 years ago and published his experience in lysing pleural adhesions in the treatment of tuberculosis and the diagnosis of tumors based in pleura. The previously mentioned procedures were the major indications for thoracoscopy during the next two decades. Interest in thoracoscopy waned with the development of percutaneous needles for pleural biopsy. Recently, there has been a renewed interest in thoracoscopy because of better endoscopic optic systems, improved technology of the instrument itself, and interest in less invasive procedures. Today, thoracoscopy

is used predominantly in the diagnostic evaluation of pleural effusions of unknown cause and for talc pleurodesis. Most procedures are performed using rigid thoracoscopes because of their superior optical systems, large working channels, and ease of maneuverability.

Usually, diagnostic thoracoscopy is performed under local anesthesia with small incremental doses of narcotics and a benzodiazepine. A chest tube is required after thoracoscopy. In diagnostic cases in which only the parietal pleura is sampled, a small chest tube can be used (16 to 20 French). With talc pleurodesis, a larger chest tube is placed and should remain in place until the pleural fluid drainage is <150 mL/d.

The diagnostic accuracy of thoracoscopy in pleural effusions of unknown cause varies depending on the duration of follow-up and the diagnostic methods employed, with the diagnostic accuracy in reported series ranging from 69%–96%. Although thoracoscopy is less invasive than formal thoracotomy and in certain circumstances is a better alternative than observation, it should not replace percutaneous needle biopsy. Although thoracoscopy is excellent for the diagnosis of metastatic cancer or mesothelioma, it should be unnecessary in the diagnosis of tuberculous pleurisy, as pleural biopsy culture and histology and pleural fluid culture will yield a diagnosis in the vast majority of patients. Furthermore, it is usually not helpful in the diagnosis of nonmalignant pleural disease, except to reveal the following: benign asbestos pleural plaques, which are large, white lesions that may resemble teeth; white patchy lesions of the visceral pleura with diffuse telangiectasia, seen in radiation pleuritis; a granular appearance on the pleural surface in rheumatoid pleurisy; and visceral and parietal pleural adhesions and gray-white plaques in tuberculous pleurisy.

Talc by poudrage is a highly effective method of pleurodesis for both malignant and nonmalignant pleural effusions. Talc slurry through a chest tube appears to have similar efficacy to talc poudrage and is less expensive, as the cost of thoracoscopy is avoided.

The mortality from diagnostic thoracoscopy in >4000 cases is <0.1%, comparable with the mortality of bronchoscopy with transbronchial biopsy. The potential complications, which are rare, include postoperative air leak, hemorrhage, hypotension, hypoxemia, subcutaneous emphysema, vagal syncope, and metastatic invasion of the access tract.

The only absolute contraindication is pleural symphysis. Cough, hypoxemia, severe cardiac disease, and coagulopathy are relative contraindications.

Open Pleural Biopsy

Although formal thoracotomy provides excellent visualization of the pleura and the opportunity to obtain the largest biopsy specimens, thoracoscopy has virtually replaced open pleural biopsy for the diagnosis of unknown pleural disease. However, in certain instances, as when attempting to establish definitively the diagnosis of malignant mesothelioma, which often requires a large amount of tissue, open pleural biopsy may be necessary. However, some clinicians have reported high diagnostic yields for malignant mesothelioma with thoracoscopy. Neither open pleural biopsy nor thoracoscopy always provides a diagnosis in unknown pleural disease, particularly with nonmalignant causes. At times, a malignancy is not discovered for months following open pleural biopsy; in these cases, the effusion was probably paramalignant at the time of the procedure.

CHAPTER

13 Preoperative Evaluation and Relation to Postoperative Complications

James E. Hansen

J. E. Hansen: Division of Respiratory and Critical Care Medicine, UCLA School of Medicine, Torrance, California 90509.

INTRODUCTION

This chapter is designed to inform internists and surgeons, including pulmonologists and thoracic surgeons, of the pulmonary dysfunctions and complications that increase morbidity and mortality in patients undergoing surgical procedures, and to suggest a cost-effective method of assessing patients preoperatively. These pulmonary complications are especially likely to occur in patients who are older, obese, or smokers, who undergo thoracic or abdominal surgery, or who have lung or other organ system diseases or undergo lung resection.

PATHOPHYSIOLOGIC FEATURES OF MAJOR POSTOPERATIVE PULMONARY COMPLICATIONS

Atelectasis and Shunting with Hypoxemia

Lung volumes change quickly during anesthesia and surgery. In Fig. 1, the declines in both vital capacity (VC) and forced expiratory volume in 1 second (FEV_1) in the week after abdominal or thoracic surgery are striking and persistent, even though no lung was resected. Concurrently, alveolar-arterial differences in partial pressure of oxygen [$P(A\text{-}a)O_2$] increased. During surgery with general anesthesia, increases in $P(A\text{-}a)O_2$ and $P(A\text{-}a)CO_2$ (alveolar-arterial difference in partial pressure of carbon dioxide) could be attributed to decreases in lung compliance, increased shunting, increased pulmonary dead space, or decreased efficiency of ventilation secondary to ventilation and perfusion mismatching—that is, mechanisms causing increases in venous admixture.

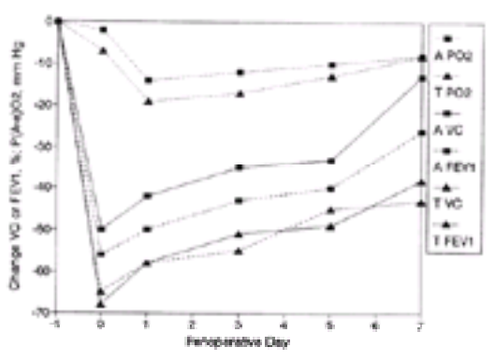

FIG. 1. Average change in spirometric values (%) and $P(A\text{-}a)O_2$ (mmHg) after thoracic (*T*) or abdominal (*A*) surgical procedures in 34 patients. (Modified with permission from Bryant LR, et al. Lung perfusion scanning for estimation of postoperative pulmonary function. *Arch Surg* 1972;104:52.)

Altered mechanics of the chest wall and diaphragm, however, with a decrease in functional residual capacity (FRC), are the primary cause of the development of areas of atelectasis and secondary hypoxemia. Ventilation during anesthesia with gas mixtures low in nitrogen (N_2) may also accelerate air space collapse. Patients undergoing upper abdominal surgery who have the greatest reduction in FRC postoperatively also have the highest incidence of pulmonary complications. If patchy atelectasis is sought, it can nearly always be demonstrated roentgenographically during general anesthesia for upper abdominal surgery. The appearance of these areas of atelectasis during anesthesia in normal individuals correlates positively with the magnitude of shunting and can usually be cleared by application of positive end-expiratory pressure (PEEP) at 10 cm H_2O. Apparently, inhalation anesthetics inhibit hypoxic pulmonary vasoconstriction more than do intravenous anesthetics, thus tending to cause more overperfusion of poorly ventilated air spaces and greater hypoxemia.

Rarely in patients undergoing cardiac transplantation or in patients with severe lung disease who are undergoing resection, sufficient pulmonary hypertension develops to open a potentially patent foramen ovale and cause shunting from the right to left atrium, with very severe widening of the $P(A\text{-}a)O_2$. The diagnosis of a patent foramen ovale can be made by having the patient breath 100% O_2. Because of the resulting high alveolar and end-pulmonary capillary PO_2 and complete saturation of hemoglobin at these high pressures, the venous admixture resulting from the development of a right-to-left shunt reduces the measured PaO_2 in an almost linear

fashion proportional to the size of the shunt.

Factors Predisposing to Postoperative Pneumonia

Impaired Transport of Mucus

Transport of mucus from the lower lobes and trachea is impaired for several days after upper abdominal surgery under general anesthesia, but only minimally after surgery of a lower extremity. It is well assessed by insufflation of the airways with tantalum. This transport deficiency, also associated with visible atelectasis, is probably related more to immobilization, diaphragmatic dysfunction, and ineffective coughing than to endotracheal intubation.

Aspiration

Aspiration of oral and gastric contents occurs occasionally in normal individuals during sleep. In the perioperative period, such aspiration of gastric or oropharyngeal contents into the tracheobronchial tree may cause pulmonary dysfunction resulting from acid burns, mechanical obstruction, or bacterial pathogens. Aspiration can easily occur during induction of anesthesia (if the stomach is not empty or emptied) whenever the endotracheal cuff is not properly inflated, or postoperatively if extubation is premature (before the gag reflex returns). Postoperatively, the use of a nasogastric tube may increase pulmonary aspiration.

Pre-existing Lung Infection

Both clinically evident and subclinical respiratory tract infection are associated with an increased risk for pneumonia. Carrel and colleagues found that pneumonia frequently developed in cardiac patients in whom immediate postsurgical tracheal aspirates were positive for micro-organisms despite perioperative antibiotic therapy (8 of 26), but rarely in those with negative aspirates (1 of 72).

Impaired Coughing

Coughing to clear secretions in the postoperative period is especially difficult in the presence of postoperative chest and abdominal pain. Coughing is less effective in patients with obstructive lung disease and low expiratory flow rates.

Respiratory Failure

Postoperative respiratory failure commonly occurs in patients with severe obstructive lung disease undergoing thoracic or upper abdominal surgery. Preoperative CO_2 retention, obesity, sepsis, and shock all increase the probability of postoperative respiratory failure. Maede and colleagues showed that the ratio of abdominal to transdiaphragmatic pressure decreased postoperatively, indicating diaphragmatic weakness, and that the greatest reductions occurred in the 4 of their 20 patients who required mechanical ventilation for 2 to 6 days. The decrease in lung volumes and flow rates during the several days following chest or upper abdominal surgery, especially when combined with pain, weakness, and sedation, necessarily reduces the drive and ability of postoperative patients to ventilate and remove metabolically produced CO_2. The elimination of CO_2 rarely is a problem except in patients with significant lung disease. In these patients, the ability to ventilate may be not only seriously reduced but also inefficient, the latter attributable to an increase in the ratio of physiologic dead space to tidal volume (V_D/V_T). Postoperative infection with fever and increased metabolism (causing high CO_2 production) and the intraoperative insufflation of CO_2 during an abdominal endoscopic procedure are additional causes of acute respiratory acidosis and respiratory failure.

The degree of V_D/V_T abnormality can be calculated from the patient's estimated or measured CO_2 output and measurement of the arterial CO_2 and minute ventilation. In patients whose ability to ventilate is compromised, repeated assessments with changes in ventilator settings and body position may be necessary to reduce the V_D/V_T and optimize CO_2 removal. With anemia, heart failure, shock, or infection, ventilation with high O_2 or high ventilatory pressures can lead to further lung damage and failure.

Pulmonary Embolism

Pulmonary emboli are common sequelae of venous thrombosis in the deep veins of the leg. In one study, the incidence of deep venous thromboses in three groups of hospitalized patients was as follows: (1) 11% in those without any of the risk factors of advanced age, obesity, malignancy, recent surgery, or history of deep venous thromboses; (2) 50% in those with three risk factors; and (3) 100% in those with four or more risk factors. Another expert group estimates the incidence of deep venous thrombosis as follows: (1) approximately 10%–20% (high risk) in patients older than 40 years with a recent history of venous thrombosis, or those undergoing extensive abdominal or pelvic surgery for malignancy, or those undergoing major orthopedic surgery of a lower extremity; (2) approximately 2%–10% (moderate risk) in patients undergoing general surgery of >30 minutes' duration (risk increases progressively with advancing age, malignancy, congestive failure, obesity, varicose veins, prolonged immobilization, and paralysis); and (3) <1% (low risk) in patients having uncomplicated or minor surgery of <30 minutes' duration. In these three groups, the risk for fatal pulmonary embolism is approximately 1%–5%, 0.1%–1%, and <0.01%, respectively, with an overall risk for general surgery of approximately 1%. Despite this known high incidence, even now in a well-known academic medical center with a major interest in thromboembolic disease, a correct diagnosis was established before autopsy in only 30% of patients who had a fatal pulmonary embolism. Wheeler and Anderson further noted a low incidence of thromboembolic prophylaxis even in high-risk patients, ranging from 9%–56% in different New England hospitals.

RISK FACTORS

The following are some of the recognized risk factors contributing to an increase in pulmonary complications postoperatively.

Age

The maximal flow rates, FEV_1, VC, FEV_1/VC, and maximum voluntary ventilation (MVV) all decline with age, so that normal individuals have less ventilatory reserve and less ability to clear secretions by coughing as they age. Additionally, and probably related to the decrease in elastic recoil and resultant increase in residual volume (RV), the $P(A\text{-}a)O_2$ increases each year on average by approximately 0.4 mmHg. Thus, even without pulmonary, neuromuscular, or other organ disease processes, there is a gradual reduction in PaO_2 with aging and less reserve for the increased ventilatory requirements that may be needed postoperatively. Postoperative hypoxemia increases with advancing age. Of course, the more frequent occurrence of other systemic diseases with advancing age necessarily adds to the likelihood of postoperative problems.

Obesity

Obesity is a major cause of postoperative complications. At least two studies found that after upper abdominal surgery, obesity was the most important risk factor associated with clinically significant atelectasis. The incidence of both preoperative and postoperative hypoxemia increases strikingly with obesity and age and is worse in the supine position (Fig. 2). Such hypoxemia is primarily a consequence of the high proportion of regions with decreased ventilation without compensatory reduction in perfusion (low $\dot{V}_A/\dot{Q}$) at the lung bases, but it may be aggravated by reduced ventilatory drive associated with CO_2 retention or metabolic alkalosis. With moderate thoracic and abdominal obesity, the VC may remain within normal limits, but the expiratory reserve volume (ERV) inevitably declines, indicating that the resting position of the diaphragm is elevated. With extreme obesity, the VC and MVV may become significantly decreased below predicted values in the absence of intrinsic lung disease and despite normal general muscle strength. Thus, hypoxemia, hypercapnia, somnolence, sleep apnea, and pulmonary hypertension are common complications of even moderate obesity. As hypoxemia and atelectasis are common postoperative occurrences even in patients who are not obese, and ventilatory work is increased with truncal obesity, obese patients have multiple handicaps in the postoperative period. Additional disadvantages for obese patients are the requirements for larger doses of many anesthetics because of their high solubility in fatty tissue, the longer time needed to eliminate anesthetics from the body, the longer time necessary to complete the surgical procedure, the increased acidity of gastric juice, and the increased frequency of aspiration of gastric contents. To this list can be added the higher incidence of diabetes mellitus and cardiovascular and thromboembolic diseases and the difficulties involved in postoperative ambulation and nursing care.

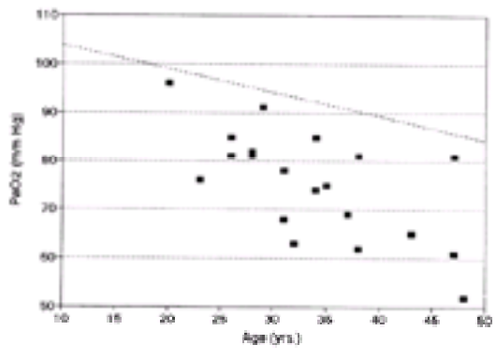

FIG. 2. Effect of age on PaO_2 in morbidly obese, awake, supine patients. The *dotted line* is regressed from data of Sorbini and colleagues for normal adults, with a standard deviation of 4 mmHg. (Modified with permission from Vaughan RW, et al. Postoperative hypoxemia in obese patients. *Ann Surg* 1974;180:877.)

Surgical and Incisional Site

Evidence is overwhelming that the incidence of postoperative morbidity and mortality is closely linked to the site of surgical intervention. It should be recalled that with upper abdominal surgery or thoracic surgery without lung resection, the FEV_1 and VC are strikingly reduced as soon as they can be measured postoperatively and do not usually return to preoperative levels within 1 week. When possible, it is desirable to choose an incisional site in thoracic surgery associated with lesser postoperative discomfort. A higher rate of atelectasis and hypoxemia occurs with vertical than with horizontal laparotomies. The overall incidence of postoperative cardiopulmonary complications becomes progressively lower in patients undergoing lower abdominal, pelvic, and extremity surgery. However, the incidence of venous thromboses and pulmonary emboli is very high in patients undergoing hip and knee surgery.

Lung Disease

Although postoperative morbidity and mortality cannot be accurately predicted for every patient, patients with significant lung disease undergoing thoracic or abdominal surgery are at high risk. Both obstructive and restrictive lung diseases are handicaps. However, the former carries a greater postoperative risk than the latter. In 1956, Miller and associates introduced a four-quadrant diagram based on the $FEV_{0.5}$ and VC, later modified by others, to categorize disturbed respiratory mechanics. This diagram graphically identifies relative postoperative risk in patients with obstructive, restrictive, and combined lung disorders (Fig. 3). All other things being equal, it can be noted in this diagram that the risk for postoperative ventilatory failure might be (1) slightly better than marginal in a patient with an FEV_1/VC of 50% and a VC or total lung capacity (TLC) that is 50% of predicted (i.e., moderate obstruction and moderate restriction); (2) prohibitive in a patient with an FEV_1/VC of 35% and VC or TLC that is 80% of predicted (i.e., severe obstruction and mild restriction); but (3) satisfactory in a patient with an FEV_1/VC of 70% and a VC or TLC that is 45% of predicted (mild obstruction and severe restriction). These differences in risk are logically related to the difficulty encountered by patients with obstructive disease in clearing airway secretions in the postoperative period.

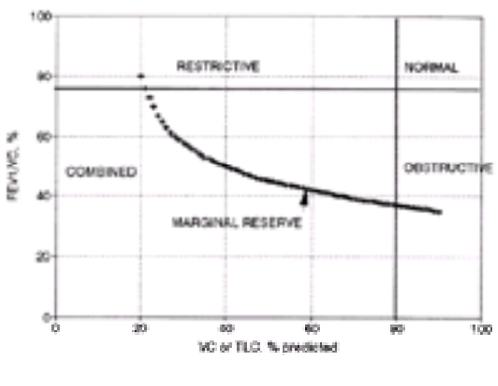

FIG. 3. Four-quadrant diagram for estimation of the relative risk of surgery in patients with lung disease. The *upper fourth* of the graph includes patients who are normal or have only restrictive lung disease; the *lower three fourths* includes patients with obstructive disease with or without restrictive lung disease. As a broad generalization, all patients below the marginal reserve line can be expected to require ventilatory support postoperatively. (Modified with permission from Hodgkin JE. Evaluation before thoracotomy. *West J Med* 1975; 122:104.)

Stein and colleagues noted that a reduced maximal expiratory flow rate ($FEF_{200-1200}$) was a potent predictor of postoperative pulmonary complications. Even patients with severe restrictive lung disease often have increased lung elastic recoil, can maintain satisfactory peak flow measurements, and can clear secretions adequately. On the other hand, patients with severe obstructive lung disease often have a very low $FEF_{200-1200}$ or peak flow readings and an ineffective cough. When either restrictive or obstructive lung disease has progressed to the stage at which CO_2 retention has occurred, the risk of surgery increases markedly. To oversimplify, the "blue bloater" chronic bronchitic patient is likely to be at greater risk than the "pink puffer" for the same severity of airways obstruction. The risk for complications in the asthmatic patient is inversely related to the adequacy of control of the asthma before the time of surgery.

Resection of Lung Tissue

It is logical to expect that morbidity and mortality would be directly related to the amount of lung tissue resected. In many series, this expectation is obscured by patient selection, because those who are not expected to survive often do not have lung resected. More important than the amount of lung tissue removed is the ability of the remaining lung tissue to transfer O_2 and CO_2 between blood and environment through the processes of ventilation, diffusion, and perfusion. Thus, in those patients undergoing resection of a significant amount of lung tissue, it is wise to quantify the total lung function.

Smoking

It may be difficult to confirm statistically significant abnormalities in cardiovascular or pulmonary function in many smokers, even those who have smoked for long periods. Nevertheless, several studies do confirm that smokers, even those without demonstrable pulmonary or cardiovascular disease, are at increased risk for postoperative complications. For example, Wightman found a 15% incidence of postoperative complications (fever, productive cough, and abnormal chest findings) after abdominal surgery in smokers, compared with a 6% incidence in nonsmokers. Laszlo and colleagues found a 53% incidence of postoperative complications in smokers, versus a 22% incidence in nonsmokers. Carrel and coworkers prospectively evaluated 100 patients undergoing cardiac surgery and found that the development of postoperative pneumonia was highly correlated with smoking, abnormal spirometry, and positive tracheal aspirates at the time of intubation. Poor oral hygiene, chronic cough, reduced ciliary function in the airways, likelihood of larger numbers of pulmonary bacterial pathogens, elevated carboxyhemoglobin levels, and the effects of nicotine on the cardiovascular system all contribute to the increased morbidity in smokers.

Cardiovascular, Neuromuscular, and Other Organ Disease

Patients with heart failure, recent myocardial infarction, or arrhythmia are at increased risk for postoperative cardiopulmonary complications, but moderate systemic hypertension is not a risk factor. Understandably, a recent stroke, psychosis or severe neurosis, degenerative neurologic processes, acute or chronic infections, damage to the upper airways or rib cage, compromised immunologic status, chronic drug or alcohol abuse, difficulty with mastication or swallowing, and chronic toxic or metabolic disorders all increase the likelihood of pulmonary morbidity.

Type and Duration of Anesthesia

Because of the many variables that influence selection of anesthetics and postoperative morbidity, it is difficult to compare different types or routes of anesthesia for the same operation. In two series of patients with severe obstructive lung disease, there was no difference in arterial oxygenation when general was compared with regional anesthesia for lower abdominal surgery. Clearly, the following are desirable: a smooth induction, adequate control of the airway and ventilation, adequate oxygenation without sudden shifts in acid-base status, reduction in atelectasis during and after surgery, adequate blood and fluid replacement, avoidance of other organ toxicity, and quick recovery from the anesthetic and muscle relaxant agents. There is consensus that the duration of the surgical procedure is much more significant than the type or route of administration of anesthesia.

PREOPERATIVE EVALUATION OF PATIENTS NOT UNDERGOING LUNG RESECTION

History and Physical Examination

It is trite but true that a good history and physical examination are extremely cost-effective and essential if unexpected morbidity and mortality are to be avoided. The history should include specific questions regarding duration and frequency of smoking; other drug history; dyspnea; activity level; cough frequency and characteristics; quantity and type of sputum production; intermittent wheezes or noisy breathing; chest pain, tightness, or distress; possible recent infections; toxic exposure; weight change; immobility; and venous insufficiency. Other major organ systems should not be ignored. For example, there is no significant cost associated with identifying patients with a high susceptibility to pulmonary embolism, who should receive appropriate prophylaxis. Likewise, Gracey and associates found that daily production of 2 oz or more of sputum was a valuable predictor of postoperative complications.

In the physical examination, poor oral hygiene, chest asymmetry, signs of airway disease, the duration (in seconds) of a complete forced expiration, body habitus, and evidence of clubbing, edema, or venous disease should be specifically noted. If the patient's subjective assessment seems inappropriate for objective physical findings, further evaluation is necessary. Wise physicians weigh their assessment of the patient's daily activity, exercise, and symptom status (or lack thereof) against the expected stress of surgery. We have all seen patients whose daily activity level is so low that they do not complain of dyspnea despite advanced heart or lung disease, and we regard highly those surgeons who walk or climb stairs with their patients before major surgery!

Roentgenography, Electrocardiography, and Other Laboratory Tests

A recent posteroanterior chest roentgenogram and electrocardiogram (ECG) should be obtained for anyone undergoing a significant surgical procedure. The necessity for other laboratory measures, including a hemogram, urinalysis, blood chemistries, and smears or cultures of body fluids, depends on the surgery contemplated and the findings elicited or suspicions aroused during the history and physical examination.

Arterial Blood Gas Analysis

An arterial blood gas analysis is indicated for obese patients, patients with neuromuscular disease, and those with symptoms or signs suggestive of recent or current respiratory disease. An elevated $PaCO_2$, regardless of the cause, is a significant finding associated with high postoperative risk. A PaO_2 significantly below that predicted for the patient's age and body habitus indicates the need for further evaluation. Unexpected acid-base disturbances may also be detected from analysis of arterial blood gases and pH.

Spirometry

In general, we recommend simple spirometry for patients undergoing upper abdominal or thoracic surgery who are moderately to severely obese or who have a history of heavy smoking or symptoms or signs suggesting lung disease or heart failure. Spirometry is probably not cost-effective in asymptomatic patients or in mildly symptomatic patients undergoing surgery of an extremity. The important measures are FEV_1, VC, $FEF_{200–1200}$ or peak flow rate, and the directly measured MVV for 10 to 15 seconds. Except for body weight, visualization of the tracings, calculation of the FEV_1/VC, division of the VC into the inspiratory capacity and the ERV, and other measurements or calculations add little. It is especially important to measure the MVV directly in a patient who appears to be infirm or who is undergoing thoracic or upper abdominal surgery; inability to perform the MVV maneuver adequately gives warning that the patient may not be able to cooperate, coordinate, learn, or perform the necessary postoperative ventilatory maneuvers.

If airway obstruction is present, spirometry should be repeated after inhalation of a bronchodilator.

A review by Zibrak and associates criticized the methodology of earlier studies and concluded (in part) that “in upper abdominal surgery, spirometry and arterial blood gas analysis did *not* consistently have measurable benefit in identifying patients at increased risk for postoperative pneumonia, prolonged hospitalization, and death.” This report went on to suggest that further critical investigation was required to reach a consensus regarding the role of preoperative pulmonary function tests in patients not undergoing lung resection.

We disagree. There is already significant evidence that preoperative spirometry is valuable in identifying patients at increased risk. Three decades ago, Stein and coworkers prospectively selected, at random, 100 ward patients admitted for surgical procedures. Of these, 32 did not have surgery because of lack of surgical indication and 5 were not operated on because of the severity of their cardiac or pulmonary disease. The 63 remaining patients were divided into two groups on the basis of their respiratory function. Group 1 patients had essentially normal lung function: $FEF_{200–1200}$ was >200 L/min (3.3 L/s) in 30 and was unmeasured in 3 patients; the single-breath O_2 test measured £2.5% in 30 and was unmeasured in 3; and the estimated $PaCO_2$ was £41 mmHg in 28 and was unmeasured in 5. Group 2 patients had abnormal lung function: $FEF_{200–1200}$ was <200 L/min in 30 patients; the single-breath O_2 test measured ³2.0% in 18, £2.5% in 8, and was unmeasured in 4; and the estimated $PaCO_2$ was ³42 mmHg in 9, £41 mmHg in 18, and unmeasured in 3. Respiratory complications occurred in only one patient in group 1 and in 21 patients in group 2. In group 2, 7 of 9 patients undergoing thoracotomy and 11 of 12 undergoing abdominal surgery experienced complications.

The positive evidence from four more recent studies should be considered. First, Gracey and colleagues in a prospective study found that 6 of 35 patients with a midexpiratory flow rate ($FEF_{25–75}$) below 50% of predicted and forced vital capacity (FVC) below 75% of predicted (group A) required prolonged mechanical ventilation, whereas only 1 of 122 patients with values exceeding these (group B) required such ventilation after several types of surgery. Four of these 7 patients died. The total number of complications also differed significantly. Complications occurred in 12 of 35 patients (34%) in group A versus 15 of 122 patients (12%) in group B.

Poe and associates prospectively examined 209 patients undergoing elective cholecystectomy and postoperatively identified 21 with atelectasis, 8 with purulent bronchitis, and 2 with pneumonia. These 31 patients were hospitalized an average of 1.5 days longer than the others. Abnormal peak flow and the single-breath O_2 test were significant predictors of postoperative pulmonary complications, whereas reduced FVC was a significant predictor of prolonged hospitalization.

Vodinh and coworkers prospectively studied 153 patients undergoing nonurgent vascular surgery. In comparing 24 clinical and laboratory factors, they found postoperative respiratory complications were significantly higher only in those with a clinical chest abnormality, recent bronchitis, aortic surgery, longer duration of surgery, low FEV_1/VC, and low PaO_2. They concluded that spirometry and blood gas analysis were helpful in assessing risk.

Finally, Carrel and colleagues, in a prospective study of patients undergoing cardiac surgery, also demonstrated that incidence of postoperative pneumonia was correlated with abnormal results of preoperative lung function studies.

It is unlikely that any test can ever clearly distinguish between those who will or will not survive, or between those who will or will not have a specific complication. We suggest that spirometry and blood gas analyses should not be performed in everyone undergoing abdominal or thoracic surgery without lung resection, but that these tests are usually indicated for patients with asthma, chronic cough, sputum production, dyspnea, wheezing, poor exercise tolerance, congestive failure, weakness, or morbid obesity.

Gas Transfer and Lung Volume

Unless lung resection is contemplated or the patient has significant spirometric abnormalities, measurement of gas transfer (D_LCO) and RV add cost and only infrequently provide additional information regarding operative risk.

Exercise Testing

If the patient has heart or lung disease or both, and the severity of the exercise limitation is uncertain, exercise testing with metabolic, ventilatory, gas exchange, blood pressure, and ECG measures may add information helpful in further assessing operative risk. Gerson and coworkers prospectively studied 177 geriatric patients undergoing abdominal and noncardiac thoracic surgery and included supine exercise testing in their multivariate analysis. They found that a patient's inability to perform 2 minutes of such exercise and raise the heart rate above 99 beats per minute (bpm) was the best single predictor of cardiac (14%), pulmonary (14%), or combined (22%) complications. There were 10 complications (9%) and 1 death (1%) in the group of 108 patients who could increase their heart rate to >99 bpm, and 29 complications (42%) and 5 deaths (7%) in the group of 69 patients who were unable to do so.

Because of the high perioperative mortality in elderly patients undergoing elective colorectal surgery or abdominal surgery for aortic aneurysm, Older and his colleagues successfully used noninvasive cardiopulmonary exercise testing with gas exchange measurements to screen 187 of 191 such patients over the age of 60. Forty-four had ECG tracings during exercise showing changes attributable to myocardial ischemia. Surgery was performed in the 187 screened patients, with an overall in-hospital mortality of 7.5%, 5.9% from cardiovascular causes. Mortality from cardiovascular causes was 18% in the 55 patients with an anaerobic threshold $\dot{V}O_2$ of <11 mL/min per kilogram, but was only 0.8% in the 132 patients with an anaerobic threshold that was ³11 mL/min per kilogram. The association of an anaerobic threshold $\dot{V}O_2$ of <11 mL/min per kilogram and preoperative ischemia resulted in a mortality of 42%, whereas those with preoperative ischemia and a higher anaerobic threshold had a mortality of only 4%. In addition to recommending exercise testing with gas exchange measurements for major abdominal surgery in the elderly, they suggest that all patients with demonstrated preoperative myocardial ischemia or an anaerobic threshold of <11 mL/min per kilogram be admitted preoperatively for stabilization. The use of these policies has measurably reduced perioperative mortality.

Conclusions

Williams-Russo has commented that “preventing cardiac morbidity may be the best approach to reducing pulmonary morbidity.” From the viewpoint of the patient, surgeon, and internist, we may unwisely evaluate the risks for morbidity and death by segregating the causes as “cardiovascular” or “pulmonary,” as these systems are so clearly interrelated in real life.

In the individual patient, the risk of operative intervention needs to be weighed against the risk of other therapies or nontreatment of the patient's disorder. It is wise to delay surgery when the likely morbidity and mortality of thoracic or upper abdominal surgery can be reduced by active intervention (e.g., through weight loss, anticoagulation, antibiotic or corticosteroid therapy, or intensive bronchodilator therapy). If such delay significantly decreases the patient's chances for recovery or cure of the primary disorder, then only very brief interventions before a decision regarding surgery are warranted. Table 1 gives some broad guidelines suggestive of high morbidity and mortality in thoracic or upper abdominal surgery.

Factor or test	Upper abdominal surgery	Lung resection[a]
Age >70 y	+	+
Abnormal ECG	+	+
FEV_1 <40% predicted	+	++
FEV_1/VC <40%	++	++
$FEF_{200-1200}$ <2 L/s	++	++
MVV <50% predicted	+	+++
D,CO <, 50% predicted	+	++
$PaCO_2$	++	+++
PaO_2 <60 mmHg	+	±
VO_2max <15 mL/min/kg	++	+++

± indicates possible increase in mortality; +, some increase in mortality; ++, considerable increase in mortality; +++, very high increase in mortality.

[a] None of these factors or values should be used as absolute contraindications to surgery.

[b] Preoperative quantitative perfusion scans with preoperative FEV_1, MVV, DLCO, and VO_2max tests values are helpful in predicting same test values postoperatively after lung resection.

TABLE 1. *Some factors associatedwith high surgical mortality*[a]

PREOPERATIVE EVALUATION OF PATIENTS UNDERGOING LUNG RESECTION

Initial Preoperative Assessment

All the evaluations considered for patients in whom lung resection is not planned, including DLCO and lung volume measurements, are useful also in the patient being evaluated for lung resection. Commonly, lung resection is performed in malignant states, but similar evaluation is indicated for patients with decreased lung function resulting from inflammatory, traumatic, hereditary, or other disorders. Roentgenographic examinations will always be more complete, and endoscopy results may be available. Bronchodilator responsiveness becomes very important if ventilatory function is significantly reduced, and DLCO should certainly be measured. If maximal inspiratory and expiratory pressures are low, preoperative pulmonary rehabilitation may reduce the incidence of postoperative complications.

In the earliest of several retrospective studies, Gaensler and coworkers found that the MVV was an important predictor of survival in patients undergoing lung resection for tuberculosis; if the preoperative MVV was <50% of predicted, 50% of the patients died, whereas if the MVV was >50% of predicted, only 1% of the patients died. Boushy and associates found that advanced age, severity of dyspnea, high RV, low gas transfer per lung volume (DLCO/VA), reduced FEV_1, and reduced MVV were all significant predictors of high morbidity and mortality. Confirming the value of the MVV, Didolkar and associates, in a retrospective study of resection for lung cancer, found that mortality from cardiopulmonary complications was much higher in those with an MVV that was <60% of predicted. There were no postoperative deaths in the nine patients older than 70 years who had a normal ECG and an MVV that was >60% of predicted.

Ferguson and coworkers retrospectively reviewed their results for lung resection in 237 patients (cancer in 203 and benign disease in 34). They took into account 38 different preoperative and operative risk factors and found, by logistic regression analysis, that the DLCO was the most important predictor of postoperative survival and the sole predictor of pulmonary complications. For DLCO values that were <60%, 61%–80%, 81%–100%, and >100% of predicted, postoperative mortality was 25%, 8%, 5%, and 0%, respectively, and pulmonary complications were 45%, 33%, 13%, and 11%, respectively.

Several investigators have utilized measures of pulmonary arterial pressure, pulmonary vascular resistance, and right ventricular injection fraction preoperatively and intraoperatively after pulmonary arterial clamping. These invasive measures are generally less useful than noninvasive exercise testing and quantitative scans in estimating postoperative morbidity and mortality.

Predicting Postoperative Function

When resting preoperative lung function, as measured by spirometry and DLCO, is significantly impaired, or when large portions of lung may be removed surgically, it is worthwhile to predict postoperative lung function to assess postoperative survival or quality of life. Bronchospirometry and the lateral position tests, introduced in the 1950s and 1960s, were of some assistance in predicting postoperative function, but they have now been supplanted by newer techniques.

Quantitative radioisotopic ventilation and perfusion scans are now commonly and effectively used to predict postoperative FEV_1, DLCO, and peak $\dot{V}O_2$ (Fig. 4 and Fig. 5). In each case, the expected postoperative FEV_1, DLCO, or peak $\dot{V}O_2$ is calculated by multiplying each preoperative value by the measured ratio of expected postoperative lung activity to preoperative total lung activity. For example, if 40% of the quantitatively measured perfusion scan activity occurs in the lung that is to be resected, the calculated postoperative DLCO or peak $\dot{V}O_2$ will be 60% of the preoperative DLCO or peak $\dot{V}O_2$. Ventilation scans or quantitative computed tomography (CT) can be similarly used to predict postoperative FEV_1 values. Using the ratio of the number of expected postoperative lung segments to the total number of preoperative segments tends to give an underestimate of postoperative function, because lung segments differ in size and because the removed segments are likely to be worse than those retained.

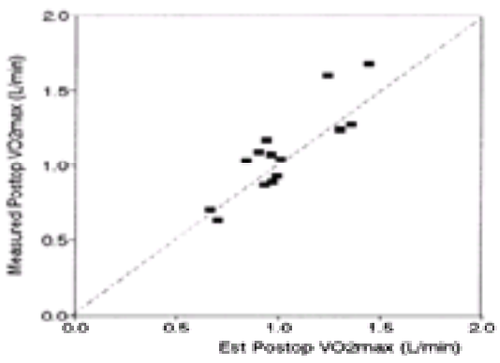

FIG. 4. Comparison of measured postoperative FEV_1 and estimated postoperative FEV_1 in 28 patients undergoing pneumonectomy. Estimated postoperative FEV_1 was calculated from preoperative FEV_1 and quantitative technetium Tc 99m perfusion scans. (Modified with permission from Corris PA, et al. Use of radionuclide scanning in the preoperative estimation of pulmonary function after pneumonectomy. *Thorax* 1987;42:285.)

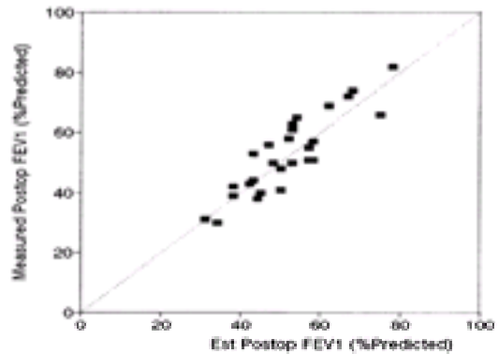

FIG. 5. Comparison of measured postoperative $\dot{V}O_{2max}$ and estimated postoperative $\dot{V}O_{2max}$ in 14 patients undergoing pneumonectomy. Estimated postoperative $\dot{V}O_{2max}$ was calculated from preoperative $\dot{V}O_{2max}$ and quantitative technetium Tc 99m perfusion scans. (Modified with permission from Corris PA, et al. Use of radionuclide scanning in the preoperative estimation of pulmonary function after pneumonectomy. *Thorax* 1987;42:285.)

Markos and coworkers prospectively studied by lung function tests and scintigraphy 55 consecutive candidates for lung cancer resection. Fifty-three underwent thoracotomy, with pneumonectomy in 18, lobectomy in 29, and no resection in 6. Postoperative FEV_1 and D_LCO were well predicted from preoperative measures. There were only 3 deaths, all occurring in the 6 candidates who had a predicted postoperative FEV_1 of 40% or less. Wahi and associates reviewed 197 consecutive cancer patients undergoing pneumonectomy. Of the 14 perioperative deaths, 13 occurred in patients undergoing right pneumonectomy. Those with a predicted postoperative FEV_1 exceeding 1.65 L had lower mortality.

Pierce and colleagues found that the predicted postoperative product, which is the predicted postoperative FEV_1 times predicted postoperative D_LCO, was the best predictor of surgical mortality in 54 consecutive patients with bronchogenic carcinoma. The mean values of their population were as follows: age, 67; FEV_1, 76% of predicted; D_LCO, 85% of predicted; and peak $\dot{V}O_2$, 18.4 mL/min per kilogram. Pneumonectomy was performed in 11, lobectomy in 29, and lesser resection in 14. There were 48 survivors. Although peak $\dot{V}O_2$ values did not predict outcome, 2 of the 3 patients with peak $\dot{V}O_2$ values that were <14 mL/min per kilogram died in the perioperative period. In 331 candidates, Kearney and associates found that the primary predictor of resectional outcome was the absolute predicted postoperative FEV_1, but they did not analyze D_LCO or peak $\dot{V}O_2$ values.

Exercise Testing

Two early studies showed the value of preoperative exercise testing in patients undergoing lung resection. Eugene and colleagues found that among 19 patients, death occurred in 3 of 4 patients with a peak $\dot{V}O_2$ of <1 L/min. In 22 patients, Smith and coworkers found no deaths and 10% morbidity if peak $\dot{V}O_2$ exceeded 20 mL/min per kilogram; 17% deaths and 67% morbidity with peak $\dot{V}O_2$ of 15 to 20 mL/min per kilogram; and 17% deaths and 100% morbidity if peak $\dot{V}O_2$ was <15 mL/min per kilogram.

Bechard and Wetstein prospectively evaluated 50 consecutive patients undergoing lung resection with the surgeon blinded to the preoperative peak $\dot{V}O_2$ values. Candidates for resection were required to have an FEV_1 of >1.7 L for pneumonectomy (10), 1.2 L for lobectomy (28), or 0.9 L for wedge resection (12). Mortality was 4% and other morbidity 12%. Both peak $\dot{V}O_2$ and anaerobic threshold measures predicted mortality and morbidity, but age, FVC, FEV_1, and MVV did not. Maurice and colleagues found 8 of 37 high-risk patients to have a peak $\dot{V}O_2$ of >15 mL/min per kilogram. All survived resectional surgery.

Walsh and colleagues prospectively evaluated 66 patients with potentially resectable non–small-cell lung cancer, considered to be high risks on the basis of preoperative FEV_1 that was <40% of predicted, predicted postoperative FEV_1 that was <33% of predicted, resting $PaCO_2$ exceeeding 45 mmHg, or at least two criteria indicating cardiac disease. In 20 patients with a peak $\dot{V}O_2$ of >15 mL/min per kilogram, there were no perioperative deaths and 40% complications. Among five patients with a peak $\dot{V}O_2$ of <15 mL/min per kilogram, there was one death. In this population, only surgical versus medical treatment and peak $\dot{V}O_2$ exceeding 15 mL/min per kilogram significantly predicted survival; age, FEV_1, $PaCO_2$, clinical stage, and T status did not. Bollinger and coworkers operated on 25 high-risk patients, with only three deaths. Lower preoperative or predicted postoperative peak $\dot{V}O_2$ values correlated with higher morbidity and mortality.

Conclusions

Physicians and surgeons are obligated to share information and expectations with patients before making final decisions on therapy. Assigning an exact risk to a major surgical procedure in the individual cancer patient is difficult, but multiple high-risk factors and common sense can dictate against surgical treatment. Debility and cardiovascular disease add to risk. Smoking cessation, vigorous bronchodilator therapy, and rehabilitating exercise therapy may help. Despite recent advances in therapy, I am not as optimistic as Olsen in believing that “almost no one” is inoperable. In a high-risk patient, measures of D_LCO, quantitative perfusion scan, and gas exchange exercise testing are all clearly useful in assessing risk. Because of differences in patient sex, size, and age, both absolute and percent predicted values should be considered.

PREVENTION OF COMPLICATIONS

Preoperative Considerations

The more severe the risk of complications, the more important it is to take effective action preoperatively. Patients should stop smoking as soon as it is realized that surgery is likely, even if the patient has normal findings on pulmonary function tests. Cessation for even a few days is advantageous. Advantages of smoking cessation include an expected reduction in cough, improvement in ciliary function and mouth hygiene, reduction in lower airway pathogens, and reduction in carboxyhemoglobin levels. Warner and colleagues, in a blinded prospective study of patients undergoing coronary bypass surgery, found that postoperative pulmonary complications developed in approximately 1 of 3 of the current smokers, 5 of 9 of those who stopped smoking for less than 2 months, 1 of 7 of those who stopped smoking for more

than 2 months, 1 of 9 of those who stopped smoking for 6 months or more, and 1 of 9 of those who had never smoked.

If the patient is obese and surgery can be delayed, weight reduction is advisable, especially if the surgery involves the thorax or upper abdomen. In those with hypoventilation and CO_2 retention, a weight loss of 10 to 20 kg may bring improvement. However, caloric and fluid intake should be adequate during the days immediately preceding major surgery.

We recommend intensive bronchodilator therapy for any patient with obstructive lung disease who shows evidence, either clinically or in the pulmonary physiology laboratory, of improvement with such treatment. Asthma should be cleared with steroids if necessary.

There is little evidence that routine antibiotic prophylaxis is beneficial, but recognized pulmonary infections should be aggressively diagnosed (smear and culture) and treated for several days preoperatively if feasible.

Several studies show that preoperative training in deep-breathing respiratory maneuvers reduces postoperative complications and is cost-effective in patients who undergo thoracic or upper abdominal surgery. Bartlett and coworkers emphasized that frequent inspiratory rather than expiratory maneuvers were essential. In a prospective study of 343 cholecystectomy patients, Thoren found roentgenographic atelectasis in 12% of those who performed preoperative and postoperative breathing exercise, 27% of those who performed postoperative breathing exercise only, and 42% of the control group. In patients undergoing abdominal surgery, Celli and associates found that clinical complications and duration of hospital stay were much diminished in patients who had respiratory treatment started 1 day before surgery and continued postoperatively than in a randomly selected control group. Roukema and colleagues prospectively randomized patients with noncompromised pulmonary status undergoing abdominal surgery into two groups. Group 1 consisted of 84 patients with no breathing exercises, whereas group 2 consisted of 69 patients treated with preoperative and postoperative exercises. Pulmonary complications occurred in 60% of group 1 versus 19% of group 2.

Stein and Cassara compared three groups of patients undergoing abdominal and thoracic surgery: (1) those considered to be of normal risk; (2) those considered, on the basis of pulmonary function tests, to be high-risk and who were not treated; and (3) those considered to be high-risk and who were treated intensively preoperatively with smoking cessation, bronchodilator drugs, inhalation of humidified gases, chest physiotherapy, and antibiotics when indicated. Postoperative pulmonary complications occurred in 1 of 17 patients in group 1, 14 of 20 patients in group 2, and 5 of 22 patients in group 3. We have often seen patients who were considered to be prohibitive risks for lung resection become acceptable risks after several weeks of intensive therapy.

Cardiovascular disease should be treated aggressively to minimize pulmonary edema, congestive failure, myocardial ischemia, arrhythmias, significant systemic or pulmonary hypertension, hypercoagulability, and the likelihood of postoperative thromboembolic disorders. Primary prophylaxis (i.e., the prevention of deep vein thromboses by drugs or physical methods) is cost-effective, may be life-saving, and should be used whenever possible in patients with high to moderate risk for thromboembolism. Primary prophylaxis consists of anticoagulation with low-dose heparin (5000 units subcutaneously 2 hours preoperatively, and then every 8 to 12 hours postoperatively without monitoring), adjusted-dose heparin (preoperative and postoperative dosage dependent on activated partial thromboplastin time), low-molecular-weight heparin, or oral anticoagulants. Alternatively, primary prophylaxis can consist of reduction in venous stasis with dihydroergotamine, intermittent pneumatic leg compression, or graduated compression stockings. The selection of specific primary prophylaxis depends on the site and type of surgery performed and the patient's other medical problems.

If aspiration occurs or is likely to occur, as in the obese patient, antacid therapy tends to minimize the expected pulmonary complications.

Intraoperative Considerations

To the best of our knowledge, there is no evidence that the route or type of anesthetic used affects the likelihood of postoperative pulmonary complications. Usually the anesthesiologist (on the basis of skill, training, and experience) selects the most appropriate agents and route for the specific problem at hand. There is no clear evidence that spinal anesthesia is superior to general anesthesia in maintaining intraoperative and postoperative oxygenation, even in patients with severe obstructive lung disease, perhaps because of better control of the airways with general anesthesia. Among other things, the anesthesiologist attempts to maintain adequate cardiac output, oxygenation, CO_2 removal, and stable fluid and acid-base status; minimize arrhythmias, pooling of blood in extremities, and microatelectasis and macroatelectasis; and prevent aspiration of oral and gastric contents into the lung.

During laparoscopic cholecystectomy in which CO_2 is used for insufflation, a significant respiratory acidosis may develop in patients with cardiac or pulmonary disease. Because end-tidal CO_2 pressures may be misleading during such insufflation, arterial PCO_2 and pH should be monitored.

Postoperative Considerations

Ventilator support after recovery from anesthesia may be brief or prolonged. Continuous positive airway pressure (CPAP) or PEEP is usually helpful in improving oxygenation and CO_2 removal by decreasing atelectasis, improving $\dot{V}_A/\dot{Q}$, and reducing barotrauma to the lung.

Hypoxemia can be reduced and ventilation of the lung bases improved by keeping the patient, especially if obese, in a sitting or semirecumbent position rather than in a supine position (Fig. 6).

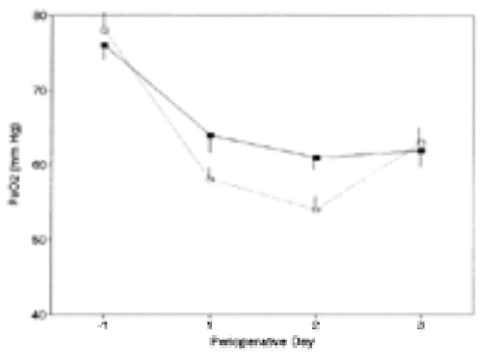

FIG. 6. Effect of body position on PaO_2 after abdominal surgery in 22 markedly obese patients. *Solid symbols* and *solid line* indicate semirecumbent position; *hollow symbols* and *dotted line* indicate supine position. (Modified with permission from Vaughan RW, Wise L. Postoperative arterial blood gas measurements in obese patients. Effects of position on gas exchange. *Ann Surg* 1975;182:705.)

Aggressive respiratory therapy to minimize atelectasis, increase FRC, improve oxygenation, and clear secretions is valuable and cost-effective. Previously, expiratory resistance and intermittent positive-pressure breathing were used frequently, but these have generally been discarded because of ineffectiveness, high cost, or barotrauma. Bronchodilator aerosol therapy alone is insufficient to improve lung volumes and oxygenation maximally after thoracic or upper abdominal surgery. There are many reports that compare the effectiveness of the following currently recommended modalities: (1) coughing and deep breathing (CDB) exercises; (2) sustained maximal inspiration or incentive spirometry (IS), using one of several available devices; (3) breathing with inspiratory resistance (IR); and (4) CPAP or PEEP by face mask. The major disadvantages of CDB, IS, and IR are the necessity for patient cooperation and the likely attendant increase in pain. PEEP or CPAP may be costlier and slightly increase the possibility of barotrauma or aspiration, but they hasten improvement in FRC and PaO_2 postoperatively in patients in whom atelectasis tends to develop. They may be detrimental to patients with severe emphysema, who are already hyperinflated because of highly compliant lung units.

Nearly all authors stress the necessity for frequent and vigilant respiratory care in the high-risk population. Because of postoperative pain, analgesics may be necessary to improve coughing and deep breathing. With severe thoracic or abdominal pain, selective and repeated nerve blocks may help the patient's performance of ventilatory maneuvers.

It is important to reduce the likelihood of aspiration with good endotracheal tube and cuff care and good technique when giving nutritional support. If a nasogastric tube is used, it should be of small caliber. Overdistention of the stomach should be avoided.

Secondary prophylaxis for thromboembolism is more costly than primary prophylaxis but is still cost-effective and life-preserving. It consists of screening high-risk patients postoperatively with tests specific for venous thromboses (e.g., fibrinogen uptake, Doppler ultrasonography, impedance plethysmography, and venography), followed by full-dose anticoagulant therapy when test results are positive. Secondary prophylaxis should be used when prophylactic anticoagulation is desired but contraindicated (e.g., urgency of surgery, neurosurgery, spinal anesthesia) or when supplementation of primary prophylaxis is required in very high-risk patients.

CHAPTER

14 Approach to the Clinical and Radiographic Evaluation of Patients with Common Pulmonary Syndromes

Gordon L. Snider · M. Elon Gale

M. Elon Gale: Department of Radiology Veterans Affairs Medical Center, Boston Massachusetts 02130.

INTRODUCTION

The invention of the stethoscope by Laennec early in the nineteenth century represented a quantum leap in the power of physicians to diagnose pulmonary diseases. The advent of radiographic imaging of the chest early in the twentieth century was an advance of equal importance; its full potential has not yet been realized, even with the invention of computed tomography (CT) about 25 years ago. The past four decades have seen the development and dissemination of other powerful tools: clinical pulmonary function testing, flexible fiberoptic bronchoscopy, ultrasonography, radionuclide scintiscanning, and improved laboratory evaluation of body fluids.

Despite the enormous advances these techniques have brought to our understanding of pulmonary diseases and the accuracy with which we can diagnose them, the physician's role in diagnosis remains undiminished. The medical history continues to be the single most powerful tool in the physician's armamentarium. It is the physician, using skills carefully honed during years of study, who separates the important from the unimportant data in the history, formulates a differential diagnosis, puts the laboratory studies into proper perspective with the history, and establishes the diagnosis. In this chapter, we present an approach to history taking and physical examination and briefly discuss the clinical and radiographic presentation of common pulmonary syndromes.

HISTORY

Patients with pulmonary disease most commonly seek medical attention because they are troubled by symptoms. Less often, they are referred to a physician because of an abnormal laboratory test result, such as a positive tuberculin test, or abnormal findings on a screening chest radiogram. Sometimes, patients are referred because of the presence of an extrapulmonary lesion known to be frequently associated with pulmonary disease, such as sarcoidosis involving the skin or eyes. The medical interview always begins with the patient's chief complaint.

Chief Complaint

The chief complaint should generally be recorded in the patient's own words; patient satisfaction is greater and the risk of the physician missing the patient's chief complaint is less if the patient is permitted to express major concerns fully and freely instead of simply responding to the physician's closed-ended questions. Each chief complaint is explored in detail. Questions should not be leading and should be expressed in words the patient can easily understand. The purpose is to permit the physician to evaluate the significance of the complaint; gathering of data and interpretation of the history proceed in parallel.

Patient's Assessment of Symptoms

It is important to involve patients in the diagnostic and therapeutic decisions that will affect their welfare. Is a symptom troubling the patient enough to justify ordering an expensive, perhaps invasive diagnostic test, or is the patient content with the physician's reassurance that a serious, potentially disabling or life-threatening condition is not present? What is the principle underlying the treatment plan? What is to be expected from the various drugs that have been prescribed, and are the expected effects immediate or delayed? What are the possible side effects of the drugs—immediate and delayed? If drugs are being used for symptom relief, as in the management of severe asthma, what options may the patient exercise as symptoms vary in severity? What changes of lifestyle are in order? Involving patients directly in their care (cooperative self-management) is an important ingredient in patient satisfaction and therapeutic success.

Pulmonary Symptoms

The number of pulmonary symptoms is limited: cough, expectoration of sputum, hemoptysis, chest pain, dyspnea, and wheezing. The precise manner of presentation of symptoms, the sequence in which they appear, the factors that worsen and alleviate them, and their response to treatment may be of value in suggesting the nature of the underlying disease process. For example, a cough with coryza and purulent sputum that abates with antibiotic treatment is compatible with an infectious bronchitis; a chronic cough with blood-streaked sputum in a cigarette smoker raises the suspicion of bronchogenic carcinoma.

Cough

Mechanisms

Cough may be defined as a forced expulsion of air associated with the generation of a harsh noise. Physiologically, cough is a reflex, forced expiratory event that comprises a rapid inspiration followed by an expiratory effort against a closed glottis, with rapid generation of a high intrapulmonary pressure. Sudden opening of the glottis is followed by an explosive expiration, which has the effect of moving excessive secretions or particulate material toward the mouth.

Cough may be initiated voluntarily or involuntarily. Irritant receptors located in the external auditory canal, larynx, trachea and large bronchi, pleurae, and stomach give rise to afferent stimuli that course centrally over the vagal nerves. The sensitivity of irritant receptors is greatest at the glottis and the main bronchial carina and diminishes rapidly after about the fourth-order bronchi. Thus, large amounts of secretion can pool in the distal airways without initiating a cough. Stimuli from the nose and paranasal sinuses travel centrally over the trigeminal nerve and from the pharynx over the glossopharyngeal nerve. Stimuli from the pericardium and the diaphragm may initiate cough by afferent impulses coursing over the phrenic nerve. Efferent pathways include the vagus, phrenic, trigeminal, facial, hypoglossal, and accessory nerves as well as the intercostal and lumbar nerves innervating the intrinsic and accessory muscles of respiration.

Normally, secretions from the lungs and airways are removed by ciliary motion, which activates the mucociliary escalator and moves secretions toward the pharynx, where they are swallowed or expectorated. When this mechanism fails or is overwhelmed, cough takes over the critical role of maintaining the clearance function of the airways. The expiratory effort against a closed glottis, which is the first phase of a cough and lasts about 0.2 second, raises the intrapleural pressure to about 100 cm

H_2O, although values as high as 300 cm H_2O may be reached. Opening of the glottis is followed by highvelocity, turbulent flow. As expiration proceeds, lung volume diminishes and dynamic compression of intrathoracic airways occurs. For a given flow, the linear velocity of gas is higher in an airway narrowed by dynamic compression than in one in which the normal geometry is maintained. If narrowing also occurs as a result of secretion in the airway, a pressure gradient is created that moves secretions toward the pharynx. These high linear velocities also set the secretions and bronchopulmonary tissues into vibration, creating the characteristic sound of a cough.

The effectiveness of cough may be impaired if any phase of the process is abnormal. The cough reflex may be suppressed by changes in irritant receptor function caused by narcotics, local or systemic anesthetics, or mucosal disease, as in bronchiectasis with severe destructive changes. Neurologic disease may affect any portion of the reflex pathways. Chest wall pain or asthenia resulting from age, illness, or neuromuscular disease may decrease the inspiratory effort preceding cough, thus decreasing the lengthening of expiratory muscle fibers required to develop a high intrapleural pressure against the closed glottis. Inspiratory as well as expiratory muscular dysfunction may result in a weak cough. Obstruction of air flow, as in asthma or emphysema, impairs the effectiveness of cough by decreasing the velocity of the flow of air available for moving secretions. Glottic closure is helpful but not essential for effective coughing; the pressure developed when the glottis is closed is 50%–100% greater than when a forced expiratory maneuver is carried out with the glottis open. Tracheotomized patients learn to carry out forced expiratory maneuvers that are effective in mobilizing their secretions, and persons with an intact glottis may elect to carry out forced, expiratory, coughlike maneuvers through a partially open glottis to minimize the pain induced by a forceful cough in the presence of acute tracheitis or chest wall pain.

The maximal expiratory pressure (MEP) is useful for assessing cough strength in patients with impaired muscle strength, and is likely a more accurate measure of cough strength than forced vital capacity. Patients with MEP values of 60 cm H_2O or more are able to generate sufficient peak flow to produce an effective cough.

Diagnostic Features

Cough of Recent Onset. Normal persons cough infrequently when they are well. The most common reason for the development of cough in a normal person is a viral respiratory infection. Such infections may be sporadic but more often occur in community epidemics or household or workplace clusters. One or more of coryza, sore throat, fever, chills, sweats, malaise, backache, retrobulbar pain, and postnasal discharge may accompany the cough. Cough may be nonproductive or productive, and an acute tracheitis may be accompanied by a tearing or burning substernal pain. The usual duration of cough resulting from an acute respiratory infection is 2 to 3 weeks, but occasionally the cough lingers much longer and is accompanied by wheezing that worsens after exercise or breathing cold air. Such patients show evidence of airways hyperreactivity on challenge with methacholine or cold air.

The history and physical findings of rhinopharyngitis, with or without middle ear disease, establish the diagnosis of cough resulting from an acute upper respiratory infection. A chest radiogram is not necessary to exclude pneumonia unless abnormalities are found on chest examination, or prostration is severe and persistent. Wheezing with cough of recent onset suggests air flow obstruction, possibly from asthma. Stridor indicates involvement of the upper airway.

Chronic cough. Cough that has persisted for more than 3 weeks may be considered to be chronic. However, it is not always easy to know whether chronic cough has been present; patients who have a mild repetitive cough (e.g., on arising) may either be unaware of it or misinterpret it as a natural phenomenon. The symptom will not be elicited unless the patient is asked whether cough occurs on arising, and sometimes it will come to light only after a family member has been questioned. It may also be helpful to determine whether cough described as of recent onset is really new or represents an exacerbation of a chronic condition. Finally, the recent cessation of a longstanding productive cough may indicate retention of bronchial secretions; this is observed occasionally in respiratory failure complicating chronic obstructive airways disease. Weakness, fatigability, fever, and night sweats suggest the presence of tuberculosis, other chronic infection, or malignancy. Physical examination, a chest radiogram, and simple laboratory studies are usually sufficient to establish these diagnoses.

The pioneering work of Irwin has established a diagnostic protocol, based on the locations of the afferent limb of the cough reflex, for investigating chronic cough that is not of obvious etiology. Some causes of chronic cough are listed in Table 1. Chronic bronchitis is the most common cause of chronic cough, occurring in up to 30% of cigarette smokers. The postnasal discharge syndrome is next most frequent. This syndrome is diagnosed when the patient describes a sensation of secretion dripping from the back of the nose into the throat, often with the need for frequent clearing of the throat. Physical examination reveals a cobblestone appearance of the oropharyngeal mucosa, sometimes with overlying mucoid or mucopurulent secretion.

Frequent
Chronic bronchitis (occurs in 30% of smokers)
Postnasal drip syndrome (caused by rhinitis ± sinusitis)
Asthma (may be variant, without wheezing)
Gastroesophageal reflux
Congestive heart failure
Cystic fibrosis
Chronic infections (tuberculosis, deep mycotic infections)
Infrequent
Occupational factors
Bronchiectasis
Psychogenic cough (may occur with stridor; is rarely nocturnal)
Interstitial lung disease
Bronchogenic carcinoma
Angiotensin-converting enzyme inhibitors
Pulmonary vascular disease
Tracheal compression (neck or mediastinal mass)
Recurrent aspiration (observed in the elderly and persons with swallowing disorders caused by neuromuscular disease; often accompanied by recurrent pneumonia)
Aspirated foreign body (rare in adults except with mental illness, mental retardation, or coma)

TABLE 1. *Some causes of chronic cough*

Asthma is easy enough to diagnose when the patient describes episodic wheezing and shortness of breath. However, it must be remembered that asthma may present as only cough, with minimal expectoration and no wheezing. The cough is frequently precipitated by exposure to cold air or exercise and is often dry. An increase of >20% in FEV_1 (forced expiratory volume in 1 second) after administration of a sympathomimetic agonist aerosol, a positive result on a cold air or methacholine challenge test, or a therapeutic response to aerosol treatment with a b-adrenergic agonist support the diagnosis (Chapter 40).

Gastroesophageal reflux (GER) as a cause of chronic cough, with or without wheezing, is controversial. There is no question that some patients have chronic cough secondary to GER. Heartburn or regurgitation of acid material into the mouth may be caused by GER or a Zenker's diverticulum. These patients tend to cough more when lying down at night and respond promptly to treatment of the GER.

Troublesome cough may complicate the treatment of hypertension with angiotensin-converting enzyme inhibitors. Congestive heart failure is a common cause of chronic cough, and this is usually easily diagnosed from the history of heart disease, orthopnea, paroxysmal nocturnal dyspnea, exertional dyspnea, and the physical examination. The presence of chronic productive cough with purulent sputum, often in a nonsmoker, with or without evidence of patchy, persistent pneumonic disease on physical examination and chest radiography, should raise the possibility of cystic fibrosis, which is the most common genetic defect of Caucasians. The disease may present in adults with minimal or no gastrointestinal symptoms of pancreatic involvement (Chapter 73). Chronic cough is a frequent symptom in patients with bronchogenic carcinoma. Tracheal compression, sometimes in the neck, as by a goiter (Fig. 1), but more often in the region of the carina, may also give rise to a dry cough.

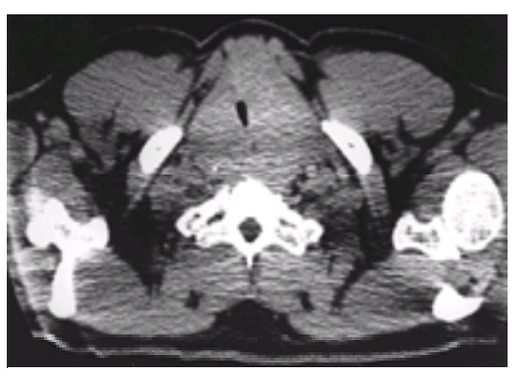

FIG. 1. Enlargement of the thyroid gland usually does not compress the trachea, which is supported by stiff cartilaginous rings. However, when a goiter becomes

extremely large, as demonstrated here, the shape of the tracheal cross-section can be distorted and diminished.

Occasionally, patients are observed with psychogenic cough. Such patients are usually young. The cough is frequent, sometimes with accompanying aphonia or stridor and a rather characteristic barking or brassy quality. The cough rarely disturbs sleep, although it may make work or attendance at school impossible. Psychologic abnormalities are not necessarily obvious, although they are usually detectable. The diagnosis is usually evident from the nature of the cough. An investigation to exclude organic disease is necessary, but clinical judgment must be exercised to keep the workup within reasonable bounds.

Complications of Cough. Cough syncope occurs mainly in middle-aged men who have chronic obstructive pulmonary disease (COPD). Fainting follows within 10 to 20 seconds of a paroxysmal cough that cannot be controlled by the patient. The mechanism is obscure; the fainting appears to be related to impairment of venous return and fall in cardiac output as a result of elevated intrathoracic pressure; at the same time, intracranial pressure is elevated by the transmitted intrathoracic pressure. The result is diminution of cerebral blood flow. Consciousness is usually promptly regained, and fatalities caused by this syndrome are rare.

Persistent cough may produce hoarseness. Large increases in muscular forces during severe cough may result in tearing of muscle fibers or rib fracture; the latter occurs most often in the posterior axillary line. Paroxysmal cough may cause headache and back pain. Chronic cough may contribute to recurrent inguinal hernia in men and to urinary incontinence in women. Persistent chronic cough seriously disrupts daily life and may be disabling.

Sputum

Mechanisms

A normal person produces between 10 and 40 mL of tracheobronchial secretion per day. The secretion, consisting primarily of an aqueous solution of mucous glycoprotein, is produced by the airways submucosal glands and goblet cells and is carried to the oropharynx by the mucociliary escalator. Increased amounts of secretion may be noted after eating, especially of highly seasoned food. The mechanism is most likely overflow vagal stimulation of the respiratory glands from intense gastric stimulation. Secretion may be stimulated in response to inhaled gaseous or particulate irritant substances. Inflammation of the respiratory tract also results in an increase in secretory activity, but the characteristics of the secretion are changed by the addition of pus cells, plasma proteins, and other inflammatory products, coming either from the bronchial walls or from the alveoli.

Differential Diagnostic Features

The quantity and quality of expectorated material are important features in bronchopulmonary diseases. The volume is usually best expressed by patients in some household unit of measurement, such as ounces, teaspoons, or tablespoons. Description of the secretions as clear and colorless (like egg white) indicates uninfected secretions; a yellow or green color indicates a purulent exudate. Purulence is most often the consequence of infection and the presence of neutrophilic leukocytes. However, large numbers of eosinophils can make sputum appear purulent. A fetid odor suggests anaerobic infection, as in aspiration lung abscess or necrotizing pneumonia. Rusty or brownish-red sputum is indicates the mixing of blood with the secretions, usually in an acute infectious process such as pneumococcal pneumonia.

In coal miners, the sputum may be black because of the presence of large amounts of anthracotic pigment; black sputum may sometimes occur long after work in the mines has ceased. Cigarette smokers may describe brownish sputum. A three-layered sputum with an uppermost frothy layer, a central mucous layer, and a thick bottom layer is said to be characteristic of bronchiectasis, but this nonspecific appearance may be seen in any bronchitic process with a large volume of secretions. Large amounts of mucoid sputum, up to a liter per day, are an unusual manifestation of alveolar cell carcinoma. Mucoid bronchorrhea may also be seen occasionally with chronic bronchitis. Fibrinous casts may be expectorated in the very rare plastic bronchitis syndrome, and “pearls” or wormlike structures comprised of bronchiolar casts are frequently expectorated in asthma. The latter are made up of eosinophils, desquamated bronchial epithelium, and Curschmann's spirals—spiral structures that consist of eosinophils and Charcot-Leyden crystals, which are eosinophil-derived. Brownish bronchiolar plugs may be observed in allergic bronchopulmonary aspergillosis.

The descriptions of sputum provided by patients are often inaccurate, and the physician should make every effort to look at secretions during the examination. Patients with chronic disease should be taught to differentiate between purulent and mucous secretions.

Hemoptysis

Mechanisms

Hemoptysis is defined as the expectoration of blood. The quantity of blood may vary from a few streaks mixed with bronchial secretions to an exsanguinating hemorrhage. The site of bleeding may be anywhere in the respiratory tract, including the nose or the mouth, and the mechanisms of bleeding are varied. The bronchial mucosa may bleed because of congestion from inflammation, often with accompanying superficial erosion of the overlying epithelium. Passively engorged blood vessels, as in mitral stenosis, may also bleed readily, either without evident cause or as a result of mucosal ulceration accompanying minor respiratory infections. Bleeding may result from ulceration of a tumor, such as a bronchial carcinoid or a bronchogenic carcinoma (Fig. 2). Indeed, hemoptysis may occur as the bronchial wall is penetrated by an eroding structure, such as an infectious or noninfectious granuloma, a calcified lymph node, or an aortic aneurysm, which may be atherosclerotic, luetic, or dissecting. Rarely, in empyema, a ventricular-bronchial communication may cause massive hemoptysis. In bronchiectasis, the bronchial arteries undergo enlargement and extensive anastomosis with the pulmonary arteries; erosion into a bronchial artery with its systemic level of blood pressure may give rise to massive hemoptysis.

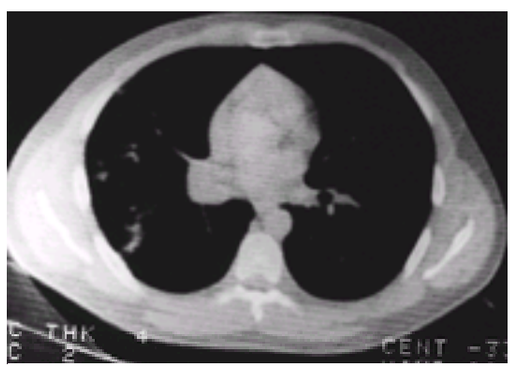

FIG. 2. This patient presented with dyspnea on severe effort; the findings on plain chest x-ray film were normal. On CT, the right hilum appeared to be enlarged. On bronchoscopy, this appearance was shown to be the result of complete occlusion of the bronchus intermedius by a bronchial carcinoid. Only minimal postobstructive parenchymal disease is present because of effective collateral air flow.

Blood may come from the pulmonary parenchyma, as from the vascular granulation tissue lining an anaerobic abscess (Fig. 3), a tuberculous abscess, an abscess of gram-negative bacillary or staphylococcal origin, or a mycetoma. If a blood vessel wall in an abscess is left unsupported by parenchyma, and especially if the blood vessel wall is eroded by the infectious process, hemorrhage may be massive and even exsanguinating. Hemorrhage commonly arises more simply from congested pulmonary parenchyma, as in pneumococcal pneumonia, or from engorged and necrotic parenchyma in pulmonary infarction (Fig. 4).

FIG. 3. A: Anaerobic lung abscess. On chest x-ray film, a large abscess cavity with an air-fluid level fills nearly the entire left upper lobe. Note that some streaky remnants of lung tissue remain visible, as do several smaller air-fluid levels. An area of pneumonia, seen here in the left infrahilar region, is commonly noted, reflecting infected but not yet necrotic lung adjacent to the abscess. **B:** On CT, the multilocular nature of the lung abscess is apparent. Small, air-containing structures in a region of perihilar pneumonia represent bronchiectasis and early foci of necrosis. Note the shaggy interior cavity wall, typical of lung abscess.

FIG. 4. This patient, with a cardiac valve replacement not clearly seen here, received excessive anticoagulant therapy with warfarin and presented with hemoptysis. In the right upper lobe, there is a dense opacification consisting of intraparenchymal hemorrhage. Unlike consolidations caused by infection, parenchymal hemorrhage tends to clear rapidly.

Differential Diagnostic Features

Patients describe hemoptysis in various ways. Pulmonary parenchymal or bronchial bleeding may be perceived as a bubbling sensation in the tracheobronchial tree, followed by the expectoration of blood. When underlying infection has been present, the patient may not be aware of any change in the quantity of secretion but may note blood mixed with mucus or replacing it. When bleeding is profuse, clots may be expectorated.

Bronchopulmonary bleeding may sometimes be manifested as vomiting of blood. Bleeding occurs during the night, and the blood reaches the oropharynx and is swallowed without the patient waking. The swallowed blood acts as an irritant and produces vomiting in the early morning hours. Roentgenographic and physical examination of the chest are therefore mandatory in the investigation of every patient with hematemesis. Hematemesis rarely masquerades as hemoptysis; the presence of gastrointestinal symptoms such as nausea and vomiting and a history of alcoholism or cirrhosis, sometimes with a past history of hematemesis, usually point to the correct diagnosis. The presence of food in a specimen of the bloody fluid and an acid pH suggest gastric origin. If the chest radiogram is negative, the presence of blood or “coffee grounds” material in the gastric aspirate settles the issue.

A history of epistaxis must be sought in patients with hemoptysis, because blood from the nasopharynx can be aspirated during the night and coughed up in the early morning. The nasopharynx should be examined in all patients with hemoptysis who have a negative chest radiogram.

Small stones or gravel may be expectorated with blood in broncholithiasis, a condition in which calcium in granulomatous lymph nodes erodes through the bronchial wall, or a foreign body aspirated years earlier becomes calcified (Fig. 5). In the extremely rare catamenial hemoptysis, resulting from endometrial implants in the bronchial wall, the expectoration of blood occurs concomitantly with menstruation.

FIG. 5. CT demonstrates partial middle lobe collapse. Some patent bronchi are visible. A focus of calcification (*arrow*) is seen centrally near the origin of the middle lobe bronchus. At bronchoscopy, a broncholith composed of calcified and encrusted aspirated vegetable material was removed.

Table 2 provides a partial list of the more than 100 disease entities that can cause hemoptysis. Tuberculosis and bronchiectasis used to be the most common causes of hemoptysis. Erosive bronchitis in smokers with chronic bronchitis is now the most frequent cause of expectoration of blood, accounting for 40%–50% of all cases of hemoptysis. Bronchogenic carcinoma is the second most frequent cause of hemoptysis, underlying 20%–25% of all cases. Blood-streaked bronchitic sputum may be the only hint that a bronchogenic carcinoma has developed in a long-time smoker.

Frequent
Chronic bronchitis
Bronchogenic carcinoma*

Infrequent
Bronchiectasis*
Tuberculosis
  Active*
  Inactive (post tuberculous bronchiectasis)
Pulmonary contusion
Pulmonary abscess*
Bronchoarterial fistula*
Cardiogenic (mitral stenosis, pulmonary edema—pink sputum)
Aspergilloma*
Coagulopathy*
Pulmonary infarction
Idiopathic pulmonary hemosiderosis
Goodpasture's syndrome
Pulmonary telangiectasis*
Amyloidosis
Bronchectasis*
Bronchiolithiasis
Sjögren's syndrome
Deep mycotic infection*
Bronchial adenoma
Metastatic carcinoma
Foreign body
Wegener's granulomatosis
Pseudohemoptysis (epistaxis, hematemesis, bleeding gums, malingering)

* Most frequent cause of massive hemoptysis.

TABLE 2. *Some causes of hemoptysis*

Massive hemoptysis, of which the most common causes are identified in Table 2, may be defined as expectoration of 600 mL or more of blood in 24 hrs. Hemoptysis of this magnitude is life-threatening and requires close monitoring and often urgent diagnostic and therapeutic intervention.

Chest Pain

Mechanisms

Pain in the chest may be derived from the chest wall (dermatomes T1-12), pleurae, trachea and main airways, mediastinum (including the heart and esophagus), and abdominal viscera. The parietal pleura is supplied with pain receptors; the visceral pleura is free of them. Pleuritic pain may be referred to the area of skin supplied by the same sensory roots that supply the area from which pain is arising. Thus, the pleurisy accompanying a right lower lobe pneumonia and involving dermatome T-11 may mimic the pain of acute appendicitis. The sensory fibers of the central tendon of the diaphragm run with the phrenic nerve (C3-4), and the pain of diaphragmatic pleurisy may be referred to the tip of the shoulder. Cardiac pain (T1-4) may radiate down the ulnar aspects of the arms, more often the left, and may radiate up into the jaws. Visceral pain from the gallbladder, pancreas, or hepatic or splenic flexures of the colon may be referred to the epigastrium, substernal area, or lower thorax, as may the pain of upper abdominal peritonitis. A variety of other reactions may accompany severe chest pain. Autonomic reactions such as tachycardia and sweating may be observed; parasympathetic reactions include bradycardia, nausea, and vomiting. Skeletal muscle splinting may accompany severe pleuritic pain of any cause, and was present in the patient with malignant mesothelioma shown in Fig. 6.

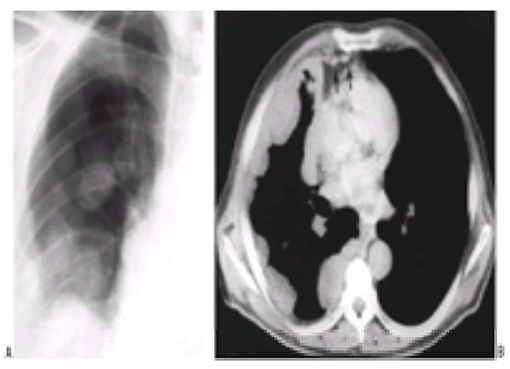

FIG. 6. A: Malignant mesothelioma presenting as multiple, large, rounded masses apparent in this right hemithorax. Some of the more centrally located lesions have the appearance of well-demarcated intraparenchymal lesions. However, others, which demonstrate broad, smooth margins merging with the chest wall, clearly have a pleural origin. **B:** It is evident on the corresponding CT image that there are no intraparenchymal lesions; rather, all the abnormalities are based in the pleura. Mesothelioma typically forms large, rounded lobules along the entire pleural surface. Microscopic invasion of the chest wall is poorly assessed on CT. Gross extension to other mesothelial surfaces, such as the contralateral pleura or peritoneum, can often be detected on CT. In this case, there is direct invasion (*arrow*) of pericardial fat immediately posterior to the sternum.

Pain, like other sensory phenomena, is poorly understood, but it begins with a noxious stimulus generated mechanically or chemically as a result of tissue injury and inflammation. The chemical mediators released from inflamed tissues that initiate pain are beginning to be understood. Tissue receptors are activated and pain stimuli are transmitted via the peripheral afferent nervous system. Visceral pain is transmitted centrally via lowvelocity, unmyelinated C-fibers; cutaneous and chest wall pain are transmitted by high-velocity, myelinated A-fibers.

The pain stimuli are processed in complex, incompletely understood ways by the central nervous system. This processing accounts for a variable dissociation of the central perception of pain from the magnitude of the peripheral stimulus. Many factors, such as emotion, depression, and competing stimuli, may influence the perception of pain. Visceral pain tends to be dull and poorly localized, whereas chest wall pain tends to be sharper and better localized.

Differential Diagnostic Features

History taking is the key to evaluating chest pain. There is only a weak relationship between the severity of chest pain and the importance of its underlying cause; accordingly, all chest pain must be taken seriously. The precise cause of chest pain cannot always be determined by taking a history and doing a physical examination, but it is generally possible to make a judgment as to whether the origin of the pain is the pleura, the chest wall, or the viscera, and to develop a diagnostic plan. Table 3 provides a partial list of causes of chest pain.

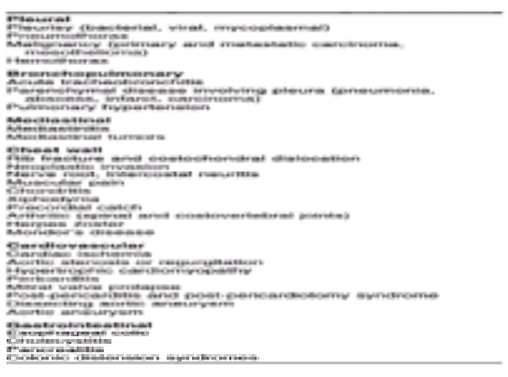

TABLE 3. *Some causes of chest pain*

Pleural Pain. Chest pain that tends to be sharply localized, worsens during coughing, deep breathing, or motion of the trunk, and is relieved by maneuvers limiting the expansion of a particular part of the chest is very likely to be pleuritic in origin. The pain, which occurs more often at the lung bases than in the upper lung zones, may range in severity from mild and aching to excruciating. Worsening during respiratory motions is its hallmark. Pleuritic pain is caused by stretching of the inflamed parietal pleura. However, in chronic pleuritis, pain endings may no longer be stimulated despite roughening of the pleural surfaces, which continue to give rise to a loud rub.

The rapidity of onset of the pain varies with its cause. Pleuritic pain accompanying a spontaneous pneumothorax or pulmonary infarct is usually sudden in onset. Pleurisy of viral origin or associated with pneumonia may be more gradual in onset and occurs in the context of an acute febrile, prostrating illness. Infection with coxsackievirus B produces a syndrome known as pleurodynia (Bornholm syndrome); this is characterized by fever, malaise, sore throat, debility, and anorexia and is followed by the sudden onset of muscular and pleuritic pain, with abdominal pain and muscle spasm in about half the cases. The disease runs its course in 3 to 7 days and may be complicated by a small pleural effusion. Tuberculous pleural effusion may be initially manifested by pleuritic pain and cough that subside rapidly. Parenchymal tuberculosis with overlying pleural disease, often occurring in the context of chronic systemic illness, may cause aching of the chest wall without a clear relation to respiration.

Pain Caused by Bronchopulmonary and Mediastinal Disorders. The lung parenchyma has no pain receptors. However, acute pulmonary diseases that involve the overlying pleura, such as pneumonia, lung abscess, and pulmonary infarction, cause pleuritic pain. Acute tracheobronchitis may give rise to substernal discomfort, with

a tearing, rasping, sharp substernal pain on coughing. Mediastinitis causes a retrosternal, aching, oppressive sensation that can occasionally be severe. Chronic disorders of the large airways, such as tracheal or bronchial tumors, chondritis, or ulcers, do not cause pain. Mediastinal tumors are usually asymptomatic but can cause chest pain if they compress or invade mediastinal structures or chest wall.

Pain Caused by Malignancy. The pain of a carcinoma invading the spine or ribs is generally well localized and of a severe, unremitting character (Fig. 7). With mesothelioma (Fig. 6) or metastatic carcinoma, as from a primary breast tumor, the pain may be more diffuse. Involvement of chest wall and nerve roots results in local, gnawing chest wall pain and radiation of the pain to the affected dermatomes. Thus, in Pancoast's syndrome, in which the brachial plexus is involved by an invasive primary lung tumor located peripherally in the extreme apex of the lung, there is pain in the shoulder, the scapular region, or the medial aspect of the arm and hand. The pain of this tumor sometimes masquerades as subacromial bursitis. The pain of vertebral metastases tends to be in the midline, often with girdle radiation, and may be associated with tenderness over the affected area. Intercostal neuropathy, which may result from irritation of an intercostal nerve by a costal metastasis or some other factor, may result in severe, lancinating, burning pain that is unilateral and segmental in distribution. There may be sensory loss or hyperesthesia over the affected dermatomes. Intercostal neuropathy is one cause of the post-thoracotomy pain syndrome; traumatic neuroma in the thoracotomy scar and recurrent tumor are other causes.

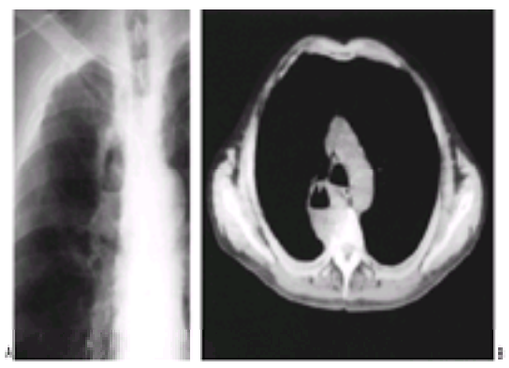

FIG. 7. A: A large mass is present in the right paramediastinal area. An air-fluid level is present within the central cavitary portion of the lesion, defining its approximate inner and outer margins. A small projection into the cavity from the lateral wall suggests the possibility of necrotizing tumor. The diagnosis of squamous cell carcinoma was confirmed by bronchoscopy. **B:** On CT, the entire anterolateral aspect of the adjacent vertebral body has been eroded. Chest wall invasion may be readily apparent or completely undetectable on CT.

Pain Originating in the Chest Wall. Fracture of a rib, either during trauma or spontaneously during cough, causes local pain in the affected area. The pain is severe, worsened by respiratory and trunk motion, and may be accompanied by a grating sensation during breathing. Local tenderness develops early, and a callus may be felt as the fracture heals. Costochondral dislocation, occurring from muscular effort or less frequently trauma, causes less severe, anterolateral chest pain.

The rare occurrence of subacute chondritis causes a dull, aching pain of the anterior chest wall that is not affected by breathing. The second, third, and fourth cartilages are most frequently involved, but the process can involve any costal cartilage or the xiphoid process. Disease of the thoracic spine may be associated with involvement of the costovertebral joints and cause discomfort or pain in the chest wall. Chest wall pain may be caused by damage to muscle fibers secondary to the severe muscular effort associated with coughing during an acute respiratory infection or with unusually severe exercise. Herpes zoster is often heralded by several days of neuritic pain in the affected dermatomes; the pain persists during the cutaneous phase of the disease, and postherpetic neuralgia with its burning and paroxysmal lancinating pain may persist for long periods.

A rare cause of superficial chest wall pain is thrombosis of the superficial vein of the thoracic wall (Mondor's disease). The process is of unknown etiology but is self-limited. It may last several weeks; an initial acute phase is followed by an indolent phase, and a palpable subcutaneous cord over the lateral chest wall is its only sign.

Precordial catch is a pricking, precordial (left parasternal) pain, usually occurring at rest and often associated with emotional stress. The pain is variably worsened by deep inspiration, is not precipitated by effort, and tends to be transient and stabbing in character. It occurs more often in men than in women and is infrequently observed after the third decade. The pain is not caused by heart or lung disease and is probably of chest wall origin. The diagnosis is made by the characteristic history, negative physical findings, and appropriate laboratory tests performed to exclude visceral disease.

Cardiovascular Pain. The pain of cardiac ischemia results from an imbalance between the supply and demand of oxygen in the myocardium, and most often results from atherosclerotic coronary arteries. The pain of angina pectoris is induced by exercise, especially after a heavy meal or in cold or windy conditions. The chest pain is vague, diffuse, and ill-defined—that is, it is visceral in nature. Generally located substernally or in the anterior midline, it is described as constricting or squeezing, or as a weight on the chest. The pain may radiate down the medial aspect of the left arm (less often the right) or into the neck or mandible. Angina is relieved by rest or sublingual nitroglycerin. The pain of myocardial infarction is usually more persistent, lasting longer than 20 minutes, and is often accompanied by sweating, nausea, hypotension, dyspnea, and arrhythmias. Unstable angina occurs episodically at rest or with little provocation, and it may herald an impending myocardial infarction.

Cardiomyopathy may cause anginal chest pain, as may aortic stenosis and, to a lesser degree, aortic regurgitation. Mitral valve prolapse may be associated with sharp, stabbing chest pain not provoked by exertion; it is more frequent in female patients.

The pain of pericarditis is in the midline but not as distinctly substernal as the typical pain of myocardial ischemia. Because of the intimate association of the pericardium and the mediastinal pleura, pericardial pain often exhibits characteristics suggesting pleural involvement—it is worsened by inspiration and coughing. When the central tendon of the diaphragm is involved, the pain is referred to the trapezius ridge. Pericardial may be so severe that it mimics myocardial infarction, or be so mild and pleuritic in nature that acute pleurisy or pulmonary infarction become diagnostic considerations. The pain is often relieved by sitting up and leaning forward or by lying on the right side. Spontaneous pneumomediastinum may also give rise to pain that has the characteristics of pericarditis.

Pain associated with acute pulmonary hypertension is similar to the pain of myocardial infarction, but the electrocardiographic and laboratory features of that disease are absent. The pain may be associated with multiple or massive pulmonary emboli or with an infectious process in a patient having a restricted pulmonary vascular bed or mitral stenosis. Its mechanism is unknown; it may be caused by the sudden distension of the main pulmonary artery and stimulation of mechanoreceptors.

Chest pain, usually excruciating and starting in an anterior substernal location, is the predominant presenting symptom in dissecting aneurysm of the aorta (Fig. 8). Unlike the pain of myocardial infarction, which waxes and wanes, this pain is usually maximal at onset. It is common for the pain to migrate posteriorly as the dissection propagates distally. Nondissecting aneurysm can produce continuous aching or lancinating pain in the chest, shoulder, and back by compressing the thoracic spinal nerves; bone erosion causes boring, intractable back pain.

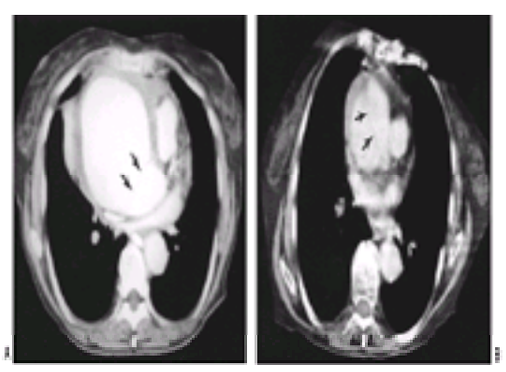

FIG. 8. A: In many cases, dissection of the aorta is easily seen on contrast-enhanced CT, as demonstrated in this example. Here, a large saccular component of the aneurysm at the root of the aorta bulges anteriorly and to the right into the sinus of Valsalva. The intimal flap is visible as a thin, dark, obliquely oriented line (*arrows*) at the posterior aspect of the large, contrast-enhanced aortic root. Note that the attenuation of the region immediately surrounding the aorta is higher than that of fat and normal soft tissue and is caused by leakage of blood into the pericardial sac, a portion of which encompasses the aortic root. **B:** In another patient with aortic

dissection, the dilatation of the aorta is not as extensive. Some intrapericardial hemorrhage is seen anterior to the aortic root. The intimal flap (*arrows*) can again be seen, in this case oriented anteroposteriorly. Note in both cases the gentle curvature of the intimal flap toward one lumen or the other, a common appearance.

Chest Pain Related to Gastrointestinal Disease. Recurrent noncardiac chest pain is a common clinical condition that is often frustrating to the physician. Such patients often have undergone angiography demonstrating normal or near-normal coronary arteries, but they continue to have angina-like chest pain that prompts repeated visits to the physician's office or emergency department. They have a low risk for myocardial infarction or cardiac death.

Spasm of the esophagus or esophageal colic is one important cause of such chest pain. The pain may mimic cardiac pain perfectly. It ranges from mild to severe and may last from 5 or 10 minutes to many hours. The pain is usually substernal and may radiate down one or both arms, and into the neck, jaws, teeth, or epigastric area. Radiation through to the back suggests an esophageal origin, as does the association of heartburn and relief of pain by the ingestion of alkali or by changing from a recumbent to an upright position.

Proving that chest pain is of esophageal origin is often difficult. Different types of esophageal motility disorders have been described in association with chest pain: achalasia, diffuse esophageal spasm, “nutcracker” esophagus, and nonspecific motility disorder. However, the precise relation between these abnormal contractions and chest pain is far from clear; chest pain is frequently not present when motility disorders are being demonstrated in the laboratory, and motility disorders are often not associated with impaired esophageal function. Katz et al., reviewing the records of 910 patients studied manometrically for noncardiac chest pain, found abnormal motility in 28% during baseline manometry; diffuse spasm and achalasia were present in only 10% and 2% of subjects, respectively. Nutcracker esophagus and nonspecific motility disorders were most common, in 48% and 36%, respectively. Ambulatory pressure monitoring and monitoring of pH have also been widely studied to evaluate chest pain, as have provocative tests such as acid infusion and intravenous edrophonium.

Distension of the splenic flexure may cause left lower chest pain; the pain is usually relieved by passing flatus and is not related to breathing or trunk motion. Gallbladder disease may also give rise to epigastric and midline chest pain mimicking angina as well as to right upper quadrant abdominal pain. The history of gastrointestinal symptoms and the atypical nature of the chest pain are helpful in differential diagnosis.

Dyspnea

Dyspnea may be defined as discomfort associated with breathing and is a symptom of both pulmonary and cardiac disease. In taking the history, it is important to determine whether dyspnea occurs only on exercise or also at rest; if the symptom occurs only on exercise, what has been the time course of its development? If dyspnea occurs at rest, how is the symptom related to the time of day, eating, and body position? A partial listing of the causes of dyspnea is given in Table 4, and a simple categorization of the severity of dyspnea is given in Table 5. The flowing section briefly summarizes our knowledge of the mechanisms of dyspnea, including the contributions of the relatively new field of respiratory psychophysics.

Acute
Upper airway obstruction (laryngospasm, aspirated foreign body, neoplasm)
Asthma
Chest trauma (rib fracture, pneumothorax, lung contusion, vascular rupture, bronchial rupture)
Pneumonia (pleural effusion may contribute)
Pulmonary embolism
Acute interstitial lung disease (hemorrhage, adult respiratory distress syndrome)
Cardiogenic pulmonary edema
Spontaneous pneumothorax
Chronic
Chronic obstructive pulmonary disease
Cystic fibrosis
Interstitial lung diseases
Pleural effusion
Fibrothorax
Chest wall abnormalities (kyphoscoliosis, neuromuscular disease, diaphragmatic paralysis)
Pulmonary vascular disease (primary pulmonary hypertension, organizing pulmonary emboli, veno-occlusive disease, vascular malformations)
Cardiovascular disease
Severe anemia
Psychogenic dyspnea

TABLE 4. *Some causes of dyspnea*

Grade	Degree	Defining clinical characteristics
0	None	Not troubled with breathlessness except with strenuous exercise
1	Slight	Troubled by shortness of breath when hurrying on the level or walking up a slight hill
2	Moderate	Walks more slowly than people of the same age on the level because of breathlessness or has to stop for breath when walking at own pace on the level
3	Severe	Stops for breath after walking about 100 yards or after a few minutes on the level
4	Very severe	Too breathless to leave the house or breathless when dressing or undressing

TABLE 5. *American Thoracic Society dyspnea scale*

Mechanisms

Dyspnea may be accounted for by a decrease in ventilatory capacity, an increase in ventilatory demand during exercise, or by the perception of increased breathing as being uncomfortable. Put somewhat differently, the symptom varies directly with the demand for ventilation and inversely with ventilatory capacity. The symptom is related to the patient's perception of whether ventilation is appropriate to a particular level of activity. Thus, the expected increase in ventilation while climbing a flight of stairs quickly is not perceived as dyspnea; a similar level of ventilation while climbing three or four stairs would be perceived as dyspnea by an observant patient. An increase in the effort required to produce a given level of ventilation, as in asthma, might also be perceived as dyspnea.

Decreased ability to move air in neuromuscular, obstructive airways, or cardiac diseases may cause dyspnea. Cardiopulmonary disease may increase ventilatory demand in many different ways, thereby causing dyspnea: hypoxemia, hypercapnia, increased hydrogen ion concentration, and increased reflex activity from the lungs, muscles, or central blood vessels. For example, ventilatory capacity is relatively well maintained in diffuse interstitial disease, but there is an increase in ventilatory demand and elastic work of breathing during exercise that gives rise to dyspnea. Dyspnea occurs in COPD primarily because of the decrease in ventilatory capacity and the increase in resistive work of breathing. However, none of these physiologic correlates of dyspnea provides an understanding of the sensory basis of dyspnea.

Differential Diagnostic Features

The duration of dyspnea, whether it is of gradual or rapid onset, whether it is episodic or continuous, and its relation to effort should all be determined. For example, gradual onset of dyspnea suggests slowly progressive disease of the heart, lungs, or musculoskeletal system. Rapid onset of dyspnea suggests an acute respiratory infection; sudden worsening of air flow obstruction, as in asthma; or a sudden event, such as a pulmonary embolus. Dyspnea produced by a level of exercise not previously causing discomfort suggests slowly progressive heart or lung disease or anemia. Dyspnea occurring only during exercise suggests slowly progressive disease; dyspnea occurring also at rest suggests heart failure of fluctuating severity or variable air flow obstruction. Breathlessness may be similar to that experienced during normal exercise, suggesting that air flow obstruction is not present, or breathlessness may be associated with labored breathing (difficulty in moving air into or out of the chest), suggesting that airflow obstruction is present. The presence of air-flow obstruction is confirmed if the dyspnea is associated with wheezing (whistling or musical noises in the chest). Sudden chest pain occurring with dyspnea suggests a pulmonary infarction, spontaneous pneumothorax, or myocardial infarction. An episode of aspiration may precede dyspnea associated with pneumonia. Hemoptysis occurring with the dyspnea may signal diffuse interstitial lung diseases, as in Goodpasture's syndrome or pulmonary hemosiderosis. Expectoration of frothy pink sputum and orthopnea suggest pulmonary edema. Coryza, malaise, cough,

expectoration, and chest pain suggest an acute upper or lower respiratory infection.

Severe dyspnea in a patient without airflow obstruction or heart disease should suggest the possibility of a diffuse interstitial parenchymal process, pulmonary embolism, or primary pulmonary hypertension (Fig. 9). The presence of fine crackles on auscultation suggests interstitial lung disease; the signs of pulmonary hypertension should be carefully sought in the absence of crackles. Paroxysmal nocturnal dyspnea can occur with either left ventricular failure or obstructive airways disease. Obstructive airways disease is not usually accompanied by orthopnea, whereas left ventricular failure and bilateral diaphragmatic paralysis virtually always are.

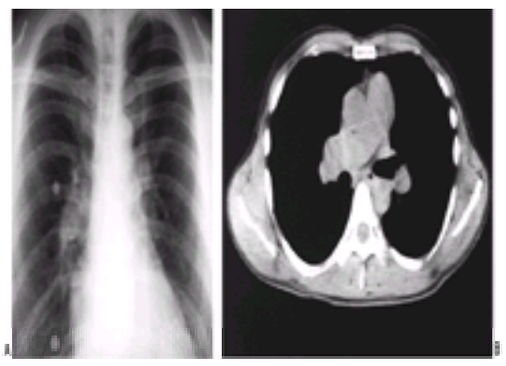

FIG. 9. A: On posteroanterior view of the chest in pulmonary hypertension, the central pulmonary arteries are enlarged and the peripheral arteries appear diminutive in size. On a lateral view, a hypertrophied right ventricle may be encroaching on the retrosternal air space. **B:** The diameters of the main and right pulmonary arteries are easily seen to be greater than the diameter of the adjacent aorta on CT of the mediastinum.

Trepopnea, or dyspnea in one lateral position but not in the other, may be produced by unilateral lung disease, unilateral pleural effusion, or unilateral airway obstruction. Platypnea, or dyspnea in the upright position relieved by recumbency, may be produced by intracardiac shunts or vascular shunts in the lungs. Differentiation of dyspnea of cardiac origin from that of pulmonary origin usually depends on demonstrating whether cardiac or pulmonary disease is present. Sophisticated tests of cardiac and pulmonary function and exercise testing may at times be necessary to settle the question, or to determine the relative contributions of heart and lung disease when both are present.

Psychogenic dyspnea occurs in several forms. The syndrome usually presents as breathlessness unrelated to exertion, occurring in women more often than in men, usually in the third or fourth decades of life. If the patient is hyperventilating (i.e., breathing in excess of metabolic needs), the partial pressure of arterial carbon dioxide ($PaCO_2$) decreases, with a resultant decrease in cerebral blood flow. Lightheadedness, faintness, visual disturbances, numbness, and tingling of the fingers and perioral areas may be noted. Patients are often disproportionately anxious.

Another form of hyperventilation is sighing dyspnea. This occurs equally often in both sexes, may occur at any age, and is not usually accompanied by symptoms of hypocapnia or severe anxiety. The symptom may appear in patients with known heart or lung disease. The patient usually complains of not being able to get enough air at rest. Effort dyspnea is not present unless associated heart or lung disease is present, and then the effort dyspnea is different from the resting breathlessness. The patient usually describes how the expected deep visceral sensation of comfort or satisfaction in the epigastrium is not felt after a sighing inspiration. Consequently, the patient repeats a series of deep inspirations to attempt to produce this normal sensation. Because normally this sensation decreases and then disappears with successive sighs, the deep breaths do not have the desired effects, and the patient complains of being unable to “fill the chest with air satisfactorily.” A precipitating event can rarely be identified. A negative chest radiogram and electrocardiogram added to the negative findings on physical examination and a careful explanation of the nature of the symptoms are usually sufficient to produce relief.

Wheezing

Some patients with obstructive airflow disease may be aware of wheezing, but most are not and rather describe difficult breathing or a sense of tightness in the chest. Sounds generated by breathing may be heard only by family members. Wheezing may be audible only during recumbency. This symptom may suggest the possibility of asthma as the underlying cause in a patient with cough or dyspnea of obscure origin.

Stridor

Stridor is a harsh, blowing noise resulting from obstruction of the trachea or larynx by tumor (Fig. 10), bilateral vocal cord paralysis, other forms of vocal cord dysfunction, tracheal compression, edema associated with inflammation, or the impaction of a foreign body. The airway must be narrowed to about 5 mm in an adult before stridor is produced. Stridor is mainly inspiratory, because air flow is more rapid during this respiratory phase. It has a characteristic crowing or musical sound. However, when upper respiratory tract obstruction is very severe and alveolar hypoventilation has occurred, stridor may be absent. Stridor may also be hysterical in origin.

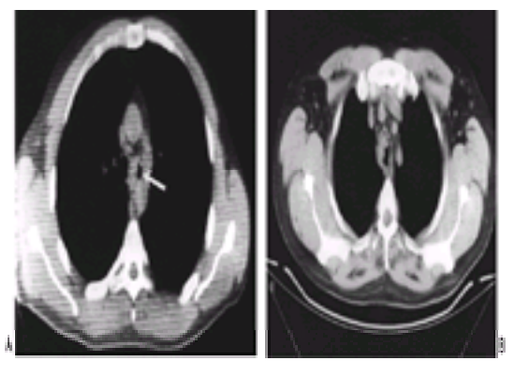

FIG. 10. A: This tracheal squamous papilloma originated near the carina. On inspiratory CT, it can be seen partially occluding the left main bronchus (*arrow*). On expiratory chest x-ray films and CT, there was significant air trapping in the left lung as the lesion created a ball valve effect. The partial obstruction also caused the patient to wheeze. **B:** This tracheal cylindroma demonstrates a lobular, intraluminal mass of soft-tissue density on CT. The affected portion of the tracheal wall is obscured by the neoplasm itself. Often, the bulk of a tracheal tumor is intraluminal rather than extraluminal.

Obstructive Sleep Apnea

Disorders of breathing associated with sleep have been reported with increasing frequency during the last four decades. Obstructive sleep apnea (OSA) is a condition in which 10 or more episodes of upper airway obstruction, each lasting 10 seconds or longer, are detected per hour of sleep. The resultant hypoxemia and impaired quality of sleep result in daytime hypersomnolence, a variety of cardiovascular abnormalities (arrhythmias, cor pulmonale), and neuropsychologic complications. The prevalence of OSA is not known, but it is estimated to affect 1%–2% of the population.

OSA should be suspected whenever excessive daytime sleepiness and snoring coexist. Obesity and alcohol abuse are well-known aggravating factors but need not be present. Nocturnal restlessness, choking spells, frequent urination at night, enuresis, and loss of libido are common. Morning headache and falling asleep during the day while working, engaging in conversation, or driving an automobile are all well-known features of this syndrome. An increased frequency of accidents at home, at work, or while driving is common. It is essential to question the spouse or dwelling partner of the patient regarding these symptoms as well as snoring and apneic episodes during sleep, as the patient may be unable to give an account of them.

The presence of systemic hypertension, plethora associated with polycythemia, and evidence of pulmonary hypertension and cor pulmonale suggest OSA. Obesity, hypothyroidism, acromegaly, and maxillofacial or oropharyngeal abnormalities are predisposing factors, but none of these risk factors, including obesity, need be present. The diagnosis is established by polysomnography.

Systems Review and Social History

After the history of present illness has been completed, a careful review should be made of the function of other body systems. Joint pain with or without skin abnormalities may indicate the presence of a systemic disease, such as rheumatoid disease or sarcoidosis. Raynaud's phenomenon with thickening of the skin of the hands or face, possibly with dysphagia, suggests the possibility of progressive systemic sclerosis. A chronic skin ulcer may be evidence of systemic spread of a pulmonary fungal infection. Late afternoon fatigue, denoting a chronic inflammatory process in the body such as tuberculosis or a deep mycotic infection, may have been so insidious in onset as not to have reached the patient's awareness until the question is carefully put.

Tobacco-Smoking History

The tobacco-smoking history should be taken in a standard manner (Table 6). Patients should be asked if they currently smoke cigarettes. If the response is in the negative, the patient should be asked, “Did you ever smoke?” It is not rare for a patient with pulmonary disease, who has stopped smoking recently because of an alarming symptom such as hemoptysis, to answer negatively when asked, “Do you smoke tobacco?” The age when regular smoking began should be determined. The risk for lung cancer is inversely proportional to the age at which smoking was begun. The total number of years smoked should be calculated. If the patient has stopped smoking, the age at cessation of smoking should be recorded. For former smokers, the number of years of abstinence should be calculated; the risk for lung cancer drops with the duration of abstinence, approaching that of nonsmokers after 10 years, although some risk is nonreversible. The average amount of tobacco smoked per day (packs of cigarettes, number of cigars, ounces of pipe tobacco) during the patient's smoking lifetime should be noted, as it provides a rough estimate of whether a patient is a light, medium, or heavy smoker.

Age when started
• How old was the patient when regular smoking began?
Duration of smoking
• Were there periods when the patient stopped smoking?
• Is the patient currently smoking?
• At what age did the patient stop smoking?
Amount of tobacco smoked
• What is the average lifetime number of cigarettes smoked per day?
• What is the average lifetime number of cigars smoked per day?
• What is the average lifetime amount of pipe tobacco smoked per day?
• Pack-years of cigarettes smoked (average packs per day times number of years smoked) may be calculated, but as the only data recorded, this provides insufficient information.

TABLE 6. *The smoking history*

Alcohol Use, Illicit Drugs, Sexual Preference

A detailed review of the use of alcoholic beverages should be routine because of the association of alcohol abuse and anaerobic, gram-negative, and other pulmonary infections (Fig. 11), as well as tuberculosis. Inquiry regarding the use of illicit drugs is essential; intravenous drug use is associated with septic pulmonary emboli, bacterial endocarditis, and human immunodeficiency virus (HIV) infection. A sexual history should be obtained. Male homosexuality, frequent use of prostitutes, anal intercourse by women, and heterosexual intercourse with intravenous drug users are risk factors for HIV infection and AIDS, with its panoply of unusual lung diseases (Fig. 12).

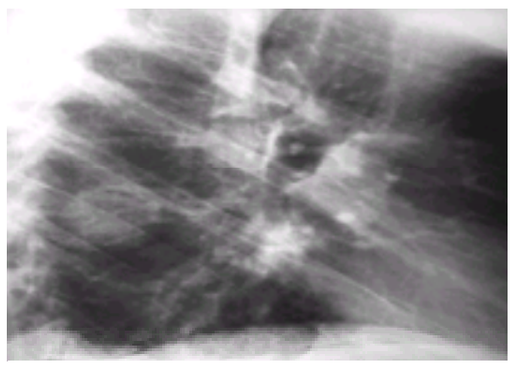

FIG. 11. In this lateral projection from an intravenous drug abuser, an abscess with a small air-fluid level is observed in the posterior segment of the lower lobe; additional parenchymal abscesses were seen elsewhere on other views. Lung abscesses associated with intravenous drug abuse or indwelling catheters tend to be smaller than those seen with underlying pneumonias; they also tend to be multiple and form cavities. In addition, abscesses in intravenous drugs abusers tend to demonstrate relatively rapid growth and cavitation.

FIG. 12. The classic radiographic appearance of *Pneumocystis carinii* infection in an immunocompromised patient is that of hazy perihilar infiltrates, although the range is broad, from normal-appearing lungs to lobar consolidation. Parenchymal cystic and thin-walled cavitary changes have been associated with *Pneumocystis* infections, typically in the upper lobes. Two such cysts are evident in the left upper lobe of this AIDS patient with *P. carinii* infection.

Medical Drug Use

A detailed record should be made of all drugs that have been taken for medical use, whether purchased over-the-counter or prescribed by a physician. The patient's history of allergic or toxic reactions to drugs should be noted. A large number of drug-induced lung diseases have been reported, and these have been summarized in recent reviews and are discussed in Chapter 22. Table 7 provides a list of the most common drug-induced pulmonary diseases.

Parenchymal reactions
Pulmonary edema
Aspirin, heroin, methadone, propoxyphen
Interstitial pneumonia
Nitrofurantoin, gold salts, sulfasalazine
Cytotoxic agents
Alkylating agents: busulfan, cyclophosphamide, chlorambucil, melphalan
Antibiotics: bleomycin, mitomycin
Antimetabolites: methotrexate, azathioprine
Nitrosoureas: BCNU (bischloroethylnitrosourea)
Pulmonary infiltrates with eosinophilia
Nitrofurantoin, methotrexate, penicillin, and many others
Diffuse interstitial lipidosis
Amiodarone
Airways reactions
Chronic cough
Angiotensin-converting enzyme inhibitors
Asthma
Aspirin, nonsteroidal anti-inflammatory agents, β-adrenergic antagonists
Obliterative bronchiolitis
D-penicillamine (treatment of rheumatoid disease and neutrophilic fascitis)
Pleural reactions
Drug-induced systemic lupus erythematosus
Hydralazine, procainamide, isoniazid, phenytoin, D-penicillamine, and many others
Pleural effusion
Dantrolene, and in association with parenchymal disease, busulfan, nitrofurantoin, amiodarone, and many others
Opportunistic infections
Corticosteroids, cytotoxic agents

[a] A partial listing.

TABLE 7. *Drug-induced pulmonary diseases*[a]

Occupational History

The relationship of lung disease to occupation is not always clear. Current symptoms may be work-related. The patient may suggest the relationship or may answer affirmatively when asked the simple question of whether respiratory symptoms are worse at work. Support for the suspected relationship is provided if other workers at the same workplace have similar symptoms. Some disorders, like byssinosis (Chapter 35), are worse on the day of return to work after a weekend at home. Other disorders, such as air flow obstruction caused by diisocyanates, improve during weekends or vacations. The connection between occupational exposure and lung disease is much less evident when there is a long latent period between the onset of exposure and the appearance of symptoms (Fig. 13 and Fig. 14). The only way of knowing whether to consider seriously the diagnosis of an occupational pulmonary disease is to obtain an occupational history in systematic fashion.

FIG. 13. The fine reticular pattern of asbestosis almost invariably tends to involve the lower lobes bilaterally. As the disease progresses, silhouetting of the diaphragm or cardiac borders by the interstitial lung disease may occur, and the appearance may be indistinguishable from that of idiopathic pulmonary fibrosis (Fig. 24). It is common to see either parenchymal asbestosis or asbestos-related pleural plaques; less commonly, both may be seen in the same patient.

FIG. 14. Characteristic findings of silicosis are demonstrated throughout both lungs of this sandblaster: diffuse, small, scattered nodules, some calcified, with a slightly greater density in the upper lobes. In addition, a dense opacity has formed in the right upper lobe, representing a cicatrized conglomerate of multiple individual nodules. Secondary distortion and irregular contours of the hila are apparent.

All jobs (part-time and full-time) should be listed chronologically, with exact dates recorded if possible. Exactly what jobs were performed and what activity each entailed should be determined exactly—not just the name given to the job. Materials used should be identified, with the appropriate government agency called if necessary to determine the constituents of a substance with a brand name. The physician should obtain general estimates of the intensity of exposure and calculate a rough duration of exposure, should ask whether protective measures were used or recommended, and should inquire about ventilation in the plant. The interval between the start of the job and the beginning of symptoms should be determined. The physician should ask about examinations offered by the industry, such as chest radiograms. The environmental history should be completed with questions about exposures during hobbies or home activities, the presence of pets, use of humidifiers, and the geographic history.

PHYSICAL EXAMINATION

Inspection

Inspection is performed while the history is taken. It will be evident whether the patient is debilitated and chronically ill or presents the appearance of good health. It will also be evident whether the patient is dyspneic at rest, is cyanotic, or has a gross chest wall deformity. It is easy to see whether respirations are shallow or deep, slow or fast, but it is notoriously difficult to assess the effects of an altered breathing pattern on the adequacy of alveolar ventilation. The patient with rapid, shallow respirations may appear to be overbreathing when in fact dead space ventilation is excessive and alveolar ventilation is inadequate. Shallow respirations may be seen with myxedema or raised intracranial pressure; deep respirations are a characteristic feature of metabolic acidosis, as in diabetic ketoacidosis or renal failure.

Flaring of the alae nasi may accompany the rapid respiratory pattern in patients with severe pneumonia. Widespread and severe obstruction of the airways is signaled by noisy breathing and labored expiration, often with pursed-lip breathing and use of accessory muscles of respiration; retraction of the lower interspaces and supraclavicular fossae may be evident during inspiration. Supraclavicular retraction and use of accessory muscles is especially prominent with stridor. Periodic respiration, with intervals of regularly recurring apnea, occurs in cardiac failure, in narcotic and sedative drug overdose, and with increased intracranial pressure. The facial grimacing and sudden cessation of inspiration accompanying pleuritic pain may be dramatic.

Cyanosis

Cyanosis, or blueness of the skin and mucous membranes, is observed when more than 5 g of reduced hemoglobin is present per 100 mL of capillary blood in tissues. Thus, cyanosis may not occur during severe hypoxemia in the presence of anemia and is more evident with erythrocytosis than with a normal level of hemoglobin. Cyanosis may also be associated with methemoglobinemia or sulfhemoglobinemia. Interobserver variability in detecting cyanosis is high unless the arterial oxygen saturation is <85%; thus, cyanosis is an insensitive tool for detecting hypoxemia. To avoid confusion with cyanosis resulting from venous stasis in cold fingers or toes, it is best to detect cyanosis by observing the tongue and oral mucous membranes. Sweating, coarse tremor, twitching, asterixis, drowsiness, and coma may accompany

the hypercapnia that often complicates severe hypoxemia.

Digital Clubbing and Hypertrophic Osteoarthropathy

Digital clubbing may be defined as a focal enlargement of the subcutaneous tissue in the terminal phalanges of the digits, especially the dorsal surfaces; the mechanism is unknown. With rare exceptions, the process is bilateral; the toes as well as the fingers may be involved. Clubbing of the digits, although a most important finding in lung disease, is not specific for pulmonary disease and may be seen in inflammatory bowel disease, hepatic cirrhosis, congenital cyanotic heart disease, and bacterial endocarditis, and as a familial occurrence. Clubbing in pulmonary disease is most frequently found in association with neoplasms, particularly bronchogenic carcinoma, but may also be seen with mesothelioma and Hodgkin's disease. Clubbing can develop rapidly with suppurative lung disease, such as lung abscess; it is common with bronchiectasis and in cystic fibrosis of the pancreas. Clubbing is observed in about 15% of patients with interstitial lung disease and in patients with arteriovenous fistula of the lung. Among the pneumoconioses, clubbing is particularly prevalent in asbestosis.

Digital clubbing is almost never seen in tuberculosis unless the disease is complicated by suppurative bronchiectasis or is a complication of cyanotic congenital heart disease. Clubbing is not observed with chronic bronchitis and emphysema, and its occurrence with either condition should raise the possibility of complicating bronchogenic carcinoma.

In hypertrophic osteoarthropathy (HOA), periosteal new bone forms over the bones of the distal arms and legs, sometimes accompanied by symmetric arthritic changes involving the ankles, knees, wrists, and elbows. There may be thickening of the skin of the distal third of the arms and legs and, rarely, facial thickening. Digital clubbing is almost invariably also present, and there may be neurovascular changes of the hands and feet. The mechanism of HOA, like that of clubbing, is unknown. HOA is always associated with some underlying disease, most often an intrathoracic neoplasm, especially bronchogenic carcinoma; it may be seen with suppurative lung diseases. When joint involvement is prominent, a mistaken diagnosis of arthritis may be made.

The diagnosis of clubbing is made entirely from physical examination. The soft tissues at the base of the nail are spongier than normal. The hyponychial angle, the angle between the dorsum of the distal phalanx and a line connecting the cuticle and the hyponychium, is greater than the normal 195º. Mild clubbing may be difficult to recognize. As the process increases in severity, the shape of the distal digit is changed, with dorsal-palmar or side-to-side thickening. It is important not to confuse filbert nails (increased supero-inferior curvature of the nails) with clubbing. The absence of a spongy nail bed and a normal hyponychial angle are the clues to correct diagnosis. Radiographs of the distal bones of the leg and arm may reveal periosteal formation of new bone that is characteristic of HOA (Fig. 15).

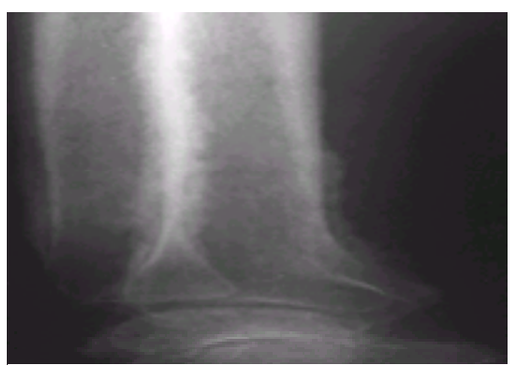

FIG. 15. Hypertrophic pulmonary osteoarthropathy typically involves the diaphyses and metaphyses of tubular bones of the extremities, often in a symmetric manner. In this patient with lung cancer, extensive periosteal new bone is evident along the cortical margins of the distal tibia and fibula.

Thorax

Inspection of the thorax is best carried out during the early part of the physical examination, with the patient sitting or standing, although the recumbent position is just as satisfactory for studying the patient's anterior aspect. Minor asymmetry of the thorax is common. In the defect known as *pectus excavatum,* the lower two thirds of the sternum is markedly depressed behind the frontal plane of the thorax. Other variants of this condition are horizontal grooves in the lower anterior thorax on one or both sides; similar horizontal grooves may remain after rickets in childhood. With pigeon breast (pectus carinatum), there is abnormal protrusion of the sternum anteriorly, especially in its upper part. This deformity may be idiopathic or may be acquired during childhood, most commonly as a result of chronic pulmonary overdistension in asthma or of severe cardiomegaly (Fig. 16).

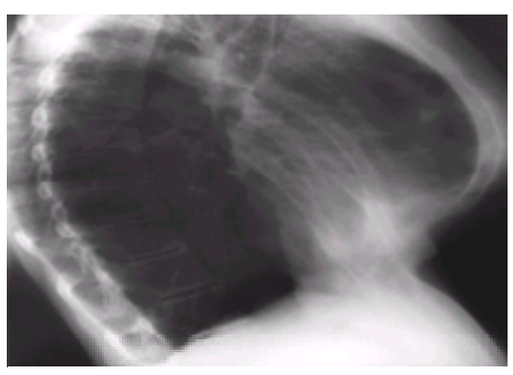

FIG. 16. In this lateral view of a patient with severe pectus excavatum, the heart is displaced posteriorly and superiorly by the lower sternum and xiphoid process. This deformity can cause silhouetting of the heart borders on the corresponding posteroanterior view, and it should not be mistaken for middle lobe or lingular disease. The normal downward slope of the ribs is accentuated as they bend toward their articulations with the sternum.

The presence of thoracic kyphosis or kyphoscoliosis and swellings of the chest wall may be observed. These may denote the presence of an inflammatory process, such as a cold abscess, a tumor of the subcutaneous tissue or chest wall, or a necessitating empyema. Patients with an increase in anteroposterior diameter (e.g., with thoracic kyphosis) need not have air flow obstruction. The increase in anteroposterior diameter often observed in emphysema is caused by an increase in functional residual capacity and total lung capacity.

As the chest is observed during respiration, a decrease or lag in motion on one side of the thorax may indicate the presence of underlying disease. Similarly, a flattening or drawing in of the chest, normally best observed in the supraclavicular fossae, may indicate the presence of an underlying fibrosing process. Differences in the two pectoral muscles (the right pectoral muscle may be larger in right-handed people) should be recognized and should not be confused with disease in the underlying lung. A completely immobile thorax is seen in ankylosing spondylitis with fusion of the costovertebral joints, or, rarely, in patients with severe bilateral pleural disease. The scars of an empyema drainage or thoracotomy should be noted. Engorged veins over the thorax and neck may be present in patients with superior vena caval obstruction. It should be remembered that expiratory filling of the neck veins is often seen in expiratory airways obstruction.

Palpation

Asymmetry or a decrease in movements that is suspected during inspiration may be confirmed by palpation of the thorax. The location and nature of the apical cardiac impulse should be determined; lateral shifts of the apical impulse along with lateral displacement of the trachea are the main physical signs of a shift of the mediastinum from its usual midline position. The finding of a right ventricular lift at the end of systole, felt in the left parasternal area, denotes the presence of right ventricular hypertrophy. Palpable pulmonic valve closure should be looked for as an additional sign of pulmonary hypertension.

The transmission of the vibrations of the spoken voice to the chest wall (vocal fremitus) may be palpated. The intensity of vibration is increased with an increase in the

loudness of the voice and a decrease in the pitch of the syllables used; hence, the common command to the patient to say “99” in a loud voice. As these vibrations are generally bilaterally asymmetric, being more intense over the right hemithorax than the left, it may be difficult to assess the significance of slight increases or decreases in vocal fremitus. However, it is usually easy to be certain of the complete absence of vibration. This denotes the presence of non-air-containing material in the thorax, such as fluid, that is totally absorbing the vibrations. Some degree of fremitus often persists with air in the pleural space, except when the pneumothorax is complete.

Percussion

The sound produced by percussion is determined by the combination of the sound made as the striking finger hits the pleximeter finger and the vibrations coming from the chest wall and the structures underlying it. Percussion over normally aerated lung produces vibrations that are maximal in the range of the natural frequency of the thorax (about 140 Hz in the average young adult man). When the lung is consolidated or the pleural space is filled with fluid, the percussion note is impaired. Relatively few added vibrations come from the underlying solid material, and the low-intensity, relatively high-pitched percussion note is predominantly caused by the sound of impact. A similar percussion note is generated by percussing over the liver. Percussion over an air-containing structure, such as a gas-filled stomach, tends to produce a louder note with a more musical quality (about 180 Hz with a harmonic at 360 Hz) than that produced by percussing over an aerated lung. Such a note is referred to as *tympanitic.*

Percussion is also useful for identifying the interface between the lung and solid structures. The interface between lung and liver, the outer margins of cardiac dullness, and the positions of the diaphragm may be readily determined. In identifying such an interface, a light, rapid percussion stroke should be used, and the pleximeter finger should be moved back and forth rapidly until the interface between normal and decreased percussion notes is accurately identified.

The exact characteristics of the percussion note vary over different parts of the thorax, depending on whether percussion is being carried out over chest wall covered only by subcutaneous tissue and skin, or whether muscles also cover the area. It should be recognized that even with the most vigorous percussion blow, vibrations do not come from a depth of more than 5 cm beneath the surface. It is not possible from percussion alone to differentiate between pleural fibrosis, pleural fluid, and pulmonary consolidation. When percussing over lung, it is generally sufficient to describe the percussion note as normal, dull, or absent. Hyperresonance may be found over a tension pneumothorax.

Auscultation

Careful clinical observations coupled with knowledge of lung physiology and the application of modern electronic technology have resulted in the development of new information regarding the genesis of the normal and adventitious sounds coming from the lungs. Recent reviews summarize much of this new information.

Sound Generation

The spectrum of normal hearing is 16 to 16,000 Hz, and most chest sounds are in the lower range of this spectrum (<1000 Hz), where the sensitivity of hearing is low. The intensity of a sound is determined by the amplitude of the vibrations, the distance the sound must travel, the medium through which the sound travels, and the amount of sound absorbed during the transit. The quality or timbre of a sound is determined by its harmonics or overtones and depends on the sound generator; we have no difficulty identifying whether the same note is played on an oboe, a violin, or a piano.

Sounds generated by the vibrations of gas bubbles in a liquid stream are termed *cavitation noise;* this mechanism may be involved in production of crackles. Sounds are also generated by complex turbulence when gas flows past a pole or a wire, through a tube into a cavity, or exits from a narrow nozzle. Flow visualization in models and casts of airways suggests that sounds are generated as gas develops turbulent flow just distal to the spurs or carinae of bifurcations in large and small airways.

The intensity of the sound generated in the airways, vibrations set up in airway walls, the direction of transmission of the sound, the nature of the material through which the sound is transmitted, the selective absorption of some sound frequencies but not others, and the reflection of sound from air-fluid interfaces all influence the characteristics of the sound detected through the stethoscope on the surface of the chest. The rate of sound transmission through lung tissue is 30 to 60 m/s, compared with 1530 m/s through soft tissue and 1600 to 1800 m/s through bone.

Breath Sounds

Auscultation over the normal lung (Fig. 17) reveals sounds having a murmuring quality; these vesicular or normal breath sounds contain a spectrum of frequencies between 100 and 500 Hz, with maximal intensity below 200 Hz. The sounds increase rapidly in intensity during inspiration, with no pause as expiratory sound begins. A rapid fall-off in intensity occurs during expiration, with little sound heard during the latter two thirds of expiration.

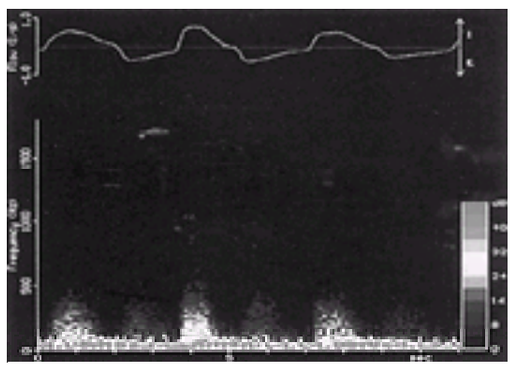

FIG. 17. Normal vesicular breath sounds. Sound spectrogram with simultaneous pneumotachogram (*top*); sound frequency in hertz (Hz) is represented on the ordinate, time (s) on the abscissa; colors designate sound intensity in decibels (dB) on the scale (*lower right*). Recorded over the left posterior lung base in a 13-year-old boy with cystic fibrosis. Note that inspiratory breath sounds are louder than expiratory sounds and that there is no pause between the respiratory phases. The frequencies are virtually all below 500 Hz and are most intense below 250 Hz. Contributions of low-frequency muscle and cardiovascular sound are visible. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) *See color plate 4.*

Auscultation over the trachea (Fig. 18) reveals a harsh, strident sound with almost equal intensity throughout inspiration and expiration, but with a distinct pause between the inspiratory and expiratory phase. Tracheal sounds contain frequencies up to about 1200 Hz, with loudest components below 900 Hz. Bronchovesicular breath sounds have features of tracheal and vesicular breath sounds; the sounds generated are harsher than vesicular sounds, are heard throughout expiration, and are similar in quality during the two phases of respiration. These sounds are normally heard only in the right infraclavicular region and posteriorly between the scapulae. There is much individual variation in the character of normal breath sounds, although they are constant in any one individual. The bronchial component is generally more evident in thin people.

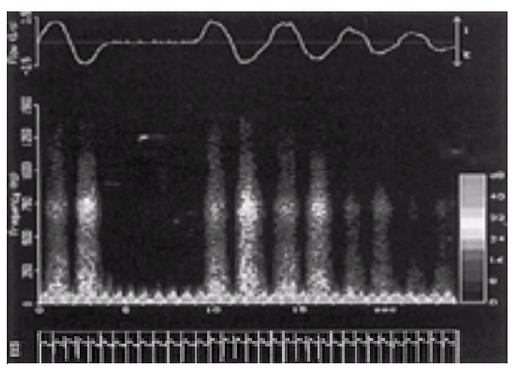

FIG. 18. Normal tracheal breath sounds. Sound spectrogram as described in Fig. 17, but with simultaneously recorded electrocardiogram (*bottom*). Recorded over the

trachea at the suprasternal notch in a healthy, 26-year-old, male nonsmoker. The typical features of normal tracheal sounds are evident, with a broad frequency distribution, extending close to 1500 Hz during both inspiration and expiration, a slightly louder expiration, and a clear break (absence of respiratory sound) between the respiratory phases. During 5 seconds of breath holding and zero air flow, the contribution of low-frequency cardiovascular sounds becomes evident. The electrocardiogram helps to identify the high-intensity, low-frequency heart sounds. The dependence of sound intensity on air flow is obvious during the latter parts of this observation, when the subject was breathing more shallowly. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) *See color plate 6.*

Calculations based on the size of the peripheral airways and the physics of gas flow in tubes show that air flow is laminar in the airways beyond the terminal bronchioles. Laminar air flow in small tubes does not produce sound. A widely accepted formulation is that the sounds heard over the periphery of the lungs are generated by turbulent air flow in the trachea and large bronchi. The sound travels at first through the gas contained in the large bronchi, but as the sound passes peripherally, airway caliber becomes too small for its transmission, and the sound energy is transmitted through lung tissue. The lung behaves as a band-pass filter, with a steep roll-off of frequencies above 200 Hz. Put differently, tracheal sounds are relatively rich in high frequencies. High-frequency absorption is characteristic of lung parenchyma; vesicular sounds that have passed through the most parenchyma have the smallest high-frequency component.

Consolidation of lung tissue (Fig. 19) with continued patency of the main bronchi results in the transmission of sounds from the large airways to the periphery with little change in their character. The sounds are similar to those heard over the cervical trachea and are termed *tubular* or *bronchial.*

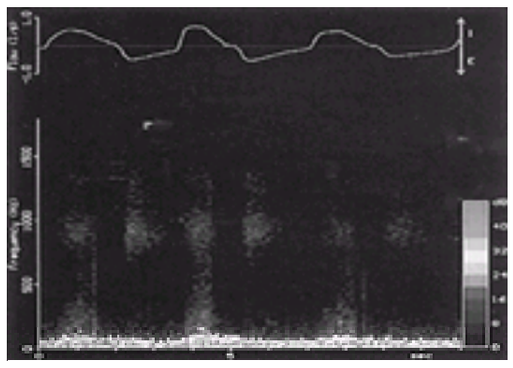

FIG. 19. Bronchial breath sounds. Sound spectrogram as described in Fig. 17, simultaneously recorded over the corresponding site on the right posterior lung base in the same patient as in Fig. 17. Pneumonia and consolidation of the right lower lobe were present, and bronchial breathing is evident. In comparison with the left side (Fig. 17), there is a decrease in intensity of breath sounds but an increase in high-frequency components extending above 1000 Hz. This is most evident during expiration; in contrast to the normal left side (Fig. 17), expiratory breath sounds are louder than inspiratory breath sounds. Contributions of low-frequency muscle and cardiovascular sound are visible. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) *See color plate 5.*

Fluid, air, or scar tissue in the pleural space forms a sound barrier that diminishes the transmission of breath sounds, either because of altered absorption of sound, reflection at the lung pleural interface, or, in the case of pneumothorax, increasing acoustic mismatching of chest wall and underlying air. If the layer of fluid or scar tissue is thick enough, the sounds are absent. Some transmission of breath sounds through a pneumothorax persists except when the collection of air is large. Sounds of higher frequencies may pass through a thin layer of fluid, which gives the breath sounds at the upper borders of a large pleural effusion a bronchovesicular quality. Consolidation of lung tissue with accompanying occlusion of the segmental or lobar bronchi also results in a complete sound barrier, with obliteration of normal breath sounds. Similar principles govern the transmission of the whispered and spoken voice to the surface of the chest.

Spoken Voice

Recordings of the spoken vowels *E* and *A* over the periphery of the chest disclose that *E* results in lower-pitched vibrations reaching the periphery than is true for *A.* Sound recordings over consolidated lung tissue or over a thin layer of fluid reveal selective transmission of the vibrations from the *E,* with attenuation of the lower harmonics and increased transmission of the higher harmonics. The transmitted sound has both the recorded and spoken characteristics of an *A,* a phenomenon referred to as *E-to-A change* or *egophony.*

Whispered Voice

A similar phenomenon gives rise to increased transmission of the whispered voice, a finding termed *whispered pectoriloquy.* The whispered words “one, two, three” are normally heard over the periphery of the normal lung as three ill-defined murmuring or rushing sounds. However, the syllables are clearly identifiable when the transmitted whispered voice is heard over consolidated lung with patent bronchi. Recordings show a marked increase in the intensity of sound transmitted between 200 and 600 Hz over consolidated lung, in contradistinction to the sharp cutoff of frequencies above 200 Hz in recordings made over a normal lung.

Adventitious Sounds

The adjective *adventitious* is reserved for sounds heard only in disease states. In recent years, a consensus has been reached that adventitious sounds arising from the lungs can be classified into continuous and discontinuous sounds. Continuous sounds are usually louder than the accompanying breath sounds, with a duration longer than 250 ms. Discontinuous sounds are explosive sounds, with a duration shorter than 20 ms. First described by Laennec, these sounds have been given a plethora of confusing names through the years by various authors. In the 1970s, the American Thoracic Society agreed on the terminology shown in Table 8.

Acoustic characteristics	American Thoracic Society nomenclature	Common synonyms
Discontinuous, interrupted sounds; loud, low in pitch	Coarse crackle	Coarse rale
Discontinuous, explosive sounds; less loud, shorter in duration, and higher in pitch than coarse crackle	Fine crackle	Fine rale
Continuous sounds longer than 250 ms; high-pitched; dominant frequency 400 Hz or more; a hissing or musical sound	Wheeze	Sibilant rhonchus
Continuous sounds longer than 250 ms; low-pitched; dominant frequency about 200 Hz or less; a snoring sound	Rhonchus	Sonorous rhonchus

TABLE 8. *Classification of common lung sounds*

Wheezes and Rhonchi

Wheezes and rhonchi are sounds whose duration is 250 ms or more. Wheezes have a hissing or less often a musical character. Their dominant frequency is 400 Hz; when wheezes are musical, harmonics of a relatively constant frequency of up to about 1000 Hz are generated. Rhonchi are lower-pitched, with frequencies predominantly below 200 Hz (Fig. 20 and Fig. 21).

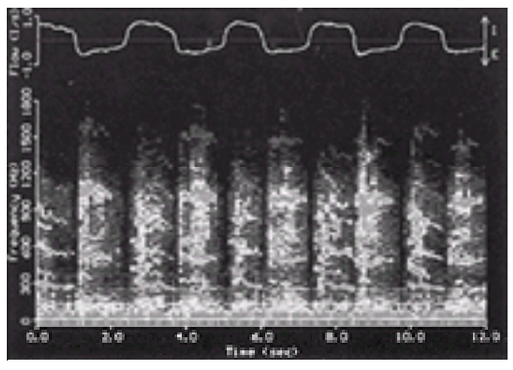

FIG. 20. Tracheal breath sounds in a patient with exercise-induced asthma. Sound spectrogram as described in Fig. 17. Polyphonic wheezing is present during both inspiration and expiration, seen as broad bands of intense sound with a narrow distribution of frequencies. Contributions of low-frequency muscle and cardiovascular sound are visible. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) *See color plate 7.*

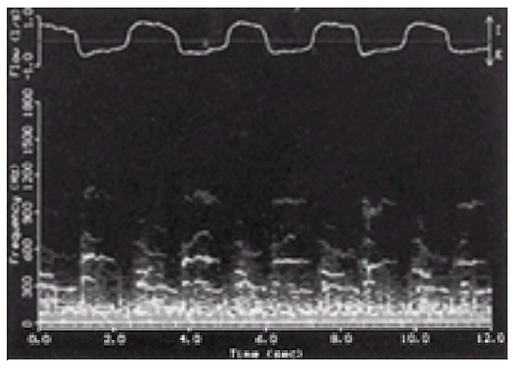

FIG. 21. Pulmonary breath sounds with wheezes. Sound spectrogram as described in Fig. 17. Sounds recorded over the right infraclavicular region in the same patient as in Fig. 20. Inspiratory and expiratory wheezes are seen as broad bands of intense sound with a narrow distribution of frequencies. The intensity of sound is less than in Fig. 20 and no sounds have frequencies higher than 900 Hz. (Reproduced from Pasterkamp H, et al. Digital respirosonography. *Chest* 1989;96:1405.) *See color plate 8.*

The best model for wheezes is thought to be sounds generated by uncoupled reeds, such as those of the oboe or clarinet. A disease process narrows the bronchus; as gas flows rapidly through the narrow region, the pressure falls because of the Venturi effect. Further narrowing occurs, almost to the point of closure, and opposite walls oscillate between the closed and nearly opened positions as air moves through, thus generating a sound. This mechanism of sound generation in collapsible tubes is known as *flutter.* The pitch of the note is determined by the tightness of the closure and by the mass and elastic properties of the solid structures set into vibration. The pitch of the sound is not affected by the length of the column of air in the airway. Thus, a high-pitched sound may be generated by marked narrowing of a main bronchus, as by tumor or fibrous stenosis, and a sound of similar pitch may also be generated from an orifice of comparable diameter in a small airway. Detailed reviews of the mechanism of wheeze generation have been published.

Wheezes vary widely in pitch, depending on the exact character of the narrowing in the bronchus. The bronchial obstruction that produces a wheeze may be caused by secretion, by an inflammatory or other structural change, or by dynamic compression of the airway. Because the airways narrow during expiration, wheezes are more frequent during expiration than inspiration.

Based on their time of appearance during forced respiration, wheezes may also be classified into one of two categories: random onset and simultaneous onset. Random-onset wheezes may be single or multiple, may be inspiratory or expiratory in timing, and may start and end at different times. The pitch of the sounds may vary considerably. The wheezes of asthma are an excellent example. Simultaneous-onset wheezes are expiratory sounds composed of several harmonically unrelated musical notes that tend to start and end simultaneously and are generated during forced expiration in all types of chronic air flow obstruction. A large number of distant, high-pitched, piping wheezes become audible suddenly during a forced expiration, presumably as the equal pressure point migrates peripherally and sounds are simultaneously generated from dynamically compressed airways.

Simultaneous-onset wheezes can often be produced by normal persons performing a forced expiratory effort. The sound produced in normal persons occurs only during very severe effort, tends to be relatively low in intensity, and occurs only toward the end of expiration; with experience, the physician can learn from the amount of effort used whether the simultaneous-onset wheeze indicates disease or is a normal phenomenon. Random-onset wheezes may, of course, be heard in obstructive airways disease before the sudden onset of simultaneous-onset wheezing; they are never heard in normal persons. Simultaneous-onset wheezes may be the only wheezes heard in patients having severe obstructive air flow disease with scanty secretions.

Crackles

Crackles are short sequences of sound with a duration shorter than 20 ms and usually shorter than 10 ms. They range from one to 20 cycles; usually no more than five cycles exceed the noise level in the recording (Fig. 22 and Fig. 23). Crackles may be few in number or may occur as showers, so close together that the individual sounds almost merge. Crackles occur during both inspiration and expiration, but they are more intense and more frequent during inspiration. The number of crackles heard tends to increase with increasing depth of respiration.

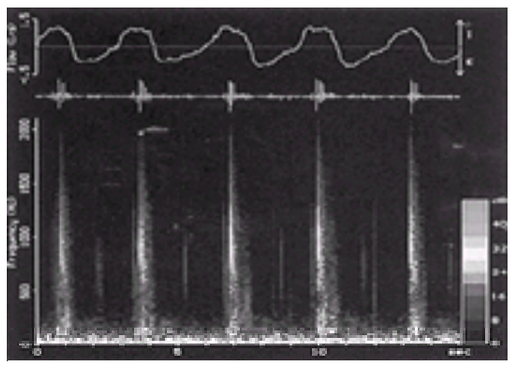

FIG. 22. Mid to late fine inspiratory crackles in a 60-year-old man with interstitial pulmonary fibrosis. These were recorded over the right posterior lung base. The broad frequency distribution is typical for fine crackles (coarse crackles would be contained largely below 1000 Hz). There are a few expiratory crackles as well. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) *See color plate 9.*

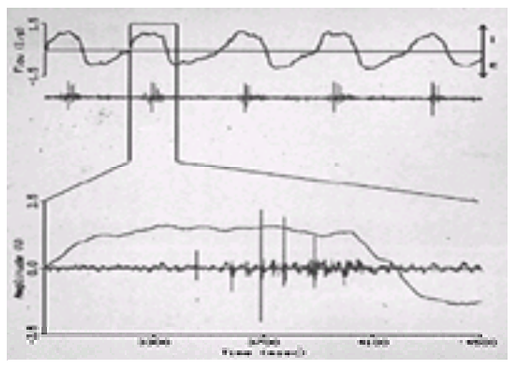

FIG. 23. The upper two records are the same as in Fig. 22. One expiration and a small part of the adjacent inspiration are shown on an expanded time-based display. The mid to late crackles are well shown. (Reproduced from Pasterkamp H. *R.A.L.E. Computer-Aided Instruction in Chest Auscultation with Digital Audio Presentation of Lung Sounds.* Winnipeg, Manitoba, Canada: PixSoft; 1990.) *See color plate 10.*

The words *fine, medium, coarse, wet,* and *dry* are often used by physicians to describe crackles but are not useful in distinguishing between disease categories. If the only information available is the character of the crackles, one cannot tell pulmonary edema from bronchopneumonia. There seems to be little purpose in dividing crackles into categories other than coarse and fine (Table 8). A recent study has confirmed the distinguishing characteristics of the fine crackles of interstitial lung disease in comparison with the coarse crackles of bronchiectasis, COPD, and congestive heart failure.

The mechanism of production of crackles is still unclear. They may be caused by air bubbling through secretions or by the sudden opening of a succession of small airways, with rapid equalization of pressures causing a series of implosive sound waves. In pneumonia and pulmonary edema, surfactant integrity is affected and respiratory air spaces readily collapse. In diffuse interstitial pulmonary fibrosis, thickening and distortion of the alveolar walls also result in instability of the air spaces, causing them to collapse during ordinary expiration, with the generation of crackles on the succeeding inspiration. Each collapsed respiratory air space opens suddenly at about the same lung volume in successive breaths as opening pressure is reached (Fig. 22 and Fig. 23).

In elderly patients without apparent lung disease, it is not uncommon to auscultate crackles at the lung bases that disappear as several deep breaths are taken. These are known as *atelectatic crackles.* Their likely mechanism is loss of surfactant with air space collapse. They disappear with successive deep breaths as surfactant is replenished and air space stability is restored. These crackles can be induced at the lung bases of normal young persons by having them breathe at low lung volume, especially if they breathe 100% oxygen, which washes out the nitrogen from the lungs and accentuates microatelectasis.

Crackles may be absent during ordinary respiration and become audible only during the deep inspiration that follows a cough or when the physician listens over the dependent lung with the patient in lateral recumbency. When the clinician must listen to a patient in lateral recumbency, it is important to remember that air motion is relatively smaller in the uppermost than in the lowermost lung. Thus, if the diseased lung is uppermost, the degree of expansion may not be sufficient to reach the critical opening pressure of the respiratory air spaces and thus generate crackles. On the other hand, when the same lung is listened to in the nether position, the increased proportion of ventilation going to that lung may generate crackles or wheezes. The same rationale applies in the evaluation of a patient who has symptoms of lung disease but negative findings on chest roentgenogram and no obvious findings when examined in the sitting position. The patient should be listened to in both lateral recumbent positions during ordinary and forced expiration, as well as in the upright position.

Showers of fine, mid to late inspiratory crackles are heard at the lung bases in interstitial lung diseases. These crackles (“velcro” crackles) sound like a velcro fastener being opened; they have a recurrent rhythm characterized by similar spacing and relative loudness. Fine crackles with these characteristics are heard in about 60% of patients with various forms of chronic interstitial pulmonary fibrosis but are heard in only about 20% of those with sarcoidosis and other granulomatous lung diseases. The fine crackles of interstitial lung disease appear to correlate with the pathologic severity of the disease, the evidence of radiographic honeycombing, and the severity of the physiologic abnormality (Fig. 24). Scanty expiratory crackles are also audible in interstitial lung disease.

FIG. 24. Honeycombing is present, predominantly at the lung bases, in this case of severe interstitial pulmonary fibrosis. Note that fibrosis is so severe that the margins of the chest wall, diaphragm, and mediastinum are all rendered indistinct and shaggy. Early findings of interstitial pulmonary fibrosis may be seen on high-resolution chest CT before becoming visible on standard chest radiographs.

Crackles are heard in many lung disorders characterized by parenchymal disease: congestive heart failure, pneumonia, bronchiectasis, and cystic fibrosis. Crackles are also frequently heard early in inspiration in patients with chronic obstructive lung disease. These inspiratory crackles are coarse, loud, scanty, audible at the mouth as well as over the chest, and often associated with a few late-expiratory crackles. They are believed to be generated by air flowing through an airway intermittently occluded by mucus or a poorly supported bronchial wall.

Quiet breathing in normal persons is a virtually silent phenomenon, but in many patients with chronic bronchitis or an exacerbation of asthma, a noise is generated during inspiration that is audible with the naked ear at a distance from the mouth. A physician can often assess the presence of airways obstruction when noisy breathing is heard while speaking with the patient on the telephone.

Pleural Friction Rub

Pleural friction rubs are sounds heard over areas where roughened visceral and parietal pleurae rub over each other during respiration. The cause of the roughening is usually a fibrinous or organizing exudate. The characteristic grating or creaking sound is usually loudest at the end of inspiration, but a rub may be heard during both phases of respiration. Pleural friction rubs vary greatly from breath to breath and may be heard only during a deep respiration. They are usually most evident over the lower lateral and anterior thorax, because this is the location of greatest chest wall motion. Very loud rubs may produce palpable vibrations. Pleural friction rubs are usually readily identified, but it may sometimes be difficult to differentiate them from muscle sounds or from very coarse crackles.

Mediastinal Crunch

Mediastinal crunch is a series of crackles that are synchronous with the heartbeat and audible even when the breath is held. These crackles are produced by air in the areolar tissues of the mediastinum. The sound is often accentuated in left lateral recumbency. Mediastinal crunch is usually more sensitive than the chest roentgenogram in detecting mediastinal emphysema, but roentgenographic signs may precede mediastinal crunch when the air collects predominantly in the posterior mediastinum.

Adventitious Sounds Originating in the Chest Wall

Crackling sounds are produced when hair is trapped between the skin and stethoscope. Although these sounds may simulate crackles coming from the underlying lung, they tend to be closer to the ear and, with experience, are usually easily recognized. Firmer application of the stethoscope or wetting the skin stops them.

Low-pitched rumbling, muffled, distant, sometimes roaring sounds may be heard during contraction of chest wall muscles. Muscle sounds may be varied by changing the patient's position. They often occur in a chilly or nervous patient who is shivering and are usually easily distinguished from crackles, which are higher-pitched and more discrete.

COMMON PULMONARY SYNDROMES

Pneumonia

The findings of parenchymal consolidation with patent bronchi vary depending on the completeness and extent of disease (Fig. 25). Chest wall motion, as determined by inspection and palpation, ranges from normal to impaired. Similarly, the percussion note ranges from normal to impaired. When consolidation is complete, the breath sounds heard over the periphery have a tubular quality, the spoken voice is increased in intensity, E-to-A change is present, and the syllables of the whispered voice can be clearly identified. Alterations in breath sounds and in spoken and whispered voice are less striking when the consolidation is patchy. Whispered pectoriloquy often gives a clear indication of the presence of consolidation, even when it is difficult to be certain of the significance of a slightly increased harshness and prolonged expiratory phase of the breath sounds. In general, increased transmission of the whispered voice is more easily identified than increased palpable vibration from the spoken voice or the E-to-A change.

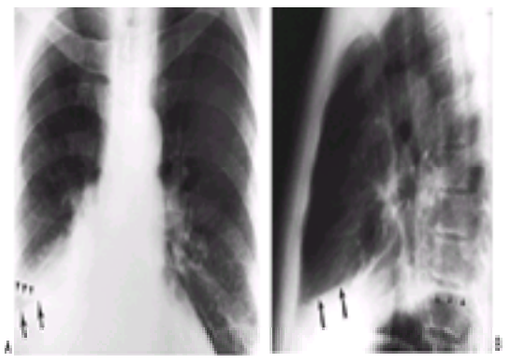

FIG. 25. A,B: Two regions of pneumonia are demonstrated in this patient, one lobar and one segmental. On the frontal view, the upper margin of a right middle lobe pneumonia is sharply demarcated by the minor fissure (*arrows*). More superiorly on the frontal view and posteriorly on the lateral view is a second segmental consolidation, also sharply demarcated inferiorly, in this case by a lower lobe superior accessory fissure (*arrowheads*). These consolidations are quite dense and do not demonstrate air bronchograms.

In pneumonia, there may be no positive findings on physical examination if the process is interstitial, or if 1 to 2 cm of aerated lung separates the disease process from the chest wall surface. If the consolidated lung lies beneath the structures of the shoulder girdle, lung abnormalities may not be evident, even if the pneumonia extends to the visceral pleura.

When the consolidation is patchy and interspersed with aerated lung tissue, breath sounds and whispered voice sound changes may be minor, and crackles may be the major evidence of parenchymal lung disease. However, it must be stressed that in most instances crackles indicate the presence of parenchymal lung disease without establishing the nature of the process. The presence of crackles in a patient who has had tuberculosis or some other pulmonary problem but who is not acutely or severely ill may merely denote a residuum of the old disease. Conversely, crackles of recent origin or occurring in an acutely and severely ill patient make pneumonia a likely diagnosis.

When pulmonary consolidation is accompanied by an obstructed bronchus, the findings are very similar to those noted in pleural effusion—that is to say, motion of the thorax is decreased, vocal fremitus is absent, percussion note is impaired, and breath and whispered voice sounds are absent. The findings are similar in patients with pleural fibrosis, except that there may be a decrease in the size of the ipsilateral hemithorax. With massive pleural effusion, the trachea and lower mediastinum may be shifted to the contralateral side; with pleural or pulmonary fibrosis, the mediastinal shift occurs to the ipsilateral side.

Obstruction of Air Flow

Moderate upper airway obstruction causes a sensation of difficult breathing but may produce few physical findings. As the obstruction becomes high-grade, wheezing and stridor become evident. The history and time course of onset are important. Slow progression in a smoker suggests the possibility of upper respiratory tumor. Sudden onset should raise the possibility of acute infection or aspiration of a foreign body. A history of endotracheal intubation suggests the possibility of tracheal stenosis.

There are few outward manifestations of abnormality in patients with mild air flow obstruction resulting from bronchial and bronchiolar disease or emphysema. In cases of moderate air flow obstruction, when the patient is asked to empty the lungs forcibly and completely, it is evident that expiration is prolonged and difficult, with incomplete pulmonary emptying. The degree of expiratory slowing may be estimated by measuring the forced expiratory time (normally 4 seconds or less) with a watch and a stethoscope. Auscultation over the larynx permits accurate determination of the end of expiration. Sounds are audible at this site at the low air flows occurring near residual volume (Fig. 18), when breath sounds are no longer audible over the lungs. As the process becomes severe, the patient's distress is evidenced by labored breathing, use of the accessory muscles of respiration, inspiratory retraction of the supraclavicular fossae and lower interspaces, and positioning of the chest near total lung capacity.

Differentiation of air flow obstruction caused by asthma from that caused by chronic bronchitis or emphysema (COPD) depends on the history. Recent acute onset and a history of atopy or recurrent bouts of reversible air flow obstruction support the diagnosis of asthma. Slowly progressive worsening of symptoms, even with recent worsening, suggests COPD. It may not be possible to exclude emphysema with certainty in a chest radiogram taken during a severe asthmatic episode; loss of lung overdistension and attenuation of the vascular pattern in a film taken with the patient in remission establishes the diagnosis. Mild or moderate emphysema is not readily diagnosed in a plain chest radiogram unless bullae are present; CT of the chest is a much more sensitive diagnostic tool, although CT is not indicated for routine diagnostic evaluation.

The key finding of wheezes in chronic air flow obstruction was referred to earlier in the chapter, but it must be remembered that when airways obstruction is very severe, wheezes may completely disappear, along with a marked decrease in the intensity of breath sounds. The velocity of air flow is insufficient to generate sound. The reappearance of wheezes indicates diminished severity of airways obstruction, perhaps in response to treatment.

Pneumothorax

The findings in pneumothorax depend on the size of the pleural air space. Motion may be normal or diminished, fremitus may be decreased to absent, the percussion note is usually normal, and breath and whispered voice sounds are decreased to absent.

Pleural Effusion

The impaired percussion note in pleural effusion extends further paravertebrally and laterally than it does in the midscapular line. This is because no lung is present medially and laterally beneath the percussing fingers, whereas in the scapular line there is just a thin layer of fluid overlying the lung. Breath sounds with a bronchial character and an E-to-A change may frequently be heard over the thin layer of fluid at the upper end of an effusion. This physical finding may be helpful in determining the site for a thoracocentesis. Elevation of the diaphragm, as in ascites, hepatomegaly, or subphrenic abscess, may simulate the findings of a pleural effusion. The chest radiogram is of great help in diagnosing small pleural effusions when physical findings are normal or equivocal. The radiogram is the only way of diagnosing loculated pleural effusions that do not present on the chest wall.

Interstitial Pulmonary Fibrosis

Interstitial pulmonary fibrosis is defined as an inflammatory process of varying etiology involving the respiratory air space walls that is accompanied by varying amounts of fibrosis. Patients may be symptom-free and come to medical attention because of the findings in a chest radiogram. Others are seen with cough, which is usually

nonproductive. Yet others seek attention because of effort dyspnea of recent onset. The history may give no hint of etiology. It may suggest the presence of a systemic disease; may reveal prior inhalation of a biologically active dust, such as asbestos or silica; or may reveal that the patient has lived in an area where an infection, such as one of the deep mycoses, is endemic. Alternatively, the patient's lifestyle may raise the possibility of HIV infection or may support a diagnosis of lung disease resulting from the intravenous injection of fibrogenic material, such as talc.

Physical examination usually discloses constant, fine, end-inspiratory crackles, which tend to be most evident at the lung bases. With advanced disease, the chest wall is diminished in volume at full inspiration, there may be right ventricular lift, and the pulmonic second sound may be accentuated, indicating the presence of pulmonary hypertension and right ventricular hypertrophy. The general examination may reveal the stigmata of a systemic disorder, such as rheumatoid disease.

The chest radiogram generally shows a diffuse parenchymal pulmonary infiltrate with a pattern that varies depending on the etiology of the process. When the plain chest radiographic findings are normal, the diagnosis may be supported by pulmonary function tests that show normal air flow, decreased vital and total lung capacity, deceased carbon monoxide diffusing capacity, and resting hypoxemia without hypercapnia that worsens with exercise. The presence of typical crackles also supports the diagnosis. The greater sensitivity of CT may reveal abnormalities not seen on the plain chest film. It is important when considering the differential diagnosis of the patient with dyspnea and normal parenchyma on CT to keep in mind the relatively rare occurrence of primary pulmonary hypertension. These patients often consult physicians for many months before the cause of their problems is established.

Deep Venous Thrombosis and Pulmonary Embolism

Each year in the United States, about 500,000 episodes of pulmonary embolism occur, which cause about 50,000 deaths. Hence, it is difficult for a practicing general physician or pulmonologist to long escape contact with this ubiquitous disease. Its underlying cause is predominantly deep venous thrombosis, risk factors for which include injury to the pelvis or lower extremities, surgery of the lower extremities, any surgical procedure requiring >30 minutes of general anesthesia, burns, pregnancy and the postpartum state, previous deep venous thrombosis, failure of the right side of the heart, prolonged bed rest, age >70 years, obesity, and use of estrogenic drugs. Deep venous thrombosis and pulmonary embolism should always be considered together. If a pulmonary embolus is suspected, a quest for the source of the embolus must follow immediately; the diagnosis of deep venous thrombosis must immediately raise the question of whether a pulmonary embolus is present.

Neither condition can be diagnosed on purely clinical grounds; deep venous thrombosis is confirmed only about half the time when clinical signs (pain, heat, redness, swelling) are present, and about half the proven incidents of recent-onset deep venous thrombosis are asymptomatic. Contrast venography, impedance plethysmography, and duplex ultrasonography are the three methods currently in use for diagnosing deep venous thrombosis (Chapter 66).

Prospective studies have shown that pulmonary embolism occurs in about 40% of patients with proven deep venous thrombosis. The most common symptoms of acute embolism are dyspnea and palpitations. Hemoptysis and pleuritic chest pain are consequences of infarction, which is an infrequent complication of embolism that occurs 12 to 36 hours after embolism. Angina, syncope, and recent onset of an arrhythmia may also accompany a pulmonary embolus. On examination, tachycardia and tachypnea may be observed. With severe embolism, signs of pulmonary hypertension may be present. The chest radiographic findings are usually normal. Large central emboli may produce enlargement of the hilar pulmonary artery shadow and give rise to peripheral oligemia. Atelectasis, which develops because of decreased surfactant production, may produce a shadow in the chest film. An infarct appears as a pleura-based shadow of any shape and is often accompanied by a pleural effusion.

A negative perfusion scintiscan excludes the diagnosis of pulmonary embolism. Perfusion defects when present are nonspecific. With larger defects, a ventilation scan in which defects match the perfusion is nondiagnostic. If the perfusion defects are well ventilated, the probability of embolus is high and the pulmonary angiogram can be bypassed. The pulmonary angiogram is the definitive test for pulmonary embolism (Chapter 66).

CHAPTER

15 Aerosols

Lewis J. Smith

L. J. Smith: Department of Medicine, Pulmonary Division, Northwestern University Medical School, Chicago, Illinois 60611.

INTRODUCTION

Aerosols are defined as any mixture of solid or liquid particles or droplets that are stable as a suspension in air. They play an important role in respiratory medicine in several different ways. First, some aerosols (e.g., toluene diisocyanate, thermophilic actinomycetes) produce lung disease in susceptible individuals, whereas other aerosols worsen pre-existing disease (e.g., sulfur dioxide or ozone in asthma and chronic bronchitis). Second, aerosols are invaluable in diagnosing and assessing the severity of lung disease (e.g., radiolabeled aerosols to detect pulmonary embolism; aerosols containing methacholine, histamine, or distilled water to determine airway hyperreactivity). Third, they are used to treat an expanding list of lung diseases (e.g., asthma, cystic fibrosis) and to anesthetize the respiratory tract before diagnostic and therapeutic procedures, such as bronchoscopy. Finally, aerosols are used in research to define pathogenic mechanisms in several lung diseases (e.g., produce disease models in animals).

This chapter is designed to provide an overview of aerosols in respiratory medicine, including their physical characteristics and deposition patterns, the devices used to generate aerosols, the role of aerosols in the diagnosis and treatment of lung diseases, the unique features of aerosol delivery during mechanical ventilation, and the determinants of systemic bioavailability from aerosols. Several comprehensive reviews of aerosol generation, deposition, and therapy are available (see reference list) for those interested in more detailed information about this important area.

CHARACTERISTICS OF AEROSOLS

Aerosols are characterized as being of uniform (monodisperse) or varied (heterodisperse) size. Monodisperse aerosols have a geometric standard deviation less than 1.2 (see below). Environmental aerosols and aerosols used in clinical practice are heterodisperse. The range of particle size is wide: aerosols formed as condensation nuclei are usually between 0.001 and 0.1 µm in diameter, those created by cigarette smoke and automobile exhaust are between 0.1 and 1 µm, and aerosols formed by pollens and grinding or mining activity are most typically between 3 and 20 µm in diameter. Therapeutic aerosols tend to be in the 1- to 5-µm range. In general, very small particles are breathed in and out of the lung without being deposited. However, condensation nuclei can grow and coalesce to form particles in the 0.1- to 10-µm size range, which favors deposition in the lung. Large particles (10 µm) characteristically settle out of aerosols, especially if a holding chamber is used, and penetrate poorly into the lung.

Most aerosols generated are heterodisperse. They fit a log-normal distribution in which a plot of particle density (number of particles per given size) versus the logarithm of size yields a bell-shaped normal distribution curve (Fig. 1). The mass median aerodynamic diameter (MMAD) of an aerosol is the aerodynamic diameter around which the mass is centered. It takes into account aspects of particles that are difficult to measure (e.g., shape and density), and it is the key determinant of particle deposition in the lung. The aerodynamic diameter (d_a) of a sphere is described as $d_a = d\ddot{O}p$, where d is the physical diameter of the particle and p is its density. The width of the size distribution is represented by the geometric standard deviation (s_g), which is the ratio of the size below which 84.13% of the mass resides to that below which 50% of the mass resides. Values of s_g of 1.2 indicate a narrow size distribution and define monodisperse aerosols. Although it is possible to generate aerosols with a narrow size distribution, most therapeutic aerosols have s_g values of 1.6 to 2.0, indicating a broad size distribution, in which a proportion of the particles will likely not be deposited in the lung.

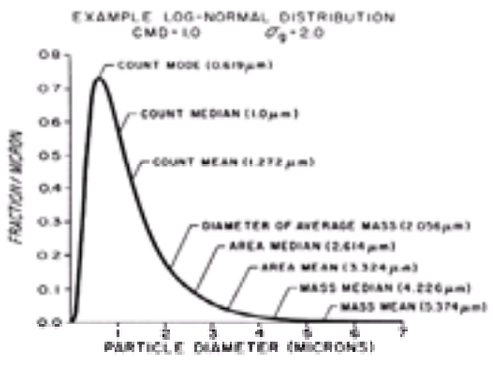

FIG. 1. An example of the log-normal distribution in normalized linear form of aerosol particle sizes for a count median diameter (CMD) equal to 1 µM and a geometric standard deviation equal to 2. Particle density is on the y-axis and particle size is on the x-axis. (Reprinted with permission from *Aerosol Sci* 1971;2:289.)

DEPOSITION OF AEROSOLS IN THE LUNG

The major mechanisms by which aerosols deposit in the lung are inertial impaction, sedimentation, and diffusion. Electrostatic precipitation and interception also play a role, but mostly under select circumstances. A particle deposits by impaction when its inertia is such that it is unable to continue to flow with the air stream as the air stream changes direction. This occurs in the upper airways when the air stream curves sharply in the nose, between the pharynx and the larynx, and in the lower airways at airway bifurcations. The degree of impaction is proportional to d^2Q, where d is the diameter of the particle and Q is the velocity of the air stream. As a result, the number of particles impacting increases with increasing flow rates, with larger particle size, with the acuteness of the angle through which the air stream turns, and with decreasing airway diameter.

Sedimentation is primarily responsible for the deposition of particles that do not impact a surface when entering the lung. Such particles, usually less than 5 µm in size, are subject to gravitational forces based on the square of their diameter. Sedimentation is enhanced by breath holding and slow, steady breathing.

Brownian diffusion is the major mechanism by which particles 0.5 µm in diameter deposit in the lung. These particles deposit in distal, nonairway lung units, and they comprise only a small fraction of the total pulmonary deposition of therapeutic aerosols. Deposition of condensation nuclei in the lung occurs mostly by diffusion.

Most aerosols are charged. As a result, electrostatic precipitation can contribute to the deposition of very small particles in the lung. Electrostatic precipitation may be most significant outside the lung, in that it increases the deposition of therapeutic aerosols in narrow plastic tubes and thereby decreases delivery to the lung, especially

when dry powders are inhaled.

Interception occurs when the distance to a surface is less than the diameter of a particle. Its major role is in the deposition of fibers (e.g., fiberglass, asbestos) on airway walls. It is of little importance in the delivery of therapeutic aerosols.

The therapeutic relevance of particle size and its effects on deposition are apparent from reports indicating that for both ipratropium bromide and albuterol, particle sizes £2.8 µm provide optimal bronchodilation. Larger particles, which would be expected to exhibit greater upper airway impaction, are less effective.

FACTORS INFLUENCING AEROSOL DEPOSITION IN THE LUNG

For the purpose of describing particle deposition in the lung and the effects of various factors on deposition, the lung can be divided into three compartments: nasopharyngeal, tracheobronchial, and pulmonary. The major determinants of particle deposition are different for each. Inertial impaction is most important in the nasopharyngeal compartment, inertial impaction and sedimentation are both important in the tracheobronchial compartment, and sedimentation and diffusion are important in the pulmonary compartment (Fig. 2).

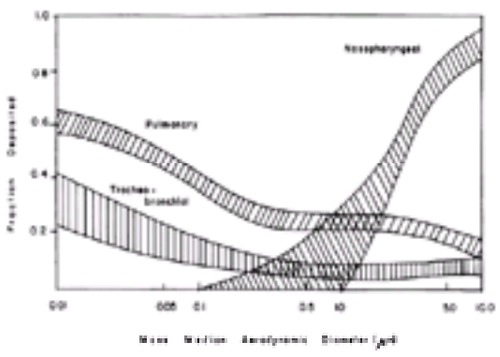

FIG. 2. Particle deposition in the respiratory tract, based on the three-compartment model of the International Committee on Radiation Protection. Each of the *shaded areas* indicates the variability of deposition for a given mass median (aerodynamic) diameter in each compartment when the geometric standard deviation varies from 1.2 to 4.5 and the tidal volume is 1450 mL. (Reprinted with permission from *Health Phys* 1966;12:173.)

In addition to particle size, factors that can influence aerosol deposition in the lung include airway geometry, the breathing pattern, and the presence of airway disease. Normal subjects differ widely in airway geometry. In those with smaller conducting airways, central (i.e., tracheobronchial) deposition of aerosols is greater than in those with larger airways. Breathing pattern also can influence deposition. Rapid inspiration and inhalation of an aerosol that is injected into the air stream at the middle or end of an inspiration increase central deposition. In contrast, slow inspiration, aerosol inhalation at the beginning of a breath, and a breath hold at the end of inspiration increase peripheral (e.g., pulmonary) deposition. Increased minute ventilation, as occurs during exercise, increases particle deposition in the lung. However, the deposition pattern may be altered by changes associated with the increased minute ventilation, such as greater inspiratory flow rates and decreased ability to humidify the inspired particles fully (reduced hygroscopic growth).

Another factor influencing aerosol deposition is its tonicity. There may be growth or shrinkage of nonisotonic particles as they pass through humidified airways. Obviously, a change in particle size will alter the deposition pattern.

Airway narrowing resulting from any cause affects particle distribution in the lung. As explained above, this has been noted for normal subjects with airways of different sizes, but it is more pronounced in the presence of lung disease. Most diseases are associated with increased airway and decreased pulmonary deposition. For example, the reduced airway caliber of patients with cystic fibrosis enhances delivery to the tracheobronchial compartment by 200%–300%. A similar phenomenon is seen in patients with asthma and chronic obstructive lung disease from other causes.

The changes in deposition pattern produced by disease and other factors have potential therapeutic and diagnostic implications that may differ depending on the specific drug or chemical administered. For example, the b-adrenergic agonist terbutaline produces an equivalent degree of bronchodilation and improvement in gas exchange regardless of whether it is deposited predominantly in the central airways or in the peripheral airways. In contrast, in patients with asthma, central deposition of methacholine produces a greater degree of bronchoconstriction than does peripheral distribution. Body position may also influence aerosol deposition. The importance of this phenomenon is obvious when aerosolized pentamidine is used to prevent *Pneumocystis carinii* pneumonia in immune-compromised patients. When a patient is in an upright position with a normal breathing pattern, less medication reaches the upper lung zones, and disease preferentially develops there.

Whether breathing is through the mouth or nose is another factor that can influence aerosol deposition. Because of the narrow nasal cross-sectional area (producing a high linear velocity), sharp bends, and hairs, most large particles (10 µm) and a high proportion of soluble gases are removed in the nose. Each of these features favors impaction. In addition, humidification causes growth of hygroscopic particles, further favoring impaction.

Finally, it is important to consider that deposition is different from retention. Retention reflects deposition plus clearance. Clearance mechanisms, including translocation of deposited particles, may have a major effect on the ability of aerosols to cause or treat disease. This concept is discussed in Chapter 2.

AEROSOL-GENERATING DEVICES

A number of inhalational devices are available to produce aerosols of respirable particles. They include pressurized metered-dose inhalers (MDI), nebulizers (jet and ultrasonic), and dry-powder inhalers. Each of these categories comprises several devices with differing characteristics. Production lots of the same device may vary such that particle distribution in the lung and the effects of the material being delivered are altered. When characterizing any aerosol-generating device, it is crucial to differentiate between the “metered” dose, the “delivered” dose, and the “respirable” dose. The metered dose is the dose filling and subsequently emptied from the metering device. The delivered dose is the dose exiting the device. The respirable dose is the dose exiting the device with an aerodynamic diameter of 6 µm or less.

Metered-Dose Inhalers

MDIs have achieved great popularity for the treatment of airways disease. Their advantages are that they are small and convenient to use, and they accurately deliver multiple doses of a drug. The drugs in MDIs are either dissolved or suspended as fine crystals in a liquid propellant mixture—usually chlorofluorocarbons (CFCs). Surfactants are added to increase the stability of the aerosolized suspensions. There are several disadvantages and problems associated with MDIs. One is the use of CFCs as a major component of the propellant. Their adverse impact on the atmosphere has resulted in a worldwide ban that will eventually make these chemicals unavailable for use in MDIs. It is anticipated that other chemicals will be adequate replacements. A second disadvantage is the sensitivity of the MDI to technique (e.g., inspiratory flow rate) and the difficulty some individuals have in coordinating triggering of the device and breathing pattern. If the MDI is triggered well after inspiration has begun, less drug reaches the lung and its distribution is not the same as when triggering occurs early during inspiration. A third problem is the initial rapid velocity imparted to the aerosol as it leaves the device. This can cause discomfort and coughing in some individuals, which may lead to discontinuation of the medication. In addition, a large number of particles deposit in the oropharynx, decreasing the dose available to the lung. It has been estimated that only about 10% of a drug dose is delivered to the lung from MDIs, while 80% or so is deposited in the oropharynx. A less commonly appreciated problem is the effect of environmental temperatures on particle size and therefore lung deposition. Lower temperatures result in larger particles and decreased lung deposition. Keeping the device in an inside pocket rather than a purse and warming it in the hand before using it out of doors in cold weather should minimize this problem.

Several innovations have been devised to deal with some of the problems associated with MDIs. One is a breath-actuated device (Autohaler and others), which triggers the MDI valve at the start of inspiration. Also, initial velocity is lower, so that oropharyngeal deposition is decreased. However, individuals with arthritis or weakness involving the hand muscles may be unable to set the trigger. In addition, the device requires sealing the lips around the mouthpiece. This is at variance with recommendations by manufacturers of other devices that the MDI be placed a few inches outside the open mouth. A second innovation has been spacer devices. They come in a variety of sizes and shapes; costs and convenience also differ. All reduce the need to synchronize triggering of the inhaler with the onset of inspiration, and they decrease oropharyngeal and increase lung deposition. They are of greatest benefit in young children, the elderly, and in anyone inhaling corticosteroids or other medication with the potential for producing adverse events when deposited in the oropharynx.

Nebulizers

Nebulizers (jet, ultrasonic) are effective when high doses of drugs need to be administered. They are also appropriate for infants and young children, who cannot use hand-held devices. Their major advantages are that coordination with the respiratory cycle is not required, and they are effective even when patients have very low inspiratory flow rates. The major disadvantages are their large size and the need for an external power source. Both of these factors limit a patient's mobility.

Jet nebulizers produce an aerosol by moving a blast of air across a narrow nozzle into which liquid has been drawn according to the Bernoulli principle. When the air hits the liquid, small droplets are formed. Because the air stream is curved in the nebulizer before the aerosol exits, larger particles (10 μm) are removed. The distribution of particles generated by a nebulizer and subsequent deposition in the lung depend on the nebulizer (model, lot, and individual unit), the number and size of baffles, the diameter of the exhalation port tubing, the use of vents, gas flow rates, fill volume in the nebulizer reservoir, viscosity and surface tension of the solution, and ambient temperature and humidity. Because of these factors, it is important to know the specific characteristics of the unit being used and to follow the manufacturer's recommendations regarding proper operation carefully.

Ultrasonic nebulizers use a piezoelectric crystal, operating in the range of 1 to 3 MHz, that transforms high-frequency electric oscillations into mechanical oscillations, thereby providing energy for producing an aerosol. Output tends to be greater than from a jet nebulizer, but particle size is usually larger. With both types of nebulizers, much of the drug initially placed in the nebulizer remains there (on the walls) after the treatment is completed. Further, the concentration of the drug being administered may increase during the time the solution is being nebulized.

Dry-Powder Inhalers

Dry-powder inhalers have been available for years. They include the Spinhaler and Rotahaler, used to deliver a single dose of cromolyn sodium, albuterol, or beclomethasone from a capsule; the Diskhaler, which provides several doses of drug from a packet containing individual compartments; and the Turbohaler, which delivers as many doses of drug from a single container as a typical MDI.

The major advantages of dry-powder inhalers are breath actuation, which reduces difficulties with triggering the device at the start of inspiration, and the absence of CFCs. Disadvantages are those associated with any breath-actuated device—variable delivery at very low rates of flow (30 to 60 L/min) and the need to insert the device in the mouth and seal the lips. Nonetheless, these devices are very effective for delivering bronchodilators and corticosteroids to the lungs of patients with airway disease.

AEROSOLS FOR THE DIAGNOSIS AND TREATMENT OF LUNG DISEASE

Aerosols are used to diagnose and help control several lung diseases. The two most frequent and established diagnostic uses are for ventilation scans in suspected pulmonary embolism and for the identification and measurement of the severity of airway reactivity in patients suspected of having asthma. The principles and technical aspects of ventilation lung scanning are found in chapters on pulmonary embolism and ventilation-perfusion lung scan. Airway reactivity to a number of nonspecific (e.g, methacholine, histamine, distilled water) and specific (e.g., antigen) bronchoprovocation agents is determined by administering aerosols containing increasing concentrations of these substances while measuring the effect of each concentration on pulmonary function. The major advantage of performing bronchoprovocation testing with aerosols rather than administering these chemicals systemically is the elimination or reduction in systemic responses. Additional information on bronchoprovocation testing is found in chapters on asthma, airway reactivity, and bronchoprovocation testing.

Aerosols can also be used to measure peripheral airway size, epithelial permeability, regional ventilation, and gas mixing in the lung. For example, peripheral airway size has been measured using a monodisperse di-2-ethylhexylsebacate aerosol with particles approximately 0.9 μm diameter. The results correlate well with mean lung density derived by chest computed tomography (CT) and with measurements of diffusing capacity and FEV_1. Alveolar epithelial permeability has been measured in numerous research studies using aerosols of technetium Tc99m DTPA (diethylenetriamine penta-acetic acid).

In addition to their value in diagnosing and managing lung disease, aerosols are invaluable for treatment. Saline aerosols are useful to add moisture to the airways to prevent and treat inspissated secretions. A more frequent use is for the delivery of drugs. The advantages of delivering drugs by this route are several. First, high therapeutic concentrations of some drugs can be achieved within the respiratory tract while systemic concentrations remain low and side effects are few. Some examples are aerosolized b_2-adrenergic agonists and corticosteroids for the treatment of asthma, antibiotics such as the aminoglycosides and amphotericin B, chemotherapeutic agents for the treatment of lung cancer, and cyclosporine for the prevention and treatment of lung allograft rejection. Second, aerosol delivery of some soluble and easily absorbed drugs provides a rapid and convenient route to the bloodstream. Atropine, lidocaine, and epinephrine fit into this category. Third, aerosols provide access for some enzymes, other proteins, and chemicals that ordinarily do not have access to the respiratory tract because of size or charge. Recombinant human deoxyribonuclease (DNase) for the treatment of cystic fibrosis, antioxidant enzymes such as catalase and superoxide dismutase, surfactant, and immune modifiers are just a few examples.

AEROSOL DELIVERY DURING MECHANICAL VENTILATION

Inhaled medications, especially bronchodilators such as b_2-adrenergic agonists and anticholinergic agents, are commonly administered to patients receiving mechanical ventilation. However, there is controversy as to the best method of delivery to such patients. For example, it has been reported that delivery of b_2-adrenergic agonists by MDI through a cylindrical chamber is superior to nebulizer delivery under *in vivo* and *in vitro* conditions. In contrast, others have suggested that even large doses of b_2-adrenergic aerosols administered by MDI to ventilated patients fail to have any appreciable physiologic effects, whereas nebulizers produce significant bronchodilation. Recently, studies using *in vitro* models of mechanical ventilation have examined the effect of different jet nebulizers and MDIs with actuator devices on the delivery of albuterol to the lung under various conditions. These studies suggest the following: (1) Adaptors play an important role in the ability of MDIs to deliver albuterol during mechanical ventilation; (2) important technical differences exist between these devices, which when not used properly can influence drug delivery; (3) spacer design is of prime importance for MDI effectiveness; (4) MDI delivery systems may be sensitive to humidification and synchronization with inspiration, such that delivery decreases with increased humidification and with lack of synchronization; and (5) jet nebulizers and MDI/actuator devices deliver comparable amounts of medication, but the latter require more direct therapist time.

It has also been shown that the delivery of an aerosol from an ultrasonic nebulizer during mechanical ventilation is inefficient and influenced by several factors, including the nebulizer used, the amount of solution placed in the nebulizer (more solution in some nebulizers results in a higher percentage of the total volume delivered to the lung), the addition of an aerosol storage chamber (increases delivery), the respiratory rate and minute ventilation (decreasing either one increases aerosol delivery), and inspiratory time (increasing this time increases delivery).

The important message is that under certain circumstances, aerosol drug delivery to patients receiving mechanical ventilation may be considerably less than anticipated. As a result, it may be necessary to give larger-than-usual doses of drug and titrate the dose according to effectiveness and toxicity.

DETERMINANTS OF SYSTEMIC BIOAVAILABILITY

It has been recognized for some time that the administration of certain medications via the airways can produce clinically significant systemic concentrations. Some examples are epinephrine, atropine, and lidocaine. The first two have been administered through endotracheal tubes during cardiopulmonary resuscitation. Systemic lidocaine toxicity with seizures is a serious complication during topical anesthesia for procedures such as bronchoscopy, especially when given to elderly individuals or those with liver disease.

The issue of systemic absorption and bioavailability is also important when drugs are delivered by aerosol to treat lung disease, especially as new inhaler delivery systems are designed to enhance lung deposition. An excellent review of this subject is provided by Lipworth. Systemic bioavailability is a consequence of absorption from the gastrointestinal tract and the lung. The amount of drug reaching the systemic circulation from the gastrointestinal tract depends on the amount deposited and the rate of first-pass metabolism in the liver. The systemic effects of inhaled corticosteroids absorbed from the gut appear to be limited by extensive first-pass metabolism. This has been reported to be 80% for beclomethasone, 89% for budesonide, and 99% for fluticasone. According to studies in which mouth rinsing, gargling, and the ingestion of charcoal were used to reduce gut absorption, it appears that systemic bioavailability of these three corticosteroids is mainly determined by absorption across the lung vascular bed. A similar conclusion has been reached for the b_2-adrenergic agonist albuterol.

As a result, it should be anticipated that aerosol delivery systems that improve lung deposition will increase lung bioavailability and at the same time enhance systemic absorption. If so, it may be necessary, as more efficient drug delivery systems are developed, to re-examine the amount of medication administered by aerosol to

patients with disease.

AEROSOLS IN RESEARCH

Studies have been performed in animals and humans using aerosols to define the role of environmental pollutants in human disease. Several investigators have explored the effects of oxidant and aerosol exposure on healthy subjects and patients with asthma. For example, by using sulfuric acid aerosols to sensitize the airways to ozone, it has been possible to quantify the effects of these pollutants on airway inflammation, physiology, and symptoms. Studies have also been performed with aerosols to test the validity of commonly used tests. One example is the commonly used technique of sputum induction to identify *Pneumocystis carinii* in the lung. Using an aerosol of technetium-labeled human serum albumin to measure lung clearance, it was found that sputum induction with 3% saline solution significantly increases tracheobronchial clearance rates.

In summary, aerosols play a major role in the diagnosis and treatment of lung disease. One can anticipate continued interest in this area, with increased use of aerosols to deliver new pharmacologic agents to treat lung diseases and also to deliver drugs that are rapidly inactivated in the gastrointestinal tract or liver to the systemic circulation, making it possible to bypass the intravenous and subcutaneous routes. However, caution must be exercised when this route of delivery is used, as the epithelium lining the lungs can be easily damaged. The potential local toxicity of agents delivered directly to the lung via aerosol must be considered and care taken to ensure this does not happen during the course of treatment.

CHAPTER

16 Theophylline and Glucocorticoids

Helen M. Hollingsworth

H. M. Hollingsworth: Pulmonary Center, Boston University School of Medicine, Boston, Massachusetts 02118.

THEOPHYLLINE

Theophylline, or 1,3-dimethylxanthine, has been used as a bronchodilator in patients with asthma and chronic obstructive pulmonary disease (COPD) for more than 60 years. The specific mechanism of action of theophylline is not well understood, but it likely involves a constellation of effects, including phosphodiesterase inhibition and adenosine antagonism.

Mechanism of Action

Phosphodiesterase inhibitors reduce intracellular degradation of cyclic AMP, thus prolonging the intracellular effects of cyclic AMP: relaxation of bronchial smooth muscle and suppression of mast cell mediator secretion. Theophylline is a weak, nonselective phosphodiesterase inhibitor. In fact, at the usual therapeutic serum concentrations, it inhibits only 10%–20% of phosphodiesterase activity. For this reason, it remains controversial whether the bronchodilator activity of theophylline is predominantly a consequence of phosphodiesterase inhibition.

Another possible mechanism is adenosine inhibition. Adenosine is a naturally occurring purine nucleoside that has been shown to be a bronchoconstrictor in patients with asthma. Local adenosine concentrations increase with methacholine and allergen stimulation, presumably because of mast cell release. Theophylline selectively inhibits adenosine-induced bronchoconstriction at the usual therapeutic concentrations. Evidence against this mechanism is the observation that some methylxanthines that are clearly active bronchodilators do not antagonize adenosine.

Other possible mechanisms of theophylline-induced bronchodilation include inhibition of the generation of contractile prostaglandins, modulation of intracellular calcium, and increased synergy between phosphodiesterase inhibitors and adenylate cyclase activators (e.g., b-adrenergic agonists).

Role of Theophylline as a Bronchodilator

Theophylline is less potent as a bronchodilator than are inhaled or subcutaneously injected b_2-adrenergic agents. It protects against exercise-induced bronchoconstriction, although it is not as effective as inhaled albuterol in terms of peak effect. On the other hand, sustained-release preparations of theophylline provide a longer duration of action than inhaled b_2-adrenergic agents, except salmeterol. This longer duration of action of 12- and 24-hr sustained-release preparations of theophylline can be helpful for patients with symptoms of nocturnal asthma or COPD.

When added to a regimen of inhaled corticosteroids and b_2-adrenergic agents, theophylline also reduces the frequency and severity of asthma symptoms in patients with moderately severe or severe chronic asthma. An additive, steroid-sparing benefit is seen when theophylline is added to a regimen of alternate-day prednisone or high-dose, daily inhaled beclomethasone.

In the setting of acute severe asthma, data are conflicting regarding the benefit of adding theophylline to the usual emergency regimen of nebulized adrenergic agents. On the other hand, theophylline may be beneficial in patients admitted to the hospital with status asthmaticus. In either situation, the drug should be continued and levels optimized in patients already on maintenance doses of theophylline.

In patients with COPD, even when spirometry findings are not improved, theophylline therapy is associated with a decrease in dyspnea. Theophylline also appears to benefit patients with COPD who are already taking ipratropium bromide and a b-adrenergic agent. Patients who have difficulty inhaling bronchodilator medication, despite education and the use of chamber or spacer devices, may derive greater benefit from orally administered theophylline.

Evidence for Anti-inflammatory Activity

Some patients with asthma experience significant deterioration when theophylline therapy is withdrawn. Because this deterioration appears greater than what would be expected based on the bronchodilating capacity of the drug, it has been hypothesized that theophylline has anti-inflammatory activity.

There is evidence that theophylline has weak anti-inflammatory activity. Although theophylline does not influence the immediate allergic response at moderate serum concentrations, it attenuates the bronchoconstriction associated with the late allergic response, possibly through an inhibitory effect on the cellular infiltration associated with the late-phase allergic response; theophylline reduces the levels of CD4 lymphocytes typically seen during this response. In patients with moderately severe asthma who are taking high-dose inhaled corticosteroids, withdrawal of theophylline results in an increase in CD4 and CD8 cells in the bronchial submucosa that correlates with a decrease in FEV_1 (forced expiratory volume in 1 second). Bronchial biopsy studies have shown a decrease in EG2-positive activated eosinophils immediately below the basement membrane in patients with mild asthma treated with theophylline. On the other hand, theophylline does not affect the increase in peripheral eosinophil counts associated with allergen challenge and does not inhibit allergen-induced increases in airway methacholine responsiveness, all evidence against significant anti-inflammatory activity.

Respiratory Muscle Effects: Force and Endurance

Theophylline has positive inotropic effects on normal diaphragm, but effects are hard to demonstrate if concentrations are in the normal therapeutic range. In patients with COPD, theophylline improves the strength of the fatigued diaphragm and makes the diaphragm more resistant to fatigue. These effects may help patients with asthma or COPD who are being weaned from mechanical ventilation, or are experiencing worsening of air flow obstruction.

Clinical Use

The specific indications for theophylline therapy may be found in Chapter 40 (Bronchial Asthma) and Chapter 43 (Clinical Aspects of COPD) of this book, and in recently published guidelines. Because of the narrow toxic-to-therapeutic window, use of this drug requires close attention to dosage, serum levels, and potential

interactions with other drugs.

Once the decision has been made to initiate oral theophylline therapy in an adult, the drug should be started at a low dose (12 to 16 mg/kg daily, up to a maximum of 300 to 400 mg/d) and titrated slowly upward. The dose should be decreased if the patient experiences nausea, headache, tachycardia, or other side effects. The final daily regimen should be guided by the degree of symptom control, side effects, and measurement of serum levels; in general, one should aim for a therapeutic serum level of 5 to 20 µg/mL. Therapeutic serum levels should be lower in elderly patients with COPD, may be higher in younger patients with asthma, and should be between 8 and 12 µg/mL in pregnant women. The serum level should be measured about halfway into a dosing interval.

Shorter-acting theophyllines have been largely supplanted by 12- and 24-hr sustained-release preparations. Patients should be instructed to take medication at the same time each day with respect to meals. Theophylline has been used extensively in pregnancy without evidence of adverse effects for the neonatal, but serum levels need to be monitored closely and should not exceed 12 µg/mL.

The main indication for intravenous administration of theophylline is an inability to take oral medication or evidence of impaired gastrointestinal absorption. Otherwise, sustained-release oral preparations provide stable blood levels and are just as effective as systemically administered preparations.

Aminophylline, a salt of theophylline with 80% bioavailability, is frequently used for intravenous therapy. Patients with an adequate serum level on admission who are switched to intravenous therapy do not need a loading dose. If the theophylline level is subtherapeutic, a supplemental loading dose can be given: each milligram of aminophylline per kilogram of body weight will increase the serum concentration by 2 µg/mL. If the outpatient oral dose of theophylline is known, then the dose of aminophylline to be given over 24 hrs as a continuous infusion can be determined by multiplying the total daily dose of theophylline by 1.25. The loading dose for patients not previously on oral therapy is 2.5 to 5.6 mg/kg of lean body weight, given intravenously over 20 to 30 minutes. The usual maintenance dose of aminophylline is 3 to 9 mg/kg/hr.

Another alternative for intravenous use is anhydrous theophylline in 5% dextrose. The usual adult loading dose for this preparation is 5 mg per kilogram of lean body weight, and the usual maintenance dose is 2 to 8 mg/kg/hr.

The maintenance dose of both aminophylline and theophylline should be decreased in older patients, and in those who have liver disease, congestive heart failure, fever, or are taking interacting drugs. Higher initial infusion rates should be used for smokers and children. Daily determinations of serum concentration should guide further dose adjustments.

The theophylline dose should be adjusted during addition or withdrawal of medications that affect theophylline metabolism (Table 1). Because theophylline is metabolized in the liver by the P_{450} system, many medications that are similarly metabolized alter theophylline clearance or are themselves affected by theophylline. When in doubt about a potential drug interaction, it is important to educate patients regarding potential toxicity, to assess theophylline serum levels more frequently, and to consider empiric reductions in the theophylline dose. For instance, the theophylline dose should be reduced by half when patients are taking erythromycin, clarithromycin, quinolone antibiotics, zileuton, or oral contraceptives. Another macrolide antibiotic, azithromycin, is metabolized in the liver, but not by the cytochrome P_{450} enzymes, so adjustments in theophylline dose are not necessary. The theophylline dose should also be reduced by half when maintenance therapy with phenytoin, carbamazepine, or other P_{450} enzyme inducers is discontinued. Amoxicillin, cefaclor, co-trimoxazole, and doxycycline do not appear to interact with theophylline.

Drugs that decrease theophylline clearance
Allopurinol — Propafenone
Birth control pills — Propranolol
Calcium channel blockers — Quinolones
Cimetidine — Ranitidine
Clarithromycin — Tacrine
Erythromycin — Thiabendazole
Methotrexate — Troleandomycin
Mexiletine — Zileuton
Drugs that increase theophylline clearance
Barbiturates — Rifampin
Phenytoin
Other interactions with theophylline
Increased lithium clearance
Increased furosemide diuresis
Enhanced β-adrenergic effects: "toxic synergism" (e.g., isoproterenol, ephedrine, albuterol)
In combination with reserpine may result in tachycardia
Decreased zafirlukast clearance
In combination with ketamine may lower seizure threshold
In combination with halothane may cause ventricular arrhythmias

TABLE 1. *Theophylline drug interactions*

Adverse Effects

The most common adverse effects are nausea, abdominal discomfort, vomiting, diarrhea, diuresis, headache, and jitteriness. Side effects tend to increase as the serum level increases but may be seen with low therapeutic levels (5 to 10 µg/mL). Although excessively high serum levels are generally accompanied by nausea and abdominal discomfort, dangerous toxicity can develop in patients without these symptoms. Therefore, monitoring of serum levels is extremely important when therapy is initiated or changed, and then at 6- to 12-month intervals. Signs and symptoms associated with toxic levels include palpitations, premature ventricular contractions, atrial tachyarrhythmias, tremors, seizures, and gastrointestinal bleeding.

Treatment of Theophylline Intoxication

Theophylline poisoning may result from inadvertent iatrogenic overdose, patient error, or suicide attempt. Serious toxicity is associated with levels greater than 30 µg/mL, and serious adverse effects are more likely to be seen at any given blood level in patients with chronic intoxication than with acute overdose. Serum levels correlate poorly with occurrence of life-threatening events. Metabolic disturbances are more common with acute intoxication.

Electrocardiographic and hemodynamic monitoring are vital components of supportive care, because of the risk of cardiac arrhythmias. Sinus tachycardia and atrial and ventricular dysrhythmias are all manifestations of theophylline toxicity. Treatment is recommended only for serious arrhythmias causing unstable hemodynamics. Adenosine, verapamil, and digoxin have been used to treat supraventricular tachyarrhythmias, and lidocaine and phenytoin for ventricular arrhythmias.

Some patients require volume repletion, because of the diuretic effect of theophylline. Metabolic acidosis is common; conservative treatment is advisable. Hypokalemia, caused by hypercatecholemia and intracellular redistribution of potassium, is seen in 30% of patients with chronic intoxication and in 85% of patients with acute overdose. Frequently, potassium levels normalize spontaneously, and vigorous repletion is not necessary.

Seizures are usually treated with diazepam or phenobarbital; phenytoin is not recommended. Refractory status epilepticus may require general anesthesia with pentobarbital or thiopental and paralyzing agents. Prophylactic phenobarbital may be used for patients with serum levels ³50 µg/mL, although this has not be studied in clinical trials.

Prevention of absorption is particularly important, because of the prevalent use of sustained-release theophylline preparations. Stomach emptying is recommended for patients who have ingested a large quantity of a slow-release preparation within 1 hour of seeking medical attention. Otherwise, it is better to inhibit absorption with 50 to 100 g of activated charcoal, given orally with 70% sorbitol (75 to 100 mL). This therapy enhances theophylline clearance in patients with moderate intoxication, but it should not be administered to patients who have depressed pharyngeal reflexes or are vomiting.

Charcoal hemoperfusion is indicated when the serum level is ³80 µg/mL in acute intoxication; ³60 µg/mL in chronic intoxication; or ³40 µg/mL if the patient is 6 months of age greater than 60 years old, has significant liver or cardiac disease, or cannot tolerate activated charcoal. Hemodialysis doubles theophylline clearance and may be helpful when hemoperfusion is not available. It should be combined with oral activated charcoal therapy. Other modalities, such as peritoneal dialysis, plasmapheresis, and hemofiltration, are unlikely to be beneficial.

GLUCOCORTICOIDS

Glucocorticoids are effective in the treatment of a wide spectrum of pulmonary diseases because of their broad anti-inflammatory activity. Asthma, COPD, sarcoidosis,

interstitial fibrosis, hypersensitivity pneumonitis, and bronchiolitis obliterans organizing pneumonia all respond significantly or partially to glucocorticoids. Unfortunately, glucocorticoids also have significant potential side effects that require careful monitoring and patient education. This section focuses on general concepts regarding the mechanisms of action, administration, and adverse effects of systemically administered glucocorticoids.

Mechanisms of Action

Recent research has increased our understanding of the cellular effects of glucocorticoids and provided insight into the reasons why glucocorticoids have such widespread anti-inflammatory effects. Glucocorticoids, when administered orally or intravenously, circulate in the blood either unbound or associated with cortisol-binding globulin. Free glucocorticoid (GC) diffuses into the cytoplasm of cells and binds to glucocorticoid receptors (GR) to form a GC-GR complex.

The GC-GR complex translocates into the cell nucleus and binds to DNA, resulting in either positive or negative modulation of gene transcription. Glucocorticoids also influence posttranscriptional events, such as RNA translation and protein synthesis and secretion (e.g., by altering the stability of certain cytokine messenger RNAs to change the intracellular steady state). Alternatively, the nuclear transcription factors NFkB and AP-1 may bind the GC-GR complex, preventing translocation into the nucleus.

Anti-inflammatory Effects

Glucocorticoids, through their effects on gene transcription and translation in many different cells, inhibit or suppress several steps in the inflammatory process. Glucocorticoids affect lymphocyte cytokine production, distribution, and activation in several ways. They inhibit transcription, directly or indirectly, of many cytokines, including interleukin-1 (IL-1), tumor necrosis factor-a (TNF-a), granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, IL-4, IL-5, IL-6, and IL-8. Trafficking of leukocytes to sites of inflammation is diminished by glucocorticoids, because of a redistribution of lymphocytes out of the vascular compartment and a downregulation of adhesion molecules. Production of integrins and selectins is inhibited by glucocorticoids through their effect on IL-1 and TNF-a. Elaboration of vascular cell adhesion molecule-1 is indirectly reduced through the decrease in IL-4 and GM-CSF production. Suppression of IL-2 production is an important effect of glucocorticoids and results in decreased activation and proliferation of lymphocytes. Phospholipase A_2 release via the annexin family of proteins, which includes lipocortin-1, is inhibited, leading to decreased production of proinflammatory arachidonic acid metabolites. Fibroblast activity is downregulated, resulting in reduced synthesis and secretion of certain cytokines, collagen, and prostaglandins. Secretion of proinflammatory molecules by mast cells and basophils is suppressed, as is basophil activation and mediator release. Although mast cell mediator release is not directly inhibited, mucosal mast cell numbers are significantly reduced. Eosinophil accumulation at inflammatory sites is decreased, probably because of several glucocorticoid effects: decrease in circulating numbers of eosinophils, inhibition of synthesis of IL-4 and IL-5, inhibition of expression of adhesion molecules, and increased local apoptosis. Microvascular leakage of fluids is also decreased. IgE levels are decreased over time, possibly by immunoglobulin catabolism and inhibition of cytokines (e.g., IL-4) that promote IgE production.

Bronchial biopsy studies in patients with asthma who are taking inhaled budesonide or beclomethasone for 3 to 4 months have revealed a decrease in airway eosinophils, mast cells, and lymphocytes. This effect is not seen with inhaled terbutaline. A similar decrease in inflammatory cells is seen in bronchoalveolar lavage studies.

Clinical Pharmacology

Several different glucocorticoid analogues have been developed for clinical use. These compounds differ in their absorption and distribution characteristics, glucocorticoid receptor-binding affinities, elimination rates, topical versus systemic potencies, and mineralocorticoid activities. The choice of a specific analogue and dose depends on the disease being treated and its severity. These issues are reviewed in the chapters on individual diseases.

Certain general observations can be made about systemic glucocorticoid use. Smaller doses administered more frequently are more immunosuppressive than larger doses administered less frequently. A longer biologic half-life may be preferred to maintain the desired clinical effect through the day. However, when the duration of action extends through the night, the risk for hypothalamic-pituitary-adrenal (HPA) axis suppression and other glucocorticoid-related adverse effects increases. Topical or focal application of glucocorticoids results in less toxicity than systemic administration and is the preferred route of administration presuming the desired clinical affect can be achieved. Thus, airway diseases, such as asthma and COPD, can usually be managed with inhaled glucocorticoids, but pulmonary parenchymal diseases, such as interstitial pulmonary fibrosis, require systemic glucocorticoid therapy.

In balancing the need to suppress disease against the desire to protect the HPA axis, a compromise arrangement is to administer analogues with intermediate biologic half-lives (prednisone and methylprednisolone) in one to three doses during the day and early evening, but not at bedtime. As patients' symptoms improve, doses can be consolidated and reduced in frequency. When the prednisone equivalent dose is at or below 30 mg/d, attempts should be made to switch to an alternate-day dosing regimen to reduce further glucocorticoid-related morbidity and enhance recovery of the HPA axis. After patients have been on systemic glucocorticoid therapy for longer than 3 weeks, the glucocorticoid dose needs to be tapered gradually to allow recovery of the HPA axis; the longer the duration of therapy, the slower the taper.

Timing of the dose of oral glucocorticoids may affect the therapeutic result, especially if the disease exhibits diurnal variation. For instance, patients with asthma tend to have nocturnal symptoms when their disease flares. A late-afternoon dose of prednisone may provide better nocturnal symptom control than the usual morning dose.

Glucocorticoid Preparations

Several glucocorticoids are available in the United States for oral or parenteral use: hydrocortisone, prednisone, methylprednisolone, triamcinolone, dexamethasone, and Celestone. Hydrocortisone (half-life, 1.9 hours) is usually used for physiologic replacement or “stress” coverage, because of its rapid onset of action and long history of efficacy. It can be given orally or parenterally. Its mineralocorticoid effects are helpful in patients who need physiologic replacement, but they may be undesirable in patients requiring the medication for immunosuppression or anti-inflammatory activity.

Prednisone is a widely used oral glucocorticoid that is inactive until converted in the liver to prednisolone by reduction at the 11-keto position. Its relative potency is approximately four times that of hydrocortisone.

Methylprednisolone differs from prednisolone in having a methyl group in the 6a position; like prednisolone, it is active without hepatic conversion. The relative potency of methylprednisolone is five times that of hydrocortisone. Its mineralocorticoid effects are slightly less than those of prednisone, and it is available for both oral and intravenous use.

Triamcinolone is essentially devoid of mineralocorticoid activity. It is available as a suspension for intramuscular use. Its potency is about five times that of hydrocortisone. Response among patients is not uniform, but a single parenteral dose four to seven times the oral daily dose controls symptoms for about 4 days up to 4 weeks. Its major role is in treating patients who are noncompliant with oral medications.

Dexamethasone has very little salt-retaining effect, which is beneficial, but its biologic half-life is even longer than that of prednisone or methylprednisolone, increasing its potential to cause morbidity. Its relative potency is about 20 to 25 times that of hydrocortisone.

Celestone is a suspension of betamethasone sodium phosphate and betamethasone acetate available for intramuscular use. The onset of action of the betamethasone esters varies, so a single intramuscular injection may provide prompt as well as sustained glucocorticoid therapy, but this is variable. As with the use of intramuscular triamcinolone, the daily glucocorticoid effect in an individual patient is difficult to titrate. This drug is usually reserved for patients who are not able to take oral glucocorticoid preparations.

Glucocorticoid Resistance

Although glucocorticoids are the most effective anti-asthma medication currently available, some patients with chronic asthma do not experience the expected improvement in symptoms and pulmonary function following oral glucocorticoid administration. This phenomenon of glucocorticoid resistance has been explored most fully in patients with asthma, but it may also pertain in other diseases that can be treated with glucocorticoids.

One definition of glucocorticoid resistance is a lack of improvement of 15% in FEV_1 after 2 weeks of treatment with prednisone at a dose of 20 mg/d, or its equivalent. In addition to failing to show an improvement in respiratory function, some patients are resistant in that they do not exhibit the clinical features of hypercortisolism and their morning cortisol level is normal. These patients usually have familial glucocorticoid resistance, which is associated with normal glucocorticoid receptor binding but low numbers of receptors. Patients with acquired glucocorticoid resistance usually do experience glucocorticoid-induced side effects, including suppression of the morning cortisol level, with high-dose oral glucocorticoids. These patients have normal numbers of glucocorticoid receptors but exhibit decreased glucocorticoid

receptor binding.

The first step in evaluating suspected glucocorticoid resistance is to determine whether the patient is adhering to the recommended dosing schedule and whether persistence of asthma triggers in the environment are responsible for the lack of response. Once these have been excluded, the most common cause for apparent glucocorticoid resistance is severe airway inflammation that ultimately requires higher corticosteroid doses over a more prolonged period. Other possible explanations would be decreased absorption or impaired metabolism of the active moiety.

In patients who have refractory asthma, the absorption and clearance of orally administered glucocorticoids should be assessed by measuring peak and trough blood levels of the specific glucocorticoid administered (available only in specialized laboratories), in addition to morning cortisol and total eosinophil levels. Enhanced plasma clearance of prednisolone or methylprednisolone has not been demonstrated to occur except in the presence of medications that enhance cytochrome P_{450} metabolism.

Another possible explanation for a lack of response to prednisone is a problem with the conversion of prednisone into biologically active prednisolone in the liver. This may be tested by administering methylprednisolone at a dose that is 80% of the usual prednisone dose and repeating spirometry after 2 weeks. If the problem is hepatic conversion of prednisone, the patient's symptoms will improve on methylprednisolone. Additionally, the total eosinophil count can be measured and compared during the two regimens.

Patients with familial glucocorticoid resistance, a rare autosomal dominant disorder with variable penetrance, have high circulating levels of cortisol and adrenocorticotropic hormone. These patients may also demonstrate signs and symptoms of excessive levels of nonglucocorticoid adrenal hormones (e.g., hypertension, hirsutism, menstrual irregularities, hyperkalemia). Measurement of endogenous cortisol levels helps to identify these rare patients. Referral to a specialized center for assessment of the cellular response to glucocorticoids may be necessary to complete the evaluation.

The treatment of glucocorticoid resistance depends on the exact mechanism (acquired or familial) and the degree of resistance. Conventional therapies, such as theophylline, salmeterol, terbutaline, ipratropium, nedocromil, or cromolyn, should be optimized in patients with asthma, while remembering that only the latter two medications have significant anti-inflammatory activity.

Steroid-sparing and other immunomodulatory therapies, such as methotrexate, cyclosporine A, intravenous immunoglobulin, and gold salts, may be considered, but studies have not shown dramatic responses in asthma. The 5-lipoxygenase inhibitor, zileuton, and the leukotriene receptor antagonist, zafirlukast, have recently been released and may be helpful in these patients. Another strategy is to try an alternate glucocorticoid analogue, such as oral methylprednisolone or triamcinolone, instead of prednisone. Ongoing, uncontrolled inflammation will likely require a course of high-dose, possibly intravenous, glucocorticoid therapy. Subsequently, the patient's glucocorticoid sensitivity is usually improved and the glucocorticoid dose can then be tapered.

Complications of Glucocorticoid Therapy

Oral glucocorticoid therapy is frequently associated with side effects that tend to become more serious and more prevalent as the dose and duration of therapy increase. Certain adverse effects, such as insomnia, emotional lability, increased appetite, and weight gain, are characteristically observed early in therapy. Insomnia can be decreased by consolidating most or all of the glucocorticoid dose to the early morning. Patient education and reassurance help with emotional instability, but serous problems in the face of an ongoing need for glucocorticoid therapy may require psychiatric assistance. Nutritional counseling helps to offset weight gain.

HPA axis suppression is to be expected when systemic therapy lasts longer than 3 weeks. After this time, steroid therapy needs to be tapered; the longer the duration of therapy, the slower the taper. The rate of tapering depends on the disease activity and the rate of adrenal recovery. When the dose of prednisone has been 30 mg/d for several weeks, a decrease in the daily dose of 10 mg every 1 to 3 weeks is usually acceptable. If the daily dose has been 20 mg, the decreases may be 5 mg every 1 to 3 weeks. With a daily dose of 10 mg, the incremental decreases may need to be 1 to 2 mg. When systemic glucocorticoid therapy is discontinued, a stimulation test with cosyntropin (Cortrosyn) can be used to determine whether the HPA axis has recovered.

Stress glucocorticoid coverage should be administered for 1 year after completion of systemic glucocorticoid therapy. Patients on high-dose inhaled glucocorticoids should also receive stress coverage during acute illnesses. Despite laboratory evidence of significant adrenal suppression with chronic glucocorticoid therapy, serious, clinically significant adverse events resulting from iatrogenic adrenal suppression are very rare.

Elevations in serum glucose are common during glucocorticoid therapy, but only in patients with underlying glucose intolerance. Patients need to be educated about signs and symptoms of hyperglycemia, and those who already require oral hypoglycemic agents or insulin should have frequent blood glucose determinations. Hypertension and acne usually occur in patients who have other underlying risk factors. Likewise, the risk for peptic ulcer disease appears to be more related to coexistent risk factors, such as nonsteroidal anti-inflammatory therapy.

The relative risk for infectious complications related to steroid therapy is about twice that of controls and varies according to the type of disease being treated, as well as the duration and intensity of therapy. The most common infectious side effect is oropharyngeal thrush, typically associated with inhaled steroids but also seen with oral steroid use, particularly when accompanied by antibiotic therapy. Patients who have never had varicella are at increased risk for generalized varicella and should receive hyperimmune immunoglobulin should they be exposed to someone with active varicella. Patients with a varicella skin rash should be treated with oral or intravenous acyclovir.

A controversial question has been whether all patients with a positive tuberculin skin test (purified protein derivative or PPD) who require glucocorticoid therapy should receive prophylaxis with isoniazid, assuming they have never previously received treatment. The current practice guideline is not to give isoniazid to patients who require intermittent steroid bursts for asthma. On the other hand, patients who require long-term glucocorticoid therapy should receive prophylactic isoniazid, barring other contraindications.

Steroids cause bone loss by decreasing the intestinal absorption and increasing the renal secretion of calcium. These changes in calcium metabolism result in lowering of serum calcium levels, which induces secretion of parathyroid hormone to facilitate resorption of calcium from bones. In a study of patients with asthma, long-term steroid treatment resulted in trabecular, but not cortical, bone loss, a pattern consistent with osteoporosis.

A reasonable strategy for patients receiving short, intermittent courses of oral glucocorticoid or high-dose inhaled glucocorticoid is to recommend that they ingest the recommended daily amounts of calcium (1500 mg in adults) and vitamin D for their age and follow a regimen of daily weight-bearing exercise for 30 to 60 min.

When patients begin long-term glucocorticoid therapy, it is important to assess the presence of other modifiable risk factors for osteoporosis, such as a sedentary lifestyle, menopause, overreplacement of thyroid hormone, and cigarette smoking. Sex hormones should be replaced if deficient. Bone density measurement of the hip and lumbar spine should be performed at baseline. If baseline bone density is adequate, primary prevention is accomplished by maintaining a daily calcium intake of 1500 mg/d through diet or supplements, and supplementing the dietary intake of vitamin D with 800 IU of vitamin D/day or 0.5 µg of calcitriol (1,25-dihydroxycholecalciferol) per day. Vitamin D supplementation maybe associated with hypercalcemia and hypercalciuria. It is recommended that serum and urinary calcium levels be measured 1 month into therapy. A low dose of a thiazide diuretic and sodium restriction can be initiated if the 24-hour urinary calcium excretion is 300 mg/d. Calcium and calcitriol supplementation may also need to be decreased. Six to 12 months after initiation of glucocorticoid therapy, a repeated bone density measurement will reveal whether this initial strategy has been successful, or whether further intervention is needed. If baseline bone density is low, consideration should be given to starting hormone replacement therapy, a bisphosphonate, or calcitonin. At this point, consultation with a rheumatologist or endocrinologist would be appropriate.

Osteonecrosis (avascular necrosis) of bone is a known complication of systemic glucocorticoid therapy, although the exact mechanism is not understood. Typically, it occurs in patients on long-term glucocorticoid therapy, but it has been described with short-term, high-dose therapy. The joints most commonly affected are the hips, knees, and shoulders. When the area involved is small, treatment can be conservative, with avoidance of weight-bearing activity and relief of pain using nonsteroidal anti-inflammatory agents or other analgesics. More severe cases require bone grafting or joint replacement.

Cataract development related to glucocorticoid administration is usually associated with higher doses and longer duration of therapy. Intraocular pressures should be monitored in patients on long-term systemic glucocorticoid therapy, because of the increased risk for glaucoma.

Steroid-induced myopathy is also associated with higher doses and longer duration of therapy. It may be a cause of diminishing exercise tolerance in the face of stable spirometry and usually improves as steroids are tapered.

Long-term systemic use of glucocorticoids in children may result in growth retardation. Studies are ongoing as to whether inhaled glucocorticoids alone have a

significant effect on growth.

Relatively few adverse drug interactions have been described in association with glucocorticoid use. Phenobarbital, phenytoin, and carbamazepine increase cytochrome P_{450} activity, thereby reducing the effectiveness of prednisolone, methylprednisolone, and dexamethasone. Erythromycin and ketoconazole impair prednisolone and methylprednisolone elimination. Rifampin decreases the effectiveness of prednisolone and methylprednisolone. Cimetidine does not interact with prednisolone, methylprednisolone, or dexamethasone, but antacids decrease the bioavailability of prednisolone. Although there is no direct drug interaction, patients receiving insulin or oral hypoglycemic agents for glucose intolerance will likely need dose adjustments as glucocorticoid therapy is added or tapered.

Median serum theophylline concentration was 9.7 mg/L.*

CHAPTER

17 Surfactant

William W. Lunn · Jean E. Rinaldo

W. W. Lunn and J. E. Rinaldo: Pulmonary Division, Department of Medicine, Vanderbilt University, Nashville, Tennessee 37212.

INTRODUCTION

In 1929, Von Neergard calculated that surface tensions in the alveoli and distal air spaces are large enough to cause collapse of the airways during normal lung functions. He postulated the existence of a substance capable of lowering airway surface tension. In 1955, two independent research laboratories isolated a material from the alveolar lining of lungs that was capable of dramatically lowering airway surface tension (surfactant). In 1959, Avery and Mead reported that alveolar washings from premature infants with infant respiratory distress syndrome (IRDS) lacked the normal amount of surface tension-lowering capacity. In 1961, it was shown that phospholipid isolated from the alveolar lining fluid of beef lungs possesses surface tension-lowering properties. These phospholipids contain hydrophilic and lipophilic moieties, which result in their forming a filmy monolayer over the aqueous alveolar luminal surface. Surfactant was found to be synthesized by type II pneumocytes and continually secreted into the air spaces, and to contain associated proteins with diverse biologic functions. Finally, in 1980, Fujiwara and associates reported the first successful use of exogenous surfactant therapy for infants with IRDS. Today, exogenous surfactant therapy for infants with IRDS is considered a clinical standard of care.

SYNTHESIS, METABOLISM, AND FUNCTIONS OF ENDOGENOUS SURFACTANT

Surfactant Lipids

Lipids constitute approximately 90% of surfactant isolated from human lungs. The lipid moiety comprises a mixture of phospholipids (90%) and other lipids (10%). The two principal phospholipids are phosphatidylcholine (PC), the most abundant phospholipid, and dipalmitoylphosphatidylcholine (DPPC), which may be the most important one. All phospholipids are structured so that they possess a polar head and a pair of hydrophobic tails, making them ideal molecules to form lipid-water interfaces, as they do in cell membranes. Most of the surface tension-lowering properties of surfactant reside in the DPPC molecule. It is the saturated palmitic acid residues that make the DPPC molecule unique, allowing them to be packed together tightly to form a monolayer with tensile strength at the air-fluid interface. The polar head of each DPPC molecule is charged, so that it has an affinity for molecules of water in the alveolar lining fluid. The long hydrophobic tails are directed away from water molecules and project into the air space. The repulsion of water molecules from the air-fluid interface results in a dramatic lowering of the surface tension in the air spaces (Fig. 1). The net effect is to retard the development of atelectasis and lung edema, to decrease lung compliance, and to diminish work of breathing. Some evidence suggests that the lipid component of surfactant may play a role in host defense, having been implicated in both bacterial killing and suppression of stimulated lymphocytes; most investigators believe that the surfactant-associated proteins play an important immunomodulatory role.

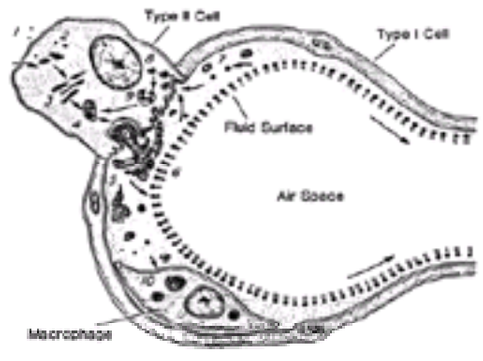

FIG. 1. Schematic diagram of a single alveolus emphasizing the movement of surfactant components through the type II cell and alveolar liquid. Components and compartments are not to scale. Key: *1,* surfactant precursors such as glucose, amino acids, and fatty acids; *2,* endoplasmic reticulum; *3,* Golgi apparatus; *4,* lamellar bodies; *5,* tubular myelin; *6,* surface film with adsorbed phospholipids; *7,* vesicular and myelin forms of surfactant possibly derived from material desorbed from the film; *8* and *9,* endocytotic compartments such as multivesicular bodies; *10,* alveolar macrophage. (From Hawgood S, Clements J. Pulmonary surfactant and its apoproteins. *J Clin Invest* 1990;86:1–6.)

Surfactant-Associated Proteins

Proteins constitute approximately 10% of isolated surfactant. Most protein found in surfactant appears to have diffused in passively from serum. Only 20% is synthesized locally. To date, three apolipoproteins (surfactant-associated proteins) have been well characterized: SP-A, SP-B, and SP-C. A fourth protein, SP-D, has been described, but there is debate in the literature regarding whether SP-D is a true apolipoprotein or simply a contaminating protein. Each surfactant-associated protein has a unique structure and function, summarized in Table 1.

	Protein structure	Functions
SP-A	Globular protein with a collagen-like domain and a short N-terminal structural similarity to C1q	Assists in the formation of tubular myelin Enhances macrophage function Inhibits surfactant secretion Promotes reuptake of surfactant
SP-B	Small cationic protein with α-helix folding	Assists SP-A in tubular myelin formation Enhances spreading of lipid film in air-liquid interface
SP-C	Small cationic protein with α-helix folding	Enhances spreading of lipid film in air-liquid interface
SP-D	Large collagenous glycoprotein	Possible role in pulmonary host defense

TABLE 1. *Surfactant-associated proteins*

SP-A is a large, collagen-like protein. It is the most ubiquitous surfactant-associated protein and appears to perform diverse functions critical to both surfactant homeostasis and immunoregulation. First, SP-A has been shown to assist in the conversion of newly secreted surfactant precursor into tubular myelin, believed to be the intracellular source of the phospholipids and the surfactant film. SP-A also participates in the regulation of surfactant homeostasis by inhibiting surfactant synthesis and promoting surfactant uptake by type II pneumocytes. Second, SP-A has clearly been shown to regulate inflammation. It enhances the activity of pulmonary macrophages. Of interest, SP-A has structural similarities to C1q of the complement cascade, possibly accounting for its ability to activate macrophages. It appears that binding of SP-A to pulmonary pathogens such as *Mycobacterium tuberculosis* permits uptake of the organisms by a specific SP-A receptor on macrophages, suggesting that SP-A may function as a hapten as well as a nonspecific activator and suppressor of intra-alveolar inflammatory effector cells.

SP-B is a small, hydrophobic protein that appears to co-operate with SP-A in the formation of tubular myelin and possibly to play a role in the packing of surfactant precursor in lamellar bodies. Additionally, SP-B has been shown to enhance the spreading of surfactant lipids in a monolayer film. SP-C is another small, hydrophobic protein that is structurally similar to SP-B. The only known role of SP-C is that it functions like SP-B to enhance the spreading of surfactant lipids in the air spaces. SP-D is a recently described large glycoprotein that many investigators believe may function to enhance the clearance of microorganisms from the airways. Not much is known about SP-D at present. There is disagreement about whether SP-D is a surfactant apoprotein or a contaminating plasma protein.

Surfactant Synthesis, Secretion, and Uptake

The lipid and protein components of surfactant are synthesized in the type II pneumocyte. Surfactant lipid is made and stored in lamellar bodies within the cell. Stimulation of the type II pneumocyte may result in the secretion of surfactant material from lamellar bodies into the air space, where it is rapidly transformed into tubular myelin with the assistance of SP-A and SP-B. The precise pathways of surfactant-associated protein synthesis and incorporation into the lipid components of surfactant have eluded scientists to date. It is not clear whether the protein components become associated with the lipid components in the lamellar bodies, after secretion of tubular myelin into the air spaces, or both.

Several stimuli can induce surfactant synthesis and/or secretion in vitro (Table 2). These include glucocorticoids, b-adrenergic agonists, estrogen, and thyroxine, which share the ability to enhance both the synthesis and secretion of surfactant. Stretching of the lung via mechanical ventilation also results in surfactant secretion. Downregulators of surfactant secretion include SP-A and b-adrenergic blockers. Corticosteroids are an extremely important inducer of surfactant synthesis and is used for clinical purposes. Glucocorticoid levels rise dramatically in the normal fetus late in gestation just before the production of surfactant. Glucocorticoid treatment of pregnant women prior to giving birth to children at risk for IRDS increases the rate at which alveolar type II cells mature and the production of surfactant.

Promoters of synthesis	Promoters of secretion
Ambroxol	Ambroxol
cAMP	β-Agonists
β-Agonists	Estrogen
Estrogen	Mechanical ventilation
Glucocorticoids	Prostaglandins
Thyroxine	Thyroxine
Inhibitor of synthesis	Inhibitors of secretion
Testosterone	SP-A
	β-Blockers

TABLE 2. *Factors involved in regulating surfactant synthesis and secretion*

Studies of surfactant synthesis indicate that new surfactant is being generated continuously and is not degraded in the airways. Therefore, mechanisms for surfactant clearance must exist. Some of the excess surfactant is undergoes phagocytosis by alveolar macrophages or is removed from the airway by the mucociliary elevator. There appears to be a sophisticated system by which type II cells “recycle” DPPC by taking it up, packaging it back into lamellar bodies in the cytoplasm, and resecreting it. SP-A appears to mediate partly the reuptake of DPPC by type II pneumocytes. Impaired mechanisms for clearance and recycling may cause alveolar proteinosis, a disease characterized by excess surfactant accumulation in alveoli. Surfactant homeostasis is an area of vigorous ongoing research.

THERAPEUTIC USE OF EXOGENOUS SURFACTANT PREPARATIONS

As described above, surfactant is necessary to prevent atelectasis and lung edema, and to maintain normal lung compliance. As atelectasis, lung edema, and reduced lung compliance occur in IRDS and many acute lung disorders in adults, it is not surprising that the effects of instilling exogenous surfactant into the lung have been the subject of considerable study. The therapeutic possibilities seem particularly attractive in critically ill patients undergoing mechanical ventilation, in whom there is ready access to a delivery conduit. Although the concept is superficially simple, practical issues have posed complex problems. Where will large quantities of human surfactant come from? Unlike many human bioactive substances, such as insulin, surfactant is predominantly lipid and thus cannot be cloned by recombinant DNA technology, so the molecular revolution has not solved the availability problem. Nor can human surfactant be isolated from human blood, like clotting factors or a_1-antiprotease; the human lung is presently the only source of human surfactant. Can animal surfactant be used? Can an artificial lipid surfactant be synthesized, and if so, what components of surfactant are most useful to instill? Must the human apoproteins be added? How can a large volume of liquid be delivered and spread evenly through the lung without causing respiratory compromise during delivery? These are some of the questions that must be answered prior to the use of surfactant as accepted practice.

Available Surfactant Preparations

The surfactant preparations may be divided into two groups: natural preparations and synthetic preparations. The natural surfactants are derived from animal sources, with bovine and porcine sources being the most common (Table 3). A natural surfactant can be prepared from human amniotic fluid, but this is not yet commercially available. Natural surfactants are either prepared by extraction from minced lung tissue or from lung lavage material. Lung lavage material has a theoretical advantage over minced lung material in that it contains less cellular and blood-derived contaminants, but obtaining it in large quantities is a laborious process. To date, there are no data from clinical studies to suggest that lung lavage preparations are more efficacious than lung mince preparations.

Name	Trade name	Source	Ingredients	Company
Surfactant TA	Surfacten	Bovine lung mince	Phospholipids, SP-B, SP-C, palmitic acid, tripalmitin	Terumo (Tokyo, Japan)
Curosurf	Curosurf	Porcine lung mince	Phospholipids, SP-B, SP-C	Chiesi Farmaceutici (Parma, Italy)
Survanta	Beractant	Bovine lung mince	Phospholipids, neutral lipids, fatty acids, SP-B, SP-C, palmitic acid, tripalmitin	Abbott Laboratories (Chicago, IL)
Alveofact	Alveofact	Bovine lung lavage	Phospholipids, cholesterol, SP-B, SP-C	Thomas GmbH (Bitersch, Germany)
Calf lung surfactant extract	CLSE	Calf lung lavage	Phospholipids, cholesterol, cholesterol esters, SP-B, SP-C	Privately produced in Canada
Infasurf	Infasurf	Calf lung lavage	Phospholipids, SP-B, SP-C	Forest Laboratories (St. Louis, MO)

TABLE 3. *Natural surfactant preparations*

Several animal-derived surfactants are in clinical use. They differ considerably in composition, as both the extraction methods and addition of specific lipids may alter the final composition of the extract sold commercially. Surfacten was developed by the Fujiwara group in Japan and was the first surfactant preparation to be successfully employed to treat infants with IRDS. It is made from bovine lung mince and is supplied as a powder that must be reconstituted in sterile saline solution. Beractant is also prepared from bovine lung mince and is similar to Surfacten. It is supplied as a liquid and thus requires no mixing. Curosurf is prepared from porcine lung mince and is supplied as a liquid. It has the highest concentration of phospholipids (80 mg/mL) of all the natural surfactants. Alveofact is derived from bovine lung lavage material. In addition to phospholipids, it contains cholesterol and other lipids. Infasurf (CLSE) also contains cholesterol and cholesteryl esters in addition to phospholipids.

There are currently two synthetic surfactant preparations available, ALEC and Exosurf (Table 4). ALEC contains DPPC and other phospholipids but does not contain any surfactant-associated proteins. The phospholipid concentration is approximately 100 mg/mL, highest of all surfactant preparations. Exosurf contains DPPC, hexadecanol, and tyloxapol. Like ALEC, it does not contain any surfactant-associated proteins. The phospholipid concentration of Exosurf when diluted as directed is much lower than that of ALEC. It is not clear whether the lack of surfactant-associated proteins in these preparations is a disadvantage. A recent meta-analysis comparing Exosurf with natural surfactants suggested that improvements in lung compliance and oxygenation were delayed in infants treated with Exosurf in comparison with those treated with natural surfactants, but both natural surfactants and Exosurf were efficacious and resulted in a clear reduction in morbidity and mortality in treated infants, with no statistically significant difference in mortality rates. Large, prospective, controlled clinical trials would be helpful to determine if the natural surfactants are superior to synthetic preparations, but even if performed carefully, these studies would be extremely difficult to interpret because of the marked differences in the available natural and synthetic preparations and the likelihood that continuous adjustments will be made in the composition of future preparations.

Name	Trade name	Ingredients	Company
Artificial lung-expanding compound (ALEC)	Pumactant	DPPC, unsaturated phosphatidylglycerol	Britannia Pharmaceuticals (Redhill, England)
Exosurf	Exosurf	DPPC, hexadecanol, tyloxapol	Burroughs Wellcome (Research Triangle Park, NC)

DPPC, dipalmitoylphosphatidylcholine.

TABLE 4. *Synthetic surfactant preparations*

Methods for Delivery of Surfactant Therapy

The goal of administration of surfactant is to deliver the drug in a simple fashion that minimizes physiologic disturbances and spreads surfactant evenly through the lung. There are two obvious ways to attempt this: tracheal instillation or aerosolization. After Avery and Mead published their findings in 1959, scientists in the 1960s experimented with surfactant therapy for infants with IRDS. Aerosolized delivery of surfactant was employed by most investigators. No beneficial effect of treatment could be demonstrated. It was because of these difficulties that Fujiwara and colleagues chose direct tracheal instillation as the method of drug delivery in their landmark study. At present, all the manufacturers of commercially available surfactants recommend tracheal instillation as the method of choice for drug delivery, but there are considerable differences in the specifics of recommended delivery. Some companies advocate multiple dosing; others suggest directed positioning of patients after instillation to facilitate drug distribution.

Tracheal instillation has been proved effective in a large number of clinical trials involving thousands of patients. Tracheal instillation allows for drug to be delivered to airways that are not being ventilated, whereas aerosolized surfactant is delivered only to ventilated lung segments. Tracheal instillation techniques are relatively simple and do not require any specialized equipment. However, there are also disadvantages. First, patients must be intubated and on mechanical ventilation for the drug to be given. Repositioning and interruption of the ventilator circuit in hypoxemic patients may result in worsening hypoxemia. Also, as most of the surfactant preparations require large volumes of drug to be instilled, transient obstruction of the airways may occur and result in respiratory and hemodynamic instability.

Despite early disappointment with aerosol delivery, there is renewed interest in the use of this technique to circumvent the problems with tracheal instillation outlined above. Aerosolization is a noninvasive technique with which physicians, nurses, and respiratory therapists are familiar, making it readily acceptable. Significant problems remain. Aerosolization results in a smaller dose of surfactant delivered to the patient compared with tracheal instillation because of the inefficiency of the delivery devices currently available, especially in ventilated patients. When a jet nebulizer is used in the ventilator circuit at high flow rates, large particles impact in the inspiratory circuit and never reach the lung, whereas particles of 1 μ in diameter may be taken into the lung only to be exhaled. There may be foaming of the surfactant aerosol and subsequent malfunctioning of valves in the expiratory circuit. These technical difficulties remain to be overcome, and trials must be performed in humans to compare the clinical efficacy of aerosolized versus tracheally instilled surfactant.

A number of factors may influence the distribution of surfactant in the lungs, regardless of the mode of drug delivery employed. The type of surfactant preparation may be of importance. The natural surfactants containing SP-B and SP-C may spread more rapidly and evenly in the air-liquid interface of the alveoli. Some in vitro data suggest that the synthetic preparations, which lack surfactant-associated proteins, spread more slowly and have higher minimal surface tensions than the surfactants that contain proteins. The clinical significance of these findings is still uncertain. The volume of fluid instilled also influences the distribution of surfactant in the lung. A more homogeneous distribution of surfactant is achieved when it is given in larger volumes of vehicle. However, larger volumes are potentially hazardous, as they are associated with a greater frequency of respiratory and hemodynamic instability during and immediately after the instillation process. Finally, it is possible that the mode of ventilation may influence the distribution of surfactant after it is administered through the endotracheal tube. Standard practice has employed conventional, volume-cycled ventilatory modes after delivery of the drug. However, some investigators have studied the effect of high-frequency ventilation in animal models of lung injury. The results have been conflicting, so more research will be required to determine whether ventilatory modes may significantly affect drug distribution.

CLINICAL APPLICATIONS OF SURFACTANT THERAPY

Infant Respiratory Distress Syndrome

IRDS is at present the only clinical condition for which surfactant instillation has been proved beneficial. The maturation of the fetal lung occurs late in the process of gestation. Type II pneumocytes begin to mature and develop lamellar bodies at approximately 24 weeks of gestation, but dramatic increases in the phospholipid concentration of amniotic fluid are not seen until approximately 28 weeks. Therefore, children born prematurely may not have a sufficient quantity of biologically active surfactant necessary to maintain normal lung function and are at risk for IRDS. More than 35 randomized, controlled trials of exogenous surfactant therapy for IRDS have been performed. The results, which have been dramatic, include a decreased incidence of pneumothorax, improved oxygenation, decreased dependence on mechanical ventilation, and a reduction of mortality. Clearly, the reduction in infant mortality rates observed in the 1980s in the United States was partially a consequence of the introduction of exogenous surfactant therapy.

Some now recommend surfactant therapy prophylactically in premature infants. Meta-analyses of data from clinical trials performed in the United States and abroad have answered important questions regarding surfactant therapy for IRDS. For example, it is clear that surfactant therapy given to infants in the delivery room who are at risk for IRDS is effective in lowering both the incidence and severity of the syndrome. However, trials comparing prophylactic therapy with rescue therapy have failed to demonstrate superiority of one style of treatment. Most investigators agree that prophylactic therapy should be given to infants at high risk for IRDS by someone with experience in neonatal resuscitation. Infants who are at low risk may be observed carefully for signs of respiratory insufficiency and treated if deterioration develops.

Some cases of IRDS do not respond to surfactant therapy. Approximately 10%–20% of infants treated with exogenous surfactant for IRDS fail to demonstrate any significant clinical response. These infants sometimes have been given an incorrect diagnosis and actually have other diseases, such as pneumonia or congenital heart disease. Meta-analyses suggest that other complications of prematurity, such as patent ductus atreriosis and interventricular hemorrhage, are unaffected by exogenous surfactant therapy.

Meconium Aspiration Syndrome

Meconium aspiration syndrome (MAS), which occurs secondary to fetal inhalation of meconium into the lungs, usually during labor, results in respiratory embarrassment shortly after birth. Infants with MAS may have hypoxemia, noncompliant lungs, and ventilator-associated barotrauma, just like infants with IRDS. Because MAS resembles IRDS clinically, many have postulated that meconium in the lungs of the neonate may interfere with the activity of surfactant. Experimental studies suggest reduced surface tension-lowering ability of surfactant after meconium contamination. In clinical and experimental studies, surfactant has resulted in improvements in lung compliance and oxygenation. The available data are promising, but randomized, controlled trials in a large number of patients need to be performed to establish a significant outcome benefit.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) is a disorder in which the fetus develops with a defect in the diaphragm that allows abdominal contents to migrate into the thoracic cavity and compress the lung. This compression results in pulmonary hypoplasia, characterized by a reduced number of alveoli, and smooth-muscle hyperplasia in pulmonary arterioles. The hypoplastic lungs of these neonates are also deficient in surfactant. Infants with CDH are usually born at term and experience respiratory compromise early after birth. Surgery corrects the diaphragmatic defect, but the immature lung persists; the mortality rate for infants with CDH is approximately 30%–50%. Current data on exogenous surfactant therapy for infants with CDH are limited, but reports suggest that surfactant may improve oxygenation in these infants and facilitate support with mechanical ventilation. Further investigation of exogenous surfactant therapy for children with CDH is ongoing.

Adult Respiratory Distress Syndrome

Adult respiratory distress syndrome (ARDS) was named after IRDS because of the clinical similarities. Both syndromes are manifested by respiratory failure, poorly compliant lungs, alveolar flooding, and profound hypoxemia. Surfactant abnormalities and alveolar damage are present in each disorder. However, there are important differences. First, although alveolar damage is present in both syndromes, the alveolar injury occurs for different reasons. The primary abnormality in IRDS is immaturity of the lung and a primary deficiency of biologically active surfactant. This results in atelectasis in surfactant-poor areas and overdistention and hyperoxic exposure in alveoli in overventilated lung units. Overdistention and oxidant injury probably result in secondary alveolar disruption and injury. In contrast, an inflammatory alveolar injury is the primary pathophysiology of ARDS. The end result is alveolar disruption and pulmonary capillary leakage of serum proteins and water into the alveolar spaces. Surfactant processing and surface tension-lowering activity are impaired in this abnormal alveolar environment. Thus, the surfactant abnormalities in IRDS are fundamentally distinct from those of ARDS. Infants with IRDS cannot synthesize surfactant, whereas the surfactant in the lungs of patients with ARDS is inactivated by contaminating serum proteins, oxidants, and poorly characterized aberrations in surfactant homeostasis. This poses two questions in ARDS that are not relevant in IRDS: (1) Is the surfactant deficiency of ARDS an important factor in poor outcome or just an epiphenomenon? (2) Will exogenous administered surfactant function well in the ARDS inflammatory milieu? Neither question has been answered to date.

Available results of clinical trials are disappointing. As has often been the case with ARDS, small studies with encouraging results have been superseded by large, multicenter trials with negative findings, most recently a large, multicenter study of 498 patients with sepsis-induced ARDS, in which patients received treatment with either aerosolized Exosurf or placebo for 5 days. Preliminary summary data reported nationally suggested no differences in mortality, although final publication of the study is pending. There are a number of reasons that may explain the lack of efficacy. Exosurf lacks surfactant-associated proteins. The dose of surfactant employed was low, normalized to weight, and given in proportion to the usual dosage regimens for IRDS. On the other hand, employing large doses of surfactant in adults may be problematic because of the large volumes (70 to 300 mL, depending on the preparation) that are required. Also, as discussed above, a number of questions remain unanswered regarding the most efficient means of delivering the drug. Finally, there is the matter of timing. Unlike the onset of IRDS, the onset of ARDS is difficult to determine with precision, and the most severe respiratory failure may occur late as a result of nosocomial pneumonia or other complications. Should surfactant be administered as an adjunct to maximal ventilatory support, or should patients identified as being at risk for ARDS receive surfactant? Thus, the issue of surfactant therapy in ARDS perfectly illustrates the problems associated with translating this “simple” therapy into a practical regimen.

Future Applications

Surfactant, because of its beneficial effects of increasing lung compliance and oxygenation and preventing atelectasis, can be viewed as a nonspecific supportive therapy likely to provide physiologic benefit regardless of the nature of respiratory failure; it has therefore been postulated that exogenous surfactant therapy may be useful in a wide range of adult diseases, including pneumonia, pulmonary fibrosis, asthma, chronic bronchitis, and after lung transplantation. Surfactant abnormalities have been described in each of these disorders. However, all the problems associated with ARDS therapy might be expected to occur and even be exacerbated in this heterogeneous group of disorders, and no large, controlled trials in humans to date have demonstrated a benefit of exogenous surfactant therapy in any of them. However, speculation and optimism continue, and research is ongoing in each of these areas.

Despite the advances of the last 40 years of research, many questions regarding the function and metabolism of surfactant remain unanswered. As progress is made in understanding the mechanisms of surfactant function in health and disease, new treatment strategies may be designed. On the horizon, investigators are working to prepare more efficacious synthetic and natural surfactants, so-called “designer surfactants” containing higher concentrations of surfactant-associated proteins and a wider range of phospholipids. Others are working to improve dosing regimens and drug delivery. Finally, clinical studies are under way to study the effects of various surfactant preparations in a wide range of disorders, including ARDS, and as postoperative respiratory support after lung transplantation. Clearly, a vast potential market for effective surfactant therapy exists that will undoubtedly continue to drive research and product development in this area. It is hoped that patients with a variety of lung disorders will ultimately benefit.

CHAPTER

18 Interstitial Lung Diseases

Kenneth G. Saag · Joel N. Kline · Gary W. Hunninghake

K. G. Saag, J. N. Kline, and G. W. Hunninghake: Department of Internal Medicine, University of Iowa College of Medicine, Iowa City, Iowa 52246.

GENERAL CONSIDERATIONS AND NOMENCLATURE

The interstitial lung diseases (ILD) are a group of disorders of both known and unknown etiology that are characterized by inflammation and fibrosis. Table 1 is a list of some of the pulmonary disorders commonly associated with ILD. This chapter covers two types of ILD of unknown cause: idiopathic pulmonary fibrosis (IPF) and ILD associated with the systemic rheumatologic disorders. The clinical presentation, physiology, pathology, and management of IPF are discussed first, and subsequently aspects of ILD associated with the systemic rheumatologic diseases.

Idiopathic
Idiopathic pulmonary fibrosis
Familial pulmonary fibrosis
Hamman-Rich syndrome
Sarcoidosis
Bronchiolitis obliterans organizing pneumonia
Systemic rheumatic disorders
Rheumatoid arthritis
Systemic lupus erythematosus
Sjögren's syndrome
Systemic sclerosis
Dermatomyositis/polymyositis
Mixed connective tissue disease
Ankylosing spondylitis
Occupational
Silicosis
Asbestosis
Berylliosis
Coal worker's pneumoconiosis
Hard metal pneumoconiosis
Infectious
Fungal disease
Postviral
Miscellaneous
Sequelae to adult respiratory distress syndrome
Hypersensitivity pneumonitis
Drugs
Oxygen toxicity
Radiation toxicity

TABLE 1. *Common cause of pulmonary fibrosis*

IDIOPATHIC PULMONARY FIBROSIS

In the mid-1930s, Hamman and Rich first described a series of patients in whom developed what today is considered a variant of IPF. For a period of time, however, the term *Hamman-Rich syndrome* was used to denote most cases of pulmonary fibrosis. This term is now reserved for cases of acute interstitial pneumonitis (AIP) with a rapidly progressive and often fatal course. Several other names have been proposed for IPF, including *cryptogenic fibrosing alveolitis, diffuse interstitial lung disease,* and *interstitial pulmonary fibrosis.* Each of these names has merit; however, we refer to the disorder in this chapter as *IPF.* IPF has also been subdivided into usual interstitial pneumonitis (UIP) and desquamative interstitial pneumonitis (DIP). We recognize this classification and, when necessary, refer to differences between these two subdivisions of IPF. It should be noted, however, that many investigators do not use these terms and consider UIP and DIP as different manifestations of IPF.

Epidemiology

The prevalence of IPF has been estimated to be about 3 to 5/100,000. It is second only to sarcoidosis as a cause for ILD of unknown etiology. Prevalence estimates vary, however. For example, one study using a New Mexico lung disease registry estimated the prevalence of pulmonary fibrosis at 29/100,000 for male patients and 27/100,000 for female patients. This estimate may reflect the prevalence for the entire United States, or it may represent employment in local mining industries resulting in occult pneumoconiosis, migration of persons with chronic lung disease to New Mexico, or over-ascertainment of cases based on the use of administrative coding. In the New Mexico population, IPF accounted for 45% of all ILD. Based on autopsy studies, IPF may be 10 times more common than is clinically recognized. Few studies have examined ethnic or racial predilections for IPF; in one study of indigenous African patients, the clinical spectrum and frequency of illness were similar to those of other groups.

Although by definition “idiopathic” pulmonary fibrosis has no known cause, it is conceivable that inhaled particulate dust or other material could cause this disorder. Of interest, 70% of patients with presumed IPF had organic dust exposure in one study. Curiously, up to 40% of IPF patients may recall an antecedent viral-type illness accompanied by cough, fever, and malaise. However, despite intense investigation, there is no clear evidence implicating an infectious etiology for IPF.

The association between IPF and cigarette smoking has generated considerable interest. Of patients with IPF, 60%–80% are either current or former smokers. Cigarette smoking is a plausible IPF risk factor, as it may alter pulmonary immune function, reduce clearance of inhaled agents, and increase permeability of the respiratory epithelia. Cigarette smoking influences bronchoalveolar lavage fluid (BALF) cellularity and is the strongest independent predictor of increased BALF neutrophils and eosinophils (Table 2). Smoking may also cause respiratory bronchiolitis, an entity histologically similar to DIP; this may, in turn, lead to fibrosis.

	Nonsmoker volunteers (n = 111)	Smoker volunteers (n = 19)	IPF study subjects (n = 83)
Cells/mL, $\times 10^4$	12.7±9.1***	48.9±40.2*	28.0±24.4
Macrophages/mL, $\times 10^4$	12.1±10.0***	47.4±39.6**	22.4±21.8
Lymphocytes/mL, $\times 10^4$	0.8±1.0	0.7±0.7	1.6±3.0

Clinical Presentation

History

The typical patient with IPF is between 40 and 60 years of age. Symptoms of the disease frequently develop 1 to 2 years before the patient seeks attention. Men are affected slightly more commonly than women. Dyspnea at rest (and worsened by exertion) and a nonproductive cough are the most common symptoms. Constitutional symptoms of malaise and weight loss are seen in some cases. Even in the absence of a well-recognized rheumatologic disease, arthralgias without actual joint inflammation may be present.

The medical history, including a comprehensive symptoms review, occupational history, and family history, is invaluable in differentiating IPF from other types of ILD. A familial form of IPF, thought to be autosomal dominant with variable penetrance, has been described.

Sudden onset of respiratory symptoms with a clinical presentation suggestive of the adult respiratory distress syndrome (ARDS) (but for which no underlying cause is apparent) should raise suspicion of AIP or the Hamman-Rich syndrome. Individuals affected by AIP are often younger adults or even children. Although this disorder has a poor prognosis, patients who recover may have completely normal pulmonary function. Like AIP, bronchiolitis obliterans with organizing pneumonia (BOOP) may develop in an abrupt fashion, but it reflects a pattern of injury in the small airways and the adjacent pulmonary parenchyma. It is often responsive to therapy and usually has a good prognosis.

Physical Examination

Physical examination findings generally include tachypnea, basilar crackles, and exercise-induced cyanosis. Chest crackles occur in 60%–75% of cases; typically they are fine and late in inspiration, and they are often described as “velcro rales.” Crackles are more common in IPF than in other forms of ILD, such as sarcoidosis, and are thought to be associated with subpleural fibrosis. Mid- and late-expiratory crackles may be detected. These more subtle findings are believed to be caused by vibrations of the airway walls and may be a clinical indicator of disease severity. Clubbing is present in about 65% of cases of IPF. It occurs more commonly in men and may begin early in the disease course. Of note, full-blown hypertrophic osteoarthropathy is rare. In one study, clubbing correlated with the extent of smooth-muscle proliferation in fibrotic pulmonary lesions. With the onset of secondary pulmonary hypertension, signs of right-sided heart failure, such as jugular venous distension, an accentuated P_2 heart sound, and pedal edema, become apparent.

Evaluation for characteristic manifestations of systemic rheumatic disease, including physical examination findings and results of selected laboratory studies, complements the history in excluding ILD associated with specific illnesses.

Diagnostic Studies

Physiologic Evaluation

Results of pulmonary function studies are among the best indicators of the severity of IPF. Diminished single-breath diffusion capacity of carbon monoxide (D_LCO), in particular, is one of the earliest and most sensitive physiologic abnormalities of IPF. It has been recommended that D_LCO be corrected for alveolar volume (D_LCO/V_A, or KCO), because KCO is a more useful indicator of the severity of gas exchange impairment during exercise and the degree of pulmonary vascular involvement. It is not clear, however, whether D_LCO or KCO is the best index of impairment. Reduction in lung volumes typical of restrictive disease is also noted. The degree of reduction in lung volumes and increase in lung elastic recoil directly correlate with the extent of fibrosis. There is, however, a very poor correlation between lung volumes and inflammation. The reduction in lung volumes also causes a reduction in forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) as measured by spirometry. Because the reductions in FEV_1 and FVC are usually of equal magnitude, there is often no evidence of airway obstruction. A widened alveolar-arterial gradient in partial pressure of oxygen [$P(A\text{-}a)O_2$], worsened by exertion, is also a useful parameter to monitor in patients with IPF.

Comorbid obstructive lung disease caused by cigarette smoking may complicate interpretation of pulmonary function data in patients with IPF, because of increased residual volume (RV) and functional residual capacity (FRC) resulting from trapping of air. The presence of both obstructive and restrictive lung diseases has opposite effects on measures of air flow and lung volumes, and smoking may appear to “normalize” these physiologic measures in IPF. The D_LCO is an accurate method of assessing lung function in patients with IPF who smoke and have obstructive lung disease. To confound matters further, small-airway obstruction is often present in early IPF, independently of smoking, and may influence physiologic parameters such as mid-expiratory flow rates. About two thirds of patients have morphometric and physiologic evidence of small-airway involvement, indicated by abnormalities of flow-volume curves and dynamic compliance.

Initially, it was thought that a fall in arterial PO_2 was most caused by diffusion abnormalities. More recent work suggests that arterial hypoxemia is explained best by ventilation-perfusion mismatch and to a lesser extent by a diffusion limitation. Patients with IPF have higher pulmonary arterial pressures both at rest and during exercise than patients who have other causes of ILD. Although pulmonary arterial hypertension may be mainly caused by destruction of blood vessel in fibrotic lung, pulmonary vasoconstriction caused by alveolar hypoxia is also important.

Physiologic changes in lung function during both exercise and sleep provide useful clues about the severity and functional consequences of IPF. Although exercise causes significant hypoxemia in most patients with long-standing IPF, there is generally little or no change in PCO_2. A small percentage of patients with early IPF may have normal or even improved levels of arterial blood gases during exercise. Pulmonary edema at maximal exercise, rather than inspiratory muscle fatigue, may account for exercise limitations observed in some patients with IPF. O_2 desaturation also develops in patients with IPF during REM sleep, similar to that seen in patients with chronic obstructive pulmonary disease (COPD). Insufficient ventilatory response to hypercapnia accounts for larger falls in O_2 saturation during sleep. Overall, O_2 desaturation during sleep is usually mild and less severe than that observed during exercise.

Like patients with COPD, patients with IPF expend about 120% of their predicted energy expenditure for body size. This is a principal component of the weight loss seen in IPF.

Quality-of-Life Evaluation

Quality-of-life considerations are of paramount importance in assessing disease severity and response to therapy. The sensation of dyspnea and limitations of physical activity are the most important considerations. Dyspnea may be quantitated (grades 1 through 4) in a simple and reliable manner, as outlined in the American Thoracic Society Shortness-of-Breath Scale. Various ordinal dyspnea scales, such as the Baseline Dyspnea Index (BDI), Medical Research Council (MRC) scale, and Oxygen-Cost Diagram (OCD), also provide semiquantitative information on disease-specific health-related quality of life (HRQL) and have good reliability. These measures of dyspnea are significantly associated with physiologic parameters of lung function. Severe breathlessness is correlated with lower resting D_LCO and an accelerated ventilatory response to exercise. Dyspnea is related to reduced lung compliance and increased elastic work of breathing. In addition to dyspnea, other disease-associated factors clearly affect patients' quality of life. The Chronic Respiratory Questionnaire and the St. George's Respiratory Questionnaire evaluate a range of pulmonary symptoms. The short-form 36 (SF-36), a generic functional assessment instrument well validated for many chronic illnesses, has been used to measure HRQL in chronic obstructive pulmonary disease, and it correlates well with the BDI. For health outcomes research, a generic instrument such as the SF-36 may be preferred to disease-specific scales for comparing health states of patients having pulmonary disease with those of patients having other chronic conditions.

Both dyspnea and quantitative declines in pulmonary function are relevant to the determination of disability. Impairment rating may be defined by pulmonary function tests; 35.6% of patients with IPF are impaired, with an FVC of 50% or D_LCO of 40%. This percentage is considerably higher than that for individuals with either sarcoidosis (12.1%), pneumoconiosis (13.6%), or asbestos exposure (1.1%).

Pulmonary Imaging

Plain Chest Radiography

Up to 10% of patients with IPF have normal chest x-ray findings despite significant functional impairment. When radiographic abnormalities are seen, the most characteristic finding is prominent bibasilar reticular or reticulonodular infiltrates (Fig. 1). These abnormalities progress to honeycombing late in the course of disease. Although the basilar findings are most easily appreciated on plain film radiograph, IPF is a diffuse process. Pleural findings on plain film are uncommon. To better quantitate and communicate plain radiographic findings, the International Labour Office (ILO) scoring system, developed for occupational lung disease, can be used. This scoring system is reliable and correlates to some degree with physiologic data. Table 3 describes demographic, clinical, and radiographic characteristics in a representative group of patients with IPF.

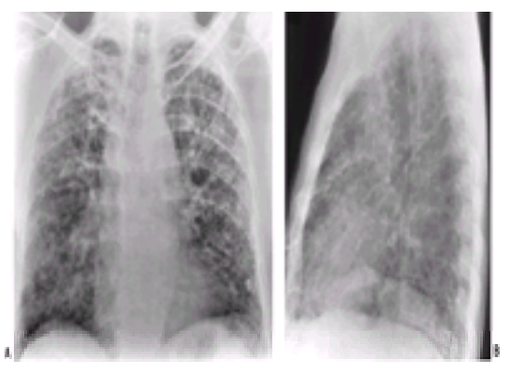

FIG. 1. Posteroanterior (**A**) and lateral (**B**) chest radiographs of a patient with IPF. A diffuse reticulonodular infiltrate is present throughout the lung with somewhat greater involvement peripherally. Cystic honeycombing is apparent in both lower lung fields.

Computed Tomography

Computed tomography (CT) is superior to plain radiography in evaluating IPF. CT may also be more useful than chest radiography in assessing the location of disease and in suggesting sites for biopsy. CT has the advantage over plain radiographs of eliminating superimposition of structures, thereby allowing better definition of the type, severity, and distribution of abnormalities seen in IPF. Subpleural shadowing is well visualized on CT and predominates in the posterior lower lobes.

Fast scan times of 1 to 2 seconds allow high-resolution, thin-section scans (high-resolution CT). High-resolution CT is often performed with the patient both supine and prone to detect minimal pathologic changes. Cystic air spaces (“honeycomb” cysts) measuring 2 to 20 mm in diameter are detected in 90% of high-resolution CT scans, compared with 30% of plain radiographs. On high-resolution CT, IPF tends to have a patchy, peripheral distribution throughout the lung (Fig. 2). The presence of subpleural fibrosis seen in IPF by high-resolution CT may help differentiate it from sarcoidosis. High-resolution CT may be especially useful in the evaluation of patients with concomitant IPF and emphysema, who may have normal spirometric findings and lung volumes. Computer-aided diagnosis using clinical, plain radiographic, and high-resolution CT values is experimental but may prove useful in the future.

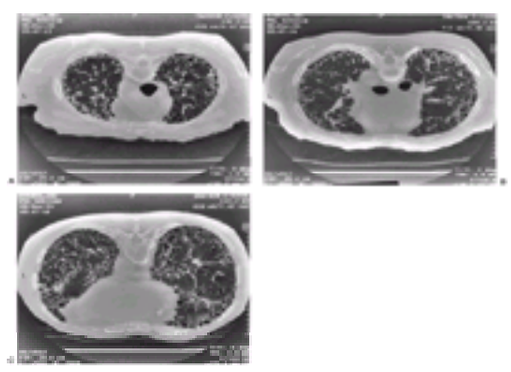

FIG. 2. High-resolution chest CT (1.5-mm slices) of a patient with IPF. Apical (**A**), midlung (**B**), and basilar (**C**) cuts are shown. These sections demonstrate marked peripheral fibrotic changes with cystic honeycombing most prominent at the bases of the lungs.

The utility of high-resolution CT for measuring disease severity and progression is controversial. A “ground-glass” appearance seen on high-resolution CT is thought to be indicative of active areas of inflammation, which may have potential therapeutic or prognostic importance. Reticular patterns seen on high-resolution CT often correspond histologically with areas of fibrosis. Traction bronchiectasis and bronchiolectasis are often found in areas of fibrosis. Despite its many attributes and the increased sensitivity of high-resolution CT over plain radiographs, there are some significant limitations to this methodology. The overall sensitivity of high-resolution CT for biopsy-proven IPF is only 88%. Therefore, although sensitive, it may miss mild cases of IPF detected by biopsy or suggested by an abnormal D_LCO. Parenchymal opacification (“ground-glass changes”) detected by high-resolution CT may not be useful to guide therapy. For instance, it may be difficult with high-resolution CT to separate inflammation from fibrosis in all cases. In one study, ground-glass appearance correlated with inflammation in 65% and fibrosis in 54% of cases of diffuse lung disease. Ground-glass infiltrates have also correlated poorly with regions of inflammation in bleomycin-induced pulmonary fibrosis of rats. It is important to note that high-resolution CT provides only a limited sample of the chest and may miss a patchy process. On the other hand, IPF is diffuse and should therefore be an ideal disease to be studied using this technique. To minimize interobserver and intraobserver variability in interpretation of high-resolution CT and provide a quantitative measurement correlated with dyspnea and physiologic parameters, investigators have examined the utility of a computer-derived density analysis of lung parenchyma, with some success.

Gallium Scanning and Other Nuclear Imaging

Scanning with gallium citrate Ga 67 is a highly sensitive test for acute lung inflammation, but its very poor specificity limits its clinical usefulness. Further, the technique is poorly standardized, although computerized imaging methods may lessen the variability. Indium-labeled neutrophil scans have been successfully used in animal models to differentiate between normal animals and those having experimental alveolitis with increased neutrophils in the lung. Overall, ventilation-perfusion scans are not helpful in the routine assessment of IPF disease activity or in assessing response to therapy.

Magnetic Resonance Imaging and Positron Emission Tomography

The usefulness of magnetic resonance imaging (MRI) in detection and surveillance of IPF has been limited historically by long imaging times that require careful respiratory gating techniques to minimize artifact from respiratory movements. MRI provides qualitative rather than quantitative information about IPF. Positron emission tomography (PET) has been used in pilot studies to evaluate variations in pulmonary vascular permeability seen in IPF. The high cost and restricted availability of PET technology are likely to limit its common use. Neither modality has a role in the routine evaluation or management of IPF at this time.

Laboratory Studies

Although laboratory studies may be useful in excluding other causes of ILD, serum and urine biochemical and serologic studies are of limited value in the management of IPF. The erythrocyte sedimentation rate is elevated in approximately 50% of cases. Polyclonal gammopathy resulting from nonspecific B-cell activation is noted in about 75% of patients. Even in the absence of a clearly defined rheumatologic disorder, elevations are seen in serum rheumatoid factor (30%) and antinuclear antibody (ANA) (15%). Measurement of serum levels of complement and immune complexes is nonspecific and not a reliable indicator of disease activity.

Bronchoalveolar Lavage

BAL is performed by instilling aliquots of saline solution through a flexible bronchoscope that has been “wedged” into a third- or fourth-order bronchus. With this technique, recovered fluid may be evaluated for cell number and differential analysis, cultures may be obtained, and secreted proteins can be identified and quantitated. BAL has been useful in the evaluation of lung cancer and infections. Its role in the management of IPF and other ILD has been controversial. Nevertheless, it can be extremely useful in the evaluation of alveolar inflammation, which can be used to establish a diagnosis, monitor response to therapy, and predict a patient's prognosis. Increased numbers of lymphocytes are seen in patients with more active inflammation and suggest an improved response to corticosteroid therapy. Neutrophils with or without eosinophils are increased in IPF BALF specimens, and neutrophilia portends a poor prognosis. BAL has been examined to assess its effectiveness as a surveillance and staging tool. BAL may be of limited value because technique is not standardized. Samples from different parts of the lung vary in cellularity, limiting reliability of BAL. It is important for both investigators and clinicians who plan to follow serial BAL in a particular patient to adopt standardized techniques to avoid high intrasubject variability. Correlation between BAL and high-resolution CT is essential to define better the role of BAL in assessment of inflammation. At the present time, BAL is still considered a research tool with no proven clinical utility in the management of IPF.

Lung Biopsy

The necessity to perform an open lung biopsy for the diagnosis of IPF is debated by many chest physicians. In the United Kingdom, the diagnosis is usually based on purely clinical grounds. Because IPF is a patchy disease, a negative or nonspecific transbronchial biopsy specimen may represent either an inadequate sample or a sample of an unaffected region of the lung. Several studies have also shown that the amount of tissue obtained by transbronchial lung biopsy is not sufficient to make a diagnosis of IPF. Transbronchial lung biopsy is often used, however, to exclude the presence of other disorders, such as hypersensitivity pneumonitis or BOOP. Many practitioners recommend an open lung biopsy for all patients with a negative transbronchial lung biopsy result if clinical suspicion of IPF is high. For many patients, open lung biopsy is required to establish a definitive diagnosis. Open lung biopsy is the “gold standard” for IPF diagnosis. With open lung biopsy, infectious and neoplastic processes can be excluded, and the specimen may provide some staging information useful for planning a treatment program. For diffuse pulmonary infiltrates of unknown etiology, open lung biopsy results in management changes in up to three quarters of all patients.

At the time of open lung biopsy, it is necessary to sample not only the most grossly affected areas, but also more central areas that are in earlier stages of the disease process. High-resolution CT before biopsy can be useful in localizing areas of particular interest. Although some disagree, it is recommended that the tip of the lingular segment and the right middle lobe be avoided, as these areas often have nonspecific changes. Open lung biopsy may result in serious complications 11%–23% of the time. This rate depends in part on the degree to which the patient is immunocompromised at the time of the procedure. The use of video-assisted thoracoscopic surgery, or thoracoscopy-guided lung biopsy, has significantly limited the need for open lung biopsy in selected centers. The diagnostic accuracy is essentially equal to that of open lung biopsy, and patients have less morbidity and shorter hospital stays.

Given the generally poor prognosis of IPF, coupled with the potential morbidity and mortality associated with open lung biopsy, many physicians decide to forego the surgical procedure when they strongly suspect the presence of IPF. Any decision to perform open lung biopsy must take into account the likelihood of the diagnosis without the test as well as the complications associated with its performance. Under certain circumstances, open lung biopsy may be omitted.

Pathology

On gross inspection, the lungs are small, with a nodular pleural surface. The subpleural areas of the lung parenchyma are most severely affected, with the development of honeycomb cystic changes in late-stage fibrosis. Fibrosis often occupies about 20% of the lung volume (Fig. 3).

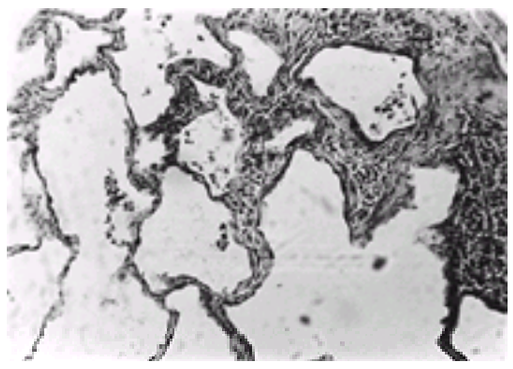

FIG. 3. Histology of open lung biopsy specimen from a patient with IPF. This reveals patchy dense fibrosis adjacent to normal alveoli. Original magnification × 200.

From a histopathologic perspective, IPF can be divided into usual interstitial pneumonitis (UIP) and desquamative interstitial pneumonitis (DIP). DIP is characterized by mild inflammation of the alveolar interstitium, relative preservation of the alveolar architecture, and the presence of large numbers of macrophages in the alveolar air spaces. In UIP, the alveolar wall is thickened with inflammatory cells and connective tissue. There is often also a reorganization of the parenchyma. DIP and UIP may simply represent different stages of the same pathologic process. Of interest, different histopathologic patterns frequently are noted even in the same specimen.

Alveolitis is thought to be the initial abnormality in all cases of ILD. Infiltrates of lymphocytes and plasma cells are noted early in the disease, with interstitial edema and eventual loss of type I epithelial and capillary endothelial cells. Desquamation, indicative of an active inflammatory process, occurs when type II pneumocytes and alveolar macrophages fill the alveolar lumen. Type II pneumocytes proliferate in areas of less severe fibrosis, whereas cuboidal and metaplastic squamous epithelial cells renew epithelium in areas of very severe lung damage. Dense alveolar septal fibrosis occurs in later stages because of the accumulation of fibroblasts and collagen within the interstitium. The pleura is also abnormal in IPF; it thickens and becomes more vascular. It is lined by hypertrophied and hyperplastic mesothelial cells. The larger airways show increased amounts of muscle and glandular tissue.

Histologic scoring systems have been developed by several groups to provide reproducible, standardized reporting techniques for clinical trials. Scoring systems use different pathologic parameters, such as the level of fibrosis and cellularity of specimens, which are uniformly interpreted by panels of pathologists. Semiquantitative systems are faster and may provide as much correlation with clinical parameters as more detailed morphometric analyses.

Ultrastructural features of IPF may be different from those observed in ILD associated with systemic rheumatologic disorders. Endothelial cell swelling and intracellular tubuloreticular structures are noted in patients with rheumatic disease-associated ILD, but not in IPF. These tubuloreticular structures are similar to those observed in viral pneumonia.

In AIP, in contrast to IPF, there are intra-alveolar hyaline membranes, interstitial septal widening, endothelial and epithelial damage, and fibroblast proliferation without extensive collagen deposition. These pathologic features are identical to findings in ARDS. However, ARDS often resolves without permanent damage, whereas fibrosis associated with hyperplastic type II pneumocytes often develops within a few weeks of onset of AIP. Pneumocytes proliferate, and the collapsed alveoli

coalesce into a single thickened septum. Type I pneumocytes proliferate along the denuded basal lamina of the alveolar septa. As the disorder progresses, intra-alveolar exudates are incorporated into the alveolar wall, contributing to its thickness. Ultrastructural changes of AIP include folding of the alveolar septa with collapse of entire alveoli and apposition of their walls. Ultimately, honeycombing appears, occasionally within weeks, and the final histology of AIP is identical to that seen in IPF. In fact, it has been hypothesized that the sequence of lung injury in individual areas of the lung are similar in IPF and AIP.

Pathogenic Theories

IPF is most likely an immune-mediated illness, and it probably results from a host response to an as-yet-unknown respiratory antigen. Although many cells play important roles in perpetuating the immune response, tissue damage is predominantly mediated by alveolar macrophages and neutrophils. Macrophages directly damage the lung parenchyma and also attract and activate neutrophils and other inflammatory cells. Direct pulmonary damage is mediated by macrophage production of free oxygen radicals; alveolar macrophages are an important source of oxygen radicals in the lungs. Of interest, excessive production of free oxygen radicals in patients with IPF correlates with abnormal physiologic parameters. Macrophages release products chemotactic for neutrophils (leukotriene B_4), growth factors for fibroblasts (platelet-derived growth factors, fibronectin, and insulin-like growth factor), and proinflammatory cytokines (interleukin-1b and tumor necrosis factor-a). Macrophages release both IL-lb and its specific inhibitor, IL-1 receptor antagonist (IL-1RA); the IL-1b/IL-1RA ratio is increased in patients with IPF, resulting in a proinflammatory environment. Macrophages also recruit mesenchymal cells to the lung and activate them as part of the fibrotic process.

Neutrophils also appear to have a number of potential pathogenic roles in IPF. Neutrophils release oxidants and proteinases, like collagenase, that are locally destructive. In normal persons who do not smoke, very few neutrophils are seen in the lower respiratory tract, but in patients with active IPF, the neutrophil represents up to 20% of BALF cells. Eosinophils release similar compounds as well as other toxic products, such as eosinophil major basic protein.

As is true of all immunologic illnesses, lymphocytes are central to the inflammatory cascade. B lymphocytes produce IgG, and IgG-containing immune complexes can be found in inflamed lung; although these complexes are associated with IPF, their pathogenic role is speculative. T lymphocytes may also play a prominent role, both in an autoimmune reaction against alveolar antigens and in enhancement of matrix production. Activated T cells produce cytokines that stimulate proliferation of fibroblasts and lead to increased collagen synthesis.

Mesenchymal cells of the interstitium synthesize type I collagen, type III collagen, fibronectin, and other matrix proteins prominent in fibrotic lungs. In IPF, these cells are numerous in the alveoli as well as in the interstitium. Both the amount of matrix proteins synthesized as well as their composition may be altered in IPF.

Treatment

As is true for many relatively rare, serious disorders of unknown cause, there is much dogma but few controlled studies evaluating IPF management. Because duration of disease is such a potent predictor of outcome, careful comparisons of therapeutic protocols are confounded by differing definitions and duration of disease. For most physicians, prednisone is the drug of first choice, and immunosuppressive agents are generally reserved for corticosteroid failures. Although early alveolitis is clearly more responsive to anti-inflammatory therapy than later, more fibrotic disease, improvements in survival with aggressive treatment are reported even in patients who have more advanced disease.

General Supportive Measures

As in the management of chronic obstructive lung disease, pulmonary rehabilitation and/or O_2 therapy are recommended for patients with limited exercise tolerance and severe arterial hypoxemia. O_2 therapy improved exercise tolerance in subjects with IPF in some but not in all studies. Continuous low-flow O_2 should be prescribed for all patients with demonstrated resting hypoxia, especially in the presence of cor pulmonale or polycythemia. Exercise- or sleep-induced desaturation should be treated with O_2 to maintain a saturation of 90%.

Vasodilators have been used in IPF as therapeutic agents for pulmonary hypertension. Isosorbide dinitrate, nitrendipine, nifedipine, and hydralazine have all been evaluated in small studies. Although nifedipine has been shown to blunt an exercise-induced increase in pulmonary vascular resistance in some studies, there is no clear evidence that any of the vasodilators have a role in the therapy of IPF. Use of these agents may be dangerous and lead to a worse outcome or even death.

Corticosteroids

Despite their significant short- and long-term toxic effects, corticosteroids remain the mainstay of therapy. Patients with highly cellular infiltrates have the best response to corticosteroids, but measurable improvements in pulmonary function are found in no more than 30% of cases. With corticosteroids, subjective improvement occurs in more than half of cases.

Early use of high-dose corticosteroid is recommended to provide the best chance for recovery. Improvement, if it is going to occur, is usually noted within several weeks. Corticosteroid therapy is begun with a daily dose of 0.5 to 1 mg of prednisone per kilogram of body weight, or the equivalent. Because of the toxicity of corticosteroids at this level, once improvement has been noted (or after 4 to 8 weeks), the dose is tapered to 20 mg/day or less.

Immunosuppressive Agents

Antimetabolites and cytotoxic drugs, broadly classified as immunosuppressive agents, have been used in numerous small clinical trials with variable results. The rationale for use of these drugs is based on both the need for steroid-sparing agents and the poor overall response of most patients to corticosteroids alone.

Azathioprine, typically administered at a dose of 2 to 3 mg/kg, has been used in conjunction with high-dose corticosteroids in several studies. As might be expected, the most favorable responses were noted in subjects with less fibrosis seen on biopsy. Favorable trends were noted in some of the studies, but there is still no clear evidence that this agent benefits patients with IPF. Azathioprine is generally well tolerated. In a few patients, evidence of significant hematologic abnormalities develops; therefore, careful monitoring of blood counts is imperative. A secondary malignancy is also a potential concern for patients.

Cyclophosphamide has also been used extensively in patients with IPF. Although several studies show benefits in isolated pulmonary parameters, others demonstrate no improvement or even a poorer outcome as a consequence of life-threatening infectious sequelae. A randomized, controlled trial of 43 patients with previously untreated IPF showed that the combination of prednisolone with cyclophosphamide was slightly superior to prednisolone alone in improving symptoms. Unfortunately, survival (although better in the cyclophosphamide group) was not significantly improved, and both groups demonstrated high overall mortality. Intermittent intravenous therapy, as biweekly pulses of between 500 and 1800 mg per dose) appears to be as effective as daily oral therapy. The benefits of cyclophosphamide may be attributable to the reduction of lung neutrophilia. With cyclophosphamide, improvement is slow, necessitating a prolonged course of up to 6 months with very careful hematologic monitoring for neutropenia. The risks for hemorrhagic cystitis and secondary malignancy, particularly uroepithelial and hematologic cancers, limit the long-term utility of this therapy. Intravenous administration may result in less bladder toxicity and allow easier monitoring of hematologic parameters. Of some concern is the development of interstitial pneumonitis secondary to cyclophosphamide therapy.

Chlorambucil, at doses between 2 and 6 mg daily, can be used as an alternate to cyclophosphamide in the treatment of IPF. It has the advantages of lower cost and an improved risk-benefit ratio, particularly because of less concern about urinary excretion of active metabolites. Close monitoring of blood counts is still very important. Preliminary studies suggest that the efficacy of chlorambucil is equivalent to that of cyclophosphamide.

Another agent with actions that may complement the effects of corticosteroids is cyclosporine A. This agent is a potent suppressor of T-lymphocyte function, and it could be useful in suppressing the cell-mediated immune responses in IPF. Because there is a high incidence of drug-induced hypertension and nephrologic toxicity associated with cyclosporine, and because there is no consensus regarding its usefulness in IPF, cyclosporine therapy is not standard at this time.

Miscellaneous Other Pharmacotherapeutic Agents

Low-dose oral colchicine is well tolerated, and it has been associated with an improvement in lung function in several small studies and case reports. Colchicine suppresses fibroblast function in vitro. The antimalarial agent chloroquine has also been successful in anecdotal use. D-penicillamine has been used to treat ILD associated with systemic sclerosis, and a small study reported better outcomes for patients with IPF who were taking this agent. Unfortunately, treatment-limiting hematologic toxicity, proteinuria, and dyspepsia are seen in a high percentage of penicillamine-treated patients.

Organ Transplantation

In selected patients with end-stage ILD, unilateral lung transplantation may provide a good functional result and can significantly improve quality of life. In terms of prolonging survival, 45% of IPF patients who receive a single lung are alive for 1 year or longer, and some have survived for up to 4 years after surgery. Unilateral transplant may be superior to total heart-lung transplant in terms of lowered surgical morbidity and mortality. In addition, single-lung transplantation potentially extends the opportunity for lung transplantation to twice the number of recipients. Physiologically, IPF and other restrictive lung diseases are most appropriate for single-lung transplantation. In these diseases, the native lung typically has very low compliance, so that ventilation and perfusion to the transplanted lung are better than in patients with emphysema who receive a single lung.

Monitoring Disease Activity

Because of the high mortality of IPF, survival is the most important marker of treatment success. Nevertheless, pulmonary function test results, bronchoscopic findings, and radiographic studies have a role in monitoring disease progression. In addition, Watters and colleagues have developed a clinical, radiographic, and physiologic (CRP) scoring system that correlates well with both pathologic changes and quality-of-life factors. In pulmonary function studies, a significant decline in D_LCO or FVC is indicative of a poor therapeutic response. The $P(A\text{-}a)O_2$ gradient also can be followed, but this is somewhat variable and may not correlate well with disease progression.

Natural History and Prognosis

Despite optimal therapy, the 5-year survival for IPF remains no better than 50%. Although mean survival is estimated at 4 years, rare patients may persist with end-stage but stable fibrosis for periods of 20 years or more. A favorable response to treatment with corticosteroids is an excellent long-term prognostic factor. Symptoms of 1 year in duration also are associated with a better outcome. Younger age, female sex, less dyspnea, fewer radiographic abnormalities, absence of right-axis deviation on electrocardiogram, and higher arterial PO_2 are other demographic and clinical factors that predict longer survival. The survival of patients with advanced disease or progressive reductions in physiologic tests (³10% in FVC or ³20% in D_LCO) is significantly worse. Cigarette smoking is the only potentially modifiable risk factor. It is associated with a poorer outcome in a dose-dependent manner. Despite the prompt response of some patients to therapy and apparent complete clinical remission, relapse can occur as many as 12 years later.

Respiratory failure from intractable hypoxemia accounts for many deaths in IPF (38.7%); this is frequently associated with the development of an acute pulmonary infection. The development of pulmonary hypertension and cor pulmonale is an indicator of imminent decline; this ultimately occurs in about 70% of patients with IPF. Other causes of death include heart failure, pulmonary embolism, and lung cancer.

Cancer

Bronchogenic cancer develops during the course of illness in approximately 5%–10% of patients with IPF. This represents an excess relative risk for lung cancer of almost 10 in comparison with a similar age- and sex-matched group. This risk ratio may be an underestimate, as many early lung carcinomas may be missed because of the shortened life expectancy of patients with IPF. It has been noted that the excess risk for cancer in male patients with IPF cannot be accounted for by cigarette smoking alone. Adenocarcinoma occurring in the periphery is the most common lesion, although all cell types have been described.

INTERSTITIAL LUNG DISEASE ASSOCIATED WITH SYSTEMIC RHEUMATIC DISORDERS

Many types of lung disease are associated with rheumatoid arthritis; the connective tissue disorders, including systemic lupus erythematosus (SLE), Sjögren's syndrome, systemic sclerosis (SSc), and dermatomyositis/polymyositis; mixed connective tissue disease (MCTD); and the seronegative spondyloarthropathies, principally ankylosing spondylitis. Of all the types of respiratory disorders associated with systemic rheumatic disorders, one of the most difficult to diagnose accurately and manage is ILD. Table 4 compares and contrasts IPF with two of the rheumatic diseases most commonly associated with ILD. The true prevalence of ILD in rheumatic disorders is unknown, and estimates vary depending on the diagnostic method used. Plain chest radiographs are least sensitive, whereas pulmonary function tests detect lung disease at an earlier stage. High-resolution CT and BAL detect more subtle abnormalities not identified by other modalities. As in IPF, the gold standard of diagnosis remains histologic examination of an open lung biopsy specimen.

TABLE 4. *Comparison of common types of interstitial lung disease: clinical and pathologic manifestations*

Rheumatoid Arthritis

Rheumatoid arthritis is the most common form of inflammatory arthritis, with a worldwide prevalence of 1%. It affects women more frequently than men, in a ratio of 3:1. Rheumatoid arthritis is a symmetric, inflammatory polyarthritis with a myriad of extra-articular features. Pulmonary manifestations range from common pleural effusions to rare bronchiolitis obliterans. The diagnosis of rheumatoid arthritis is based on the characteristic historical feature of morning stiffness, evidence on physical examination of swollen and tender joints, and supportive laboratory data, including a high titer of serum rheumatoid factors and characteristic bone erosion detected by radiograph. The American College of Rheumatology has developed rheumatoid arthritis classification criteria useful in clinical studies. Rheumatoid arthritis causes substantial morbidity, predominantly from progressive joint destruction, that results in a 50% work disability rate after 10 years of active disease. Rheumatoid arthritis also leads to premature mortality, shortening life expectancy by 8 to 13 years on average. Mortality is most often related to infectious illnesses. Rheumatoid arthritis is strongly associated with an increased frequency of the class II major histocompatibility complex (MHC) serotype HLA-DR4, and specific DR4 haplotypes (HLA-DRB1*0401 and *0404) predict more severe rheumatoid arthritis.

Epidemiology

Rheumatoid lung involvement may be manifested by many disease patterns. Although pleuropulmonary disease is seen quite often, ILD may be most common overall, based on series of patients undergoing lung biopsy.

Ellman and Ball were the first to link diffuse pulmonary fibrosis with rheumatoid arthritis. Since that time, numerous case series and several controlled studies have confirmed their observation. Many authors now refer to this entity as *rheumatoid arthritis-associated interstitial lung disease* (*RA-ILD*). The reported prevalence of RA-ILD ranges from 2% to 40% of patients with rheumatoid arthritis. Variability in prevalence relates to different diagnostic modalities used to define this condition. Whereas only about 1%–5% of patients with suspected RA-ILD have abnormalities detected by plain chest radiography, the percentage of affected individuals increases dramatically if diagnosis is established by abnormal pulmonary function studies (about 40%) or abnormal tissue histology (up to 80% of patients).

Prior investigations into risk factors for RA-ILD have yielded disparate results. Although rheumatoid arthritis is three times more common in women than in men, RA-ILD has a stronger male predilection. Traditional measures of severity of rheumatoid arthritis, such as serum rheumatoid factor and subcutaneous nodules, Sjögren's syndrome, antirheumatic therapies, immunogenetic markers of disease severity (HLA-DR4 and HLA-B40), and cigarette smoking, all have been identified as potential predictors of RA-ILD, although other studies have failed to confirm these associations. The two risk factors that have generated the most interest have been cigarette smoking and serum rheumatoid factor. As in IPF, cigarette smoking has a consistently positive association with RA-ILD based on multiple epidemiologic analyses (Fig. 4). A positive correlation between rheumatoid factor titer and abnormal diffusion capacity has also been demonstrated. Cigarette smoking is also associated with elevated serum rheumatoid factor. It is uncertain whether rheumatoid factor plays an independent pathogenic role in RA-ILD or is only an

epiphenomenon. In conjunction with rheumatoid factor, smoking may synergistically contribute to diminished DLCO. Whether cigarette smoking alone is responsible for many of the pulmonary features of rheumatoid arthritis is also a point of contention.

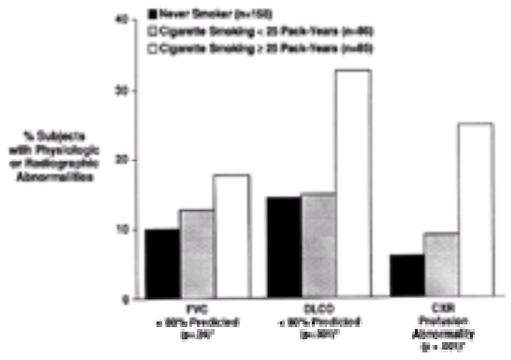

FIG. 4. Bar graph histogram demonstrating the association of cigarette smoking (expressed in pack-years) with abnormalities in pulmonary function studies (diffusion capacity of carbon monoxide [*DLCO*], forced vital capacity [*FVC*]) and chest radiograph (*CXR*) profusion abnormalities (interstitial infiltrates). Values for *p* are for the c^2 trend test. (Reproduced with permission from Saag KG, Kolluri S, Koehnke RK, Georgou TA, Rachow JR, Hunninghake GW, Schwartz DA. Rheumatoid arthritis lung disease; determinants of physiologic and radiologic abnormalities. *Arthritis Rheum* (1996;39:1714. Reproduced with permission.)

Many studies of RA-ILD have selected subjects with known pulmonary symptoms or have utilized control populations of patients without rheumatoid arthritis. Additionally, very few studies have been large enough to estimate with confidence the confounding risks of occupational exposures or infectious agents. Thus, knowledge about risk factors for the development of ILD in rheumatoid arthritis patients is limited.

Clinical Presentation

In all but a few studies, RA-ILD follows the development of joint disease, although the time interval from disease onset to lung involvement is often as short as 5 years. The medical history and physical examination are neither sensitive nor specific for the diagnosis of RA-ILD, but certain clinical features are common. In contrast to patients with IPF, many patients report symptoms of dyspnea or pleuritic chest pain. Clubbing has also been detected in some series, but less often than in IPF and usually later in the course of the disease. Chest crackles are strongly correlated with radiographic changes. Recurrent bronchitis with sputum production may occur in well-established RA-ILD. A surprisingly low percentage of patients with RA-ILD have pulmonary disease-related disability. This may be because physical disability resulting from rheumatoid arthritis limits patients' functional status and precludes exertional activities strenuous enough to produce pulmonary symptoms.

Diagnostic Studies

Physiologic Evaluation

Pulmonary function tests suggest a diagnosis of RA-ILD in a high percentage of clinically significant cases. Abnormality in diffusion capacity is the best predictor of fibrosis on biopsy. Indeed, reductions in diffusion capacity may precede other extra-articular manifestations of rheumatoid arthritis in many patients. Frequently, the coexistence of both restrictive and obstructive airway disease in cigarette smokers with rheumatoid arthritis confounds the interpretation of pulmonary function test abnormalities. In these patients, although both lung volumes and flows may be normalized, DLCO can be markedly reduced. Obstructive changes may also result from coexisting bronchiectasis or bronchiolitis obliterans. Because of the high concurrence of chronic disease-associated anemia, in rheumatoid arthritis it is necessary to adjust the DLCO reading for the hemoglobin level.

Pulmonary Imaging

Characteristic ILD findings are present on chest radiographs in about 12% of patients with rheumatoid arthritis. The plain radiographic appearance is identical to that of IPF except for an increased prevalence of nodules and pleural thickening. High-resolution CT can be used to identify very early evidence of RA-ILD, which may not be visible on plain radiographs. High-resolution CT often reveals fibrotic changes in the periphery, similar to those of IPF, as well as subpleural nodules and cavitations that are unique to RA-ILD. Some patients with rheumatoid arthritis who have abnormalities visible on high-resolution CT but not on plain x-ray films also have physiologic abnormalities. The clinician must be aware that the significance of high-resolution CT abnormalities in asymptomatic patients without other diagnostic abnormalities is unclear from both a therapeutic and prognostic perspective.

Laboratory Studies

No serologic study is sufficiently accurate to assist in the diagnosis of RA-ILD. As noted, serum rheumatoid factor is a strong predictor of RA-ILD, but it is not a good screening test. A study of 600 patients with rheumatoid arthritis and controls identified the ANA as a potential marker of disease.

Bronchoalveolar Lavage and Lung Biopsy

Although BAL is of greater value in excluding infectious and neoplastic causes of ILD, it may provide usefully prognostic information in RA-ILD. Both neutrophilic and lymphocytic alveolitis have been described in the BALF of patients with RA-ILD. As in IPF, elevated lymphocyte counts in BALF occur early in RA-ILD, whereas a neutrophilic predominance is found later in the disease process. Despite the value of BAL, the gold standard in the diagnosis of interstitial fibrosis is histopathologic examination of open lung biopsy specimens. In the absence of nodules that raise the index of suspicion, and because results are unlikely to alter clinical therapy, open lung biopsy is less often performed in RA-ILD than in IPF.

Pathology

The histologic features of RA-ILD are nearly indistinguishable from those of IPF. Biopsies show thickened alveolar septae and in some cases alveolar cell hyperplasia. Lymphocytic infiltration of the alveolar wall and cuboidalization of the type I pneumocytes are also present. Features that help differentiate RA-ILD from IPF include the prominent lymphocytic infiltrates, hyperplasia of lymphoid follicles, and characteristic rheumatoid pulmonary nodules. Rheumatoid nodules in the lung, the only pulmonary lesion specific to rheumatoid arthritis, impart a better prognosis. Disease based in the pleurae is more common in RA-ILD than in IPF and may help further separate the two entities.

Treatment and Prognosis

The treatment of RA-ILD is confounded by the fact that many of the traditional therapies used to manage both the articular and extra-articular manifestations of rheumatoid arthritis may also cause pulmonary toxicity. Intramuscular gold, cyclophosphamide, and methotrexate have all been linked to pneumonitis that may mimic early pulmonary fibrosis. Because methotrexate is currently the most commonly used second-line agent for the treatment of rheumatoid arthritis, pulmonary toxicity attributable to this therapy is of special concern. Unfortunately, there are no pathognomonic findings of methotrexate pneumonitis, and like RA-ILD, it may present with nonspecific bilateral reticulonodular or interstitial infiltrates. In one study, methotrexate did not cause restrictive disease or abnormalities with gas exchange, but instead it was associated with air trapping. Although some studies have suggested that methotrexate, gold, or D-penicillamine may be independent risk factors for RA-ILD, most investigations have failed to substantiate these associations.

Careful monitoring of RA-ILD progression is crucial in guiding therapy, as many potential therapeutic agents may cause significant iatrogenic morbidity. Therapy of early, symptomatic RA-ILD consists of high-dose corticosteroids, usually given as 1 mg of prednisone per kilogram of body weight, or the equivalent. It is important to start corticosteroids early in the inflammatory phase, as more advanced fibrotic disease is steroid-resistant. For RA-ILD that is refractory to corticosteroids or necessitates protracted high-dose therapy, cyclophosphamide, methotrexate, and more recently cyclosporine have been used with anecdotal success.

Survival statistics for RA-ILD are limited. For many individuals with mild disease, the prognosis is better than for IPF. However, among patients with extensive manifestations, the 5-year survival rate for RA-ILD is reported to be as low as 39%. Prognosis is significantly improved if a component of the fibrosis appears to be drug-related. As in IPF, histologic findings of UIP portend a particularly bad prognosis. Likewise, very rare upper lobe fibrosis, akin to ankylosing spondylitis, is also a

poor prognostic factor. Lastly, bronchogenic carcinoma can complicate rheumatoid arthritis. Controversy surrounds the potential independent roles of cigarette smoking, commonly used immunosuppressive agents, and the underlying rheumatoid arthritis disease process in carcinogenesis.

Systemic Lupus Erythematosus

SLE is a heterogeneous multisystem disorder of unknown cause with a predilection for young black and Asian women. SLE is diagnosed on the basis of a constellation of characteristic symptoms, signs, and laboratory abnormalities. Because SLE is a clinical diagnosis and there are no pathognomonic features, SLE is both underdiagnosed and overdiagnosed by many physicians. It is estimated that the average patient with lupus waits for 2 years from the time of symptom onset until a correct diagnosis is achieved. Although some individuals, particularly those with discoid skin lesions, have a milder disease course, organ involvement affecting the kidneys, central nervous system, or respiratory tract is associated with significant morbidity and premature mortality.

Epidemiology

The most common form of lupus lung disease is pleurisy with or without pleural effusions; pleuropulmonary disease has an overall prevalence in SLE of about 70%. In addition, both acute and chronic ILD frequently develops in SLE. In most cases, ILD occurs in patients who have had other serious SLE-associated organ disease, although it may rarely precede the development of frank SLE. Studies that assess the frequency of lupus lung disease are predominantly small, uncontrolled investigations that suffer from referral and selection biases. Clinically significant ILD occurs in 3% of adult patients with SLE. However, physiologic abnormalities are noted in up to 88% of cases.

Several independent reviews have shown that parenchymal lung disease coincides directly with other manifestations of SLE in 20% of cases. In autopsy series of SLE, infection, congestive heart failure, coagulopathy, and O_2 toxicity account for the majority of the pulmonary abnormalities. These studies, however, are potentially limited by the selection of specific subsets of SLE patients likely to undergo autopsy and of those seen in referral centers.

Clinical Presentation

Numerous pulmonary SLE syndromes have been defined that present with clinical parameters suggestive of ILD.

Acute Lupus Pneumonitis

This fulminant process almost always develops in patients with established SLE. Patients are acutely ill, with the rapid development of tachypnea, dyspnea, fever, cough, and occasionally blood-tinged sputum. Physical examination and laboratory studies demonstrate cyanosis and hypoxemia, and chest examination with radiography reveals prominent alveolar consolidation findings. The most important differential diagnostic considerations are elimination of both conventional and atypical infectious etiologies. Of concern, up to 75% of patients with acute lupus pneumonitis have persistent lung dysfunction after resolution of the acute process.

Chronic Interstitial Disease

Chronic ILD may develop independently of acute pneumonitis or as its sequela. Dyspnea both at rest and with mild exertion is the predominant symptom. Cough and pleuritic chest pain each are reported in about two thirds of cases. Unlike IPF, chronic ILD is associated with pleuritis in about 40% of cases. Clubbing of the digits is also considerably less common than in IPF and is perhaps secondary to decreased digital perfusion resulting from Raynaud's phenomenon. Chronic ILD is more common in the subset of SLE patients who display overlapping features of scleroderma, such as edema of the hands and abnormalities of the nailfold capillaries.

Acute Reversible Hypoxemia

A syndrome of reversible hypoxemia has been observed in hospitalized SLE patients that is independent of pulmonary parenchymal infiltrates. This presentation has been attributed to pulmonary leukoaggregation in SLE patients who are acutely ill. These white cell clumps lead to substantial ventilation-perfusion mismatching.

Acute Pulmonary Hemorrhage

The sudden development of severe pulmonary insufficiency coupled with hemoptysis and rapidly progressive infiltrates should raise strong concerns about pulmonary hemorrhage. Pulmonary hemorrhage may complicate acute lupus pneumonitis or can occur independently. Unexpected elevation in D_LCO, blood visualized by bronchoscopy, and hemosiderin-laden macrophages visible on biopsy all support this very serious complication.

Shrinking Lung Syndrome

Shrinking lung syndrome is another type of lupus-associated lung disease that may mimic ILD. Basilar atelectasis is a frequent radiographic finding that can be at least partially attributed to this pathologic process. Shrinking lung syndrome is not an intrinsic pulmonary disorder, but rather is caused by diaphragmatic dysfunction and respiratory muscle weakness that result in restrictive physiologic parameters and an elevated diaphragm. Some lupus patients may also demonstrate decreased respiratory muscle strength in the absence of chest radiographic abnormalities.

Diagnostic Studies

Physiologic Evaluation

Pulmonary function tests are the most sensitive indicators of chronic ILD in SLE. Diminished lung volumes, low diffusion capacity, and abnormal compliance occur in both acute and chronic lupus ILD. In one study, D_LCO was reduced in 72% and lung volumes in 49% of all patients with SLE. Of younger patients with SLE (mean age, 15.5 years), restrictive pulmonary function test defects were found in 35% and diminished D_LCO in 25%. Decreased ability to generate inspiratory and expiratory pressures is observed in patients with diaphragmatic dysfunction. Curiously, in SLE patients without known lung disease, a significant and progressive longitudinal decline occurs in small-airway physiologic parameters but not in lung volumes or D_LCO. These changes are independent of smoking history.

Pulmonary Imaging

Plain radiographic findings are often normal early in the course of chronic lupus ILD. In contrast, in both later stages of chronic lupus ILD and acute lupus pneumonitis, prominent lower lobe infiltrates are present. Chest radiographs show abnormalities in about 30% of chronic ILD cases. As in other forms of ILD, high-resolution CT may noninvasively suggest the diagnosis of lupus ILD. A ground-glass appearance suggestive of more active inflammation has been correlated with a better response to therapy.

Laboratory Studies

ANA is detectable in the sera of 95% of patients with SLE. The most common ANA pattern is diffuse (also called *homogeneous*), but the peripheral (or rim) pattern is more specific. Although higher levels of antibodies to native (double-stranded) DNA and lower serum complement fractions are associated with more aggressive SLE in some patients, similar associations with lung disease have not been substantiated. Based on small series, the presence of antibodies to U1-RNP as well as SSA (Sjögren's syndrome antigen A) appears to be predictive of chronic restrictive lung disease and a decreased D_LCO. Because of very poor specificity, assays for immune complexes are not recommended for either the diagnosis or surveillance of SLE pneumonitis.

Bronchoalveolar Lavage and Lung Biopsy

Particularly with acute infiltrates, BAL is often necessary to exclude infectious causes. Some authors advocate repeated BAL as a measure of response to therapy, but this approach cannot be strongly advocated in SLE, as there is no evidence of improved management or outcome based on BAL findings.

Pathology

Many of the pathologic lesions of SLE lung disease are at least partially attributable to immune complex deposition. In acute pneumonitis, interstitial edema, hyaline membranes, acute alveolitis, arteriolar thrombosis, intra-alveolar hemorrhage, and alveolar cell hyperplasia are all seen on histology. Immune complexes are identified

in alveolar walls, interstitium, and near small vessels.

The pathology of chronic ILD is nearly identical to that of IPF. Chronic inflammatory cell infiltrates and deposition of immunoglobulins and complement are seen in the interstitium. In a large autopsy series, interstitial inflammatory infiltrates and thickening were ubiquitous, but significant fibrotic changes were not found. In this same series, the pattern of alveolar septal loss and panacinar emphysema was similar to the fibrosis of mild SSc. Rarely, lymphocytic interstitial pneumonitis has been seen in SLE. Thorough searches for chronic infectious agents have been consistently unrevealing in both acute and chronic lupus lung disease.

Treatment and Prognosis

After all types of both typical and opportunistic infections have been excluded, treatment of acute lupus pneumonitis begins with O_2 therapy, to correct hypoxemia, and moderate doses of corticosteroids (typically started at 1 mg of methylprednisolone per kilogram per day in divided doses). If pulmonary disease is refractory to this regimen, pulse methylprednisolone at 1 g/d, often for 3 days, has been advocated along with the concomitant use of immunosuppressive agents, such as intravenous cyclophosphamide. Plasmapheresis also has been used in rapidly deteriorating patients with anecdotal success.

The management of chronic ILD is more controversial. Treatment decisions should be geared toward alleviating symptoms, as few data exist to suggest that therapy alters disease progression. Chronic fibrosis indicated by irreversible honeycombing and the absence of inflammatory alveolitis is poorly, if at all, responsive to therapy. Pharmacotherapy should be reserved for patients with some evidence of an active inflammatory disease process, which is more likely to respond to the traditional agents. When treatment is indicated, corticosteroids remain the mainstay of the therapeutic armamentarium. They are usually administered as 40 to 60 mg of prednisone per day, or the equivalent. Steroid-sparing therapy with azathioprine or oral cyclophosphamide should be considered in refractory cases, or when treatment is necessary for a protracted period. Careful monitoring of physiologic studies and chest radiographs provides guidance on response to treatment.

Acute lupus pneumonitis carries a 50% mortality rate. Because improved chemotherapeutic regimens have increased the survival of patients with nonpulmonary manifestations of SLE, the final outcome of patients who have SLE associated with chronic lung disease often depends on the development of pulmonary hypertension and cor pulmonale. Reports of successful heart-lung transplantation in patients who have lupus-associated pulmonary hypertension without pulmonary fibrosis raise the hope that this therapy may be successful in patients with end-stage lupus lung diseases.

Sjögren's Syndrome

Sjögren's syndrome is an autoimmune exocrinopathy defined by the constellation of keratoconjunctivitis sicca and xerostomia. Sjögren's syndrome occurs as both a primary disorder and as a secondary condition in other rheumatologic disorders—most commonly, rheumatoid arthritis, SSc, and SLE. Although most patients with Sjögren's syndrome have symptoms limited to the exocrine glands, a myriad of well-described extraglandular features range from renal tubular acidosis to central nervous system lesions. Although Sjögren's syndrome is typically a benign lymphoproliferative disorder, progression to pseudolymphoma and frank B-cell lymphoma are uncommon but well-described disease transformations.

Epidemiology

The most common pulmonary manifestation of Sjögren's syndrome is desiccation of the airway (xerotrachea), leading to chronic cough and recurrent tracheobronchitis. Other types of pulmonary abnormalities that have been described include obstructive airway disease, lymphocytic interstitial pneumonitis (LIP), chronic interstitial fibrosis, pseudolymphoma, and pulmonary lymphoma. Pulmonary disease of all types occurs in up to 75% of patients with primary Sjögren's syndrome. In one study, significant pulmonary involvement was noted in 9% of 343 patients with Sjögren's syndrome. ILD detected in Sjögren's syndrome may begin as an LIP but can progress to frank pulmonary fibrosis. LIP is seen in about 1% of cases of Sjögren's syndrome, whereas nonlymphocytic ILD is observed in approximately 4% of patients with Sjögren's syndrome. More than half of all patients with Sjögren's syndrome and LIP also have rheumatoid arthritis; therefore, it is hard to know which pathologic process is directly responsible for this pulmonary condition. Not surprisingly, pulmonary involvement is both more common and more severe in secondary rather than in primary Sjögren's syndrome. Smoking is not a proven risk factor for the development of pulmonary disease in Sjogren's syndrome, as it is in RA-ILD and IPF.

Clinical Presentation

Characteristic clinical features of Sjögren's syndrome include sicca symptoms and, less commonly, salivary gland enlargement. Extraglandular tissues that can be involved include those of the central nervous system, gastrointestinal tract (primary biliary cirrhosis), and kidney (type II renal tubular acidosis). In one cross-sectional study, >40% of patients with recently diagnosed Sjögren's syndrome had respiratory symptoms in the absence of physical signs or radiographic evidence of lung disease. Dyspnea on exertion is a common complaint in these patients. Cough and pleuritic chest pain are also reported frequently and correlate with lymphocytosis on BAL. Wheezing is infrequently reported and clubbing is uncommonly seen except in patients in whom end-stage pulmonary fibrosis develops. The initial presentation of pulmonary Sjögren's syndrome may be misdiagnosed as an infectious pneumonia, because of the fevers and pulmonary symptoms and signs noted above. Pneumothorax also has been reported as a complication of LIP.

Diagnostic Studies

Physiologic Evaluation

D_LCO is diminished in about 19%–25% of patients with primary Sjögren's syndrome, often in the absence of radiographic abnormalities. The abnormality of diffusion capacity is more severe if Raynaud's phenomenon is present. Positive findings in biopsy specimens of minor salivary glands are correlated with a reduction in lung function. Although restrictive pulmonary disease patterns are most commonly reported, tests indicative of abnormalities in small-airway function also can be seen in the same patient.

Pulmonary Imaging

Bibasilar interstitial infiltrates are the most common plain radiographic finding of LIP. Nodular chest lesions secondary to atypical lymphoid hyperplasia are seen in the setting of pseudolymphoma. Most nodules are small, peripheral areas of consolidations, frequently containing air bronchograms. Multiple isolated nodules with better-defined margins, a more central location, and mediastinal adenopathy should raise concern of a transformation to a malignant pulmonary lymphoma.

Laboratory Studies

Although a variety of autoantibodies are frequently present in the serum of patients with Sjögren's syndrome, including rheumatoid factor (found in the majority of cases of both primary and secondary), ANA (70% of primary), SSA/Ro (70% of primary), and SSB/La (50% of primary), these serologic markers are generally indicative of nonpulmonary extraglandular disease and have very little bearing on pulmonary manifestations. Elevated levels of b_2-microglobulin are found in patients with lymphoproliferative complications and in subjects with obstructive airway disease.

Bronchoalveolar Lavage and Lung Biopsy

Patients with primary Sjögren's syndrome have a higher percentage of lymphocytes in their BALF than do normal controls, a finding potentially consistent with their underlying disease process.

Pathology

LIP consists mostly of large and small mature B lymphocytes and plasma cells. LIP is analogous to other aspects of Sjögren's syndrome; however, instead of infiltration of exocrine glands, the lungs are invaded by lymphocytes. Prolonged LIP may be complicated by amyloidosis. Pulmonary fibrosis can occur late in LIP, although a lymphocytic predominance may persist.

Lymphoproliferation in Sjögren's syndrome can progress to a pseudolymphoma. Pseudolymphoma is often heralded by a rising IgM level and the presence of germinal centers on lung biopsy. If malignant transformation follows, there is a notable decline in the IgM level, generalized hypogammaglobulinemia, and disappearance of rheumatoid factor. Patients usually have Sjögren's syndrome for 15 years or longer before malignant lymphoproliferation develops. If lymphoma occurs, the lungs are involved in at least 20% of cases.

An additional lymphoproliferative disorder that is included in the differential diagnosis of pulmonary Sjögren's syndrome is lymphomatoid granulomatosis. In this disorder, there is a proliferation of T lymphocytes (rather than the B lymphocytes of Sjögren's syndrome) and lesions exhibit angiodestructive infiltration, with frequent involvement of the upper airways in addition to the lungs. There are rare reports of concurrent lymphomatoid granulomatosis in patients with pre-established Sjögren's syndrome.

Although the cause of Sjögren's syndrome and its pulmonary syndromes are unknown, interesting work has focused on the potential role of viruses, such as the Epstein-Barr virus and retroviruses, as possible etiologic agents. Deposition of circulating immune complexes followed by complement activation appears to account partially for the pulmonary manifestations.

Treatment and Prognosis

Standard treatment of ILD associated with Sjögren's syndrome is not well established. In addition to general supportive measures, corticosteroids are often recommended for treatment of LIP despite an absence of good data to provide clear support for their beneficial use. Chloroquine has also been used successfully in case reports.

Pseudolymphomatous transformation is believed to merit aggressive chemotherapy with combined corticosteroid and alkylating agent regimens (chlorambucil or cyclophosphamide). When feasible, resection of lymphomatous mass lesions affords another therapeutic option.

Systemic Sclerosis

SSc, also called *scleroderma,* is a rare autoimmune disorder characterized by progressive fibrosis of the skin, vasculature, and internal organs. Estimates of the prevalence of SSc range from as few as 2 to as many as 265/100,000 people, and the predominance of women in their 50s is significant. Hidebound skin of the digits and distal extremities is the most characteristic finding of this disorder. Systemic sclerosis is subdivided into diffuse (dSSc) and limited (lSSc) variants. Limited SSc, or CREST (an acronym for *c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia), has a significantly better short-term prognosis, with a paucity of proximal skin, renal, and intestinal involvement. However, over the long term, the life span of patients with CREST is also reduced, often because of the development of pulmonary hypertension. In the recent past, survival from dSSc was decreased most significantly by hypertensive renal crisis and end-stage renal disease. The advent of angiotensin-converting enzyme inhibitors has revolutionized the modern approach to dSSc and has significantly improved the short-term prognosis. Although pulmonary disease in dSSc is third in frequency, behind skin and gastrointestinal manifestations, it is now the most lethal feature of SSc. Interstitial pulmonary fibrosis remains one of the most difficult-to-manage aspects of this disabling and life-shortening disorder.

Epidemiology

Pulmonary disease is estimated to occur in 70%–85% of patients with SSc. The exact prevalence of lung disease is difficult to determine because of the rarity of SSc, difficulties with characterization of SSc subtypes, and the inaccurate diagnosis of the variable pulmonary pathologies. Although the percentage of ILD in dSSc is much higher, and although most serious end-stage fibrosis occurs in dSSc, ILD is also described in patients with lSSc. Severe restrictive lung disease appears more likely to develop in African-American men with cardiac involvement than in other demographic groups.

Intense interest has focused on potential environmental factors that may predispose to SSc, and such interest has been further increased by the development of scleroderma-like disorders, such as the 1981 toxic oil syndrome and the eosinophilia-myalgia syndrome caused by adulterated L-tryptophan. Of particular interest with respect to lung disease, exposure to silica may increase a person's risk for development of SSc 25- to 100-fold. More recently, attention has focused on the putative role of augmentation mammoplasty and the implantation of silicone elastomers in the development of SSc. Despite numerous associations noted in case reports and series of patients, large epidemiologic studies as yet have failed to confirm a significant association between exposure and disease.

Clinical Presentation

Sclerodermatous skin changes and Raynaud's phenomenon are frequent and striking physical findings that greatly aid in the differential diagnosis. Symptoms of pulmonary disease in SSc include dyspnea on exertion and an occasional dry cough. The presence of abnormal nailfold capillary loops with vessel dropouts, dilations, and severe ectasia help establish the diagnosis of an underlying connective tissue disorder and predict more severe pulmonary disease as manifested by a diminished DLCO. Pulmonary symptoms rarely antedate the skin manifestations of SSc, although cases of scleroderma *sine* scleroderma have been described. Hemoptysis, in some cases secondary to bleeding telangiectases, occurs uncommonly. SSc is associated with the development of significant impairment; the overall work capacity of patients with SSc is only 50% of the predicted normal. Although pulmonary disease contributes to this functional impairment, myocardial ischemia, ventricular arrhythmias, and limitations in locomotor function are also significant cofactors.

Diagnostic Studies

Physiologic Evaluation

Abnormalities in pulmonary function testing are detected in up to 70% of patients with CREST, often in the absence of symptoms or chest radiographic evidence of parenchymal disease. Decline in DLCO is more strongly correlated with abnormalities in nailfold capillaries than are decrements in lung volumes. Although 20% of patients with SSc who are nonsmokers have an isolated reduction in DLCO, they have a good prognosis overall in regard to pulmonary morbidity and mortality. A decline in DLCO in lSSc may be caused by Raynaud's phenomenon of the pulmonary vasculature. An increase in dead space ventilation in various connective tissue diseases associated with Raynaud's phenomenon lends credence to the theory of redistribution of blood flow resulting from pulmonary Raynaud's phenomenon. Whether pulmonary Raynaud's phenomenon coincides with digital Raynaud's phenomenon and how commonly pulmonary Raynaud's phenomenon occurs in SSc are matters of current controversy.

Pulmonary Imaging

In dSSc, diffuse or bibasilar infiltrates are the typical findings. A bibasilar reticulonodular pattern is also seen in cases of lSSc with pathologic evidence of UIP. As in ILD of other causes, the chest radiograph, albeit more specific, is considerably less sensitive for early ILD than are pulmonary function tests.

High-resolution CT has been evaluated as a diagnostic and surveillance tool for ILD in SSc. It is better than plain radiography in detecting interstitial pulmonary abnormalities that may indicate early disease, such as ground-glass opacities, and reticular abnormalities consistent with fibrosis. High-resolution CT showed changes consistent with ILD in 19 of 21 patients with SSc; in comparison, unequivocal ILD abnormalities were revealed by plain chest x-ray films in only 8 subjects. Areas of inflammatory ground-glass appearance on high-resolution CT correlate well with BAL findings of elevated percentages of eosinophils.

Laboratory Studies

ANA is present in the majority of patients with SSc, most commonly in a speckled pattern on immunofluorescence. Two serologic markers are of particular clinical interest in SSc: antibodies to centromere (ACA), detected in about 50%–80% of patients with limited disease, and anti-Scl-70 (an antibody to DNA topisomerase I), seen in one third of patients with diffuse SSc. Although ACA is generally protective for lung involvement, anti-Scl-70 predicts restrictive lung involvement and other ominous visceral disease in many studies. In one study, antihistone antibodies, seen commonly in drug-induced lupus, were predictive of more severe pulmonary fibrosis in SSc.

Bronchoalveolar Lavage and Lung Biopsy

BAL is touted by many as a useful tool for accurately identifying patients with SSc and active alveolitis who may respond to aggressive anti-inflammatory therapy. Neutrophil influx associated with increased collagen production may be an early pathologic finding in SSc-associated pulmonary fibrosis. Collagenase activity is significantly elevated in patients with BAL neutrophilia, suggesting an increased level of matrix turnover. However, a lymphocyte predominance is more frequently seen in many patients, particularly if they have secondary Sjögren's syndrome. Increased ratios of lymphocytes to granulocytes are associated with milder impairment in physiologic parameters.

Pathology

Interstitial fibrosis, bronchiolectasis with cyst formation, and intimal proliferation with medial hypertrophy of small pulmonary vessels are the classic histologic findings of

ILD associated with dSSc. Based on open lung biopsy specimens in which IPF was compared with SSc, endothelial or epithelial injury and focal lymphoid hyperplasia may differentiate SSc from IPF. Raynaud's phenomenon of the lungs may account for some of the changes noted on pulmonary function studies and may play a role in the development of secondary pulmonary hypertension. Both lung fibrosis and vascular hyperplastic changes are common in SSc and may independently contribute to right-sided heart failure. Patients with lSSc can have pathologic features of UIP, particularly those who present with bilateral lower lobe infiltrates.

Treatment and Prognosis

No pharmacologic agent has been identified that is of unequivocal value in modifying the natural course of lung disease in SSc. Notwithstanding, therapeutic interventions may be indicated for severe pulmonary disease if diagnostic evidence of an active inflammatory process is found. For instance, in patients with rapidly declining lung function and an increased proportion of lymphocytes on BAL, high doses of corticosteroids and immunosuppressive therapy are reasonable. This regimen may lead to a decrease in pulmonary inflammation, as assessed by BAL. Based on retrospective data analysis and open-label trials, cyclophosphamide appears to improve FVC over time and should likely be added to corticosteroids in patients with refractory, inflammation-related pulmonary decline. Because of its ability to interrupt molecular cross-linking of collagen, D-penicillamine has been of considerable interest to many investigators as a potential disease-modifying agent in SSc. Despite negative findings in several studies, three small studies support a small but statistically significant benefit for D-penicillamine in treating lung disease. However, the true clinical benefits may be very limited. Further, poor patient tolerance and the hematologic and renal toxicity (of concern in a patient population at already at high risk for kidney disease) associated with D-penicillamine have substantially dampened enthusiasm for its use. A long-term study of high versus low-dose D-penicillamine is currently under way and, it is hoped, may resolve still unanswered questions about its clinical role in SSc-associated lung disease.

Several experimental therapies loom on the horizon. Small, open-label studies of interferon-g (IFN-g) have shown no serious adverse effects from this agent, and in one study patients treated with IFN-g showed mild improvement in some pulmonary parameters. IFN-g cannot be advocated as an effective conventional therapy at this time. In open-label trials and retrospective reviews, potassium *p*-aminobenzoate has been demonstrated to produce modest softening effects in sclerodermatous skin, and in one investigation it resulted in a slower decrease in vital capacity and DLCO.

Based on data from an inception cohort, the estimated 5-year survival rate for all patients with SSc is about 70%. However, the natural history of SSc is highly variable, and a large percentage of patients have a protracted disease course with survival in excess of 20 years. Worsening of ILD in SSc is less rapid than in IPF, and patients with fibrosis secondary to SSc may have a better long-term prognosis than those with other fibrotic lung diseases. Isolated impairment in DLCO (£55% predicted) does not indicate a poor prognosis. Although abnormalities in static lung compliance and diffusing capacity may worsen over time, the lung volumes did not appreciably deteriorate in one large series of untreated patients followed on average for 3 years. Abnormal cardiopulmonary signs and, in particular, severely impaired gas exchange (DLCO 40% of predicted) are associated with significantly worse survival in several series. Patients with long-term SSc tend to have a rate of decline in pulmonary function tests not substantially different from that of the general population, but this could be partially because of a survival bias. Anti SSA/Ro, the autoantibody seen most often in Sjögren's syndrome and potentially predictive of lung disease in SLE, is also a poor pulmonary prognostic marker in SSc based on results from small studies.

Death was caused by pulmonary hypertension in 60% of cases in one of the largest prospective series of patients with both dSSc and lSSc. Although pulmonary hypertension is a more common outcome in lSSc, secondary pulmonary hypertension may develop in patients with dSSc after years of pulmonary fibrosis. For patients with advanced interstitial disease in whom secondary pulmonary hypertension and cor pulmonale develop, long-term O_2 therapy at home may significantly lower pulmonary vascular resistance and improve quality of life and survival. Once cor pulmonale with peripheral edema has developed, the 5-year mortality rate for patients with SSc is 70%. In a subset of patients with severe pulmonary vascular changes, rapidly progressive respiratory failure and severe pulmonary hypertension often develop, and these patients die quickly.

Independently of cigarette smoking but in relation to pulmonary fibrosis, SSc confers an increased risk for lung cancer, with increased risks estimated at 4- to 17-fold. Alveolar cell carcinoma in particular, as well as lymphoma and leukemia, has been reported most commonly. Small-cell carcinoma of the lung in the absence of a history of smoking has also been noted.

Idiopathic Inflammatory Myopathy

The idiopathic inflammatory myopathies (IIM) comprise a group of illnesses including polymyositis (PM), dermatomyositis (DM), and inclusion body myositis. The IIM are rare, with 5 to 10 new cases per million per year in the United States. These related yet distinct disorders all produce nonsuppurative muscle inflammation that leads to weakness and disability. Inclusion body myositis, a disorder of older Caucasian men characterized by both distal and proximal weakness, is the least prevalent of the three condition and seldom has associated respiratory features; it is not discussed further here. Despite differing histopathologic findings and putative immunologic mechanisms, PM and DM have many characteristics in common, including a predilection for the proximal musculature and a spectrum of pulmonary disorders.

Epidemiology

Lung disease of all types occurs in up to 50% of cases of DM/PM. Pulmonary disease in IIM commonly occurs through four processes: (1) aspiration from bulbar weakness, (2) ventilatory insufficiency resulting from myositis of the chest wall and diaphragm, (3) secondary infection, and (4) ILD. The first three entities are discussed in Chapter xx; the remainder of this section focuses on IIM-associated ILD. Either radiographic or physiologic evidence of ILD is estimated to occur in from 5%–30% of large series of IIM. Ethnic and racial variation in prevalence of IIM-associated ILD is uncertain, but in one Japanese series radiographic evidence of ILD was reported in 81% of cases.

Clinical Presentation

Patients with IIM note prominent bilateral proximal weakness that inhibits simple activities of daily living. In patients with DM, a prominent, scaly erythroderma erupts in a v-shaped distribution on the chest and back. Over the knuckles of the proximal interphalangeal and metacarpophalangeal joints of the hands, a scaly rash known as *Gottron's papules* is nearly pathognomonic for DM. A heliotrope rash, a purplish edematous discoloration over the eyelids, is also often noted. Constitutional symptoms of fatigue, fevers, and weight loss are additional harbingers of IIM, and it is difficult to determine whether these are caused by myopathy or pulmonary pathology.

In as many as one third of cases, lung disease antedates muscle involvement or occurs in patients with only minimal myopathy. The antisynthetase syndrome, named for the response to autoantibodies to aminoacyl transfer RNA synthetase (discussed below), is an IIM variant in which seronegative, nonerosive arthritis, fevers, “mechanic's hands,” Raynaud's phenomenon, and ILD can strongly overshadow a mild or even clinically insignificant myopathy. Clubbing is uncommon in IIM-associated ILD but has been reported.

Diagnostic Studies

Physiologic Evaluation

Although ILD associated with IIM frequently causes physiologic abnormalities similar to those of IPF, additional physiologic parameters, such as maximal ventilatory volume (MVV) and inspiratory effort, should be measured. If results of these studies are abnormal, they point toward respiratory muscle weakness as an explanation for at least a component of the pulmonary findings.

Laboratory Studies

At a minimum, minor but usually striking elevations of muscle enzymes such as creatinine kinase and aldolase are almost always present at some point in the disease course of all patients with IIM. Diagnosis of PM/DM is ultimately confirmed based on characteristic abnormalities present on electromyographic recordings and muscle biopsy specimens. Elevations in erythrocyte sedimentation rate nonspecifically mirror changes in disease activity or herald the development of opportunistic infections. The ANA is elevated in a small percentage of cases, often indicative of antisynthetase antibodies. One of the most exciting serologic associations is the established relationship between antisynthetase antibodies and IIM-associated ILD.

Antibodies to histidyl tRNA synthetase, known as *anti-Jo-1,* occur in 25% of patients with DM/PM. Of special interest, this antibody is found in 50% of patients with IIM and concomitant ILD. The presence of this antibody in patients with IIM, therefore, should raise concern for concomitant ILD. Additionally, a small percentage of patients have antibodies to signal recognition protein (SRP), and they are less likely to have ILD. Autoantibodies to other amino tRNA synthetases have also been identified but are less strikingly associated with lung disease.

Bronchoalveolar Lavage and Lung Biopsy

The need for BAL and/or lung biopsy is uncertain. Histopathologic and BAL data may predict therapeutic response, but this has not been shown to significantly alter management or outcome.

Pathology

A mononuclear cell infiltration of the muscle and surrounding tissue with fiber degradation, regeneration, and fibrosis are the major systemic features of PM and DM. Of note, DM is not simply PM with a rash; it is a humorally mediated disease with immune complex deposition in the perimysium and a perivascular vasculitis that is presumed to be responsible for the pathology. PM results from lymphocytic infiltration of the true muscle fibers and is the manifestation of a cell-mediated immune process.

In the lungs, histologic features are typical for interstitial pneumonitis resembling IPF. Investigators have identified three major histopathologic groups for IIM-associated ILD that have prognostic significance: BOOP, UIP, and diffuse alveolar damage (DAD). Patients with BOOP had the best prognosis, while those with DAD fared the worst. A histologic finding seen more commonly in hypersensitivity pneumonitis than in ILD, Masson bodies and intra-alveolar buds are prominent in many cases of IIM-associated ILD. Immune complex deposition in the lungs has not been frequently detected in IIM-associated ILD. Several cases of pulmonary cryoglobulin deposition have been documented.

From a pathogenic perspective, antibodies to Jo-1 have been observed only in patients with myositis. An interesting line of investigation has detected amino acid homology between the Jo-1 antigen and the genomic RNA of certain picornaviruses. The authors speculate that as in pathogenic mechanisms proposed for other autoimmune disorders, such as reactive arthritis, molecular mimicry could lead to tissue damage. Curiously, patients with antisynthetase syndrome (antibodies to Jo-1) typically have an abrupt onset of symptoms in the spring of the year.

Treatment and Prognosis

High-dose corticosteroids, initiated with at least 1 mg of prednisone per kilogram of body weight, or the equivalent, in divided doses, forms the starting point for regimens directed at both the muscle disease and newly diagnosed pulmonary involvement. Methotrexate is a commonly used second-line agent for general manifestations of IIM, and despite its own association with pneumonitis, it is safe to use in IIM-associated ILD. Although some authors question the efficacy of cyclophosphamide in IIM, given its potential value in other types of ILD and anecdotal reports of its success in IIM, it is prudent to consider this agent if the patient is failing with other options. Cyclosporine has also led to improvement in patients with steroid resistant IIM-associated ILD. The effective use of intravenous immunoglobulin for refractory myositis has been reported in several case series and at least one controlled trial. Although study end points included only measures of motor function and no mention was made of lung involvement, given the reasonable safety of this therapy, it should be strongly considered as an early second-line agent.

For many patients, adequate control of muscle inflammation is achieved with anti-inflammatory agents. Notwithstanding, a significant percentage of individuals continue to require a maintenance dose of corticosteroid to avoid relapse. In these patients, sustained morbidity and even mortality may ultimately ensue from the treatment. With respect to IIM-associated ILD, response to corticosteroids and other immunosuppressive agents is variable. Some studies report very disappointing results, with up to 60% mortality despite aggressive therapy. In another series, the 5-year mortality rate for IIM with ILD was 40%. ILD with minimal myopathy is a poor prognostic sign.

An association between IIM and malignancy has been suspected for many years, and well-conducted population-based studies now fully support both a higher incidence of cancer and a higher rate of mortality from cancer. Adenocarcinoma (particularly ovarian cancer) is reported most commonly. Some authorities advocate aggressive cancer screening for all patients with newly diagnosed IIM. Based on the need to consider patient comfort and safety, avoid false-positive results that can occur with excessive testing, and constrain health care costs, we recommend a thorough physical examination (including breast, genital, and rectal examinations) and prudent use of age-appropriate and clinically directed cancer-screening modalities (i.e., Pap test, mammogram, flexible sigmoidoscopy) for all patients with newly diagnosed IIM.

Mixed Connective Tissue Disease

The term *mixed connective tissue disease* (*MCTD*) was coined in 1972 by Sharp to describe a subset of patients with connective tissue disease who have overlapping features of SLE, SSc, and idiopathic inflammatory myopathy. The initial cases described had a set of common clinical and laboratory features that, in addition to pulmonary disease, frequently included erosive inflammatory arthritis with diffuse hand swelling, esophageal dysmotility, myopathy, Raynaud's phenomenon, high-titer speckled ANA, antibodies to U1-RNP, and an absence of antibodies to Smith (Sm) and double-stranded DNA (dsDNA).

Not all experts agree that MCTD merits a separate diagnostic label. Physicians experienced in caring for patients with connective tissue diseases recognize that many patients with the idiopathic inflammatory disorders have variable presentations and often do not present with “classic” features of any one particular diagnostic entity. As such, it has been suggested that the MCTD paradigm is conceptually flawed, as it may not identify a unique patient population, provide direction on specific treatment options, or offer guidance on prognosis.

Epidemiology

Most of the pulmonary reports on MCTD have focused on pulmonary hypertension. However, ILD may be more frequent and severe in MCTD even than in SSc. In one series, 80% of all patients with MCTD had pulmonary disease, and 69% of the asymptomatic patients had pulmonary dysfunction on physiologic tests, chest radiographs, or both.

Clinical Presentation

The most common and worrisome pulmonary feature of MCTD, significant pulmonary hypertension, cannot be accurately predicted based on symptoms, signs, or laboratory data. Pleural effusions, not commonly seen in SSc, may aid in the differential diagnosis. When ILD occurs in MCTD, it mimics that seen in SSc.

As in the other connective tissue disorders, reduction in diffusion capacity is the single most sensitive test to show physiologic dysfunction in MCTD. Despite abnormal physiology, chest radiographs demonstrated identifiable abnormalities in only 21% of cases. A lower lobe predominance has been described most commonly. The features of patients who have SLE with U1-RNP and those of patients with scleroderma overlap; they include edematous hands and nailfold capillary loop abnormalities.

Treatment and Prognosis

Authors report pulmonary improvements in 38%–86% of patients with MCTD who are treated with corticosteroids and/or cyclophosphamide. Patients may have fatal outcomes related to respiratory disease, in part because the disease may not be diagnosed until it is far advanced. Pulmonary outcome is worse if features are more characteristic of SSc.

Seronegative Spondyloarthropathies

This group of heterogeneous disorders includes ankylosing spondylitis, psoriatic arthritis, reactive arthritis (Reiter's syndrome), and arthritis associated with bowel inflammation. Although these conditions are in many ways heterogeneous, they share common features, including inflammatory arthritis of the spine and sacroiliac joints, enthesopathy (inflammation at the insertion of ligaments and tendons into bones), an association with HLA-B27, and a spectrum of similar mucocutaneous lesions. The occurrence of ILD in ankylosing spondylitis is the best described, although similar changes have been reported in psoriatic arthritis with a lower frequency.

Clinical Presentation

Noninfectious fibrobullous disease of the lung upper lobes is nearly pathognomonic for ankylosing spondylitis. The abnormality usually appears late in the disease course and does not correlate with severity of extrapulmonary disease. In a series of 2080 patients with ankylosing spondylitis seen at the Mayo Clinic, the prevalence

was 1.3%.

The pulmonary process often begins unilaterally, with linear opacities on radiographs. As it advances, these changes can be seen in both apices, and bullae gradually develop. In advanced cases, pleural thickening and cavitary disease can occur and are not uncommonly confused with tuberculosis.

Pathology

Specimens show intra-alveolar fibrosis, hyalinized connective tissue, and degeneration of elastic fibrils. Despite extensive investigations, no infectious organism has been identified as an etiologic agent for these lesions.

Treatment and Prognosis

In one large study of 836 patients with ankylosing spondylitis, the number of cases of respiratory disease was 1.5 times higher than expected. Although many of the problems are caused directly by the fibrobullous disease, secondary infection of bullae with bacteria, mycobacteria, or fungi (particularly *Aspergillus*) may lead to considerable morbidity and mortality.

PULMONARY IMMUNE DEFENSE MECHANISMS

The lungs are defended by a successive series of mechanisms that for the most part prevent deposition of pathogens in the alveoli and eliminate those that do arrive there. The first line of pulmonary defense against infections consists of mechanical impediments to aspiration, such as cough and glottic closure. These mechanisms are largely defeated by tracheal intubation and anesthetics, which in part accounts for the increased risk for pneumonia in critically ill patients.

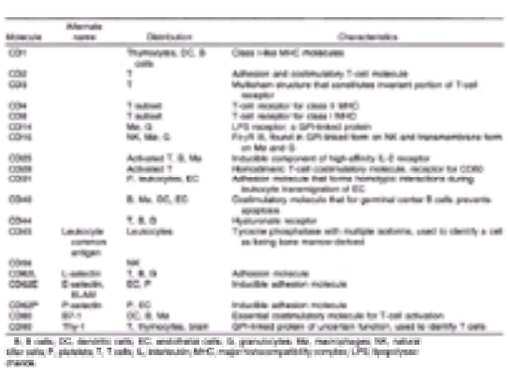
Deposition of airborne particles depends on aerodynamic size (See Chapter 1). Inhaled particles with an aerodynamic diameter than 2 to 5 mm seldom reach the distal air spaces, because they become trapped in the nose or conducting airways. Repeated branching of the airways is another physical facet of lung defense; it induces local turbulence, which causes particles to impinge at branch points. In these sites, particles are trapped in airway mucus and are carried away by normal ciliary motility and the mucociliary escalator. Particles in the 2- to 5-mm size range can remain in inspired air and be deposited in the alveoli. Of course, larger particles may also reach the alveoli when aspirated. Mucociliary clearance does not extend beyond the respiratory bronchioles. Thus, particles that reach the alveoli must be handled by cellular defenses.

Small numbers of pathogens reaching the alveoli can be contained by resident phagocytes without recruitment of bloodborne inflammatory cells. Alveolar lining fluid is also bacteriostatic, in part because of its high concentration of free fatty acids and in part because of the opsonic activity of specific proteins, notably surfactant protein A (SP-A) and immunoglobulins (Ig). Pathogens can at times survive these mechanisms, either because they arrive in large numbers, or because they are intrinsically resistant to elimination by them. In this case, recruitment of bloodborne phagocytes and specific immune responses must be mounted to aid in elimination. Because parenchymal inflammatory and immune responses have considerable potential to interfere with gas exchange, their development is under tight regulation.

Although this chapter focuses largely on the destructive aspects of immune mechanisms, it is important to recall that these potent processes have evolved precisely because they normally prevent pulmonary infection efficiently with minimal impact on the gas exchange function of the lungs. The introductory sections of this chapter detail the cellular and soluble components of pulmonary immune defense, describe the regulation of pulmonary immune response generation, and detail the mechanisms that control the recruitment of activated inflammatory cells to sites of pulmonary inflammation.

Cellular Effectors

The molecules on the surface of human leukocytes are named by a unique cluster of designation (CD) numbers. CD numbers are assigned by an international workshop; as of the Fifth International Workshop on Leukocyte Differentiation Antigens, held in November 1993, 130 CD numbers have been assigned. The characteristics of several important CD molecules are listed in Table 1.



Molecule	Name	Distribution	Characteristics
CD1		Thymocytes, DC, B cells	Class I-like MHC molecules
CD2		T	Adhesion and costimulatory T-cell molecule
CD3		T	Multimeric structure that constitutes invariant portion of T-cell receptor
CD4		T subset	T-cell receptor for class II MHC
CD8		T subset	T-cell receptor for class I MHC
CD14		Mø, G	LPS receptor; a GPI-linked protein
CD16		NK, Mø, G	FcγR III, found in GPI-linked form on NK and transmembrane form on Mø and G
CD25		Activated T, B, Mø	Inducible component of high-affinity IL-2 receptor
CD28		Activated T	Homodimeric T-cell costimulatory molecule; receptor for CD80
CD31		P, leukocytes, EC	Adhesion molecule that forms homotypic interactions during leukocyte transmigration of EC
CD40		B, Mø, DC, EC	Costimulatory molecule that for germinal center B cells prevents apoptosis
CD44		T, B, G	Hyaluronate receptor
CD45	Leukocyte common antigen	Leukocytes	Tyrosine phosphatase with multiple isoforms, used to identify a cell as being bone marrow-derived
CD56		NK	
CD62L	L-selectin	T, B, G	Adhesion molecule
CD62E	E-selectin, ELAM	EC, P	Inducible adhesion molecule
CD62P	P-selectin	P, EC	Inducible adhesion molecule
CD80	B7-1	DC, B, Mø	Essential costimulatory molecule for T-cell activation
CD90	Thy-1	T, thymocytes, brain	GPI-linked protein of uncertain function, used to identify T cells

B, B cells; DC, dendritic cells; EC, endothelial cells; G, granulocytes; Mø, macrophages; NK, natural killer cells; P, platelets; T, T cells; IL, interleukin; MHC, major histocompatibility complex; LPS, lipopolysaccharide.

TABLE 1. *CD number of important molecules*

The predominant phagocyte in the normal alveolar space is the alveolar macrophage (AM). These cells comprise 2%–5% of parenchymal cells in the normal human lung. Most AM are derived from bloodborne monocytes, although local macrophage proliferation may contribute to maintenance of AM numbers in the normal state. The primary function of AM is to ingest and eliminate foreign materials entering the alveoli. States in which AM are overwhelmed by substances that have undergone phagocytosis, as in silicosis or alveolar cell proteinosis, are characterized by increased susceptibility to opportunistic infections. AM avidly bind particles opsonized by IgG or complement because of their high-density surface expression of three classes of Fc receptors (FcR) and of two classes of complement receptors (CR1 and

CR3). However, to combat certain intracellular pathogens successfully, notably *Mycobacterium tuberculosis,* AM must be activated by lymphocyte-derived cytokines, such as interferon-g (IFN-g) or granulocyte-monocyte colony-stimulating factor (GM-CSF). Absence of these activating signals appears to be the principal cause of the increased susceptibility to opportunistic infections in AIDS. Activated AM secrete a wide variety of important enzymes, cytokines, and other mediators (e.g., complement components C1q, C2, C3, and C5) that are essential for clearance of opsonized organisms and immune complexes. Alternatively, AM can be induced (by signals that are currently uncertain) to differentiate along an alternative pathway with chiefly secretory activity. Secretory AM produce platelet-derived growth factor (PDGF), fibronectin, and insulin-like growth factor-1 (IGF-1). These factors probably are important in repair of lung injury as in wound repair elsewhere in the body, but they also may contribute to lung fibrosis by stimulating fibroblast recruitment and survival and collagen secretion. In addition to AM, the normal lungs contain interstitial macrophages. It is uncertain whether these cells, far less well characterized than AM, are an independent cell type or an intermediary stage between monocytes and AM.

Dendritic cells are the primary antigen-presenting cell in the airways and lung parenchyma. Dendritic cells are a type of bone marrow-derived cell unrelated to monocytes and macrophages. Antigen exposure induces large numbers of dendritic cells to be recruited to the airway epithelium. Dendritic cells carry antigens back to regional lymph nodes, where the dendritic cells bind to and potently activate naïve T cells. Hence, there is considerable experimental interest in manipulating dendritic cell numbers and function to control asthma and to facilitate protective immunization. Two types of dendritic cell are found in the lungs and in T-cell zones of lymph nodes: Langerhans cells (which express CD1 and contain Birbeck granules) and interdigitating or lymphoid dendritic cells (which do not express CD1 or contain Birbeck granules). Whether Langerhans cells and interdigitating dendritic cells are distinct cell types or different stages of the same lineage is unclear. Langerhans cells are increased in the bronchoalveolar lavage fluid (BALF) of smokers and are prominent in the lesions of eosinophilic granuloma. Demonstration of increased numbers of cells that are $CD1^+$ (by immunofluorescence) or that contain Birbeck granules (by electron microscopy) in BALF supports a diagnosis of eosinophilic granuloma. A third type of dendritic cells, follicular dendritic cells, is found within the lungs only in the B-cell zones of organized lymphoid tissue. The origin of follicular dendritic cells and their relationship to other dendritic cells are uncertain. Follicular dendritic cells retain immune complexes on their surfaces for prolonged periods, and therefore provide one explanation for the remarkable persistence of immune memory at sites of previous antigenic stimulation within the lungs.

Lymphocytes are crucial for the generation and regulation of all specific immune responses. Lymphocytes are divided into three major lineages: T cells, B cells, and natural killer (NK) cells. They are found in the normal lung in the following ratios: T cells, 70%–80%; B cells, 10%; NK cells, 10%.

T cells are central to the generation of protective and destructive immune response by their secretion of immunoregulatory cytokines; additionally, some are cytotoxic T lymphocytes (CTL). T cells are identified by surface expression of CD2, CD3, or Thy-1 (CD90). Almost all human T cells express either CD4 or CD8 surface receptors, which determine the class of major histocompatibility complex (MHC) molecules to which the T cell responds. $CD4^+$ T cells primarily induce ("help") both antibody production by B cells and maturation of $CD8^+$ CTL. A small group of $CD4^+$ function as class II-restricted CTL. $CD8^+$ T cells either mediate cytotoxicity or suppress other immune effector cells. Both $CD4^+$ T cells and $CD8^+$ T cells secrete cytokines, as discussed below.

Regardless of whether they express CD4 or CD8, mature T cells express a heterodimeric T-cell antigen receptor (TCR). In the vast majority, this TCR is composed of ab chains; these cells mediate virtually all the functions conventionally associated with T lymphocytes. The minority of T cells, which have gd variable chains, have been suggested to provide immune surveillance of mucosal surfaces. In some anatomic sites (e.g., skin and female urogenital tract), gd T cells exhibit very limited junctional diversity, suggesting that they should recognize a very restricted antigen repertoire. However, restricted diversity is not the case for lung gd T cells in the lungs. Despite the fact that gd TCR^+ cells have been isolated from the lungs or pleural spaces of humans and experimental animals, especially during the primary response to mycobacteria, most T cells in normal lung, in pulmonary granulomas, or adjacent to pulmonary tumors bear ab TCR.

B cells produce antibody when activated, secrete some cytokines, and serve as antigen-presenting cells for memory T cells. Initial B-cell activation leads to IgM secretion, whereas secretion of other Ig isotypes requires T cell-derived cytokines, which induce class switching of B cell Ig genes. B cells are identified by expression of surface Ig or B220 (a subspecies of CD45).

Most immunologists recognize NK cells as a separate lineage of lymphocytes, although the relationship of natural killer cells (NK) to lymphokine-activated killer (LAK) cells induced by high dose treatment with interleukin-2 (IL-2) remains controversial. NK cells require no prior activation or immunization to mediate their functions, which include cytotoxicity and cytokine production. Thus, NK cells are an important component of the innate immune system discussed below (see Innate Versus Specific Immunity). Human NK cells can be identified by surface expression of CD16 and CD56. How NK cells recognize their targets, tumors, and possibly other dividing cells, as well as some pathogens, is not understood. Within the lungs, NK cells are found primarily in the interstitium and are poorly represented in BALF. Some investigators have detected very little functional activity of human pulmonary NK cells, possibly because of the suppressive effects of AM and surfactant. NK cell deficiency is an extremely rare condition manifested by life-threatening relapsing herpesvirus and polymicrobial infections.

Neutrophils are rarely found in the alveoli or interstitium of normal subjects. However, the normal pulmonary vasculature contains a large population of neutrophils, which, because of their size, pass through alveolar capillaries much more slowly than do erythrocytes. In response to chemoattractants such as C5a, bacterial products such as lipopolysaccharide or formylmethionine-containing peptides, platelet-activating factor (PAF), leukotriene B_4 (LTB_4), or IL-8, these intravascular neutrophils are readily activated and recruited into the lung parenchyma. During transmigration, activated neutrophils can release three types of products destructive to lung parenchyma: reactive oxygen products, proteolytic enzymes, and products of lipid peroxidation. The reactive oxygen products of the respiratory burst (superoxide, hydrogen peroxide, hydroxyl radicals, and hypochlorous acid) react with essentially all cellular components, causing denaturation and cross-linkage of proteins, changes in the permeability of plasma membranes and cellular organelles, and base modifications or strand breakage in nucleic acids. Proteolytic enzymes such as elastase and metalloproteinases released from neutrophil granules can digest all components of the lung interstitium. Neutrophil oxidants act synergistically with these enzymes to cause local tissue damage; hypochlorous acid inactivates the proteolytic inhibitors (including a_1-antitryptase) that would otherwise check the action of neutrophil elastase. Oxidants are also essential for activation of neutrophil collagenase. Finally, lipid peroxidation products, especially LTB_4 and PAF, cause changes in vascular permeability and are chemotactic for neutrophils, eosinophils, and lymphocytes. For these reasons, it should not be surprising that the presence of increased numbers of neutrophils in BALF correlates with a poor prognosis in pulmonary fibrosis. Nevertheless, neutrophils are clearly important in clearance of certain pathogens from the alveoli (to a larger degree than previously recognized) and can also carry particles to regional lymph nodes for initiation of specific immune responses.

Eosinophils are a second type of granulocyte possessing considerable potential for tissue destruction via release of their granular proteins: major basic protein (MBP), eosinophil peroxidase, eosinophil cationic protein, and eosinophil-derived neurotoxin. MPB can damage epithelial cells directly; it also activates basophils, mast cells, neutrophils, and platelets. Major basic protein (MBP) may also increase airways hyperresponsiveness by blocking inhibitory M2 cholinergic receptors. Eosinophil degranulation is not inhibited by glucocorticoids.

Mast cells are increasingly recognized as integral components in the pulmonary immune response to various stimuli in addition to IgE. For instance, degranulation of mast cells can be triggered by complement fragments (C3a or C5a), eosinophil MBP, or substance P. On degranulation, mast cells liberate large quantities of LTB_4 and LTC_4, as well as prostaglandin D_2 (PGD_2) and PAF. These substances are potently chemotactic for inflammatory cells, and may increase the accessibility to the lung parenchyma of serum proteins such as immunoglobulins and complement components. Mast cells produce a spectrum of cytokines (IL-3, IL-4, IL-5, GM-CSF) similar to that of Th2 T cells (described below). Mast cell proteases, which constitute 20% of the cellular weight, can activate the Hageman factor-dependent pathways linking the complement, fibrinolytic, and kinin pathways. Additionally, cultured murine mast cells induce fibroblast proliferation in vitro through secretion of an uncharacterized soluble factor. Together with the observation of large numbers of mast cells in the lungs in idiopathic pulmonary fibrosis and chronic hypersensitivity pneumonitis, these findings suggest that mast cells may be important in the generation of pulmonary fibrosis.

Type II alveolar epithelial cells are known chiefly for their capacity to secrete surfactant and to serve as a regenerative source for epithelium in the damaged lungs. However, based on recent studies showing their capacity to express class II MHC molecules and to elaborate IFN-g and GM-CSF, type II cells should also be considered as important components in pulmonary host defense.

Humoral Aspects of Pulmonary Host Defense

The humoral elements, including Ig and complement cascade components, are the early warning system of the respiratory tract against inhaled and aspirated pathogens. Ig and complement components opsonize pathogens, identifying them as foreign and facilitating their ingestion. Both of these humoral elements can directly lyse some pathogens (certain viruses by immunoglobulins, many bacteria by complement components). Products of complement activation are also chemotactic for phagocytic cells.

All the major Ig isotypes have been identified in bronchial secretions, although IgM and IgE are present in only minute quantities. IgA predominates in the upper and proximal airways. Most IgA appear to be secreted locally; at least 90% is dimeric (secretory) IgA linked by the J components. IgA is not an opsonin and does not activate complement. Instead, it blocks attachment of potentially pathogenic bacteria.

The concentration of IgG rises progressively in the lower respiratory tract until it predominates over IgA in BALF. IgG probably enters the lungs largely by transudation from the serum in normal hosts, whereas the increased relative amounts of IgG in the lower respiratory tracts of smokers may come from local secretion. The major

known role of IgG is complement-independent neutralization of viruses. IgG, especially of subclasses IgG_1 and IgG_3, efficiently opsonizes a variety of pathogens. AM have subclass-specific Fc receptors for IgG_1 and IgG_3. IgG_4, which does not fix complement and for which macrophages do not have Fc receptors, functions largely as a reaginic or cytophilic antibody that counteracts IgE by sterically hindering its binding to its cell-surface receptors.

Experimentally, antibody-secreting cells have been observed to persist within lung parenchyma for years after local antigenic stimulation. Deficiencies of IgG and especially of subgroups IgG_2 and IgG_4 are associated with chronic sinopulmonary infections. Although panhypogammaglobulinemia usually causes devastating immunodeficiency, the infections associated with IgG subclass deficiencies may be subtle and largely limited to the lungs. In cystic fibrosis, hydrolysis of alveolar IgG with removal of the Fc fragment by pseudomonal metalloproteinase may lead to impaired opsonization.

The complement system is analogous to the clotting or kinin pathways in its sequential activation of proteolytic factors that in turn activate the next downstream component. The central factor in the complement system is C3, which can be activated by either of two major pathways (Fig. 1). The classic pathway is usually activated by antigen-antibody complexes (immune complexes). Binding of the Fab portion of an antibody molecule activates the Fc portion, which is then capable of binding and activating the first three components of the classic pathway: C1q, C1s, and C1r. The proteolytic portion of this interaction, activated C1s, cleaves its targets C2 and C4 into an active complex (C4b,2a), called *classic C3 convertase.* By contrast, the more phylogenetically ancient alternative complement pathway is activated directly by complex polysaccharides such as fungal zymosan and bacterial lipopolysaccharide, leading to production of alternative C3 convertase (C3b,Bb). Both pathways converge to cleave C3 into C3b, which in turn activates the alternative pathway in a positive feedback loop to produce more C3 convertase. Consequently, the complement system can rapidly deposit large amounts of C3 on targets. Both of these convertases can also activate C5 to produce a cytotoxic terminal attack complex consisting of C5b,6,7,8,9. This sequential family of enzymes, each activating the next, provides for powerful amplification of inflammatory signals.

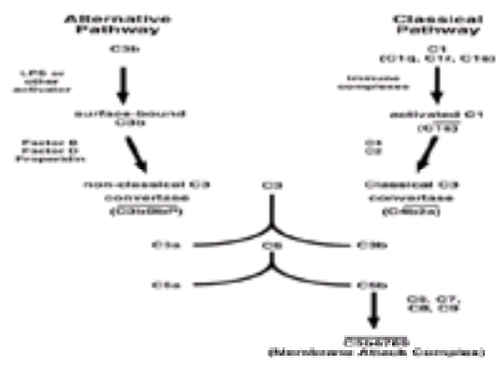


FIG. 1. Complement pathways. See text for explanation.

Proteolytic cleavage of C4, C3, and C5 produces high-molecular-weight fragments (C4b, C3b, and C5b), which attach to the target, and diffusible low-molecular-weight fragments or anaphylatoxins (C4a, C3a, and C5a), which mediate inflammation. Anaphylatoxins increase vascular permeability, induce contraction of smooth muscles, including those of the bronchi, and induce noncytotoxic release of histamine from mast cells and basophils.

Complement contributes to host defense against some pulmonary infections. Experimentally, mice depleted of complement by cobra venom factor have impaired clearance of *Streptococcus pneumoniae* or *Pseudomonas aeruginosa,* but not of *Klebsiella pneumoniae* or *Staphylococcus aureus.* Normal function of the classic complement pathway appears essential for clearance of immune complexes from the bloodstream, and patients with inherited deficiencies of C2 or C4 are at markedly increased risk for development of systemic lupus erythematosus. Massive activation of the complement system in gram-negative and gram-positive bacteremias may be one factor that mediates lung injury in the sepsis syndrome.

Because of its immense potential to destroy host tissues, the complement system is tightly regulated by a series of related plasma and membrane glycoproteins, called the *regulators of complement activation* (*RCA*) *cluster.* The RCA cluster comprises six proteins: decay accelerating factor (DAF, CD55), complement receptors type 1 (CR1, CD35) and type 2 (CR2, CD21), C4-binding protein (C4-bp), factor H, and membrane cofactor protein (CD46). The genes for all six are tightly clustered on the long arm of chromosome 1. RCA proteins regulate complement activation by interacting with C3b and C4b bound to targets or as part of C3 convertases via either of two mechanisms. The first mechanism is decay accelerating activity, by which the protease component of the C3 convertase (C2a or Bb) is cleaved from C4b or C3b, respectively. The second regulatory mechanism is cofactor activity, by which a cofactor protein binds to the C3b or C4b, rendering it susceptible to degradation by a plasma serine protease, factor I. There are additionally complement regulatory proteins outside the RCA. The serum protein C1 inhibitor antagonizes complement activation by releasing C1r and C1s from C1q, thereby blocking the classic pathway. Deficiency of C1 inhibitor causes angioedema. Mammalian membranes also possess an inhibitor of C8 binding, CD59, which prevents insertion of the membrane attack complex.

Cytokines in Immune Lung Defense and Disease

Cytokines are low-molecular-weight peptides (usually 20 kDa) that mediate intracellular communication and regulate cellular homeostasis, inflammation, and repair. Because they were originally identified through their production by and action on leukocytes, several cytokines have been termed *interleukins* (*IL*). However, it is now recognized that many cytokines can be produced by pulmonary interstitial and parenchymal cells, indicating that these cells can participate actively in both defense and immune injury of the lungs.

As of 1996, there are 17 commonly accepted interleukins (IL-1 through IL-17). For a peptide mediator to be recognized as an interleukin, it must have been molecularly cloned. This requirement prevents the previous confusion in which the same substance was referred to by multiple names based on bioassays (e.g., T-cell growth factor for IL-2). For purely historical reasons, such important, well-characterized cytokines as tumor necrosis factor-a (TNF-a), transforming growth factor-b (TGF-b), and IFN-g have not been assigned numbers as interleukins.

Most cytokines may have both stimulatory or inhibitory actions, depending on the cellular target and the concurrent actions of other cytokines. Attempting to explain the complexity of these interactions, Kunkel and associates have advanced the concept of cytokine networking, which highlights the dependence of cytokine secretion by certain cell types on more proximal cytokines (e.g., dependence of secretion of IL-8 by pulmonary fibroblasts on macrophage-derived IL-1 or TNF). Sporn and Roberts have likened the complex interplay of cytokines to a cellular signaling language, suggesting that the ultimate response of a target cell is determined by a number of different messages received concurrently at the cell surface. It is likely that individual immunologic lung diseases are not caused by deficiencies or excessive activities of single cytokines, but rather by the net effect of inflammatory and anti-inflammatory cytokines and other mediators.

Although most cytokines are produced by and affect a broad range of cell types, it is conceptually useful to divide these cytokines into three broad groups: inflammatory cytokines, lymphokines, and chemokines. The biochemical attributes of several important cytokines are summarized in Table 2.

Cytokine	M[a]	Structure	Source[b]	Target
Monokines				
IL-1	17.5	Monomer	Ma/M (E, F)	B, E, F, H, N, T
TNF-α	17	Homotrimer	Ma/M (F, T)	E, F, H, Ma/M, N
IL-6	23–30	Monomer (multiple isoforms)	Ma/M (E, F, T)	B, E, F, H, T
IL-12	35, 40	Heterodimer	Ma/M	T, NK
Lymphokines				
IL-2	15–17	Monomer	T	B, T, Ma/M
IL-3	20–26	Monomer	T	MC, N (other hematopoietic)
IL-4	20	Monomer	T, MC	B, T
IL-5	22	Homodimer	T, MC	B, Eo
IL-10	18	Homodimer	B, Ma/M, T	
IFN-γ	20–24	Heterodimer	T	B, Eo
GM-CSF	14–35	Monomer	T (E, F, M)	Eo, MC, Ma/M, N
Chemokines				
IL-8	6.5	Monomer	Ma/M, N (E, F, H)	N, T

IL, interleukin; TNF-α, tumor necrosis factor-α; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN-γ, interferon-γ; B, B lymphocyte; E, endothelial cell; Eo, eosinophil; F, fibroblast; H, hepatocyte; M, monocyte; Ma, macrophage; MC, mast cell; N, neutrophil; NK, natural killer cell; P, platelet; SM, smooth muscle cell; T, T lymphocyte.

[a] Relative molecular weight of subunits (kilodaltons).

[b] Major source of cytokine (minor sources in parentheses).

TABLE 2. *Biochemical attributes of cytokines*

Inflammatory cytokines, which have both paracrine and endocrine effects, are secreted principally by monocytes/macrophages and by parenchymal cells. This group of cytokines consists of IL-1, TNF, IL-6, and IL-12, all of which have broad ranges of cellular targets. There are two varieties of IL-1, products of distinct genes: IL-1a, produced primarily as a cell-associated protein by endothelial cells, and IL-1-b, primarily a secreted protein. Although sharing only 26% homology at the amino acid level, these peptides interact with the same receptor with identical activities. IL-1 is secreted by macrophages in response to bacterial products and to phagocytosis of other particles. In response to macrophage-derived IL-1, endothelial cells and fibroblasts elaborate additional IL-1, thereby amplifying the inflammatory response. IL-1 induces endothelial cell expression of adhesion molecules and is chemotactic for lymphocytes. Prolonged local secretion of IL-1 is central to granuloma formation, especially in sarcoidosis. IL-1 is important as a competence factor for lymphocytes and as an inducer of angiogenesis and fibrosis. Distant effects of IL-1 include fever, anorexia, somnolence, leukocytosis, and decreased pain perception. A very important recent observation is the dynamic interplay between IL-1 and IL-1 receptor antagonist protein (IRAP), a pure receptor antagonist that blocks all effects of IL-1.

TNF-a (also called *cachectin*), also secreted in response to lipopolysaccharide and probably other pathogenic products, mediates most of the toxic effects of the sepsis syndrome. Of course, TNF also has a protective role, as it is chemotactic for inflammatory cells and activates neutrophils and endothelial cells. TNF-a appears to play a crucial role in the chronic interstitial pneumonitis associated with graft-versus-host disease and in experimental immune complex disease. TNF-b (also called *lymphotoxin*), a related protein, is secreted by cytotoxic lymphocytes. Although only 30% homologous to TNF-a, lymphotoxin binds to the same receptor and causes a similar range of effects.

IL-6 is a multifunctional mediator produced by a wide variety of cell types (including T cells, AM, mast cells, endothelial cells, and fibroblasts) in response to IL-1 and TNF-a. IL-6 has both local and systemic actions, with many of its effects overlapping or synergizing with those of IL-1 and tumor necrosis factor (TNF). For example, IL-6 is the major inducer of hepatic acute-phase reactants and is itself an endogenous pyrogen. It also induces terminal differentiation of B cells and T cells. IL-6 stimulates hematopoiesis by synergizing with IL-3 to induce stem cells to enter the cell cycle. IL-6 was originally described as IFN-b_2, but is now known to be unrelated to the other interferons.

IL-12 is a heterodimeric protein produced primarily by phagocytes in response to bacterial products and to a lesser degree by B cells and connective tissue mast cells. IL-12 acts as a growth factor for activated NK cells and T cells. It importantly pushes the balance of immune responses toward cell-mediated immunity by upregulation of IFN-g.

Lymphokines, secreted primarily by lymphocytes, have complex regulatory actions that account for many of the differences between nonspecific inflammation and specific immune responses. This group consists of IL-2, IL-3, the various colony-stimulating factors (of which only GM-CSF is considered here), IFN-g, IL-4, and IL-5. Lymphocytes are also potent secretors of IL-6 and have the capacity to elaborate TNF-a and TNF-b.

IL-2 is an essential growth factor for most T cells and some B cells. IL-2 also increases the cytotoxic activity of monocytes and macrophages, and, at least in pharmacologic dosages, results in endothelial cell damage. Local secretion of IL-2 within the lungs is especially prominent in active pulmonary sarcoidosis.

IL-3 is a growth factor for precursors of multiple hematopoietic lineages and for mast cells. It also may regulate the function of mature monocytes and eosinophils. Granulocyte-monocyte colony-stimulating factor (GM-CSF), in addition to stimulating the growth of granulocyte and monocyte precursors, potentiates microbial killing and production of IL-1 and TNF-a by mature macrophages, neutrophils, and eosinophils. GM-CSF potently inhibits neutrophil migration, immobilizing neutrophils at sites of inflammation. GM-CSF also increases phagocyte longevity at sites of inflammation by blocking apoptotic cell death.

IL-4 and IL-5, typically secreted together by both $CD4^+$ T cells and mast cells, regulate allergic responses by affecting multiple cell types. IL-4 is required for the generation of both primary and secondary IgE responses. Many actions of IL-4 antagonize those of IFN-g, although both IL-4 and IFN-g induce class II major histocompatibility complex (MHC) expression. Both IL-4 and IL-5 are growth and differentiation factors for B cells and T cells. IL-5 is chemotactic for eosinophils. IL-5 also supports the growth and differentiation of eosinophils and lengthens their survival in tissues by preventing their elimination by apoptosis. IL-5 further acts on basophils to increase their release of histamine and leukotrienes.

IFN-g is perhaps best known as the major macrophage-activating factor; it increases AM expression of Fc receptors and phagocytic capacity. IFN-g also increases the adhesiveness of endothelial cells for lymphocytes and induces expression of class II MHC molecules on macrophages and endothelial cells, permitting them to become antigen-presenting cells. IFN-g antagonizes the isotype-regulating actions of IL-4 and IL-5 on B cells. Additionally, IFN-g is a growth factor for fibroblasts, suggesting that it may be important in both normal wound repair and in fibrosis. Because steroids inhibit the release of IFN-g *in vitro,* one of their important therapeutic actions infibrotic lung diseases may be to inhibit fibroblast proliferation.

IL-10 is a 178-amino acid glycoprotein (expressed as noncovalently linked homodimers) that appears to be a natural brake on immune responses. IL-10 was initially identified as a T-cell product that suppressed production of other T-cell cytokines, especially IFN-g and IL-3. Subsequently, other cell types, including AM, have been shown to produce IL-10. IL-10 decreases production of TNF-a, IL-12, and the chemokines MIP-1a and MIP-2 (discussed below). IL-10 also decreases expression of class II MHC, of the adhesion molecules ICAM and VCAM, and of the co-stimulatory molecule B7-1 (CD80) on several types of antigen-presenting cells. IL-10 inhibits T-cell proliferation in vitro both by these effects and by directly inhibiting IL-2 mRNA elaboration.

A major conceptual breakthrough in understanding immunoregulation is the observation that $CD4^+$ T cells can be divided into at least two mutually exclusive subsets, Th1 and Th2, based on the range of lymphokines they secrete. Th1 cells produce IL-2 and IFN-g, whereas Th2 cells produce IL-4, IL-5, and IL-10; both subsets can produce IL-3, GM-CSF, and TNF. These two subsets differ in function: Th1 cells mediate delayed-type hypersensitivity reactions, activate macrophages for microbicidal functions, and induce IgG_1 and IgG_{22}, whereas Th2 cells provide superior help for antibody responses and induce IgG_4 and IgE. The two subsets are also mutually inhibitory. IFN-g (produced by Th1 cells) inhibits growth of Th2 cells, whereas IL-10 (produced by Th2 cells) inhibits cytokine secretion by Th1 cells. $CD8^+$ T cells principally secrete a Th1-like spectrum of cytokines, although examples of Th2-producing CD8 clones exist.

In some cases, the cytokine profile and hence the nature of the host response appears to be directed into one of two mutually exclusive patterns, namely, Th1-predominant delayed-type hypersensitivity responses or Th2-predominant antibody-forming responses. The classification of $CD4^+$ T cell clones into Th1 and Th2 subsets is well established in mice, in which strain differences in the balance between these two subsets lead to either fatal infection or protective immunity for several different pathogens. The classification also appears to pertain to humans. Whether dysregulation of the balance between these cross-regulatory T-cell subsets underlies any immunologic lung diseases, especially asthma, is a matter of active study. Th2 cells may play an important regulatory role in normal immune responses by limiting the tissue-damaging effects inherent in responses of Th1 cells and activated macrophages.

Chemokines form a large supergene family of small cytokines that possess important chemotactic, activating, and angiogenesis-influencing properties. Cross-linkage of internal cysteine residues is believed to render chemokines highly resistant to proteolytic degradation. Based on the position of the terminal four cysteine (C) residues, two major subfamilies of chemokines are distinguished: C-X-C (a) chemokines have an amino acid between the two cysteine residues, whereas C-C (b) chemokines do not. Distinction of these two subfamilies is important, as they differ in target specificity. C-X-C chemokines are predominantly chemotactic for granulocytes, whereas C-C chemokines are chemotactic for mononuclear cells. Both C-X-C and C-C chemokines can be elaborated by a wide variety of cell types, although there is a degree of stimulus specificity for their production. Recent evidence indicates that chemokines play a variety of roles other than leukocyte chemotaxis. For example, individual chemokines can promote or inhibit the proliferation of blood vessels during wound repair or tumor growth. One receptor for C-C chemokines, CC-CKR-5, was very recently identified as a cofactor in entry of wild-type HIV into cells.

IL-8 is the prototypic C-X-C chemokine. IL-8 is very potently chemotactic for neutrophils; some investigators have also suggested it is chemotactic for lymphocytes. IL-8 is a major cause of neutrophil recruitment in cystic fibrosis, bronchiectasis, chronic bronchitis, and empyema. Interestingly, elaboration of IL-8 is induced in pulmonary epithelial cells by neutrophil elastase and in mesothelial cells by asbestos. Signal transduction of IL-8, like that of other chemotactic stimuli such as f-MLP and C5a, occurs via GTP-binding proteins and activation of phosphatidylinositol-specific phospholipase C. Other C-X-C chemokines include ENA-78, *gro*-a, IP-10, MIP-2, and PF4.

Monocyte chemotactic peptide-1 (MCP-1) is the prototypic C-C chemokine. MCP-1 is a 13-kDa glycosylated, heparin-binding protein produced by AM, fibroblasts, and pulmonary epithelial and endothelial cells. It is chemotactic in vitro for T cells and monocytes. MCP-1 is induced by lipopolysaccharide (LPS), IL-1, TNF-a, IL-4, IFN-g, TGF-b, and PDGF. MCP-1 plays a crucial role in host defense against gram-negative organisms. Other C-C chemokines include MCP-2, MCP-3, RANTES, MIP-1a, and MIP-1b.

Innate Versus Specific Immunity

Recognition of infectious agents, especially bacteria, elicits a rapid and vigorous response of neutrophils and monocytes. This initial response does not depend on prior immunization, as does the specific immune response. Instead, this innate or natural immune response relies on a phylogenetically more primitive system that recognizes danger signals found on pathogens but not on mammalian cells. Examples of such danger signals are repeated polysaccharides, mannan, LPS, or

formylated peptides. Recognition of such signals mobilizes a vigorous but nonspecific response characterized by complement activation and recruitment of phagocytic cells. The alternative complement pathway is always activated in an antibody-independent fashion, via recognition of repeated polysaccharides (especially those lacking sialic acid) or LPS. However, even in the absence of specific antibody, complement activation can occur via the classic pathway following recognition of C-reactive protein, mitochondrial membranes, or naked DNA.

The best-understood danger signal to which the innate immune system responds is LPS of gram-negative bacteria. LPS is recognized by phagocytic cells owing to two proteins, CD14 and LPS-binding protein (LBP). CD14 is a 55-kDa glycoprotein expressed both as a membrane receptor linked to GPI (glycerol phosphatidylinositol) and as an abundant (3 g/mL) soluble serum protein (sCD14). Each CD14 molecule directly binds 1 to 2 LPS molecules. Recent evidence suggests that CD14 can bind other microbial products, including those of gram-positive organisms and possibly fungi. Binding of LPS to CD14 is markedly accelerated by the transfer protein LBP. LBP also catalyzes the transfer of LPS from CD14 to serum lipoproteins, which renders LPS biologically inactive. This process provides a means for temporally limiting responses to only newly formed LPS.

LPS is an extremely potent stimulant for phagocytic cells to produce IL-1, TNF-a, and IL-12. Sepsis is a failure to contain locally the response to LPS or other microbial products, resulting in dangerously high quantities of these inflammatory cytokines circulating throughout the body. Phagocytic cell production of IL-12 early in immune responses appears to be a crucial bridge between innate and specific immunity. IL-12 production biases responses towards cell-mediated Th1 responses and away from IgE secretion. LPS also nonspecifically activates components of specific immunity (e.g., by polyclonally activating B cells to secrete IgM). LPS inhaled in large amounts causes cotton worker's pneumoconiosis.

Recent evidence suggests that $CD4^+$,$NK1.1^+$ cells, another apparent component of innate immunity, constitute an antigen-independent pathway that provides IL-4 necessary to initiate Th2 immune responses. These natural T (NT) cells express a relatively invariant TCR and are activated by the nonclassic MHC class I-like CD1 molecules on macrophages. This capacity explains the otherwise puzzling dilemma of how Th2 responses can be initiated without pre-existing Th2 T cells.

RECRUITMENT OF INFLAMMATORY AND IMMUNE CELLS TO SITES OF INFLAMMATION

Enormous strides have been made in the last decade toward understanding the molecular basis of leukocyte recruitment. Considerable effort has been expended in this investigation, because it is widely anticipated that it will lead to the development of novel immunomodulatory therapies. This process involves an interaction in which both the leukocyte and the endothelial cell are active participants. Recruitment is a complex phenomenon facilitated by activation of either the leukocyte or the endothelial cell. For example, neutrophil activation leads to cytoplasmic stiffening, which increases retention within the pulmonary microvasculature. Endothelial cell activation rapidly leads to upregulation of a variety of adhesion receptors, detailed below. An additional means of arresting groups of activated leukocytes, even within the lumina of larger vessels, is adhesion of individual leukocytes to each other. These interactions (mediated by a host of receptor/ligand interactions, including LFA-1/ICAM, CD2/LFA-3, and CD44/hyaluronate) can contribute to tissue injury by leukostasis, as in cerebral lupus and possibly in sepsis.

The process of leukocyte recruitment can be divided into seven steps, each of which is controlled by multiple cell surface receptors and cytokines: (1) leukocyte rolling along endothelium; (2) leukocyte triggering; (3) firm adhesion to endothelial cells; (4) transmigration of the endothelial layer; (5) penetration of the vascular basement membrane; (6) migration through extracellular matrix into parenchyma; and (7) selective tissue retention.

Videomicroscopy studies indicate that neutrophils roll along vascular endothelia, making transient interactions that probably facilitate leukocyte arrest at sites of inflammation. Together with considerations of physical size, rolling probably accounts for the large pool of marginated neutrophils and lymphocytes within the pulmonary vasculature. In the case of neutrophils, rolling is mediated by the interaction of L-selectin with endothelial cell ligands bearing the sialylated carbohydrate sLEX. Initial adhesion of neutrophils to activated endothelia appears to be mediated in a similar fashion when carbohydrate determinants on the neutrophil are recognized by the inducible endothelial ligands E-selectin (CD62E) and P-selectin (CD62P). A subgroup of human memory T lymphocytes also binds to E-selectin, whereas other lymphocytes bind to the lymphocyte-specific endothelial ligand, VCAM, via the action of VLA-4 (CD29/CD49d). Expression of these endothelial ligands is regulated by inflammatory cytokines: IL-1 and TNF-a induce ICAM-1 and E-selectin, and together with IL-4 induce VCAM.

Triggering appears to be mediated by chemokine receptors that recognize chemokines presented by an endothelial cell surface protein such as CD44. Triggering increases the stability of the initial adhesion through rapid changes in the avidity of binding of leukocyte b_2-integrin receptors such as LFA-1 (CD11a/CD18) and MAC-1 (CD11b/CD18). Both of these b_2-integrins interact with ICAM-1 on the surface of endothelial cells. Changes in avidity are followed by changes in receptor density that result in firm adhesion and the transformation of the leukocyte from a spherical cell to an ameboid, motile cell.

Transmigration of endothelial cells depends on leukocyte b_2-integrins such as LFA-1 and on the homotypic interaction of CD31 on both leukocytes and endothelial cells. Interdigitation of CD31 is believed to act like a zipper, allowing reversible disruption of the endothelial cell tight junctions, permitting leukocyte transmigration without fluid leakage. LFA-1 is increased on human memory T cells, and has been suggested to be increased by IL-1.

Penetration of vascular basement membrane requires enzymatic digestion, which is mediated by leukocyte metalloproteinases, especially plasminogen activator bound to its receptor, and collagenases. It is likely that secretion of these potent enzymes, as well as of high concentrations of cytokines such as TNF, account in part for immune-mediated damage to vessel walls. The reparative phase of this immune angiitis can involve vessel wall fibrosis, resulting in some cases of pulmonary hypertension seen in association with a variety of interstitial lung diseases. Directed migration is necessary for inflammatory cells to arrive at sites of inflammation; migration is clearly increased by some cytokines *in vitro.* IL-1, IL-2, IL-4, IL-8, and IFN-g are all chemotactic for lymphocytes in vitro. RANTES, a C-C chemokine, is selectively chemoattractant for memory T cells.

Finally, selective retention is probably an important component of immune response generation. Lymphocytes are recruited to sites of inflammation nonspecifically (i.e., without regard to antigen specificity), but they are retained if activated by recognition of antigen, as described below. Selective retention could be mediated by the matrix-binding domains of the b_1-integrins VLA-4, VLA-5, and VLA-6, which are upregulated on human memory T cells. Chemokines and inflammatory cytokines could increase selective retention both by increasing surface expression and binding avidity of these adhesion receptors, and by acting at high doses as migration inhibition factors.

Generation of Pulmonary Immune Responses

To generate protective immune responses, nonself antigens must be recognized by lymphocytes. Each lymphocyte clone bears an antigen receptor that generally recognizes only a single antigen. B cells can be activated directly by binding of antigen to surface immunoglobulin molecules. However, in most biologically relevant cases, B-cell maturation to an immunoglobulin-secreting cell requires specific interactions with $CD4^+$ T cells through both receptor-mediated and cytokine-mediated interactions. Both of these interactions generally require recognition of the same antigen by the T cell and the B cell. This requirement is called a *cognate interaction.* Thus, T-cell help is mediated primarily by direct cell-to-cell contact, permitting considerable control over which individual B cells produce antibody.

T-cell activation is required to initiate and maintain immune responses to virtually all antigens of clinical relevance. T cells have heterodimeric antigen receptors composed of ab or td chains, which recognize antigen only as fragments in the context of appropriate MHC molecules on specialized antigen-presenting cells (Fig. 2). T cells are activated when they receive two types of signals. The first signal consists of recognition of polypeptide fragments displayed by MHC molecules of antigen-presenting cells. Antigen is recognized by a macromolecular complex consisting of (1) antigen-specific variable chains of the T-cell antigen receptor (TCR), (2) an MHC restriction element (CD4 or CD8), and (3) a signal-transduction complex collectively called *CD3.*

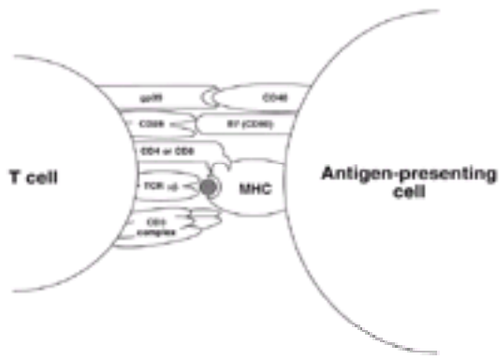

FIG. 2. Schematic representation of receptors involved in T-cell activation. Antigen is recognized in the context of the MHC molecule on the antigen-presenting cell by a complex including the TCR, the CD3 complex, and CD4 or CD8. T-cell co-stimulatory molecules, including CD28 and gp39, provide necessary second signals to permit

completion of the cell cycle.

$CD8^+$ T cells respond to antigen presented by class I MHC molecules, whereas $CD4^+$ T cells respond to antigen presented by class II MHC molecules. Class I MHC molecules present intracellular antigens, especially viral products. Class I MHC molecules are constitutively expressed by virtually all cell types. In contrast, class II molecules are constitutively expressed only by a few cell types, notably B cells and dendritic cells; however, class II MHC expression can be induced on many cell types by IFN-g. Because of this requirement for antigen presentation in conjunction with MHC molecules, regulation by lymphokines of the MHC expression of parenchymal cells such as fibroblasts and endothelial cells is central to the control of immune responses. Class II MHC molecules present extrinsic antigens, which enter the antigen-presenting cell by phagocytosis or pinocytosis.

A second type of signal, which is antigen-nonspecific and termed *co-stimulatory,* is required for complete activation leading to cell division. True co-stimulatory molecules fulfill two criteria. First, these molecules provide signals necessary (together with TCR or CD3 ligation) for activation of naïve T cells. Second, in their absence, stimulation via TCR or CD3 not only fails to activate the T cell but in certain settings induces it to become refractory to further stimulation or even die by apoptosis. Hence, the fate of an activated T cell can be determined by co-stimulatory signals during activation.

The best-understood of these necessary co-stimulatory receptors is CD28. Signaling through CD28 leads to IL-2 mRNA stabilization. CD28 recognizes two ligands displayed by antigen-presenting cells, B7-1 (CD80) and B7-2 (CD86). Human AM are deficient in expression of B7-1 and B7-2, even when stimulated with IFN-g. Proliferation of human $CD4^+$ T cells to recall antigen or anti-CD3 in the presence of AM improves if CD28 is cross-linked. These findings indicate that deficient co-stimulation through CD28 is a major reason for poor function of antigen-presenting cells, and suggest that AM may induce T-cell unresponsiveness or apoptosis. A second true co-stimulatory T-cell molecule is gp39, the ligand for CD40. CD40 is highly expressed by B cells and DC. Co-stimulatory activity that does not meet these two criteria has also been ascribed to adhesion molecules, including CD44, and b_1-integrins such as VLA-4 or b_2-integrins such as LFA-1. Proliferation of mitogen-activated lymphocytes is increased when these molecules are ligated. The conventional interpretation is that improved adhesion to the antigen-presenting cells increases proliferation because of enhanced signaling through TCR or CD3.

Lymphocyte Distribution and Recirculation

Thus, generation of immune responses is constrained both by the relative paucity of antigen-specific lymphocytes for any given determinant and by the necessity that antigenic determinants be presented by immunocompetent cells. The solution that has evolved to solve both of these constraints is drainage of antigens to lymph nodes, between which virgin lymphocytes continuously recirculate. In this way, the few lymphocytes specific for any given antigen have a greatly increased likelihood of being activated efficiently.

Lymphocytes enter organized lymphoid tissue principally by adhering to and crossing specialized postcapillary venules, known for their hypertrophied (“heightened”) endothelial cells as *high endothelial venules* (*HEV*). HEV endothelial cells express unique ligands, called *vascular addressins,* to which lymphocytes adhere. Lymphocyte recirculation is not random, but instead appears to be organized into several anatomic recirculatory circuits. One circuit involves the skin and extremities draining into the peripheral nodes. This circuit is controlled by the lymphocyte receptor L-selectin (CD62L), which binds an endothelial addressin called *glyCAM.* The other well-characterized circuit involves migration of IgA-secreting B cells from Peyer's patches to intestinal lamina propria. This circuit is controlled by the a_4b_7-integrin on lymphocytes, which binds an endothelial addressin called *MadCAM,* an immunoglobulin supergene family member.

Lymphocytes are found within the lung in four distinct anatomic compartments: (1) a marginated intravascular pool that differs in composition from peripheral blood, (2) the interstitium, (3) the alveolar spaces, and (4) organized lymphoid tissue. Organized lymphoid tissue includes lymphoid aggregates, both encapsulated and unencapsulated. Traditionally, bronchus-associated lymphoid tissue (BALT) is considered a part of the lymphoid compartment of the lung. BALT consists of nodules of unencapsulated lymphoid tissue lacking germinal centers, initially described in a variety of animal species. BALT nodules lie in immediate apposition to airways; their lymphocytic areas are separated from the airway lumina by a single layer of specialized epithelium (lymphoepithelium), through which lymphocytes and possibly antigens are believed to pass. However, the importance of organized intrapulmonary lymphoid tissue, especially BALT, in the generation of pulmonary immune responses has been questioned by some recent investigators. In fact, compared with that of experimental animals, the lung parenchyma of healthy humans contains relatively little organized lymphoid tissue and few parenchymal lymphocytes. Therefore, pulmonary immune responses are likely initiated in regional lymph nodes and mediated largely by recruitment of lymphocytes and other leukocytes from extrapulmonary sources, as discussed above.

Nevertheless, large numbers of lymphocytes can be released from enzyme-digested fragments of human lung tissue (probably reflecting recovery of cells from all four anatomic compartments, especially the marginated intravascular compartment), suggesting that overall the lung contains a large number of lymphocytes. Results of studies that have compared the phenotype and function of lymphocytes recovered from the lungs of patients with interstitial lung diseases indicate that alveolar lymphocytes closely resemble lymphocytes recovered from minced lung tissue (interstitial plus some organized lymphoid tissue). Thus, analysis of BALF is generally believed to reflect accurately processes occurring in the lung interstitium.

It has been suggested that the lungs and upper airways are part of the gastrointestinal circuit, comprising along with the gut, breast, and urogenital tract what has been called a *common mucosal immune system.* Supporting this hypothesis, BALT morphologically resembles gut-associated lymphoid tissue (GALT), such as Peyer's patches. Moreover, in adoptive transfer experiments, lymphocytes derived either from bronchus-associated lymphoid tissue (BALT) or from Peyer's patches repopulated both the lungs and the gut with IgA-bearing cells, whereas lymphocytes derived from peripheral lymph nodes did not. However, a number of findings are difficult to reconcile with the hypothesis that the lung parenchyma is part of a common mucosal immune system. Studies in several species have shown that lymphoblasts isolated either from bronchial nodes or from efferent pulmonary lymph localize to the lungs significantly better than to the gut or peripheral nodes. Moreover, two groups of investigators have found that antigen priming of the trachea does not result in significant dissemination of memory cells to the gut. These data argue that the lungs and their draining lymph nodes are not part of a common mucosal immune system, but instead constitute a separate recirculatory circuit. Also consistent with a separate pulmonary circuit of lymphocyte recirculation, experimental studies show that the initial immune response to intratracheal antigens occurs in the bronchial lymph nodes. This observation has led to the proposal that primary immune responses in lung parenchyma develop by recruitment of lymphocytes activated in these nodes back to the lungs. To date, however, no mechanism has been proposed to explain this postulated recruitment of lymphocytes back to lung parenchyma. In summary, despite compelling evidence from in vivo studies, it is uncertain whether there is a distinct recirculatory circuit involving the lung and bronchial lymph nodes, and if so, how important such a circuit is in the maintenance of immunologic lung diseases.

Analysis of surface markers shows that lung T cells are predominantly primed cells, that is, they are the progeny of cells that have been activated previously by encounter with an antigen. At present, it seems likely that accumulation of primed T cells in the normal lung results from their increased expression of adhesion receptors; however, in immunologic lung diseases like sarcoidosis, local lymphocyte proliferation may contribute as well.

In vitro studies have shown multiple factors that could limit lymphocyte activation and proliferation within the lungs. AM are poor antigen-presenting cells compared with other mononuclear phagocytes. Their poor antigen-presenting cellular function is explained by limited expression of class II MHC molecules in some species and by secretion of inhibitory factors, including prostaglandin E_2 (PGE_2), IL-1 receptor antagonist, TGF-b, and reactive nitrogen intermediates. In vitro, rodent and human AM block proliferation of mitogen-activated lymphocytes *in vitro* without interfering with CD3 downmodulation, CD25 expression, or IL-2 elaboration. AM also inhibit the antigen-presenting cellular function of pulmonary dendritic cells. Although AM can transport particles to mediastinal nodes to initiate immune responses, eliminating AM *in vivo* increases the pulmonary immune response, suggesting that their net effect is inhibitory. Alveolar lining fluid inhibits lymphocyte proliferation in vitro, in part because of its lipid components. BALF of sensitized guinea pigs before challenge with inhaled mycobacterial antigens increases pulmonary inflammation, supporting an immunosuppressive effect of normal alveolar lining fluid *in vivo*. Alveolar epithelial cells may also directly suppress lymphocyte proliferation via PGE_2 and by a mechanism not involving surfactant phospholipid or prostaglandins. Hence, factors secreted by both AM and alveolar epithelial cells appear able to block proliferation (but not necessarily cytokine secretion) of activated lymphocytes recruited to the lungs during pulmonary immune responses.

The factors that regulate physiologic immune responses to prevent prolonged interference with gas exchange are incompletely understood. Antigen elimination, through macrophage ingestion, is probably very important. Some lymphocytes migrate out of the lungs, probably to contribute to specific immune memory against pathogens. Recent evidence suggests that many activated lymphocytes die in the lungs by apoptosis, as do the majority of neutrophils and eosinophils. There are excellent teleologic reasons why lymphocyte apoptosis should contribute to immune response termination. By eliminating obsolete clones, apoptosis prevents competition with clones expanding in subsequent responses. Apoptosis also eliminates potentially autoreactive cells, especially activated B cells, which can produce novel autoantibodies during Ig gene hypermutation. The role of immunosuppressive cytokines, especially IL-10 and TGF-b, is just beginning to be explored, and it may lead to novel immunomodulatory therapies.

ALLERGIC PULMONARY TISSUE INJURY

There is evidence that four standard types of allergic tissue injury are operative in the lungs and play important roles in the pathogenesis of many of the interstitial and

immunologically mediated diseases discussed later in this chapter. One should remember that such classifications are by no means absolute, because in an actual disease process several types of hypersensitivity are likely to be operative, either simultaneously or at different stages of the disease.

Type I (Anaphylactic) Tissue Injury

Antigen characteristically reacts with specific antibody of the IgE class, which is attached to a basophil or mast cell by means of its Fc fragment. Both tissue mast cells and circulating basophils concentrate IgE on their surfaces; the surface of one cell contain 500,000 IgE molecules. IgE fixes to a glycoprotein receptor site on the cell membrane, resulting in an arrangement permitting exposure of the antibody-combining sites (Fab) to the surrounding milieu. Cross-linking of two IgE antibody molecules by specific antigen aggregates the corresponding IgE and receptor sites and results in the initiation of a series of cellular biochemical events culminating in the expulsion of secretory granule contents. The biochemical events involved in the secretory process have been well described, and they include an extracellular Ca^{++}dependent conversion of a membrane-associated serine esterase from its precursor to an activated form. Among the many preformed granule-associated and newly synthesized mediators released during type I (IgE-mediated) reactions are histamine; the leukotrienes C, D, and E; eosinophil chemotactic factor of anaphylaxis (ECFA); heparin; superoxide dismutase (SOD); peroxidase; prostaglandins; thromboxanes; PAF; neutrophil chemotactic factor of anaphylaxis (NCFA); bradykinin; major basic protein; and a wide variety of inflammatory factors of anaphylaxis that may be important in so-called late-phase reactions. Once these mediators are discharged or synthesized, they are active for finite periods. For example, histamine is destroyed by several enzymes found in all tissues. Other enzymes, proteases, or peptidases specifically destroy mediators such as leukotrienes and ECFA, and the prostaglandins are metabolized by dehydrogenases and reductases. Many of these mediators, before their deactivation, promote vasodilation and smooth muscle contraction, which are the pathophysiologic hallmarks of IgE-mediated allergic tissue injury. Activation of the complement cascade is not involved in this type of reaction, although effects identical to those noted in IgE-mediated reactions can be produced after nonimmunologic activation of the alternative pathway of complement. For example, the C5a component of complement can trigger release of all the above-mentioned mediators through a non-IgE-dependent mechanism. In the respiratory tract, it is well recognized that type I allergic tissue injury is operative in the production of uncomplicated seasonal allergic rhinitis and true allergic bronchial asthma.

Type II (Cytotoxic) Tissue Injury

Type II allergic tissue injury involves the reaction of specific complement-fixing antibody of the IgG or IgM class with an antigenic component of the cell or with an antigen or hapten firmly bound to a cell surface, which in turn causes activation of the complement cascade and resulting cell damage or death. An example of type II, cytotoxic allergic tissue injury at the pulmonary level might be that of Goodpasture's syndrome. The finding of complement receptors on the surface of AM and the detection of C3 bound to AM in lung biopsy specimens from patients with farmer's lung disease also suggests that type II reactions may be involved, to a minor extent, in the pathogenesis of certain forms of hypersensitivity pneumonitis.

Type III Allergic Tissue Injury

Type III allergic tissue injury (Arthus or serum sickness reactions) is produced by soluble circulating immune complexes, generally under conditions of slight antigen excess, that theoretically become trapped under endothelial cell linings along capillary membranes. There is mounting evidence that increased small-vessel permeability as a result of an antecedent type I allergic reaction plays an important role in allowing localization and entrapment of immune complexes in vessel walls and along basement membranes. Immune complexes then interact with serum complement and activate the complement sequence. The resulting complement-induced neutrophil chemotaxis ultimately leads to tissue destruction (basement membrane or endothelial cell damage plus necrosis and vasculitis) caused by lysosomal enzyme release. In tissue spaces such as the lung under conditions of relative antigen excess, complexes may tend to be insoluble and be removed by the reticuloendothelial system. In general, the organ or area of deposition of soluble immune complexes will determine the clinical picture. Serum sickness, the classic example of this type of reaction, was commonly seen in humans after administration of antitoxins or antibacterial sera prepared in nonhuman species (e.g., it may be seen after repeated administration of horse antitoxins). Currently, it is more commonly noted after administration of some drugs, including antibiotics, particularly penicillin and sulfonamides. The presence of serum precipitins, the time course of development of lung lesions, and the demonstration of dual type I and type III skin test reactions in some patients with hypersensitivity pneumonitis suggest that this mechanism may be partly involved in pathogenesis. However, other more recent evidence strongly indicates that AM activation and cell-mediated (delayed) hypersensitivity (type IV) play a more prominent role in production of these lesions. The histologic findings in lung biopsy specimens from patients with hypersensitivity pneumonitis also usually do not reveal the hemorrhagic necrosis, vasculitis, and polymorphonuclear cell infiltration characteristic of type III allergic reactions.

Type IV Allergic Tissue Injury

Type IV allergic tissue injury (delayed or cell-mediated hypersensitivity) is mediated through sensitized T cells plus other recruited effector lymphocytes and macrophages rather than through circulating or fixed antibodies, as in the previous three types. After antigen contact with sensitized cells, there is generally a latent period of 24 to 72 hrs before clinical expression of a type IV reaction. Complement is not involved in the reaction. The characteristic histologic lesions seen in type IV allergic tissue injury involves infiltration of tissues with the two effector cells of these reactions, lymphocytes and macrophages, often in a perivenular distribution. On contact with antigen, specifically sensitized T cells release lymphokines, which either directly lead to or augment the characteristic reactions of type IV allergic tissue injury.

Type IV allergic reactions can be passively transferred by specifically sensitized lymphocytes or by an enzyme-resistant dialyzable crude extract of lymphocytes called *transfer factor.* This factor may play an important role in converting nonsensitized lymphocytes to specific antigen-responsive cells, although more recent evidence suggests that it acts in a nonspecific manner. The production of certain lymphokines, such as interferon-g, on exposure of sensitized lymphocytes to antigen forms the basis for in vitro assays of the type IV reaction, as are employed in the diagnosis of certain forms of hypersensitivity pneumonitis.

Expression of cell-mediated immunity and of specific antibody reflect the activity of different types of $CD4^+$ T cells. T cells include $CD4^+$ (helper) and $CD8^+$ (suppressor/cytotoxic) subsets. $CD4^+$ cells can be divided into Th1, Th2, or Th0 subsets according to their patterns of cytokine secretion. Th1 cells preferentially secrete IL-2, IFN-g, and TNF-b; activate macrophages; and are responsible for cell-mediated immunity reactions and T-cell toxicity. Th2 $CD4^+$ cells secrete IL-4, IL-5, IL-9, IL-10, and IL-13; provide help for immunoglobulin (particularly IgE and IgG_4) secretion; enhance eosinophil production, survival, and activity; and promote mast cell maturation and proliferation. Development of either a predominant Th1 or Th2 response in mice depends on many factors, including attributes of the antigen, site of delivery, adjuvant used, and type of antigen-presenting cell encountered. Cytokines secreted by one $CD4^+$ subset inhibit the development of the reciprocal subset, leading to a predominance of one of the subsets and polarization of the immune response. Th0 cells secrete a mix of cytokines characteristic of both Th1 and Th2 cells and may represent progenitors of both Th1 and Th2 cells. The above models developed in mice have not been entirely confirmed in humans in the sense that Th1 and Th2 cells may not exist as exact counterparts in humans. However, the concept that the cytokine milieu (derived from many possible sources, such as $CD4^+$, $CD8^+$, NK, mast cells, and gd T cells) at the time of $CD4^+$ cell differentiation determines the later pattern of cytokine secretion and function is valid. More recently, $CD8^+$ cells have been found to differentiate into Tc1 and Tc2 subtypes, with cytokine secretion profiles apparently similar to those of Th1 and Th2 $CD4^+$ cells.

EOSINOPHILIC PULMONARY SYNDROMES

In adult animals, most eosinophils are produced in the bone marrow and released into the blood; emergence time is generally 60 to 80 hrs and the half-life in the circulation is 8 to 12 hrs, but tissue half-life is approximately 24 hrs. T lymphocytes are necessary participants in the production of soluble eosinophilopoietic factors such as IL-3, IL-5, and GM-CSF by immunologic mechanisms in vitro and *in vivo*. Immunologically elicited eosinophilia is independent of B lymphocytes and antibody formation.

Eosinophils are positioned predominantly in tissues, but full expression of their unique functional capabilities requires directed influx, accumulation, and activation at sites of specific tissue reactions. Many distinct factors from several sources are known to be selectively chemotactic for eosinophils, including certain complement components, ECFA, certain leukotrienes, lymphokines, and chemokines. IL-4 selectively induces the appearance of specific adhesins (VCAM-1) on endothelial cells that interact specifically with eosinophils and basophils. This might explain the intermediate steps by which certain stimuli lead to the accumulation of eosinophils in tissue. As in the case of other leukocytes, eosinophils can respond to a variety of fluid phase and particulate stimuli with increased adherence, expression of membrane receptors, phagocytosis, cytotoxicity, enhancement of certain synthetic activities, lysosomal degranulation, and oxidative metabolism.

Eosinophilic granules contain a wide array of enzymes comparable with those in neutrophil lysosomes; however, the eosinophil lacks lysozyme, and there are many other major differences in enzyme content between eosinophils and neutrophils. Some eosinophilic granule enzymes and several cationic polypeptides that are present predominantly in eosinophils are of special importance in pulmonary eosinophilias and hypersensitivity reactions. At least three different cationic polypeptides are major constituents of eosinophilic granules. These are MBP and two eosinophilic cationic proteins (ECP). Eosinophils are capable of generating superoxide and hydroxyl radicals at rates higher than those observed in neutrophils, and the production of superoxide by eosinophils remains at maximal levels for several hours. The specificity and intensity of the microbicidal activity of eosinophils differs substantially from those of other leukocytes in that eosinophils have less bactericidal capacity. Other specialized functions of eosinophils, however, are operative in the destruction of metazoan nematodes, trematodes, and cestodes known to be characteristically associated with eosinophilia. The most striking degrees of eosinophilia are found during the tissue-invasive or tissue-migratory phases of helminthic infections. At least two different populations of eosinophils can be distinguished by density. Hypodense eosinophils are activated according to the criteria of partial degranulation,

increased oxygen consumption and deoxyglucose uptake, cytotoxicity against schistosomes, LTC_4 production, and expression of certain receptors for IgG, IgE, and complement. An increased number of hypodense eosinophils are found in some patients with asthma and may be the mediators of tissue damage in some of the syndromes described below.

Eosinophilic infiltrates around invading helminths and ticks have been documented for some time. Eosinophils adhere to helminths by C3b- and IgG-dependent mechanisms. They then degranulate and deposit granule-associated proteins on the surface of the helminth, leading to the appearance of microscopic defects in the organism's cuticle. ECPs are 10-fold more active in this regard than MBP. The efficiency of helminthicidal activity of eosinophils is enhanced markedly by ECFA and LTB_4. Several monokines and lymphokines also enhance eosinophilic helminthicidal activity.

Downregulatory eosinophilic activities are attributable to certain factors, including PGE_2, which suppresses the release of mediators by mast cells; MBP, which binds heparin; and a set of specific enzymes capable of degrading mediators. In addition, mast cell granules are ingested by intact eosinophils. Pertinent to the discussions in this text are the fact that at concentrations attained in the airways, MBP is capable of injuring bronchial epithelial cells and increasing airways permeability to luminal factors. It is clear that eosinophils are tissue cells with the capacity to augment and prolong or inhibit and terminate immediate and late-phase reactions evoked by mast cells and basophils. The net outcome of eosinophil-mast cell interactions at any time during the hypersensitivity response is likely a function of the relative number of each type of cell and their degree of activation. Eosinophils alone and in concert with mast cells and macrophages thus have the potential to participate in host defense or to promote processes that injure host tissues. The finding of elevated concentrations of specific eosinophilic constituents in sputum and lung tissues of patients with asthma and other inflammatory lung diseases of suspected allergic origin emphasizes the importance of further analysis of the eosinophil in normal lung function and lung diseases. Although eosinophilia can occur in association with many illnesses, it is generally most prominent in diseases affecting organ systems in contact with the external environment—namely, the skin, gastrointestinal tract, and respiratory tract. The eosinophilic involvement of the lung in many of these syndromes is well defined and of considerable clinical importance. The clinical features of eosinophilic syndromes are reviewed in the following sections.

The group of miscellaneous pulmonary eosinophilias generally characterized by eosinophilic radiodensities with or without peripheral blood eosinophilia is poorly understood and ill-defined. These eosinophilias are assumed to represent some type of altered immunologic response to exogenous allergens or infectious agents, but the etiologic agents and immunopathogenic mechanism involved usually are not known.

In 1952, Crofton and co-workers described these disorders as *pulmonary eosinophilias* and divided them into five general categories, with some degree of overlap, as follows:

Group 1:	Pulmonary eosinophilia (Loeffler's syndrome); pulmonary infiltrates with eosinophilia (PIE syndrome)
Group 2:	Prolonged pulmonary eosinophilia
Group 3:	Tropical eosinophilia
Group 4:	Pulmonary eosinophilia with asthma
Group 5:	Pulmonary lesions of polyarthritis nodosa

Crofton clearly recognized the inadequacy of this classification and, in an attempt to create order out of this heterogeneous group of diseases, decided that the generic term *pulmonary eosinophilia* could be used for the entire group. Despite many other useful classifications of this type, there are still few new data available concerning the immunopathogenesis and etiology of these diseases, with the exception of allergic bronchopulmonary aspergillosis (ABPA).

Loeffler's Syndrome

Loeffler's syndrome was described in 1932 as a benign and often symptomless association of transient migratory or successive pulmonary infiltrates and peripheral blood eosinophilia, generally lasting for 20 days. Because of the benign nature of this syndrome, few if any of the clinically documented cases were studied morphologically. Pulmonary eosinophilia that is more prolonged (group 2 of Crofton, lasting 6 months or longer) and frequently has a more severe clinical course has also been characterized. Overall, the primary features of Loeffler's syndrome are a high degree of peripheral eosinophilia together with rapidly fluctuating, varied, and fleeting chest roentgenographic shadows and a benign course. This syndrome has often been associated with infestation of parasites, including *Ascaris, Strongyloides, Necator americanus, Fasciola hepatica,* and *Entamoeba histolytica* among others.

Other, more severe types of pulmonary eosinophilia with features unlike those described by Loeffler and characterized by weight loss, high fever, and night sweats have also been described. These cases (chronic eosinophilic pneumonia) have usually been associated with massive pulmonary radiodensities in a pattern of a “negative image” of pulmonary edema, with peripheral but not central radiodensities. Despite the often life-threatening nature of these disorders, corticosteroid therapy usually induces complete clinical recovery and clearing of roentgenographic abnormalities within a few days, although symptoms may promptly recur on cessation of therapy. Patients tend to be middle-aged, Caucasian women with a history of asthma.

In all cases of suspected Loeffler's syndrome or chronic eosinophilic pneumonia, appropriate skin tests and serologic tests should be performed with various *Aspergillus* species in view of the emergence of ABPA and its increasing recognition in the United States.

Drug-Induced Eosinophilia

Pulmonary eosinophilia may occur after the administration of a variety of drugs, including para-aminosalicylic acid, penicillin, nitrofurantoin, chlorpropamide, sulfonamides, aspirin, acetaminophen, beclomethasone, carbamazepine, chlorpromazine, imipramine, mephenesin, metho- trexate, naproxen, diclofenac, certain phenylephrinecontaining nose drops, penicillamine, tetracycline, cromolyn sodium, inhaled pentamidine isethionate, inhaled heroin, and crack cocaine. An extensive list of drugs reported to be directly or indirectly associated with adverse pulmonary actions was compiled by Rosenow, and the subject of drug-induced pulmonary disease is discussed in more detail in Chapter 22 in this text. In many cases, the relationship between eosinophilia or other lung lesions and drug administration is primarily anecdotal, but in others peripheral or pulmonary eosinophilia is clearly associated with drug administration.

A specific cause of eosinophilia with pulmonary infiltrates caused by ingestion of a drug was identified in subjects who used L-tryptophan as a sleeping aid. It is likely that a contaminant (designated as *peak E*) found in some lots of L-tryptophan is responsible for the syndrome. Although pulmonary involvement is not uniform in the eosinophilia-myalgia syndrome, dyspnea and cough occur in 60%–70% of reported cases and pulmonary radiodensities occur in approximately 20%–50% of such cases. The radiodensities tend to be basilar and resemble those seen in interstitial fibrosis. Histologically, there is pulmonary vasculitis and perivasculitis associated with a mild chronic interstitial pneumonitis. Pleural effusions, arterial hypoxemia, and pulmonary hypertension are common. BAL during acute illness demonstrates an increased number of eosinophils. Lavage several months after onset of symptoms may indicate lymphocytosis with a predominance of $CD8^+$ cells. Respiratory failure may result from muscle weakness.

Tropical Eosinophilia

Peripheral blood eosinophilia and asthma with or without eosinophilic infiltrates have been commonly associated with various parasitic infestations. The term *tropical eosinophilia,* a symptom complex of dyspnea, fever, intense eosinophilia, pulmonary infiltrates with or without wheezing, and weight loss, as defined by Weingarten, has been used to refer to many of these conditions. Unfortunately, the term has gradually come to be applied to virtually any case of pulmonary or blood eosinophilia occurring in a person who resides in a tropical area.

Intriguingly, in some cases of tropical eosinophilia, the pulmonary radiodensities can be minimal, whereas generalized lymphadenopathy and eosinophilia are far more prominent. It is not known why primarily pulmonary eosinophilic manifestations develop in some patients and more pronounced lymphadenopathy develops in others. Characteristics of tropical eosinophilia include extreme peripheral blood eosinophilia (generally 3000 eosinophils per cubic millimeter), often high titers of anti-filarial antibody, and extreme elevation of serum IgE, typically to 1000 ng/mL. In classic cases of tropical filarial eosinophilia caused by *Wuchereria bancrofti,* there is an absence of circulating microfilariae in the presence of high anti-filarial antibody titers. Lung biopsies, when performed in these cases, show varying degrees of parenchymal changes and, in more acute phases of the illness, patchy pulmonary lesions consisting of histiocytic and eosinophilic infiltrates in the alveolar, interstitial, and peribronchial spaces. With longer duration of disease (up to several months), massive eosinophilic pneumonias with occasional abscesses develop. In even more chronic cases, of several years' duration, marked fibrosis is often apparent.

Diethylcarbamazine is the drug of choice in patients with tropical eosinophilia. Most patients show considerable improvement after 2 weeks on this drug in a dose of 6 to 8 mg/kg/day, although relapses may be noted.

Many roundworm larvae and other parasites have also been reported to be associated with pulmonary eosinophilic infiltrates and wheezing. Among these are *Necator*

(hookworm), *Toxocara, Ascaris, Strongyloides,* microfilariae (*Wuchereria bancrofti*), *Ancylostoma braziliense* (creeping eruption), *Trichuris trichiura, Fasciola hepatica,* and others. Some of these diseases may be associated with type I (IgE-mediated) hypersensitivity in view of positive wheal and flare skin reactions to antigens derived from certain roundworms. Precipitating and complement-fixing antibody to parasites has also been detected in the sera of patients with some of these conditions.

Pulmonary Eosinophilias Induced by Fungi, Bacteria, and Related Agents

Certain fungal, bacterial, insect, and related antigens can produce eosinophilia and pulmonary radiodensities with asthma and, at times, alveolitis. Among these are inhaled mites, grain dusts, coffee dusts, grain weevils (*Sitophilus granarus*), and proteolytic enzymes derived from *Bacillus subtilis,* the latter being used in the preparation of washing powders. These agents commonly produce asthma, and only occasional cases of eosinophilic or related pneumonia have been reported. Only one of such induced conditions—ABPA, which is associated with fungal antigens, namely *Aspergillus fumigatus* and a few other fungal species—has been well described.

Allergic Bronchopulmonary Aspergillosis

The previously described ill-defined diseases characterized as PIE syndrome, Loeffler's syndrome, or chronic pulmonary eosinophilia stand in sharp contrast to the well-described entity of ABPA, which also presents a pattern of wheezing, peripheral blood and sputum eosinophilia, and fluctuating pulmonary infiltrates. With the original general description of ABPA by Hinson and colleagues in 1952 and the development of diagnostic tests for the disease, many of the ill-defined eosinophilic pneumonias continue to fall into this better-defined category. ABPA has long been known to be common in the United Kingdom, where it is the cause of 50%–80% of the cases of pulmonary eosinophilia. Originally, it was not recognized with great frequency in the United States and was considered a rarity. However, an increasing number of cases are being recognized, and some patients with asthma without evident ABPA have evidence of central bronchiectasis, the hallmark of ABPA. This raises the possibility that unrecognized ABPA may be common in the asthmatic population. It is likely that the syndrome is being missed in this country because of lack of availability or inadequate use of diagnostic tests and lack of familiarity with the syndrome.

There are no absolute criteria for the diagnosis of ABPA, but the disease is to be clearly distinguished from the two other forms of aspergillosis originally described by Hinson and co-workers—namely, the saprophytic form (aspergilloma, mycetoma) and the septicemic or pyemic form characterized by generalized mycotic abscesses and granuloma. McCarthy and Pepys, in an extensive review of 143 cases of ABPA, noted the following features: (1) intense blood and sputum eosinophilia; (2) wheezing and transitory pulmonary radiodensities (Fig. 3); (3) evidence of type I and type III skin reactions to *A. fumigatus;* (4) positive sputum cultures for *A. fumigatus* in 50% of cases; (5) the expectoration of brownish, tough sputum plugs containing fungal mycelia (Fig. 4); (6) the presence of serum precipitating antibody to *A. fumigatus* or related *Aspergillus* antigens by conventional double gel diffusion analysis (Fig. 5); and (7) the presence of central bronchiectasis (Fig. 6). Other strongly supportive features of the disease are dual (immediate and late) bronchial responses on bronchoprovocation challenge testing with *A. fumigatus* antigen, and dramatically elevated levels of serum total IgE, particularly after episodes of eosinophilic pneumonitis, with gradual return of serum IgE to normal during quiescent periods.

FIG. 3. A: Chest roentgenogram of a patient with ABPA at the time of hospital admission. Note the radiodensities in the left upper lobe. **B:** Chest roentgenogram of the same patient as in A after 1 week of corticosteroid therapy. Note almost complete resolution of the radiodensity in the left upper lobe.

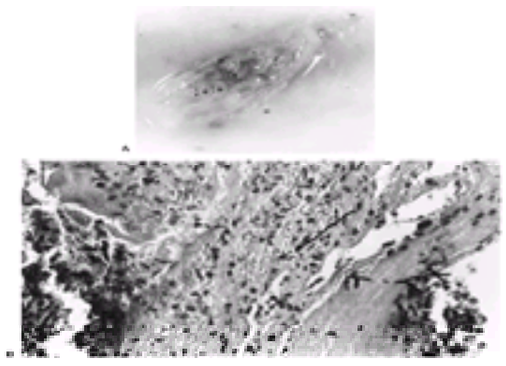

FIG. 4. A: Bronchial plug expectorated by a patient with ABPA. The plug is a cast of a medium-sized bronchus, is golden brown, and is composed of *Aspergillus* mycelial elements. **B:** An expectorated bronchial plug, composed of degenerating cells, mucus, amorphous debris, and *Aspergillus* organisms (branching, septate, methenamine silver-positive structures). Gomori's methenamine silver stain, ×400.

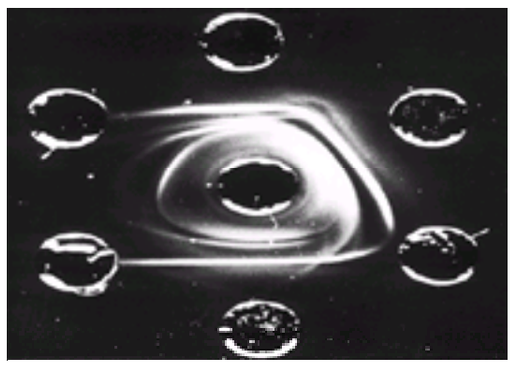

FIG. 5. Precipitin lines to *M. faeni* (“Ouchterlony” or double diffusion in agar technique). Central well contains serum from a patient with farmer's lung disease. Outer wells contain different preparations of *M. faeni* antigen. Note the multiple lines and lines of identity between the antigen preparations.

FIG. 6. Bronchogram from a patient with central bronchiectasis and ABPA. Note the greatly dilated proximal bronchi with normal distal bronchi (*arrow*). This is characteristic of central bronchiectasis. Note also the branching of the dilated bronchi, so that a gloved-finger radiodensity would result if the bronchiectatic cavity was filled with exudate.

There are no population-based studies of the incidence or prevalence of ABPA in unselected asthmatic patients. However, Schwartz and associates found that 28% of asthmatic patients seen in private allergy practice in Cleveland, Ohio, had positive immediate-type *Aspergillus* skin test reactivity. In a later study, these authors reported that 10%–28% of 100 asthmatic patients with positive *Aspergillus* skin test reactivity had ABPA according to sets of criteria that either included central bronchiectasis (10%) or did not include demonstrable central bronchiectasis (28%), as well as the presence of serum IgE and IgG anti-*Aspergillus* antibody or serum precipitins. Therefore, an estimate of the prevalence of ABPA in asthmatic patients is 2.5%–7%. Clearly, more community-based studies of the incidence and prevalence of ABPA are indicated.

Clinical Features and Sequelae

ABPA is almost always a complication of asthma, in that almost all patients with ABPA have had a previous ABdiagnosis of asthma. Acute symptoms are wheezing, localized transitory pulmonary infiltrates, chest pain, cough, and production of mucoid or mucopurulent sputum, often containing brownish flecks or plugs (Fig. 4). These symptoms usually occur in atopic individuals with a previous history of asthma and may occur in familial aggregates. This is not surprising, considering the familial nature of atopy and exposure to common sources of *Aspergillus* species. The disease often is incorrectly diagnosed as tuberculosis, bronchiectasis, or bacterial pneumonia. Although many patients in whom the disease initially is detected demonstrate isolated skin reactivity to *Aspergillus* antigens later in life, younger patients with the disease appear to have a high incidence of atopic respiratory disease and broad patterns of positive wheal and flare skin reactivity to common inhaled allergens. Wheezing, roentgenographic shadows, intensity of eosinophilia, and serum IgE response appear to be worse during the autumn and winter months, when *Aspergillus* spores are usually more prevalent in the atmosphere. At times, a source of *Aspergillus* can be identified, such as moldy marijuana, a municipal leaf-compost site, garden mulch, or a soy sauce and bean brewery.

Patients with an early onset of asthma often demonstrate a lengthy interval (mean, 24 years) between the onset of wheezing and initial detection of pulmonary radiodensities. This does not hold for the late-onset group, suggesting that intense and prolonged antigen stimulation is necessary for induction of ABPA in atopic subjects. During initial episodes, reversible airways obstruction is the rule, but obstruction tends to become more fixed later during the course of the disease, although cor pulmonale and pulmonary hypertension rarely are noted. Progressive central bronchiectasis commonly associated with upper lobe fibrosis is frequently present in chronic cases and often is a hallmark of the disease. A protracted course extended over many years with multiple episodic flares is the rule.

Patterson and colleagues reported their experience with 84 patients with ABPA followed for a mean of 5 years. They found that ABPA could be divided into five stages: acute (I), remission (II), exacerbation (III), corticosteroid-dependent asthma (IV), and fibrosis (V). Only 16 of the patients remained in remission, with most being in the corticosteroid-dependent asthma stage (38 patients) or the fibrotic stage. Most of the eligible patients (not in the fibrotic stage) experienced an exacerbation of ABPA despite alternate-day glucocorticoid therapy. This confirms the findings of earlier studies that ABPA tends to recur. It further implies that most patients with ABPA require long-term corticosteroid therapy and that doses sufficient to control asthma may not prevent flares of ABPA.

When patients with stage V disease (fibrosis) are considered separately, two subgroups are evident. The first includes those with low FEV_1 (forced expiratory volume in 1 second) 6 months after initiation of therapy (mean, 0.8 L). These patients have a very poor prognosis, all dying within 7 years (most of respiratory failure). Patients in the second group have less severe obstruction of air flow (mean FEV_1, 1.3 L) and survive 3 to 8 years taking moderate doses of glucocorticosteroids. These data are consistent with a beneficial effect of glucocorticosteroid therapy.

Roentgenographic Changes

Radiologic features of ABPA can be classified as acute or chronic changes. Chronic changes occur as a result of repeated episodes of acute disease and are often associated with physiologic impairment.

Acute Changes. Parenchymal abnormalities are the most common, manifested in 80%–90% of patients by the presence of ill-defined homogeneous radiologic shadows, without evidence of volume loss, that may be either limited (5 to 15 mm) or massive (lobar) in extent. These shadows can appear in any part of the lung but predominate in the upper lobes. They often resolve (e.g., are fleeting) after expectoration of a bronchial plug but tend to recur in the same location. Half of the episodes of homogeneous shadows (consolidation) leave permanent residue, mainly ring shadows. Corticosteroid therapy hastens resolution. Homogeneous shadows presumably are caused by bronchial obstruction with plugs, localized eosinophilic pneumonia, or both. Fig. 3 depicts the chest x-ray films of a patient with ABPA on admission to the hospital and 1 week later after glucocorticosteroid therapy.

Bronchial abnormalities occur in 50%–70% of episodes of acute ABPA and are manifested as tramline, parallel line, and ring shadows (which represent normal or abnormal bronchial walls) and“toothpaste”and“gloved-finger”shadows (which represent intrabronchial exudate). Tramline shadows are the thickened walls of undilated bronchi, so the distance between the walls is that of a normal bronchus. Parallel line shadows represent walls of bronchiectatic bronchi; the distance between the walls is greater than normal. Ring shadows are either bronchiectatic bronchi seen *en face* or small abscesses. When a normal or bronchiectatic bronchial segment becomes filled with exudate, tramline or parallel line shadows change to toothpaste shadows. Removal of the intrabronchial exudate may cause the tramline or parallel line shadows to reappear. Tramline, parallel line, and toothpaste shadows not only are present in patients with ABPA but also may occur in patients with asthma but no ABPA and those with cystic fibrosis and other pulmonary diseases.

Mucoid impaction of bronchi occurs in 15%–30% of patients with ABPA. A proximal impaction of large bronchi (toothpaste shadow) may extend into second-, third-, and fourth-order bronchi. Involvement of several second-order bronchi results in gloved-finger radiodensities, which are tubular radiodensities, 2 to 3 cm long and 5 to 8 mm wide, that branch distally from the hilus and represent dilated branching bronchi filled with inflammatory exudate (Fig. 7). These occur in 10%–20% of episodes of acute ABPA. Thirty percent of episodes of mucoid impaction of bronchi in ABPA cause permanent changes to bronchial walls.

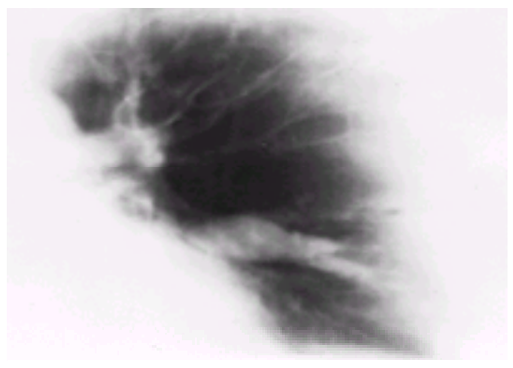

FIG. 7. Gloved-finger radiodensity in a patient with ABPA. This represents thick exudate in dilated third- and fourth-order bronchi, including branches.

Atelectasis of a lobe or a lung with evidence of shrinkage from occlusion of a bronchus by a plug is present in 10%–20% of patients with acute ABPA. Perihilar radiodensities simulating hilar adenopathy occur in 40% of episodes of ABPA. These represent central dilated bronchi filled with fluid and debris, associated with perihilar parenchymal infiltrates. Other acute changes include abscesses with air-fluid levels (10%–20%), diffuse nodulation (10%–20%), avascular areas (10%), and signs of hyperinflation (10%–30%). Pleural effusion occurs in 5% of episodes.

Chronic Changes. Chronic changes reflect permanent histologic abnormalities resulting from repeated acute episodes of ABPA. Bronchial wall changes (tramline, parallel line, and ring shadows) may persist. In addition, because pulmonary fibrosis generally occurs at these sites, the upper lobe usually is involved in chronic ABPA. Physiologic impairment in patients with fibrosis is often significant. The incidence of pulmonary fibrosis in patients with ABPA varies from none of 20 patients followed for 44 months to 18 of 50 patients (36%) followed for 11 years and is directly related to the frequency of acute episodes of ABPA. The association between ABPA and interstitial fibrosis with upper lobe predominance is so strong in Great Britain that a patient with this radiologic finding, a negative tuberculin skin test, and a positive immediate *Aspergillus* skin test reaction is considered to have ABPA.

Central bronchiectasis is apparently a unique feature of ABPA (Fig. 6). In contrast to saccular bronchiectasis, in which small bronchi and bronchioles are dilated, central bronchiectasis is associated with normal small bronchi and bronchioles. This probably is the result of growth of *Aspergillus* only in relatively large (second-, third-, and fourth-order) bronchi, with localized damage to bronchial walls and no injury to smaller bronchi. This peculiar pattern of bronchiectasis can occur even when chest radiographic findings are normal, presumably as a result of relatively few episodes of ABPA insufficient to cause tubular or ring shadows. In instances of severe bronchiectasis, the characteristic changes can be visible on plain films or tomograms without bronchographic dye. It should be noted that bronchography is associated with more complications in asthmatic patients than in normal subjects and that 4 of 16 patients with ABPA who underwent bronchography in the early experience of the Northwestern group had adverse reactions to dye.

High-resolution computed tomography (CT) of the chest detects central bronchiectasis in 35%–40% of the bronchi of patients with ABPA. Interestingly, 5%–15% of the bronchi of control subjects (asthmatic patients with skin test reactivity to *Aspergillus* but without a diagnosis of ABPA) also demonstrate central bronchiectasis. Thus, it is possible that central bronchiectasis is more common than previously appreciated in asthma and may not be unique to ABPA. Alternatively, some of the *Aspergillus*-sensitive asthmatic patients may have ABPA. The resolution of this question awaits further development of specific and sensitive diagnostic tests. In a direct comparison, using bronchography as the gold standard, high-resolution CT was 100% sensitive in detecting central bronchiectasis in patients with ABPA. When individual bronchial segments were compared, CT was 83% sensitive and 92% specific. In view of these findings, the safety and noninvasive nature of CT negates the need for bronchography in patients with suspected ABPA. Table 3 lists the radiologic features of ABPA.

Abnormality	Approximate frequency, %
Central bronchiectasis	100
Homogeneous shadows ("fleeting infiltrates")	80–90
Parallel line shadows	70
Ring shadows	45
Lobar shrinkage	35
Toothpaste shadows	35
Honeycomb shadows (pulmonary fibrosis)	25
Tramline shadows	20
Atelectasis	20
Cavitation	15
Gloved-finger shadows	10

TABLE 3. *Radiologic features of allergic bronchopulmonary aspergillosis*

Diagnostic Considerations

Positive sputum cultures for *A. fumigatus* are found in 50% of the patients, often associated with brownish flecks or sputum plugs containing *Aspergillus* mycelia. Such positive cultures may have little clinical meaning, however, because *A. fumigatus* is ubiquitous and many patients with chronic lung disease have positive *Aspergillus* sputum cultures.

Most patients with ABPA also demonstrate serum precipitating antibody against *A. fumigatus.* However, anti-*Aspergillus* and related antifungal antibody is detectable in the population at large when more sensitive procedures are employed, strongly suggesting that antifungal antibody *per se* only reflects environmental exposure to ubiquitous antigens. Also, precipitins diminish remarkably after treatment with corticosteroids and may be undetectable after 2 years, only to reappear following another episode of pneumonitis.

There are significant problems with antigen preparations used to test for the presence of sensitization to *Aspergillus.* Crude *Aspergillus* antigen from either culture supernatant or mycelia are used clinically. Because these materials include a variety of proteins (including proteolytic enzymes), lipids, lipoproteins, and other substances, and because the method of preparation is not standardized, there are substantial differences between different preparations. The precipitin test with crude *A. fumigatus* is adequately sensitive for practical diagnostic purposes but is inadequate for specificity. Serum IgE and IgG anti-*Aspergillus* antibodies are higher in patients with ABPA than in comparable *Aspergillus*-sensitive asthmatic patients without ABPA. There is some evidence that serum IgA (particularly IgA_1) antibody against *Aspergillus* increases before and during flares of ABPA. It is possible that selected serologic and immunologic findings (skin test reactivity, elevated serum IgE, elevated levels of serum IgE and IgG anti-*Aspergillus* antibody) in patients without demonstrable central bronchiectasis represent a stage of ABPA (ABPA-serologic or ABPA-S). It remains to be seen how frequently ABPA-S precedes ABPA-central bronchiectasis (ABPA-CB) and whether therapy can influence this progression.

There is substantial overlap of antibody levels of asthmatic patients with ABPA and those without ABPA but with positive skin test reactivity to *Aspergillus.* This has led to efforts to purify various *Aspergillus* components to increase specificity. The level of IgE antibodies that react with a concanavalin A nonbinding fraction has been reported to distinguish between *Aspergillus*-sensitized asthmatic patients with and without ABPA. A major 18-kD allergenic *Aspergillus* protein cloned and expressed in bacteria has been useful in distinguishing asthmatic patients or patients with cystic fibrosis with ABPA from those with sensitization to *Aspergillus* but without ABPA, in that sera from patients with ABPA exhibit more IgE and IgG_4 anti-*Aspergillus* antibody. However, some patients with ABPA who had positive skin test reactivity to commercial *Aspergillus* preparations had negative skin tests to the recombinant protein. This illustrates the issue of proper antigen selection. It is likely that different patients respond to slightly different antigenic *Aspergillus* epitopes, so that it is unlikely that any purified antigen will detect all patients with ABPA.

In addition to serologic assays, stronger diagnostic evidence for the role of hypersensitivity to *A. fumigatus* in ABPA comes from the demonstration of dual immediate type I and late or type III skin reactions to this agent. In most patients with ABPA, positive skin tests have been more reliable than precipitins as diagnostic aids. Dual skin reactions also correlate with the elicitation of similar dual early and late bronchial and nasal responses to *Aspergillus* antigen on provocative challenge. There is, however, considerable controversy over the type of reagent best suited to elicit the dual skin test response. There is also controversy over whether the late skin test response represents a local type III immune complex-mediated reaction or a late-phase IgE-dependent reaction. The controversy over the optimal reagent might be expected in view of the lack of precise information on characterization and purification of appropriate antigens. Pepys and McCarthy originally used a saturated ammonium sulfate precipitated protein extract of *A. fumigatus* prepared according to the method of Longbottom, but most preparations marketed today for skin testing consist of crude extracts of the mat and spores. All these agents seem satisfactory, provided that sufficiently high concentrations of the crude antigen are employed. Skin test reactive materials are also present in culture filtrates of the organisms, but there are no adequate studies comparing culture filtrates with mycelial extracts, nor are there any standards of potency for these extracts. In addition, there is a problem with specificity of the skin test in ABPA. In a group of asthmatic patients without aspergillosis and a group of normal subjects, skin tests were positive in 12% and 4%, respectively. There is also evidence to indicate the antigens that react in the skin are not among those detected with a precipitin test and that the *Aspergillus* antigens that elicit IgE antibodies in patients with ABPA do not elicit IgG antibodies.

In addition to skin tests, precipitins, and other immunoassays, lymphocyte stimulation studies with *Aspergillus* antigens have been employed as diagnostic aids in allergic aspergillosis. Lymphocyte proliferation in response to *Aspergillus* antigens may be a feature of ABPA. In one study comparing antigen-induced lymphocyte transformation, precipitins, and skin reactivity, it was noted that patients with aspergilloma had a low incidence of wheal and flare skin reactivity and low lymphocyte responses to *Aspergillus* antigens *in vitro* but extremely high levels of precipitins. On the other hand, patients with ABPA all have immediate positive wheal and flare reactivity but low levels of precipitins. The invasive cases of *Aspergillus* were too heterogeneous to characterize completely.

A limited number of BAL specimens from patients with ABPA have demonstrated increased numbers of neutrophils and eosinophils and increased concentrations of IgG, IgA, and IgM antibodies directed against *Aspergillus* antigens, suggesting local production of these antibodies.

ABPA can occur in patients with cystic fibrosis with an incidence of up to 1% annually and a prevalence of 10%–15%. Because patients with cystic fibrosis without ABPA are subject to episodes of fleeting radiodensities (infectious pneumonia and atelectasis) and have bronchiectasis, an increased prevalence of atopy, and a higher prevalence of *Aspergillus* colonization of the respiratory tract and sensitization to *Aspergillus* compared with age-matched controls, the diagnosis of ABPA can be difficult to establish. There is some evidence that cystic fibrosis patients with ABPA exhibit increased levels of serum IgE and IgG (especially IgG_1 and IgG_4) antibodies to *Aspergillus* and evidence of lymphocyte sensitization when compared with cystic fibrosis patients without ABPA. In addition, peripheral blood B cells from patients with cystic fibrosis and ABPA secrete increased amounts of IgE, and T cells secrete factors that increase B-cell IgE production (perhaps IL-4). Many of the indicators of sensitization to *Aspergillus* in such patients wane spontaneously, so that it can be difficult to determine the importance of these indicators in a patient with cystic fibrosis. In any case, new pulmonary densities in conjunction with deterioration of pulmonary function tests, evidence of sensitization to *Aspergillus,* and elevation of serum IgE in some patients with cystic fibrosis respond to the addition of corticosteroids to antibiotic therapy.

Immunopathogenesis

Currently, there is some evidence to support the contention that a combination of IgE-mediated type I hypersensitivity and immune complex-mediated type III hypersensitivity plays an important role in inducing ABPA. In ABPA in humans, inhibition of type I pulmonary reactions with cromolyn sodium has also prevented the occurrence of subsequent late bronchial pulmonary provocation challenge reactions, whereas the administration of corticosteroids inhibits the late, but rarely the early, responses. In addition, human serum that contains high levels of IgE antibody, when injected intradermally into primates, leads to increased translocation of specific IgG-containing human hyperimmune serum into the skin sites. These findings suggest that deposition of immune complexes is facilitated by IgE antibody acting as a“gatekeeper.”Other evidence for a possible role of type I and type III hypersensitivity in ABPA is obtained from the appearance of dual skin reactivity and pulmonary lesions in a primate challenged by aerosol with *Aspergillus* antigen following passive infusion of serum from a patient with the disease who had both precipitins and reaginic activity against *A. fumigatus.* In contrast, similar challenge after passive transfer of serum containing anti-*Aspergillus* reaginic activity with no precipitins failed to produce such lesions on challenge. There are many alternative explanations for the pathogenesis of ABPA. In view of the high levels of IgE (as high as 90,000 ng/mL of serum) and the fact that most of this IgE is not specific for *A. fumigatus,* Patterson has suggested that *A. fumigatus* growing in the respiratory tract may result either in stimulation of helper T cells for IgE production (i.e., Th2 cells) or of B lymphocytes capable of producing IgE. The Th2 characteristics of *Aspergillus*-specific $CD4^+$ cell lines derived from peripheral blood of patients with ABPA supports this hypothesis. There is also mounting evidence that pharmacologic intermediates such as ECFA and leukotrienes (i.e., LTB_4) released by basophils during type I reactions can attract eosinophils to the site of the initial allergic reaction, resulting in late-phase IgE-dependent eosinophilic reactions. Eosinophil-derived cationic proteins, MBP, and peroxidase are all capable of further stimulating mast cells and basophils to release mediators, and they can damage pulmonary tissues directly as well. Finally, mediators released from eosinophils, such as LTC_4, can act as further late-phase bronchoconstrictors and secretagogues for bronchial glands and epithelial cells. These late reactions are not precipitin-dependent and are not associated with deposition of complement or immunoglobulin. Furthermore, they can be inhibited by agents that inhibit the type I reaction. It is likely that such a mechanism involving attraction of eosinophils to the site of intense type I allergic reactions by chemotactic agents released during the reaction will be shown to be important in the production of many types of eosinophilic pneumonia.

Although attractive, the preceding formulation does not explain the distinction between those asthmatic patients with positive skin tests to *Aspergillus* and circulating IgG anti-*Aspergillus* antibody but without ABPA (25%–30% of unselected asthmatics) and those asthmatic patients in whom ABPA develops (probably 5% of unselected asthmatics). A possible explanation is the observation that circulating basophils from patients with ABPA release more histamine when exposed to both *Aspergillus* antigen and anti-human IgE. This suggests that asthmatic patients in whom ABPA is destined to develop have abnormal basophils that release more mediators on contact with *Aspergillus.* The basis for this abnormality (intrinsic to the cell or a result of exposure to serum factors) has not been elucidated.

Pathologic Features

Lung biopsy of confluent patchy infiltrates demonstrates an interstitial granulomatous infiltrate with a predominance of eosinophils. MBP (derived from eosinophils) is present in the interstitium and in macrophages as well as in activated lymphocytes (increased expression of IL-2R). Mucous plugs containing eosinophils and Charcot-Leyden crystals may be visible in large bronchi, and their presence correlates with shadows seen on chest roentgenograms. Bronchial biopsy generally demonstrates basement membrane thickening, mucosal edema, hypertrophy of mucous glands and smooth muscle, infiltrates of neutrophils and eosinophils, atrophic cilia, some mucous plugs firmly attached to the bronchial wall with profuse intraluminal mucopurulent secretions, and areas of bronchial wall squamous metaplasia.

It should be noted that the tissue reaction in ABPA overlaps with those of other clinical, radiologic, and pathologic entities. Mucoid impaction of the bronchus is often present in ABPA, although it can occur without evidence of sensitization to *Aspergillus.* Eosinophilic pneumonia can be present in ABPA and is believed to be the cause of many of the fleeting radiologic shadows. Finally, the pathologic entity of bronchocentric granulomatosis (BCG) as described by Katzenstein and associates is often found in ABPA. Katzenstein's series of 23 patients with BCG included 10 with asthma. Nine had eosinophilic pneumonia, nine had fungi present in resected specimens, and four had positive serum precipitins to *Aspergillus.* Skin testing was not reported in this series. It is probable that some of these patients had ABPA. Therefore, one of the common causes of BCG may be ABPA. In this regard, Bosken and associates reported that 18 of 18 excised lungs from patients with ABPA demonstrated mucoid impaction of the bronchus, BCG, or both.

Prognosis

There is a lack of prospective population-based studies of the outcome of patients with ABPA. It is clear that some patients progress to end-stage pulmonary fibrosis with cor pulmonale and that some maintain stable pulmonary function tests for many years. Because reports of ABPA originate from referral centers (and thus may not be representative of all patients with ABPA), it is difficult to determine the fate of unselected ABPA patients. In a retrospective study, Malo and coworkers found that after 5 years asthmatic patients with ABPA had more compromised pulmonary physiologic tests than did asthmatic patients without ABPA. Both groups (asthmatics with and without ABPA) had features of asthma (decreased flow rates, increased lung volumes), but asthmatic patients with ABPA tended to exhibit decreased diffusing capacity and total lung capacity. This is compatible with the superimposition of a restrictive defect (pulmonary fibrosis associated with bronchiectasis) on a pre-existing obstructive defect (asthma).

Therapy

Treatment of ABPA is directed toward three goals: treatment of the symptoms of asthma, resolution of acute symptoms of ABPA, and prevention of permanent lung damage. Therapy consists of 40 to 60 mg prednisone daily in divided doses for 2 weeks. The prednisone is rapidly tapered to a maintenance dosage, 0.5 mg/kg on alternate days, and is maintained at that level for 3 months. It should be noted that this schedule is empiric, as there have been no formal studies of different glucocorticoid schedules. Flares can occur while a patient is taking low-dose corticosteroids. Follow-up consists of monthly, and then bimonthly, serum analyses of IgE levels and chest radiographs for 2 to 3 years. If there are no flares, monitoring can be at semiannual intervals, as most patients destined to have recurrent episodes have their first flare within 3 years after the first episode. However, it should be noted that an occasional patient may have a flare after an extended remission.

Systemic glucocorticoid treatment (20 to 40 mg of pred- nisolone per day) significantly hastens clearing of pulmonary radiodensities, so that 4 weeks after the onset of infiltrates, 58% of the new radiodensities cleared in treated patients, in contrast to 23% in untreated patients. In addition, clinical symptoms of asthma, expectoration of bronchial plugs, and sputum production remitted more quickly in treated patients. Permanent lung damage, as manifested by new persistent pulmonary radiodensities, is less frequent if patients are treated. Safirstein and associates, in a retrospective review of patients followed for 5 years, found that therapy with as little as 7.5 mg of prednisone daily prevented the appearance of new radiologic shadows, whereas new persistent shadows appeared in 7 of 19 patients who were not treated with steroids. Capewell and associates, in another retrospective study, found that treatment with 20 mg or more of prednisolone per day was associated with more frequent resolution of radiodensities and peripheral blood eosinophilia, in comparison with treatment with no drug or 20 mg/d.

Twenty percent to 35% of ABPA flares are asymptomatic and can be detected only radiologically. In addition, some patients with ABPA experience only one episode during their lifetimes, and others exhibit flares only at long intervals. This has led to attempts to identify those patients with ABPA most likely to benefit from glucocorticoid therapy. Such patients would be those with frequent flares of acute ABPA resulting in chronic radiologic changes and physiologic impairment.

The striking increase in total IgE in patients with acute ABPA has been used to monitor patients. Most of the IgE is not directed against *Aspergillus* antigens but rather is nonspecific. Total serum IgE increases during flares of ABPA and in some instances before flares. This has led to the recommendation that serial IgE determinations be obtained and patients be treated on the basis of rising concentrations of IgE. Although *Aspergillus* is a potent stimulus for IgE production, it is not the only cause of rising IgE levels. Reed's group demonstrated that most (9 of 13), but not all, increases in serum IgE levels in ABPA were associated with flares. Therefore, it is somewhat precarious to initiate corticosteroid therapy solely on the basis of increasing serum IgE.

The following treatment regimens cannot be recommended and have not been demonstrated to be effective in controlled studies, although there have been anecdotal reports of effectiveness: (1) hyposensitization therapy with *Aspergillus* species (which may cause immediate bronchospasm, would also raise IgG levels to *Aspergillus,* and could theoretically worsen the disorder); (2) inhaled corticosteroids; (3) systemic or inhaled antifungal agents, such as ketoconazole, natamycin, or itraconazole.

Allergic Bronchopulmonary Mycosis

Recently, a series of cases that clinically resemble ABPA, without evidence of sensitivity to *Aspergillus* but with evidence of sensitization to dematiaceous hyphomycetes *Curvularia* and *Drechslera, Candida, Helminthosporium, Fusarium, Rhizopus, Penicillium, Torulopsis, Bipolaris*, or *Pseudallescheria boydii,* have been reported. The course of this illness (allergic bronchopulmonary mycosis) is currently unknown but presumably resembles that of ABPA. However, it appears that most instances of allergic bronchopulmonary fungal disease are caused by exposure to *Aspergillus,* although other fungi rarely can cause a similar clinical and radiologic syndrome.

Other Forms of Pulmonary Eosinophilia

In addition to ABPA and the forms of eosinophilia described in this chapter, one must consider several other types of pulmonary eosinophilia in the differential diagnosis. Among these are allergic granulomatous angiitis, a probable variant of polyarteritis, characterized by severe asthma and intense peripheral blood eosinophilia plus prominent granulomatous infiltrates and Churg-Strauss vasculitis.

Hypereosinophilic syndrome, a separate form of pulmonary eosinophilia, is defined by peripheral and bone marrow eosinophilia and infiltration of multiple organs by mature eosinophils. Any organ system may be involved, but characteristically the lung, heart, skin, muscle, and central nervous system are more prominently affected. The heart is almost uniformly affected, and the lungs are involved in 50% of cases. This disease take several forms. A more benign form consisting of hypereosinophilia with lung involvement and angioedema is often responsive to steroids. In other patients, severe cardiac or central nervous system impairment develops that is unresponsive to either steroids or cytotoxic agents, and in a few cases overt eosinophilic leukemia with documented cytogenic abnormalities develops. Because this disease is of unknown etiology, one must rule out parasitic, allergic, or other autoimmune or related etiologies. The most common pulmonary defect in hypereosinophilic syndrome appears to be a paroxysmal nocturnal cough without airways obstruction. A few patients have underlying asthma. Treatment depends on proving the existence of progressive organ system involvement. In this event, corticosteroid therapy is initiated, and if a response does not occur, treatment with hydroxyurea and occasionally vincristine may result in improvement. When patients are unresponsive to steroids, hydroxyurea often has altered survival rates significantly.

Finally, in the United Kingdom, where ABPA constitutes 50%–80% of all pulmonary eosinophilic pneumonias, those pulmonary eosinophilias that do not fulfill the diagnostic criteria for ABPA are considered merely as a single category of cryptogenic pulmonary eosinophilia. In describing 27 cases of this syndrome, McCarthy and Pepys noted that the cryptogenic form was associated with a lesser degree of blood and sputum eosinophilia when compared with ABPA and that it more frequently involved younger women. There was also no seasonal predilection in the cryptogenic variety. Cough and sputum production were not prominent, and the brownish mucous plugs noted in ABPA rarely were seen. These patients did not have a type I or type III skin test reaction to *Aspergillus,* high levels of circulating total IgE, or cytophilic antibody directed to *Aspergillus,* and did not progress to the bronchiectasis, fibrosis, and atelectasis that are often noted in ABPA. The fact that systemic polyarteritis was ultimately diagnosed in several patients of this series with cryptogenic eosinophilia suggests that many of these cases were perhaps variants of allergic granulomatous angiitis.

Acute Eosinophilic Pneumonia

Recently, a small number of patients with acute onset of fever, diffuse radiodensities, and hypoxemia, at times progressing to adult respiratory distress syndrome (ARDS), with a high proportion of eosinophils in bronchoalveolar lavage (BAL) specimens and sputum and many eosinophils in the pulmonary parenchyma, have been described. Peripheral blood eosinophilia is usually present during the course of the illness, but often not at presentation. The chest radiographic densities are diffusely distributed and not peripheral and therefore are different from those described in chronic eosinophilic pneumonia. CT demonstrates diffuse bilateral ground-glass densities, micronodules, or both. These patients do not have evidence of parasitic infection or atopic disease. Mild cases of acute eosinophilic pneumonia improve rapidly without specific therapy, whereas more severe cases respond promptly to corticosteroid therapy with no permanent sequelae. In some patients, acute eosinophilic pneumonia is related to exposure to environmental fungi or ascarids, with some evidence of sensitization to these antigens. The relationship of this syndrome to other forms of PIE and ARDS is unknown.

HYPERSENSITIVITY PNEUMONITIS

The term *hypersensitivity pneumonitis* (or *extrinsic allergic alveolitis,* the British term) denotes a group of lung diseases caused by inhalation of a wide variety of different materials that are usually organic and always antigenic. The stereotypic clinical events are transient fever, hypoxemia, myalgias, arthralgias, dyspnea, and cough that occur 2 to 9 hrs after exposure and resolve in 12 to 72 hrs without specific treatment.

Hypersensitivity pneumonitis was first clearly described in Dr. Jon Finsen's doctoral thesis in 1874, when he described *heykatarr* in Iceland.

> “This is a chronic chest disease. I do not know its incidence, as my observations thereupon are incomplete. The disease occurs only in winter, or rather during the time when the animals are kept inside, and is found only in the man whose job it is to loosen the hay in the barn and handle it before it is fed to cattle. The hay is always more or less dusty and has to be shaken to eliminate the dust before it is used as fodder. When this dust is inhaled, especially when the harvesting has been difficult and the hay has moulded in the barn, the man who works with the hay becomes ill with this disease, which lasts as long as he continues the same occupation, but usually disappears in summer. The disease expresses itself by cough, rather scant expectoration, and chest heaviness, especially in the evening (the hay is usually loosened in the afternoon, i.e., when it is intended to be given in the evening and the next morning). When examining the chest of those men, I have on a few occasions found signs of bronchitis, but in most cases I have never found anything abnormal. I have never had the occasion to examine a patient during an acute episode.”

This syndrome was described again in British farmers in the 1930s and called *farmer's lung disease.* Dr. Finsen's description is notable for the association of the illness with a particular environmental exposure, its relationship to the season of the year, its occurrence several hours after exposure, the nature of the symptoms, and even the association with bronchitis. Many other diseases have since been described that exhibit the same clinical features and are denoted as hypersensitivity pneumonitis. Despite the terms *hypersensitivity* and *allergic,* hypersensitivity pneumonitis is not an atopic disease and is not associated with increases in IgE or eosinophils. Drug reactions are sometimes described as representing hypersensitivity pneumonitis, usually because certain BALF findings resemble those in hypersensitivity pneumonitis. However these reactions are not hypersensitivity pneumonitis, as the inciting agent is administered systemically and the pathogenic mechanisms are likely different from those of hypersensitivity pneumonitis.

Table 4 is a listing of currently described examples of hypersensitivity pneumonitis.

TABLE 4. *Currently described examples of hypersensitivity pneumonitis*

Some of these diseases have apparently disappeared from the originally described clinical settings (e.g., bagassosis in Louisiana) but presumably exist in areas with similar agricultural or industrial settings, and other diseases are being newly recognized (e.g., potato riddler's lung and machine operator's lung). Both the disappearance of previously described examples of hypersensitivity pneumonitis and the appearance of new examples are the consequence of changing agricultural and/or industrial practices that result in changes of exposure of subjects to antigenic material that can cause hypersensitivity pneumonitis. At the present time, farmer's lung disease, bird fancier's disease, ventilator lung, and Japanese summer-type hypersensitivity pneumonitis (in Japan) are the most commonly recognized forms of

hypersensitivity pneumonitis.

Recognition of new examples of hypersensitivity pneumonitis usually requires a cluster of new cases with a unifying exposure history. Because complete occupational and vocational histories are at times not obtained from patients with pneumonia, it is likely that substantially more examples of hypersensitivity pneumonitis exist that have not yet been recognized and described. For example, introduction of a new metal-working fluid led to recognition of machine operator's lung in an auto parts manufacturing facility because of the clustering of cases and a common, unusual exposure (pseudomonads in cooling fluid).

Clinical Presentation

There are two different clinical presentations of hypersensitivity pneumonitis.

Acute hypersensitivity pneumonitis (dyspnea, nonproductive cough, myalgias, chills, diaphoresis, lassitude, headache, and malaise) occurs 2 to 9 hrs after a particular exposure, peaks typically between 6 and 24 hrs, and resolves without specific treatment in 1 to 3 days (sometimes longer after a particularly intense exposure). Patients exhibit fever, tachypnea, bibasilar rales, and occasionally cyanosis. Fig. 8 diagrams the course of acute hypersensitivity pneumonitis. There is peripheral blood leukocytosis with neutrophilia and lymphopenia, but not eosinophilia, and BAL neutrophilia.

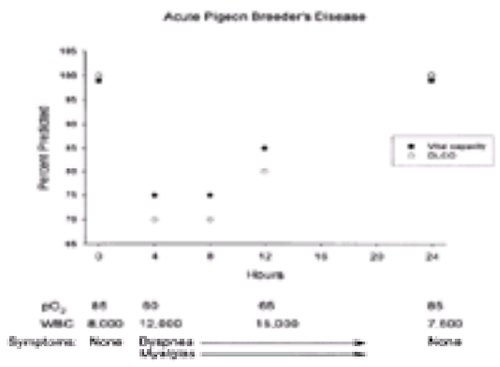

FIG. 8. Diagram of a typical episode of acute pigeon breeder's disease induced by exposure to pigeon serum at 0 h.

Chronic hypersensitivity pneumonitis is characterized by progressively more severe dyspnea, nonproductive cough, weight loss, and often anorexia in a patient exposed to a recognized cause of hypersensitivity pneumonitis. Symptoms are usually present for months to years. There is typically no fever, but tachypnea and bibasilar dry rales are usually present. Symptoms and signs of cor pulmonale are not uncommon at presentation. In general, clubbing occurs infrequently, although Selman, using retrospective chart review, reported clubbing in up to 50% of subjects with pigeon breeder's disease in Mexico City.

A proportion (20%–40%) of patients with chronic hypersensitivity pneumonitis first have symptoms of chronic bronchitis (e.g., chronic productive cough), some even without radiologic parenchymal densities on standard chest radiographs. There is substantial morphologic evidence of bronchitis in the large airways of patients with farmer's lung disease. As most patients with hypersensitivity pneumonitis are nonsmokers without any other cause for the development of chronic bronchitis, these symptoms are likely to be a result of hypersensitivity pneumonitis and may correlate with evidence of airway hyperreactivity in patients with chronic hypersensitivity pneumonitis.

The reasons for the different clinical presentations (acute and chronic) of hypersensitivity pneumonitis are not clear, but they could include differences of intensity and duration of exposure (i.e., low intensity and long duration tending to cause chronic hypersensitivity pneumonitis, and high intensity and short duration tending to cause acute hypersensitivity pneumonitis). This is most clearly demonstrated in hypersensitivity pneumonitis caused by exposure to birds. Bird fancier's disease (chronic exposure to low amounts of bird antigens) is associated with chronic hypersensitivity pneumonitis. Pigeon breeder's disease presents differently in different geographic areas. Intermittent exposure of pigeon breeders to large amounts of pigeon antigens in the United States and Europe is associated with acute disease and a good prognosis, whereas chronic exposure to a few household pigeons in Mexico is associated with chronic disease and a much poorer prognosis. In the United States and Europe, pigeon breeders keep their animals in an enclosure separate from their living areas and visit it periodically, so that exposure is intermittent. In Mexico, birds are kept in living quarters, so that exposure is continuous. It is of interest that bird antigens can persist in a room for a substantial length of time (18 months) after removal of the birds, so that Mexicans with pigeon breeder's disease would be expected to be exposed to pigeon antigens for prolonged periods of time even after removal of the pigeons. Therefore, pigeon breeder's disease in Mexico resembles bird fancier's disease in the United States and Europe in type of exposure, clinical presentation, and prognosis, and differs from pigeon breeder's disease in the United States and Europe. Because the relevant antigens are similar in these two examples of bird-associated hypersensitivity pneumonitis, it is likely that type of exposure, not antigen characteristics, determines clinical presentation and prognosis.

Although the recognition of a new example of hypersensitivity pneumonitis is usually associated with the acute presentation of hypersensitivity pneumonitis, most patients with well-recognized types of hypersensitivity pneumonitis have chronic disease. This might be related to the difficulties in establishing a link between chronic disease and chronic exposure, as opposed to the relative ease in making the association of acute disease and acute exposure.

The above discussion indicates that hypersensitivity pneumonitis, and particularly chronic hypersensitivity pneumonitis, may be more prevalent than is readily apparent and may be a cause of some cases of idiopathic pulmonary fibrosis. Detailed histories are not always obtained from patients with idiopathic pulmonary fibrosis, serum antibody to the agent responsible for hypersensitivity pneumonitis tends to wane after cessation of exposure, and high-resolution CT scans of the chest in chronic hypersensitivity pneumonitis can resemble those of idiopathic pulmonary fibrosis, so it is possible that some patients with idiopathic pulmonary fibrosis have chronic hypersensitivity pneumonitis.

Radiology

In acute hypersensitivity pneumonitis, chest radiographs demonstrate diffuse, poorly defined nodular radiodensities, at times with areas of ground-glass radiodensities or even consolidation. These radiodensities tend to occur in the lower lobes and spare the apices. Linear radiodensities (presumably representing areas of fibrosis from previous episodes of acute hypersensitivity pneumonitis) may also be present. The nodular and ground-glass densities tend to disappear after cessation of exposure, so that the chest radiograph findings may be normal after resolution of an acute episode of hypersensitivity pneumonitis. Figure 9 demonstrates radiologic resolution of acute hypersensitivity pneumonitis. High-resolution CT often demonstrates ground-glass densities better than chest radiographs and at times reveals a diffuse increase of pulmonary radiodensity, but findings may also be normal after resolution of an acute episode. Pleural effusions or thickening, calcification, cavitation, atelectasis, localized radiodensities (coin lesions or masses), and intrathoracic lymphadenopathy are rare.

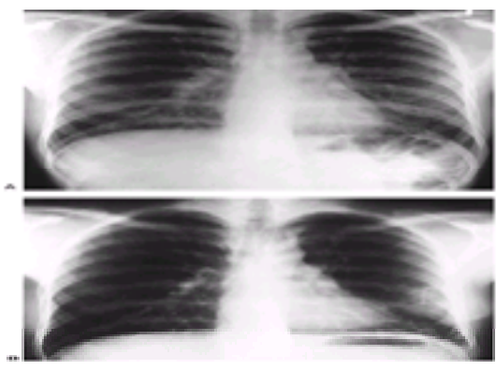

FIG. 9. A: Chest radiograph of a patient with pigeon breeder's disease having symptoms of fever, dyspnea, and bibasilar rales. The patient had kept pigeons for 5 years and was seen with fever, dyspnea, and myalgias approximately 8 hours after cleaning the pigeon coop. He had serum antibody to pigeon dropping extract. Note 2- to 3-mm nodules bilaterally in lower lobes. **B:** Chest radiograph of the same patient 2 weeks later. No specific treatment was given. Note clearing of the lower lobe nodules and the staples in the left chest from the open lung biopsy.

In chronic hypersensitivity pneumonitis, diffuse linear and nodular radiodensities with upper lobe predominance, sparing of the bases, and volume loss (Fig. 10) are apparent on chest radiographs. Pleural effusions and thickening are very unusual, although subcutaneous emphysema (presumably as a consequence of pleural rupture caused by bronchiolitis and lobular overinflation) has been reported.

FIG. 10. Chest radiograph of a patient with bird fancier's disease who was first seen with progressive dyspnea and weight loss. She had kept two or three parakeets in her home for the past 15 years and did not notice episodic fever or acute dyspnea. Her serum was positive for precipitins to parakeet serum, and she had severe restrictive disease and resting hypoxemia. Note the diffuse radiodensities, loss of volume of the upper lobes, and pulmonary hypertension.

High-resolution CT of patients with chronic hypersensitivity pneumonitis demonstrates several patterns. Most commonly, there are multiple centrilobular nodules, 2 to 4 mm in diameter, throughout the lung fields, with some areas of ground-glass radiodensities, especially in the lower lobes (Fig. 11). The nodules are seldom attached to the pleura or bronchovascular bundles, as they are in sarcoidosis, and the border between the nodules and the surrounding lung is well demarcated. There are also well-delineated areas of increased radiolucency; these are presumably overinflated pulmonary lobules subserved by partially occluded bronchioles. The ground-glass densities and micronodules tend to resolve after cessation of exposure. Although these findings are suggestive of hypersensitivity pneumonitis, they are found in only a subset (50%–75%) of patients with hypersensitivity pneumonitis, and high-resolution CT findings in hypersensitivity pneumonitis can resemble those of idiopathic pulmonary fibrosis. Cormier reported a substantial prevalence of mild to moderate emphysema detectable by high-resolution CT in nonsmoker patients with farmer's lung disease. It is not clear if this represents lobular overinflation or emphysema. Magnetic resonance imaging (MRI) is inferior to high-resolution CT in demonstrating anatomic detail, but it is equal to CT in demonstrating ground-glass areas and may be useful in determining the course of ground-glass densities without necessitating radiation exposure.

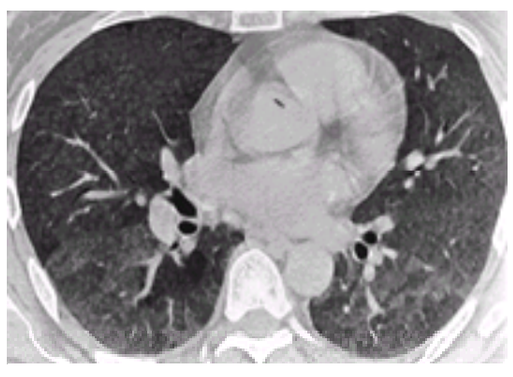

FIG. 11. High-resolution CT of a nonsmoker with exposure to both birds and shells who had progressive dyspnea, weight loss, hypoxemia, and a restrictive ventilatory defect. Note the diffuse nodular radiodensities in the lower lobes with areas of ground-glass densities posteriorly.

Epidemiology

The prevalence of hypersensitivity pneumonitis is quite variable in different populations, presumably related to differing intensity, frequency, and duration of inhalation exposure. Among pigeon breeders, 8%–30% of those who are members of pigeon-breeding clubs and participated in surveys exhibited pigeon breeder's disease. Among farmers, 0.5%–5% have symptoms compatible with farmer's lung disease. The prevalence of symptoms is decreased in farms that use hay-drying methods that reduce exposure to the responsible antigens and is increased following a wet summer season.

The population at risk and the season of the year of occupance vary with the type of hypersensitivity pneumonitis. For example, most cases of farmer's lung disease occur in cold, damp climates in late winter and early spring, when farmers (usually men) use stored hay to feed their livestock. Pigeon breeder's disease occurs chiefly in men in Europe and the United States; it occurs predominantly in women in Mexico because of differing patterns of exposure, but there is no seasonal preference in either population. Bird fancier's disease in Europe and the United States occurs in subjects who keep domestic birds and does not exhibit a predilection for either sex. Japanese summer-type hypersensitivity pneumonitis occurs mostly in women not employed outside the home from June to September in warm, moist areas of Japan.

Unlike what occurs in other pulmonary diseases, there is a remarkable predominance of nonsmokers (80%–95%) among patients with all types of hypersensitivity pneumonitis, substantially greater than the proportion of nonsmokers in similarly exposed subjects who are not ill. The mechanisms of this striking phenomenon are unknown, but they could include smoking-induced alterations of lung defense mechanisms or immunologic reactivity. This clinical finding indicates that active smoking weighs substantially against a diagnosis of hypersensitivity pneumonitis.

An important feature of hypersensitivity pneumonitis is the great variability in susceptibility among exposed populations and the apparent resistance to illness of most exposed individuals. Possible reasons include differences of exposure or differences among hosts, either inborn or acquired. There are no differences in the prevalence of atopy or of HLA-A, -B, -C, or -DR haplotypes in exposed subjects with and without hypersensitivity pneumonitis. There is an increased prevalence of HLA-DPb1 glutamate 69 in berylliosis, a disease with many similarities to hypersensitivity pneumonitis, but HLA-DP haplotypes have not been reported in hypersensitivity pneumonitis. The prevalence of hypersensitivity pneumonitis, unlike that of most other lung diseases, is not increased but rather is substantially decreased in cigarette smokers. This protection against development of hypersensitivity pneumonitis in smokers extends to serum antibody, so that smokers have a lower prevalence of serum antibody than apparently equally exposed nonsmokers. The reasons for these phenomena are unknown but could include depression of immune responses to antigen delivered to the lung, which is well documented in smokers.

Pathology

Lung biopsy specimens (almost always from patients with chronic hypersensitivity pneumonitis) show chronic interstitial inflammation with infiltration of plasma cells, mast cells, histiocytes, and lymphocytes, usually with poorly formed nonnecrotizing granulomas. There is often bronchiolitis and sometimes (25%–50%) bronchiolitis obliterans (Fig. 12). Organizing pneumonia is often also present, so that 15%–25% of patients with hypersensitivity pneumonitis have bronchiolitis obliterans with organizing pneumonia (BOOP). Conversely, in patients with recognized BOOP, hypersensitivity pneumonitis may be the cause. Interstitial fibrosis is often present to a varying extent. Unlike what is seen in sarcoidosis, the interstitial inflammatory cell infiltrate is distal as well as proximal to the granulomas. The granulomas do not occur in groups and do not tend to occur near bronchi or in subpleural locations; they are often adjacent to bronchioles and usually occur singly. These characteristics help to differentiate hypersensitivity pneumonitis from sarcoidosis. Giant cells, at times with Schaumann or asteroid bodies or cholesterol clefts, are present both within and outside the granulomas. Foamy AM are often observed in patients with hypersensitivity pneumonitis caused by bird exposure (Fig. 13). Vasculitis and eosinophilia are not evident.

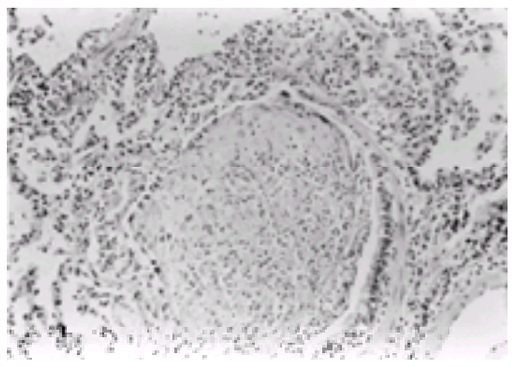

FIG. 12. Bronchiolitis obliterans in the same patient with pigeon breeder's disease as in Fig. 9.

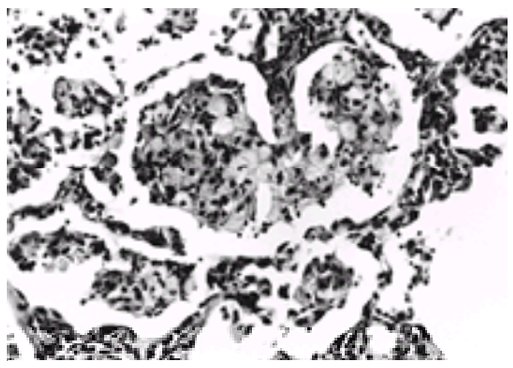

FIG. 13. Foamy alveolar macrophages in the same patient as in Fig. 10.

The specific histologic changes of hypersensitivity pneumonitis, when present, can be diagnostic. However, the granulomas and respiratory bronchiolitis may not be present years after cessation of exposure, so that only interstitial inflammation and fibrosis remain. Therefore, these changes are quite specific, but their sensitivity is unknown.

Differential Diagnosis

The symptoms, signs, and laboratory findings of acute hypersensitivity pneumonitis can resemble those of many other lung diseases, including pulmonary edema, bronchoalveolar cell carcinoma, organic dust toxic syndrome (ODTS), and some forms of pneumoconiosis. Acute hypersensitivity pneumonitis is most often confused with infectious pneumonia (usually thought to be of viral or mycoplasmal origin) and at times with psittacosis in subjects exposed to birds.

ODTS has been described in some of the same populations exposed to materials that cause hypersensitivity pneumonitis. ODTS, which occur in a larger proportion of the exposed population than hypersensitivity pneumonitis, is characterized by transient fever, dyspnea, nonproductive cough, peripheral blood leukocytosis, and BALF neutrophilia; unlike hypersensitivity pneumonitis, however, it is not associated with chest radiographic changes, permanent lung damage, or prior sensitization (as indicated by the absence of serum antibodies). Endotoxin, activated complement, and cytokine released from AM have been implicated as mediators of ODTS. Patients who present with ODTS tend to have had a more intense exposure of shorter duration than those who present with farmer's lung disease.

Exposure to the same agents that cause ventilator lung may result in humidifier fever. This is characterized by fever, chills, myalgias, arthralgias, headache, malaise, cough, dyspnea, peripheral blood leukocytosis, and arterial hypoxemia that begins 4 to 12 hrs after exposure. Some investigators report decreased lung volumes with normal flow rates (“restrictive pattern”) and decreased diffusing capacity, whereas others report normal lung volumes and diffusing capacity. The clinical syndrome remits after 12 to 24 hrs without specific therapy. Symptoms and signs are exaggerated after exposure that follows a period of no exposure (such as vacation or a weekend), but then they become blunted despite continued exposure (“Monday illness”). Monday illness with tolerance to apparently the same exposure later in the work week also occurs in byssinosis and metal fume fever. All signs and symptoms of humidifier fever remit after cessation of exposure, and no permanent physiologic or roentgenologic changes occur. Serum antibodies to thermophilic organisms are rarely present, but antibodies are often present to extracts of humidifier water or slime, gram-negative and gram-positive bacteria (*Bacillus, Flavobacterium, Pseudomonas, Streptomyces*), fungi (*Cephalosporium, Penicillium, Sporotrichum, Aspergillus, Fusarium, Mucor, Phoma, Rhizopus*), or amebae.

There is evidence that some cases of humidifier fever may be caused by endotoxin. Many of the symptoms of humidifier fever can be reproduced by exposure to endotoxin. Rylander described a printing factory in which symptoms of humidifier fever developed in 20 of 50 workers. The humidifier water was heavily contaminated with pseudomonads and endotoxin, and airborne endotoxin was detected in the factory atmosphere when the humidifier was operating. However, other investigators have not detected endotoxin in humidifier water using a pyrogen assay, so that the role of endotoxin in humidifier fever is uncertain.

Treatment consists of removing subjects from exposure to contaminated humidifier water by frequent cleaning of the humidifiers or by changing their job location. It is frequently difficult to clean humidifiers permanently, as any agent used to cleanse water must be removed before humidifiers can be put back in use, so that workers are not exposed to the cleansing agent. Prognosis in humidifier fever after removal from exposure seems to be excellent, as no permanent physiologic or roentgenologic changes occur.

Chronic hypersensitivity pneumonitis resembles idiopathic pulmonary fibrosis, and in some instances the two are indistinguishable. The differential diagnoses includes pulmonary fibrosis of other causes (chemotherapeutic agents, radiation, inhaled toxins, sarcoidosis, idiopathic pulmonary fibrosis, pneumoconiosis) and heart failure.

A thorough and complete occupational and vocational history is essential to diagnose both forms of hypersensitivity pneumonitis. The history should seek to establish a link between a particular exposure (at work, home, or elsewhere) and previous episodes of pneumonia. Information about other exposed individuals with similar symptoms should be sought.

If the history suggests a relationship between exposure and pulmonary symptoms, evidence of sensitization and the nature of the pulmonary inflammatory response should be determined. Sensitization is indicated by the presence of serum antibody to an agent known to cause hypersensitivity pneumonitis. A large proportion of lymphocytes in BALF (usually >40%) is suggestive of hypersensitivity pneumonitis, although many other pulmonary processes can cause BALF lymphocytosis.

Evidence of repetitive appropriate symptoms and laboratory and radiologic abnormalities associated with exposure to a particular environment is sufficient to diagnose hypersensitivity pneumonitis. In questionable instances, a natural exposure (i.e., documentation of appropriate symptoms and laboratory abnormalities after exposure to an environment suspected of causing hypersensitivity pneumonitis) can be used to diagnose hypersensitivity pneumonitis. A natural exposure challenge should not be considered positive unless there is objective evidence of a change in temperature, total peripheral white blood cell number, chest radiograph or high-resolution CT, or increased alveolar-arterial gradient as reflected by the development or worsening of decreased arterial oxygen tension. In some patients, lung biopsy may be required to differentiate hypersensitivity pneumonitis from other causes of diffuse pulmonary inflammation and/or fibrosis. Transbronchial lung biopsy specimens often do not provide sufficient material to establish fully the presence and interrelationships of granulomas, bronchiolitis, and interstitial inflammation, so that either open or thoracoscopic lung biopsy is often required.

Deliberate aerosol inhalation exposure to the suspected antigens should not be performed outside research settings because of the lack of standardized antigens, the possibility of severe adverse effects from the inhaled material in a sensitized person, and the need to demonstrate the lack of a reaction in normal subjects without prior exposure to the same material, thereby possibly inducing sensitization in previously unsensitized individuals.

Terho and colleagues have established major and minor criteria for the diagnosis of farmer's lung disease. An adaptation of their criteria follows.

Major criteria for hypersensitivity pneumonitis:

1. Evidence of exposure to appropriate antigen by history or detection of serum antibody
2. Symptoms compatible with hypersensitivity pneumonitis
3. Findings compatible with hypersensitivity pneumonitis on chest radiographs or high-resolution CT

Minor criteria:

1. Bibasilar rales
2. Decreased diffusing capacity
3. Arterial hypoxemia, either at rest or during exercise
4. Pulmonary histologic changes compatible with hypersensitivity pneumonitis Positive natural challenge
5. BALF lymphocytosis

The diagnosis is confirmed if the patient fulfills all the major criteria and at least four of the minor criteria, and if all other diseases with similar symptoms can be ruled out (e.g., sarcoidosis). Normal chest radiographic findings are acceptable if pulmonary histology is compatible with hypersensitivity pneumonitis. A normal result of high-resolution CT eliminates the possibility of active or chronic hypersensitivity pneumonitis but is possible between acute episodes, so that a normal CT result is acceptable if compatible pulmonary histologic changes are present.

Laboratory Findings

In addition to peripheral blood leukocytosis with neutrophilia, usually BALF lymphocytosis is present (typically 40%–80% of BALF cell number increased two- to fourfold) when BAL is performed 5 days or more after the last exposure. Earlier lavage (especially <48 hours after exposure) is characterized by BALF neutrophilia. BALF lymphocytosis, at least in dairy farmers, is related to continued antigenic exposure and not to the presence of disease, and it does not predict outcome. In most instances of hypersensitivity pneumonitis, the BALF lymphocytes are virtually all $CD3^+$ with a relative increase of $CD8^+$, cells so that the CD4/CD8 ratio is <1. Many of the $CD8^+$ cells express CD57, a marker of cytotoxic cells, and also express CD25 (the IL-2 receptor) and other activation markers. However, the BALF CD4/CD8 ratio is 1 in ventilator lung, some cases of bird fancier's disease, and some cases of farmer's lung disease in Japan, although the BALF CD4/CD8 ratio is <1 in Japanese summer-type hypersensitivity pneumonitis. These differences between Japanese and non-Japanese patients with some types of hypersensitivity pneumonitis might be related to different types of exposure, differing periods of time between last important exposure and BAL, or genetic differences. In support of the importance of timing between last exposure and lavage, Soler demonstrated that cessation of exposure is associated with an increase of BALF $CD8^+$ cells. There is some suggestion that an increase of BALF $CD8^+$ cells is associated with protection against pulmonary fibrosis. BALF NK cell activity is increased in patients with hypersensitivity pneumonitis who continue to be exposed to the responsible antigen. The killer cell activity is found in cell populations with characteristics of both NK cells and non-NK cells, including LAK cells. Most of the $CD3^+$ cells are TCR ab^+, but there is an increase of TCR gd^+ cells and some tendency towards T-cell oligoclonality as demonstrated by increased V_b8, V_b6 and V_b5 TCR usage in some patients with hypersensitivity pneumonitis. BALF macrophages display many aspects of activation, including spontaneous secretion of TNF-a and IL-1 and expression of CD25. Monokines that can activate macrophages and cause chemotaxis of $CD8^+$ cells (i.e., MIP-1a, MCP-1, and IL-8) are present in BALF and AM from patients with acute hypersensitivity pneumonitis. Mast cells, often with ultrastructural markers of degranulation, are increased in both the lung parenchyma and BALF of patients with hypersensitivity pneumonitis. The concentration of IgG, IgM, IgG, and albumin are increased in BALF, presumably as a result of pulmonary inflammation. BALF histamine and tryptase is increased in some patients with acute hypersensitivity pneumonitis.

Virtually all patients with hypersensitivity pneumonitis have easily demonstrable antibody (typically IgG, IgM, and IgA) to the offending material in serum and often also in BALF. A multitude of methods have been used to demonstrate antibody (ELISA and variants, indirect immunofluorescence, complement fixation, latex agglutination, counterimmunoelectrophoresis, radioimmunoassay, Western blot). As most clinical studies have used simple agar diffusion (“Ouchterlony”) methods to detect antibody, this is considered the standard method, but other methods are also acceptable (Fig. 5). The key issue is the ability of the antigen to detect antibody in the serum of patients with hypersensitivity pneumonitis. This varies with the methods of bacterial growth (for bacterial antigens) and of extraction of soluble antigens from either cultured material or material that causes hypersensitivity pneumonitis (e.g., hay in farmer's lung disease, bird droppings in bird fancier's disease). Because antigen preparations are not standardized, it is difficult to be confident of the meaning of a negative result unless the antigens have been tested against panels of sera from patients with and without hypersensitivity pneumonitis, so that reports of a negative hypersensitivity pneumonitis panel do not exclude the diagnosis of hypersensitivity pneumonitis. At times, it is useful to use antigens prepared from the environment suspected of causing hypersensitivity pneumonitis. This is especially important in patients with ventilator lung.

Serum antibody is also present in many subjects who are exposed but not ill, in virtually the same amounts as in patients with hypersensitivity pneumonitis. Therefore, the presence of antibody indicates exposure and sensitization and not necessarily disease. There is some suggestion that the presence of IgG and IgA antibody to *Trichosporon cutaneum* correlates with symptoms in subjects with Japanese-type hypersensitivity pneumonitis, whereas IgG antibody alone correlates with exposure but no symptoms. This correlation of exposure and symptoms with IgA antibody is not found in pigeon breeders or farmers. In asymptomatic pigeon breeders, the prevalence of antibody to pigeon antigens is 30%–60%. In farmers, the prevalence of anti-*Micropolyspora faeni* serum antibody is 2%–27%. The occurrence of serum antibody is not consistently related to apparent exposure (i.e., hours or intensity of exposure) in most instances of hypersensitivity pneumonitis. This may be related to a threshold effect, in that most exposures are above the minimum required to induce antibody and increases above that threshold are not associated with increases of the prevalence of antibody. In addition, serum antibody tends to wane after cessation of exposure, so that patients with chronic hypersensitivity pneumonitis who have not been exposed for some time may not have demonstrable antibody. In farmer's lung disease, approximately 50% of patients with initially positive serum antibody to *M. faeni* (*Saccharopolyspora rectivirgula*) lose demonstrable antibody 6 years after cessation of exposure. Farmers who continue to farm also lose detectable antibody (35%–50% in 5 years), and in some asymptomatic farmers initially without serum antibody, antibody later develops without farmer's lung disease. In pigeon breeder's disease and bird fancier's disease, approximately 50% of patients with initially positive serum antibody to avian antigens lose demonstrable antibody 2 to 3 years after cessation of exposure. Therefore, it is possible no serum antibody will be detectable in patients with hypersensitivity pneumonitis, either because an inappropriate antigen is used or because antibody has waned since the last exposure.

Nonspecific markers of inflammation, such as sedimentation rate and C-reactive protein, are often elevated during an acute episode of hypersensitivity pneumonitis. There are a few reports of increased prevalence of rheumatoid factor in patients with hypersensitivity pneumonitis. Antinuclear antibody or other autoantibodies are not present. There is increased uptake of gallium 67 in the lungs of patients with active hypersensitivity pneumonitis, which declines with improvement of the disease. Serum angiotensin-converting enzyme is not elevated, as it is in sarcoidosis.

Skin tests (of either immediate or delayed type) to detect sensitization to the suspected antigens are not useful, as extracts of agents that cause hypersensitivity pneumonitis produce nonspecific reactions that do not indicate sensitization and do not discriminate between sensitized and unsensitized subjects. In addition, preparations of antigens that cause hypersensitivity pneumonitis are not readily commercially available. Early reports indicated that some patients with hypersensitivity pneumonitis demonstrate 4- to 8-hour skin test reactivity (“Arthus type”), which correlates with the presence of serum antibody. However, the presence of this reaction does not add information important in the diagnosis of hypersensitivity pneumonitis, as antibody can be readily detected in serum.

Tests designed to detect cell sensitization (most commonly antigen-induced lymphocyte proliferation or lymphokine secretion) are not useful in the clinical diagnosis of hypersensitivity pneumonitis, although they have been performed in specialized research settings. Patients with hypersensitivity pneumonitis have depressed delayed-type skin reactivity to recall antigens, similar to that observed in patients with sarcoidosis.

Pulmonary function tests typically demonstrate a restrictive ventilatory defect with small lung volumes, normal or increased flow rates, increased lung elastic recoil, and usually decreased diffusing capacity. There is frequent occurrence of a mild obstructive defect and increased upstream airway, resistance probably related to either bronchiolitis or emphysema. Arterial hypoxemia with hypocapnia, reflecting an increased alveolar-arterial oxygen gradient, is common either at rest or after exercise.

Many (20%–40%) patients with hypersensitivity pneumonitis exhibit increased nonspecific airway reactivity, which may be related to increased numbers of mast cells in the lung and BALF or to bronchial epithelial damage, and in some (5%–10%) clinical asthma develops. The increased airway reactivity and asthma tend to diminish after cessation of exposure.

Pathogenesis

Multiple immunologic markers present in subjects with hypersensitivity pneumonitis suggest that immune mediation is important in the pathogenesis of this syndrome. In addition, the necessity for previous sensitization (indicated by the presence of serum antibody in virtually all patients with hypersensitivity pneumonitis) suggests immunologic mediation.

The presence of serum antibody in patients with hypersensitivity pneumonitis and the timing of symptoms after exposure (2 to 9 hrs) led to the hypothesis that

hypersensitivity pneumonitis represents an example of immune complex-mediated lung disease. However, the presence of antibody in subjects who are exposed but not ill, the lack of correlation between the presence of serum antibody and abnormalities on pulmonary function tests, the lack of evidence of complement consumption during acute exposure, the pathologic features that include granulomatous changes, and findings from animal models strongly suggest that cell-mediated immune processes are very important in hypersensitivity pneumonitis.

Many of the agents responsible for hypersensitivity pneumonitis can act as adjuvants and are particulate (promoting retention of antigen within the lung for prolonged periods of time), persistent, and nondegradable. They can interact with humoral mediators (complement and antibody) and cells in the lung to produce inflammation. The agents can induce injury by causing polymorphonuclear leukocytes and macrophages to release phlogistic substances such as reactive oxygen compounds, proteolytic enzymes, and products of arachidonic acid metabolism (prostaglandins and leukotrienes). The agents can also cause the production and release of IL-1, TNF-a and IL-6 from macrophages and lymphokines (IL-2, interferon-g, and B-cell growth and differentiation factors) from lymphocytes. Injury to the lung caused by the above factors could enhance pulmonary exposure to inhaled antigen, which might promote immunologic sensitization and subsequent further pulmonary damage. The result of all these processes is pulmonary inflammation.

In animal models of hypersensitivity pneumonitis, T cells and macrophages are central in the induction and expression of hypersensitivity pneumonitis. Macrophage-derived cytokines, such as IL-1a, IL-6, TGF, and TNF-a, seem to play a central role in models involving intrapulmonary administration of materials that cause hypersensitivity pneumonitis.

Administration of cyclosporine A ameliorated pulmonary lesions in animals subjected to airway challenges with *Thermoactinomyces vulgaris,* another agent causing hypersensitivity pneumonitis, and nude mice did not exhibit pulmonary lesions of hypersensitivity pneumonitis after exposure that produced lesions in thymus-intact littermates. Ability to express pulmonary lesions can be transferred with T cells from sensitized mice. Pulmonary fibrosis induced by repeated challenges with *M. faeni,* but not an increase of BALF inflammatory cells, can be reduced by administration of anti-CD11a, implicating integrins in the processes that lead to fibrosis in this model.

Adoptive transfer models of hypersensitivity pneumonitis allow differentiation between direct lung damage (toxicity), sensitization (the development of antibody and cellular reactivity), and the results of immunologic reactions (the interaction of antigen with antibody and/or cells). We have developed such a model in inbred guinea pigs and mice that allows transfer of susceptibility to *M. faeni* by cultured cells from sensitized animals.

Culture of peritoneal exudate, spleen, or peripheral or lung-associated lymph node cells with a soluble extract of *M. faeni,* the agent that causes farmer's lung disease, confers the ability to induce susceptibility to pulmonary injury in recipients of transferred cells 4 days after an intratracheal injection of *M. faeni.* The pulmonary injury is characterized by increased number of mononuclear cells in the lungs in both perivascular and peribronchiolar locations. This phenomenon depends on sensitization of the donor with *M. faeni,* culture with soluble *M. faeni,* and the number of transferred cells, and it persists for at least 8 weeks after cell transfer. Serum from sensitized animals cannot transfer experimental hypersensitivity pneumonitis. Three different mouse strains (C3H/HeJ, SJL/J, and C57Bl/6) do not differ in response. The postculture cells responsible for transfer are $CD3^+$, $CD4^+$, $CD8^+$, and $SIGM^-$ T cells. Development of cells able to transfer depends on the presence of $CD3^+$ and $CD4^+$ but not $CD8^+$ cells at the onset of culture. The transferring cells are a mixture of naïve and memory (as defined by CD44, CD45RB, and L-selectin, markers) $CD4^+$ cells. The presence of recipient $CD3^+$ and $CD4^+$ but not $CD8^+$ cells is required for expression of adoptive experimental hypersensitivity pneumonitis. IFN-g and IL-2 are present in substantial quantities in culture supernatants, suggesting a predominance of Th1 $CD4^+$ cells. The presence of serum IgG_4 antibody to pigeon antigens correlates with lack of symptoms in pigeon breeders. As IgG_4 is an immunoglobulin isotype that is induced by IL-4 and suppressed by IFN-g, this suggests that hypersensitivity pneumonitis may be characterized by predominance of Th1 type immunologic reactivity.

Prognosis and Treatment

Prognosis varies considerably with the type of hypersensitivity pneumonitis or even the geographic location. For example, farmer's lung disease has a good prognosis in Quebec, even in farmers who continue to farm. However, in Finland it often results in significant physiologic impairment and even death. Pigeon breeder's disease in the United States and Europe has an good prognosis, whereas the same disease in Mexico has a 30% 5-year mortality. The reasons for these differences are not clear, but they likely include differences in the antigen, differences in the nature of the exposure, or both.

Removal from exposure to the offending antigens is usually sufficient to effect a resolution of symptoms and physiologic abnormalities within a few days for acute hypersensitivity pneumonitis and within a month for chronic hypersensitivity pneumonitis. In some patients, symptoms and signs of pulmonary fibrosis persist more than 6 months, which suggests a poor outcome. Removal from exposure completely is most effective, but cleaning of the environment in situations in which removal is impractical (e.g., Japanese summer-type hypersensitivity pneumonitis) can prevent further episodes of hypersensitivity pneumonitis. There is one report of resolution of symptoms of hypersensitivity pneumonitis after installation of filters in an air-conditioning system, which greatly lowered mold colony counts. Pigeon lofts in which litter materials designed to absorb pigeon excreta are not used have significantly lower levels of airborne pigeon antigens than lofts in which litter material is used. It is not known whether avoidance of litter materials is associated with a decrease in pigeon breeder's disease.

Systemic glucocorticosteroids are sometimes required to treat severe disease, although there is no formal evidence that such treatment is associated with long-term improvement in symptoms or radiologic or pulmonary function test abnormalities. The usual treatment is 40 to 60 mg of prednisone or prednisolone per day for 2 weeks, followed by a gradual decrease to no medication within 1 to 2 months. Patients with farmer's lung disease treated with prednisolone demonstrated slightly more rapid resolution of some radiologic abnormalities (ground-glass opacities) and physiologic abnormalities (slight improvement of diffusing capacity, no difference in lung volumes or arterial oxygen tension) than did untreated patients. However, there were no differences between the groups 6 months after the diagnosis of hypersensitivity pneumonitis. The above evidence suggests that systemic steroids may slightly increase the rate of resolution of acute pulmonary inflammation but have little or no effects on chronic residue of hypersensitivity pneumonitis. Inhaled glucocorticosteroids, nonsteroidal anti-inflammatory agents (cromolyn or nedocromil), and systemic immune modulators are not indicated in the treatment of hypersensitivity pneumonitis.

If patients are removed from exposure before permanent radiologic or physiologic abnormalities develop, the prognosis is excellent, with little evidence of long-term ill effects. If removal from exposure is impossible, the use of efficient masks during exposure can result in the prevention of acute hypersensitivity pneumonitis and is associated with an excellent prognosis. If exposure persists, some patients (proportion unclear, but probably 10%–30%) will progress to diffuse pulmonary fibrosis with resultant cor pulmonale and premature death. Mortality from farmer's lung disease is reported to be between 0% and 20% and usually occurs after 5 years of recurrent symptoms, although there are a few case reports of death after acute massive exposure to antigen. The prognosis varies considerably with different types of hypersensitivity pneumonitis. In general, long-term, relatively low-level exposure seems to be associated with a poorer prognosis, whereas short-term, intermittent exposure is associated with a better prognosis. This is well illustrated by pigeon breeder's disease, which in the United States and Europe has an excellent prognosis; most patients were asymptomatic and no deaths had occurred 10 years after diagnosis in a group of 24 patients with pigeon breeder's disease. In contrast, for patients in Mexico City who have pigeon breeder's disease, the mortality is 30% after 5 years. Unfortunately, many patients who present with chronic hypersensitivity pneumonitis also have pulmonary fibrosis and physiologic abnormalities that are only partially reversible after cessation of exposure.

Markers of pulmonary inflammation at the time of presentation, such as a high proportion of BALF lymphocytes, neutrophils, or mast cells, or the presence of procollagen III, hyaluronic acid, fibronectin, and fibroblast growth factors in BALF, do not predict outcome.

In conclusion, hypersensitivity pneumonitis is an immunologically mediated lung disease in which T cells and macrophages play important roles. It is diagnosed by a careful history and appropriate laboratory tests. Avoidance of exposure is usually associated with a good prognosis. Because of constantly changing environmental exposures, new examples of hypersensitivity pneumonitis are constantly being described and represent a continuing challenge to astute clinicians.

Role of NK1.1$^+$ T cells in a Th2 response and in immunoglobulin E production. *Science* 1995;270:1845–1847. *This report describes an unusual cell type that provides an explanation for source of IL-4 needed to induce Th2 differentiation of naïve T cells, especially for help in IgE production. Because these cells recognize antigen presented by CD1$^+$ antigen-presenting cells, dysregulation of CD1 expression may be one cause of atopy.*

CHAPTER

20 Systemic Sarcoidosis

Lynn T. Tanoue · Jack A. Elias

L. T. Tanoue and J. A. Elias: Department of Internal Medicine, Yale University School of Medicine,New Haven, Connecticut 06510.

INTRODUCTION

Between 1865 and 1875, Sir Jonathan Hutchinson is believed to have encountered the first case of what we now recognize as sarcoidosis. In 1889, Besnier described a patient with raised violaceous facial lesions that he called *lupus pernio.* His report was followed by one by Tenneson describing the presence of granulomas and the absence of tubercle bacilli in similar skin lesions. In 1899, Boeck described a patient with pronounced lymphadenopathy and multiple nodules of the skin, face, and back. When these lesions were examined histologically, Boeck was struck by their close resemblance to a sarcoma and gave them the name *benign sarcoid.* Schauman in 1914 and Kuznitsky and Bittorf in 1915 recognized that sarcoid skin lesions, lupus pernio, and visceral lesions were all part of the same multisystem disorder. This important observation set the stage for the recognition of sarcoidosis as a distinct entity. In the years since its recognition, sarcoidosis has been the topic of intense investigation. These studies have shed light on some of the clinical manifestations, epidemiologic characteristics, and pathogenic mechanisms of the disease. However, although commonly encountered and frequently diagnosed, sarcoidosis is still poorly understood. Its etiology is unknown, our knowledge of its pathogenesis is incomplete, and its diagnosis, staging, and treatment are steeped in controversy. In this chapter, we have attempted to outline the areas of certainty and uncertainty regarding this disorder. We also hope to provide a rational approach that can be used for evaluating and treating affected patients.

DEFINITION

A number of attempts have been made to formulate a definition of sarcoidosis. In 1948, the National Academy of Sciences proposed a definition that was essentially an extensive clinical definition of the manifestations of the disease. In 1976, the Subcommittee on Classification of the Seventh International Conference on Sarcoidosis proposed the following definition:

> Sarcoidosis is a multisystem granulomatous disorder of unknown etiology most commonly affecting young adults and presenting with bilateral hilar adenopathy, pulmonary infiltration, and skin or eye lesions. The diagnosis is established most securely when clinical or radiographic findings are supported by histologic evidence of widespread noncaseating epithelioid granulomas in more than one organ or by a positive Kveim-Siltzbach skin test. Immunologic features are depression of delayed-type hypersensitivity, suggesting impaired cell-mediated immunity and increased or abnormal immunoglobulins. There may also be hypercalciuria with or without hypercalcemia. The course and prognosis may correlate with mode of onset. An acute onset with erythema nodosum heralds a self-limited course and spontaneous resolution, whereas an insidious onset may be followed by relentless progressive fibrosis. Corticosteroids relieve symptoms and suppress inflammation and granuloma formation.

This definition is dated, overly descriptive, and its sheer bulk limits its utility. It is more useful to define sarcoidosis as a systemic granulomatous disorder of unknown etiology. In this definition there are three points that need emphasis: that sarcoidosis is a systemic disorder, that it is a granulomatous disorder, and that, despite many attempts, its etiologic agent or agents are unknown.

EPIDEMIOLOGY

The majority of patients with sarcoidosis are either asymptomatic or have such trivial symptoms that they do not bother to consult a physician. This makes an accurate assessment of the incidence of sarcoidosis in the United States difficult. Best estimates are that sarcoidosis in the United States occurs in 1 in 10,000 people per year, making for some 22,500 cases annually. Within the United States, sarcoidosis is 10 times more frequent in black than in white persons. It was thought to be particularly prevalent in the southeastern states. However, more recent epidemiologic studies have cast some doubt on this latter contention, as corrections of previous studies for differences in black and white population densities and new case-matched studies have shown that the incidence of sarcoidosis in the south and southeast is similar to that in other parts of the United States.

In parts of the world where mass radiographic screening is performed, more accurate estimates of the prevalence of sarcoidosis can be obtained. These studies have shown a prevalence rate of 64/100,000 in Sweden and 20/100,000 in the United Kingdom. Interestingly, rates as high as 200/100,000 are noted among Irish women of childbearing age, whereas the disease is quite rare in China and southeast Asia.

ETIOLOGY

The granulomatous lesions in sarcoidosis are similar to those caused by infectious agents, such as mycobacteria and fungi, or inorganic agents, such as zirconium and beryllium, and to those seen in hypersensitivity reactions to organic agents, such as thermophilic actinomycetes. These similarities have caused many to speculate that infectious agents or organic or inorganic dusts may be etiologic in sarcoidosis. Particular interest has been directed at the possibility that sarcoidosis is the result of an unusual host response to a common agent, or the result of an infection by, or inhalation of, a poorly characterized agent. Efforts to test these speculations have been ongoing for many years. These studies have failed to observe consistent associations between the occurrence of sarcoidosis and a person's place of birth, place of residence, or personal history of allergies, drug ingestion, exposure to pets, or occupational exposure. In addition, contentions that common and exotic agents such as viruses (including human immunodeficiency virus, or HIV-2), corynebacteria, fungi, and pine pollen play an etiologic role have not stood up under close scrutiny. The polymerase chain reaction (PCR) has recently been used to reinvestigate the role mycobacteria play in this disorder. Using this technique, some investigators have reported enhanced detection of mycobacterial DNA in patients with sarcoidosis. These studies overall had a high rate of false-positive PCR reactions. In contrast,

others have found mycobacterial DNA in only a small minority of patients with sarcoidosis. As a result, it cannot be concluded that *Mycobacterium tuberculosis* is etiologic in the majority of cases of sarcoidosis. Additional studies will be required to clarify this issue.

Epidemiologic studies have demonstrated that sarcoidosis is commonly encountered in people from northern Europe, is more common in American blacks than American whites, and can cluster in families. These observations suggest that genetic predisposition may be an important variable in disease acquisition. However, to date, no consistent mode of inheritance has been found. In addition, most studies have shown no consistent association between human leukocyte antigen (HLA) type and disease. The report that sarcoidosis is five and a half times as frequent in American blacks that are HLA-Bw15-positive than in those lacking this antigen is interesting, but it will require additional confirmation.

PATHOLOGY

The histologic features of sarcoidosis consist of varying degrees of granulomatous inflammation, interstitial pneumonitis, and tissue fibrosis. Which of these lesions predominates depends on the stage of the patient's disease.

Granulomatous Inflammation

The epithelioid granuloma is the characteristic lesion of sarcoidosis. These granulomas are usually not necrotic. When necrosis occurs, it is usually minimal and confined to the central portions of the lesion. The granulomas are usually distinct, even when densely clustered. Epithelioid cells and multinucleated giant cells are found in the center of the granulomas. They are intermingled with and surrounded by macrophages, monocytes, and lymphocytes (Fig. 1). In some cases, the granulomas are surrounded by fibroblasts and fibroblast-derived connective tissue products. The epithelioid cells are felt to be derived from tissue macrophages and are approximately 20 µm in diameter and 25 to 45 µm in length. They have ample, pale-staining cytoplasm, well-defined boundaries, and a central or eccentrically placed oval nucleus. Ultrastructural studies reveal abundant mitochondria, abundant rough and smooth endoplasmic reticulum, large numbers of vesicles, and a well-developed Golgi apparatus, suggesting that these cells have an enhanced secretory capacity. The multinucleated giant cells are believed to form from fused epithelioid cells. They are 150 to 300 µm in diameter and resemble the epithelioid cells ultrastructurally.

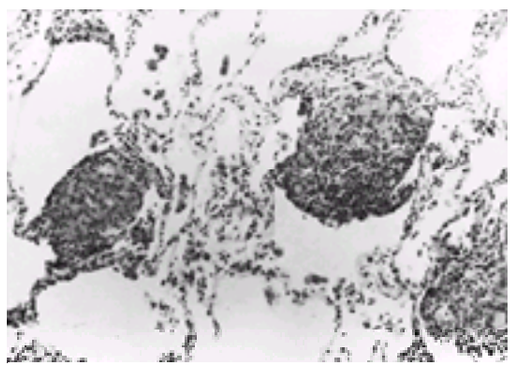

FIG. 1. Lung biopsy specimen demonstrating noncaseating granulomas in the lung interstitium.

The lymphocytes in and around these granulomas are often larger and contain more organelles than their circulating relatives. Characterization using monoclonal antibodies has shown that most of the T cells express the CD4 (OKT4) antigen, which is usually associated with a helper/inducer phenotype, and a minority express the CD8 (OKT8) antigen, which is usually associated with a cytotoxic/suppressor phenotype. As a result, the ratio of helper/inducer lymphocytes to cytotoxic/suppressor lymphocytes (CD4/CD8 ratio) in sarcoid granulomas is increased and parallels that noted in the cells obtained by bronchoalveolar lavage (BAL).

Noncaseating granulomas may be found in any organ in the body. In the lung they tend to be peribronchial, interstitial, and subpleural in location. Perivascular granulomas are also commonly noted. These lesions rarely extend past the vascular adventitia, and luminal distortion and endothelial cell disruption are rare. True vasculitis can be found in 42%–67% of lung biopsy specimens in sarcoidosis. However, in the vast majority of cases, the vasculitis is a minor aspect of the lesion. When vasculitis is prominent, alternative diagnostic possibilities should be considered, such as necrotizing sarcoidal vasculitis or Wegener's granulomatosis.

Interstitial Pneumonitis

Although the epithelioid granuloma is the characteristic lesion of sarcoidosis, it is probably not the first lesion to be present. The granulomas are preceded by, and then noted in conjunction with, an interstitial pneumonitis characterized by macrophages and lymphocytes, the majority of which are T cells. The macrophages and lymphocytes in these infiltrates appear to be activated, as they are larger and contain more organelles than corresponding cells in the circulating pool. The exact relationship between the intensity of the interstitial pneumonitis and the density of granuloma formation is not understood. The possibility that the granulomas are a consequence of the interstitial pneumonitis may explain why most studies find that the granulomas are most prominent when the interstitial pneumonitis is least intense, and vice versa.

Tissue Fibrosis

The interstitial pneumonitis and granulomatous inflammation seen in sarcoidosis are dynamic processes. Some lesions remain cellular for an extended period of time. In contrast, the majority resolve, either spontaneously or in response to steroid therapy. Approximately 75%–80% of these resolving lesions heal with preservation of the normal parenchymal architecture. In the rest, the fibroblasts at the periphery of the granulomas proliferate and increase their production of collagens and other matrix molecules. As a result, the granuloma is replaced in a centripetal fashion with scar tissue. In the process, normal alveolar and bronchial architecture are distorted and the pulmonary vascular surface area is compromised. Bronchiectasis and cystic parenchymal lesions can result, and in the most severe cases, honeycombing and pulmonary hypertension can occur.

IMMUNOPATHOGENESIS

Sarcoidosis is the prototypic example of a compartmentalized immune response. Heightened cell-mediated immunity is seen within the lung and at other sites of disease involvement. In contrast, depressed cell-mediated immunity, often with cutaneous anergy, is seen in the peripheral circulation. Studies during the last few decades have added significantly to our understanding of the cellular events involved in the inflammatory and fibrotic phases of this disease. As a result, we have an improved understanding of the state of activation and effector function of the cells in sarcoidal infiltrates, a picture of how these alterations mediate pulmonary inflammation, and a preliminary understanding of the role that cytokines may play in granuloma formation.

T Cells

In sarcoidosis, helper T lymphocytes accumulate at sites of disease activity. The ratio of helper ($CD4^+$) to suppressor ($CD8^+$) cells is increased in bronchoalveolar lavage fluid (BALF). The T cells that accumulate in the lungs of patients with sarcoidosis and are found in BALF are activated, as they express markers of cell-surface activation, such as the major histocompatibility complex (MHC) DR antigen, the VLA-1 late activation antigen, and the interleukin-2 (IL-2) receptor (Tac antigen). Unlike unstimulated T lymphocytes, they also spontaneously produce a variety of cytokines, including IL-2, interferon-g (IFN-g), monocyte chemotactic factor (MCF), and a factor (possibly IL-6) that induces the differentiation of B cells to immunoglobulin-secreting cells. The IL-2 that is produced by sarcoid T cells appears to bind to the IL-2 receptor and stimulates T-cell proliferation in an autocrine and/or paracrine fashion. Interestingly, although BALF T cells are spontaneously activated, like peripheral lymphocytes, their response to “recall” antigens such as purified protein derivative (PPD) and *Candida* is decreased. The reason for this is not clear. This decreased memory function may explain in part the cutaneous anergy observed clinically in some patients with sarcoidosis.

T cells recognize foreign antigens via their T-cell receptors (TCR). Each T cell expresses a receptor for a unique antigen. The diversity of receptors necessary to encode an appropriately diverse immune repertoire is generated by creating TCR that differ in the constant (C), joining (J), and variable (V) regions of the two proteins that make up the heterodimeric TCR complex. In an attempt to identify the agent(s) causing the lymphocytosis in sarcoidosis, the TCR on the surface of BALF and peripheral blood lymphocytes have been extensively studied. These studies have shown that BALF T lymphocytes are not a clonal population. Some studies have, however, detected a distinct bias for the use of TCR with the V_b8 and $V_a2.3$ variable region subtypes and the C_b1 constant region subtype. Others have reported

subgroups of individuals who have sarcoidosis with expression in blood or lung of one or more of five V_b gene families (V_b5, V_b8, V_b15, V_b16, V_b18). These findings suggest that T-cell activation in sarcoidosis is not a nonspecific process. Instead, the lymphocytosis appears to be a specific response to a limited number of antigens.

The majority of T cells in sarcoidosis lesions express a and b TCR proteins (e.g., they are ab T lymphocytes). However, a subgroup of individuals with sarcoidosis has been reported in which the BALF T lymphocytes contain gd TCR. This observation is quite interesting, as gd T cells may play an important role in the cellular immune response to mycobacterial antigens and mucosal immunity. Immunohistochemical studies, however, have failed to detect gd T cells within sarcoid lymph nodes. This discrepancy has not yet been resolved. However, it may reflect differences in the kinetics of T-cell accumulation, as gd T cells may be found only at sites of active early alveolitis.

T-Lymphocyte Subsets

Recent studies of murine, and to a lesser extent human, lymphocytes have demonstrated the existence of subpopulations of cells based on the patterns of cytokines that they produce. Two major subpopulations of CD4 (and other) lymphocytes have been noted, Th1 (T helper) and Th2 cells. Th1 cells produce IFN-g and IL-2, cytokines that are important in macrophage activation. These cells are felt to be mediators of delayed-type hypersensitivity responses. In contrast, Th2 cells express IL-4 and IL-5, cytokines that are important in antibody-mediated responses, IgE class switching, and eosinophilia. Th2 cells are therefore felt to be mediators of humoral and eosinophil-mediated disorders, such as atopy and allergy. These lymphocyte subsets also cross-regulate each other, with Th1 cell-derived IFN-g downregulating the cytokine production and proliferation of Th2 cells, and Th2-derived Il-4 and Il-10 having similar inhibitory effects on Th1 cells. In addition, the macrophage-derived cytokines IL-10 and IL-12 play an important role in the regulation of these processes, with IL-12 augmenting Th1 responses and IL-10 augmenting Th2 responses.

The Th1-Th2 paradigm provides a theoretical explanation for why cell-mediated immunity dominates in some circumstances, whereas antibody-based responses predominate in others. A variety of lines of evidence suggest that Th1-mediated processes play an important role in sarcoidosis. A variety of experimental granulomatous models have been shown to be Th1-mediated. In addition, BALF studies of patients with sarcoidosis have demonstrated increased levels of IFN-g, IL-2, and IL-12 and low or undetectable levels of IL-4, IL-5, and IL-10. Similarly, T cells from the lungs of patients with sarcoidosis produce exaggerated amounts of IL-1 and IFN-g. Additional experimentation will be required to confirm the impression that sarcoidosis is a Th1-predominant disorder.

Monocytes/Macrophages

Monocytes, macrophages, epithelioid cells, and giant cells are important participants in the alveolitis of patients with sarcoidosis. The macrophages appear to be activated in vivo, because, in contrast to the alveolar macrophages of normal persons, they spontaneously release proinflammatory cytokines, such as IL-1, IL-6, tumor necrosis factor (TNF), granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF), and secrete increased quantities of 1,25-dihydroxyvitamin D, angiotensin-converting enzyme, and reactive oxygen metabolites, such as hydrogen peroxide. Sarcoid alveolar macrophages also have an increased capacity to present antigen compared with normal macrophages. This may reflect the increased adhesiveness of sarcoid macrophages and lymphocytes. In accord with this concept, sarcoid alveolar macrophages express increased amounts of the cellular surface adhesion molecules leukocyte function-associated antigen-1 (LFA-1) and intercellular adhesion molecule-1 (ICAM-1). In addition to secreting cytokines, these macrophages express cell surface IL-2 receptors and can thus be activated by the IL-2-secreting T cells at sites of inflammation.

Fibroblasts

Fibroblasts have been traditionally thought of as effector cells that, under the influence of T cells and macrophages, produce matrix components, such as collagen. The demonstration that IL-1 and TNF regulate fibroblast production of types I and III collagen has provided additional support for the concept that dysregulated cytokine production by activated mononuclear cells can lead to fibroblast activation and tissue fibrosis in sarcoidosis. It is now being increasingly appreciated, however, that fibroblasts are also important immune effector cells at sites of inflammation. IL-1 and TNF can induce fibroblast production of a wide variety of cytokines, including IL-6, monocyte chemotactic peptide-1 (MCP-1), IL-8, IL-11, leukemia inhibitory factor, G-CSF, and GM-CSF. IL-6, MCP-1, and the CSFs may be particularly important in sarcoidosis. IL-6 activates the acute-phase response, B-cell immunoglobulin production, and T-cell proliferation; MCP-1 recruits fresh peripheral blood monocytes to sites of inflammation; and the CSFs activate local macrophages. IL-1 and TNF can also increase the adherence of T lymphocytes to lung fibroblasts, a mechanism by which fibroblasts may contribute to the compartmentalized activation of T cells seen in this granulomatous disorder.

Mechanisms of Tissue Inflammation in Sarcoidosis

Inflammatory responses in the sarcoid lung are therefore regulated, at least in part, by a complex network of interacting cytokines. The majority of the alveolar macrophages in the lung are derived from circulating blood monocytes. They enter the lung along chemotactic gradients and have a limited but definite capacity to proliferate locally. Infectious agents and/or noxious stimuli that reach the lung via the airways can activate resident macrophages to produce TNF, IL-6, IL-8, transforming growth factor-b (TGF-b), platelet-derived growth factor (PDGF), modest amounts of soluble IL-1b, and insulin-like growth factor (IGF). IL-8, in conjunction with IL-1, TNF, activated complement fragments, and other chemotactic agents, activates and recruits leukocytes to the lung. This recruitment is at least partially a consequence of cytokine-enhanced endothelial cell adhesion molecule expression. The cytokines also interact with antigen-presenting cells (such as alveolar macrophages and/or dendritic cells) to activate T lymphocytes. Activated T lymphocytes express high-affinity IL-2 receptors and produce a variety of cytokines, most notably IL-2, IFN-g, and IL-6. IL-2, as noted above, acts in an autocrine and/or paracrine fashion to stimulate lymphocyte proliferation. IFN-g and IL-2 activate local macrophages, and IL-6 contributes to the proliferation and terminal differentiation of B lymphocytes into antibody-producing plasma cells. IL-1, TNF, and other moieties also stimulate local stromal cells, such as fibroblasts, to produce cytokines such as IL-6, MCP-1, IL-1a, and colony-stimulating factors. These proinflammatory molecules further augment local T-cell and B-cell responses and activate local macrophages. The IL-1, TNF and IL-6 that are produced also enter the systemic circulation, where they stimulate the production of acute-phase proteins and induce fever. In addition, TGF-b, IL-1, PDGF, and IGF may also stimulate the fibrotic response, as under appropriate circumstances each can stimulate fibroblast proliferation and/or collagen production.

As noted above, the alveolar macrophages and T cells in the lungs of patients with sarcoidosis appear to be activated in vivo. These cells express cytokine receptors and produce, in an exaggerated fashion, many of the cytokines responsible for the interactions noted above. Specifically, alveolar macrophages express IL-2 receptors and produce IL-1, TNF, GM-CSF, PDGF, and TGF-b. T-cell IL-2 receptor expression and IL-2, IFN-g, and MCF production are also augmented. The IFN-g that is produced may be a key mediator in the pathogenesis of this disorder, as IFN-g activates macrophage IL-1 production, 1,25-dihydroxyvitamin D production, hydrogen peroxide production, IL-2 receptor expression, and macrophage fusion into multinucleated giant cells. MCF encourages monocyte entry into sites of inflammation, and the IL-1 and TNF that are produced activate stromal cell IL-6 production. IL-1, TNF, and IL-6 induce fever and stimulate the heightened acute-phase response characteristically seen in patients with sarcoidosis. The elevated levels of IL-6 may also contribute to the polyclonal hypergammaglobulinemia seen in this disorder.

The Kveim Reaction

It has been known since 1941 that in patients with sarcoidosis a localized cutaneous nodule often develops 2 to 6 weeks after intradermal injection of an extract of spleen or lymph node from another patient with sarcoidosis. Biopsy specimens of these Kveim-Siltzbach test lesions exhibit histopathologic similarities to sarcoid granulomas. Moreover, Kveim-Siltzbach lesions and sarcoid granulomas have a similar distribution of $OKT4^+$ and $OKT8^+$ lymphocytes and a similar distribution of specific Vb and T-cell subsets. Despite these similarities, there are several reasons why the Kveim reaction cannot be classified as a true immunologic response. First, a delayed-type hypersensitivity reaction becomes positive within 48 to 72 hours and resolves within a week. In contrast, Kveim nodules develop after 4 to 6 weeks and persist for several months. Second, despite an intensive search, a specific antigen has not been identified in this material. Attempts to induce patient lymphocytes to proliferate or secrete cytokines after in vitro exposure to Kveim material have been largely unrewarding.

CLINICAL MANIFESTATIONS

The manifestations of sarcoidosis in persons who come to medical attention vary with their ethnic and racial background and the degree to which the local medical community utilizes chest radiographic screening that would detect milder or asymptomatic forms of the disease. Sarcoidosis can involve and cause symptoms in virtually any organ in the body. A detailed description of every manifestation is beyond the scope of this chapter. Instead, attention is focused on the major modes of presentation and patterns of organ involvement.

Presentation

As many as 50% of patients with sarcoidosis are asymptomatic at the time of diagnosis. Physicians become aware of these patients as a result of abnormalities noted incidentally on chest x-ray films that have been performed for other reasons. Patients who are symptomatic at the time of presentation generally have pulmonary, ocular, dermatologic, or systemic complaints (Table 1). Overall, pulmonary symptoms are noted in 15%–40% of patients presenting with sarcoidosis. Shortness of breath, dyspnea on exertion, cough, and substernal chest pain are common. Between 10% and 32% percent of patients with sarcoidosis present with skin lesions. Erythema nodosum is seen approximately twice as often as the other, more specific skin manifestations, and is frequently found in association with fever, malaise, and

polyarthralgias. Maculopapular lesions, nodules, and ulcers also can be presenting manifestations. Granulomatous infiltration of old scars resulting in swelling, purple discoloration, and occasionally tenderness also may cause the patient to seek medical attention. Approximately 10%–25% of patients present with ocular symptoms, most commonly caused by acute uveitis and consisting of redness of the eye, tearing, cloudy vision, and photophobia. This type of acute ocular involvement is often seen in association with erythema nodosum and bilateral hilar adenopathy. Systemic symptoms are reported by approximately 40% of patients and are more common in blacks and Asians from the Indian subcontinent. The fever is usually mild, and weight loss is usually limited to 5 to 15 lb within the preceding 3 months. However, temperatures as high as 104°F, more severe weight loss, and night sweats, anorexia, fatigue, and myalgias are well described.

Complaint	Percentage of patients
Asymptomatic	12–35
Systemic	15–40
Fatigue	20–30
Malaise	15
Weight loss	20–30
Fever	15–22
Night sweats	15
Weakness	10
Chills	10–15
Respiratory	15–40
Cough	30–40
Dyspnea	20–30
Sputum production	10–12
Hemoptysis	1–3
Chest pain	15–25
Skin lesions	10–28
Ocular symptoms	10–20
Joint complaints	5–17
Neurologic symptoms	2–5
Cardiac symptoms	1–5

TABLE 1. *Presenting complaints of patients with sarcoidosis*

Intrathoracic Involvement

Respiratory tract involvement is the most common manifestation of sarcoidosis. In 90% of patients, signs and symptoms of respiratory sarcoidosis are present at some time during the disease. The true incidence of respiratory involvement may actually be higher, as biopsy specimens of patients with sarcoidosis whose lungs are radiographically and physiologically normal often reveal granulomas. Parenchymal lung involvement and lymph node enlargement are the most common thoracic manifestations. Airway, pleural, and blood vessel involvement are also well documented.

Lymph Node and Parenchymal Involvement

By international convention, a staging system for sarcoidosis has been devised based on the appearance of a patient's chest x-ray film (Table 2). Up to 8% of patients present with stage 0 disease. They have evidence of extrathoracic disease and normal chest x-ray findings. As mentioned, a high percentage of these patients have granulomas on lung biopsy, indicating subclinical involvement of the pulmonary parenchyma. Approximately 40%–60% of patients present with stage I disease. The chest x-ray films of these patients demonstrate bilateral hilar lymphadenopathy, with or without paratracheal adenopathy, but without radiographically apparent lung infiltrates. Stage II radiographs are noted in 15%–30% of patients at the time of diagnosis. These radiographs demonstrate bilateral hilar adenopathy (with or without paratracheal adenopathy) with associated lung field involvement. The remaining 10%–15% of patients with sarcoidosis present with stage III radiographs, which show lung field involvement only. Patients without adenopathy whose lung field involvement is notable for severe pulmonary fibrosis, volume loss, cysts, bullae, and honeycombing are defined as having stage IV disease by some (but not all) investigators (Fig. 2).

Stage	Radiographic abnormality
0	None
I	Hilar, mediastinal, or paratracheal adenopathy
II	Hilar, mediastinal, or paratracheal adenopathy with pulmonary parenchymal abnormalities
III	Pulmonary parenchymal abnormalities without adenopathy
IV	Fibrobullous pulmonary paraenchymal disease without adenopathy

TABLE 2. *Staging of sarcoidosis by chest radiograph*

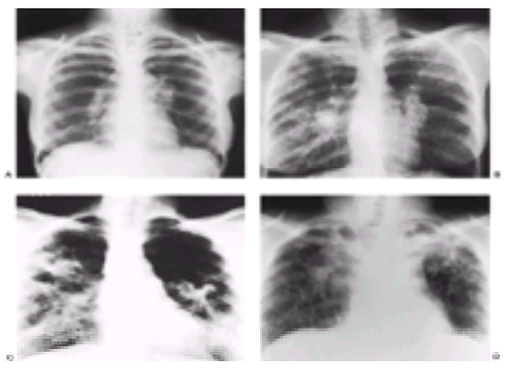

FIG. 2. Radiographs illustrating the different stages of sarcoidosis. **A:** Stage I. Bilateral hilar adenopathy and paratracheal adenopathy with normal lung fields. **B:** Stage II. Bilateral hilar adenopathy with interstitial lung field involvement. **C:** Stage III. Lung field involvement only. **D:** Stage IV. Severely fibrotic lungs with volume loss and cyst formation.

Radiographically, bilateral hilar adenopathy is the most common pattern of lymph node involvement in sarcoidosis. This enlargement can be striking, causing some to refer to the lymph nodes as “potato” nodes. Paratracheal adenopathy has been reported in up to 71% of cases. This adenopathy is less common on the left, because the left paratracheal lymph nodes are located more posteriorly, are smaller in size, and are fewer in number than their counterparts on the right. Aortopulmonary window and subcarinal adenopathy are noted in 33%–75% and approximately 21% of patients, respectively. By virtue of their location, these lymph nodes can, on rare occasion, cause symptoms by compressing the esophagus and nearby bronchi and vessels. When sarcoidosis causes anterior mediastinal lymph node enlargement, hilar adenopathy is almost always present. Lymphomas, metastatic malignancies, and other pathologic conditions must be strongly considered when isolated anterior mediastinal adenopathy is present. Similarly, posterior mediastinal adenopathy and unilateral hilar adenopathy are rare in sarcoidosis and should cause the physician to pursue other diagnostic possibilities. Parenchymal involvement in sarcoidosis can take on a variety of radiographic appearances. It is most commonly symmetric, diffuse and reticular, reticulonodular, or finely nodular in appearance. Symmetric bilateral lesions of the upper lobe or lesions predominant in the mid-lung field are also well documented, as are diffuse alveolar infiltrates. Unilateral disease, multiple large nodules, and even solitary nodules have been reported. However, alternative diagnostic possibilities must always be looked for when these patterns are noted. When sarcoidosis progresses, the parenchymal infiltrates become coarser and coalesce, and pulmonary architecture becomes distorted. This can cause the development of bronchiectasis, cysts, bullae, and, at worst, a honeycombed lung with volume loss, signs of pulmonary hypertension, and cor pulmonale.

Computerized tomography (CT) and magnetic resonance imaging (MRI) of the chest are more sensitive than plain chest radiographs, as they can reveal focal pulmonary parenchymal abnormalities in patients with stage O or stage I disease by chest radiograph. It has been suggested that the presence of ground-glass densities on CT in sarcoidosis and other infiltrative lung diseases may correlate with an inflammatory state likely to be responsive to treatment. The practical value of

this information in terms of prognosis or correlation with functional status remains to be determined.

The architectural distortion that takes place in patients with advanced sarcoidosis predisposes them to a number of complications. Areas of cavitation and bronchiectasis are susceptible to repeated infections. In addition, mycetoma caused by *Aspergillus* (and rarely other fungi) can form in these cavities and have been reported in as many as 40% of patients with cavitary disease. Progressive pleural thickening in the area around a cavity may be the earliest indication that an aspergilloma is forming. CT may be useful in demonstrating these structural abnormalities. Diagnosis requires the presence of IgG-precipitating antibodies to the fungus and demonstration of a mycetoma in the cavity by conventional chest radiography or CT. These aspergillomas can cause hemoptysis that, on occasion, may be life-threatening. Treatment of patients with mycetoma and massive hemoptysis is often problematic, as their underlying respiratory insufficiency precludes surgery for some and increases the risk of surgery for the others. In patients who cannot be treated surgically, anecdotal evidence suggests that bronchial arterial embolization and intracavitary instillation of amphotericin B may be useful. Less commonly, in patients with mycetoma a hypersensitivity reaction develops to the colonized fungus. This can be manifested as a bronchospastic lung disorder with many of the clinical and immunologic characteristics of allergic bronchopulmonary aspergillosis.

Airways Involvement

Endobronchial biopsy specimens reveal a granulomatous infiltration of the mucosa and submucosa in 30%–70% of patients with sarcoidosis. At its mildest, this involvement does not alter the appearance of the bronchial mucosa. When more severe, nodules are seen, and a cobblestone pattern has been described. As in the interstitium of the lung, this granulomatous infiltration can lead to a fibrotic reaction causing fixed lesions and, in its most severe form, diffuse bronchial stenosis with bronchial occlusion (Fig. 3). Endobronchial involvement can be seen in all radiographic stages of the disease. The lesions may cause airway narrowing, atelectasis, and ventilation-perfusion mismatching. The clinical manifestations of patients with severe endobronchial involvement are often different from those of the usual patient with sarcoidosis. Like patients with asthma, chronic obstructive pulmonary disease (COPD), or upper airway obstruction, they can have repeated pneumonias and bronchitis and experience dyspnea, stridor, chronic cough, and recurrent episodes of bronchospasm. Bronchiectasis may also result.

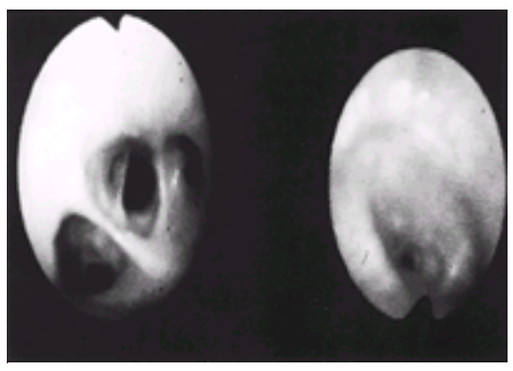

FIG. 3. Comparison of the appearance of a normal endobronchial tree (*left*) and the endobronchial tree of a patient with bronchial stenosis caused by sarcoidosis (*right*).

Pleural Involvement

Pleural involvement in sarcoidosis is relatively uncommon, occurring in 1%–12% of patients. This involvement can be manifested as pleural thickening, pleural effusion, or spontaneous pneumothorax. Effusions occur with equal frequency on the right and left and are bilateral 33% of the time. They are usually small or moderate in size. Massive effusions are rare. Pleural biopsy may show noncaseating granulomas, and presumably this granulomatous infiltration is the cause of the effusion. Vascular compression from mediastinal adenopathy is rarely a cause of pleural effusion in patients with sarcoidosis. The pleural fluid is usually exudative, occasionally hemorrhagic, and usually shows a predominance of lymphocytes. An increase in eosinophils may also be seen. Effusions have been described in patients with all radiographic stages of sarcoidosis. However, they are more common in patients with widespread parenchymal lung disease and have not been reported as the sole manifestation of the disease. The presence of a pleural effusion in a patient with sarcoidosis must always be interpreted with caution, and other causes of pleural disease, including tuberculosis, mycotic or bacterial infections, congestive heart failure, and malignancies, must always be considered. The natural history of pleural effusions in sarcoidosis is not totally known. Most appear to resolve without gross residua, either spontaneously or in association with steroid therapy. Progression to chronic pleural thickening has been reported.

Spontaneous pneumothorax in sarcoidosis is usually caused by the rupture of subpleural blebs or the necrosis of subpleural granulomas. This occurs most commonly in patients with advanced fibrotic lung disease with upper lobe bullae, but it can also occur in patients with stage O or stage I disease.

Pulmonary Vasculature

Granulomatous vasculitis involving both arteries and veins has been described in patients with sarcoidosis but is generally asymptomatic. On rare occasions, it can cause pulmonary hypertension.

Pulmonary Physiology

In 1940, Bruce and Wassen demonstrated a reduction in vital capacity and total lung capacity in the first study of the lung function of patients with sarcoidosis. Subsequent studies have confirmed these observations and have demonstrated that although the pulmonary physiologic parameters of some patients with sarcoidosis are normal, in most cases they are not. Like most other interstitial lung diseases, sarcoidosis commonly causes restrictive physiology and a gas transfer abnormality. The restrictive defect is manifested by reduced lung volumes and decreased lung compliance in the presence of normal large-airway function. The gas transfer abnormality is characterized by a reduced diffusing capacity for carbon monoxide.

Dysfunction of large and small airways resulting from the peribronchial distribution of granulomas is also an important component of the pathophysiology of sarcoidosis. Large-airways obstruction with a decreased FEV_1/FVC ratio is noted in a minority of patients. It has been described in all radiographic stages of sarcoidosis but is more common in patients with stage III or stage IV disease. It is usually caused by bronchial distortion and/or bronchiectasis from granulomas, edema, and scarring. It is rarely reversible and may cause symptoms of wheezing and dyspnea. If appropriately tested for, small-airways dysfunction can be seen in the majority of patients with sarcoidosis. These alterations are the result of peribronchial and endobronchial involvement or airways hyperreactivity and can be seen in all radiographic stages of the disease.

Patients with normal or mildly abnormal pulmonary function tests usually have normal alveolar-arterial oxygen gradients, normal arterial blood gases, and normal exercise tests. Occasionally, exercise testing unmasks modest abnormalities in the alveolar-arterial oxygen gradient, even in patients with stage O or stage I sarcoidosis. As the disease worsens, the alveolar-arterial oxygen gradient at rest increases. This is followed by exercise-induced desaturation and then hypoxia at rest. When carbon dioxide retention is noted, it is almost always the result of advanced disease, often with incipient respiratory failure.

The fact that a significant percentage of patients with stage O or stage I disease on chest x-ray films have restrictive pulmonary function demonstrates that pulmonary function tests are more sensitive in detecting parenchymal lung disease than are chest radiographs. Increases in alveolar-arterial oxygen gradient with exercise may be the most sensitive physiologic parameter, followed by the carbon monoxide diffusing capacity and then the vital capacity. Overall, the degree of physiologic impairment in sarcoidosis correlates with the radiographic stage of disease. Patients with stage O or stage I disease usually have mild physiologic derangements, and patients with stage III or stage IV disease tend to be the most severely restricted (and/or obstructed). The overlap between these categories is large enough, however, to make it difficult and not clinically useful to predict a given patient's pulmonary function from the radiographic stage.

Studies of structure-function relationships in sarcoidosis have shown that pulmonary function tests generally correlate with the overall severity of morphologic changes on lung biopsy. Patients with normal or minimally abnormal pulmonary function tend to have mild inflammatory changes with minimal fibrosis on biopsy. Patients with severely abnormal pulmonary function tend to have more extensive inflammatory changes and/or severe fibrotic changes on biopsy. However, these studies have also shown that the correlation between physiologic abnormalities and pulmonary histology has limitations. Pulmonary function tests may differentiate extremes of histology but do not accurately differentiate moderate from severe disease. In addition, pulmonary function tests do not distinguish the degree to which a defect is caused by interstitial pneumonitis, granulomas, or fibrosis. Thus, in a given individual at a single point in time, pulmonary function tests cannot predict with absolute certainty the

severity, character, or reversibility of the histologic lesion that is present.

Studies of the natural history of sarcoidosis have demonstrated that pulmonary physiologic alterations over time tend to correlate with changes in the severity and activity of disease. Patients whose parenchymal lesions are improving roentgenographically usually have an improvement in their vital capacity and diffusing capacity. Similarly, patients whose parenchymal sarcoidosis is radiographically stable or worsening usually exhibit declines in their vital capacity and/or diffusing capacity. The correlations between histologic severity, disease progression, and pulmonary function provide the rationale for the use of pulmonary function tests in the ongoing evaluation of patients with sarcoidosis. It is important to point out, however, that at the present time there are no pulmonary function criteria that allow the clinician to predict accurately the natural history or response to therapy of a given patient.

Extrathoracic Manifestations

Ophthalmic

In 1936, Heerfordt's syndrome of uveitis, salivary gland involvement, seventh cranial nerve palsy, and fever was recognized to be a form of sarcoidosis. Subsequent studies have shown that the eye and adnexa are involved in 11%–60% of patients with sarcoidosis and that ocular involvement is an important cause of morbidity in this disorder. The types of ocular disease noted in patients with sarcoidosis can be conveniently classified according to whether they involve the anterior eye, the posterior eye, or the orbit and other structures.

The anterior structures of the eye are involved in 80%–90% of patients with ophthalmic sarcoidosis. Granulomatous uveitis and granulomatous conjunctivitis are the two most common lesions. Iris nodules, band keratopathy, and interstitial keratitis occur far less frequently. The granulomatous uveitis can be acute or chronic. Patients with acute uveitis can experience the sudden onset of unilateral optic injection with tearing, blurred vision, and photophobia. Physical examination often reveals circumcorneal ciliary injection, aqueous cells and flares, and “mutton fat” keratitic precipitates. In contrast, chronic uveitis develops more slowly and insidiously. It may be unilateral or bilateral, and when symptomatic, it usually causes pain and blurring of vision. Although keratitic precipitates are often noted, ciliary injection can be absent. Chronic uveitis can lead to adhesions between the iris and lens, glaucoma, cataract formation, and blindness. Chronic uveitis is often seen in association with other manifestations of chronic sarcoidosis, such as lupus pernio, cutaneous plaques, bone lesions, and pulmonary fibrosis. Granulomatous involvement of the conjunctivae occurs in 10%–60% of patients. These conjunctival lesions can appear as tiny, translucent, pale yellow conjunctival follicles. Biopsy specimens of normal-appearing conjunctivae also can show granulomatous inflammation. This involvement can be asymptomatic or cause irritation, resulting in a gritty feeling in the eye.

The posterior structures of the eye are involved in approximately 25% of patients with ocular sarcoidosis. The retina, vitreous, and optic nerve can all be affected. Chorioretinitis, periphlebitis, and chorioretinal nodules are the most frequent lesions. Periphlebitis may be associated with visible evidence of lymphocytic infiltration of venous walls, termed “candle wax drippings.” Cellular aggregates (particularly $CD4^+$ T lymphocytes), hemorrhage and opacities in the vitreous, and local neovascularization are less common. Optic nerve involvement in sarcoidosis can take a number of forms. Papilledema resulting from increased intracranial pressure, optic atrophy, papillitis, optic neuritis, and optic disk granulomas are all well documented. Ninety-five percent of patients with posterior eye involvement also have anterior eye involvement. In addition, the presence of posterior eye involvement should alert the clinician to possible concomitant central nervous system disease, as the incidence of central nervous system involvement is increased in these patients.

Granulomatous infiltration of the lacrimal gland is the most common form of orbital involvement, occurring in 5%–15% of patients with ocular sarcoidosis. It is usually bilateral, often associated with parotid swelling, and can be the sole ocular manifestation. Chronic mass effect from extralacrimal soft-tissue involvement may also be seen. Hyposecretion of tears may occur with any of these and can cause a severe sicca syndrome mimicking that of Sjögren's syndrome. Retro-orbital granulomas are a less common orbital manifestation of sarcoidosis that have been reported to cause unilateral proptosis and hamper extraocular muscle function.

Lymphadenopathy

Granulomatous infiltration of lymph nodes is found in up to 95% of patients with sarcoidosis and may be solely microscopic. Granulomatous involvement may cause visible and palpable adenopathy that is usually symmetric and rarely massive. The nodes tend to be firm, rubbery, discrete, mobile, and painless and are rarely associated with changes in the overlying skin, ulceration, or sinus formation. All major lymph node groups can be involved. Cervical, axillary, epitrochlear, and inguinal lymphadenopathies are found in the order noted. The cervical lymph nodes are enlarged on the right more often than on the left and in the posterior triangle more often than in the anterior triangle. Preauricular, postauricular, submaxillary, submental, mesenteric, and retroperitoneal nodes also can be enlarged. Occipital lymphadenopathy is rare. Massive involvement of retroperitoneal or abdominal lymph nodes may rarely cause abdominal discomfort sufficient to warrant systemic therapy.

Cutaneous Involvement

Cutaneous involvement is seen in 20%–50% of patients with sarcoidosis and can be conveniently divided into two categories: nonspecific, nongranulomatous lesions and specific, granulomatous lesions. Erythema nodosum is the principal nongranulomatous skin lesion, occurring in 9%–17% of patients. Most commonly it is manifested as subcutaneous, erythematous, tender nodules that involve the anterior tibial and other extensor surfaces. Its onset is usually sudden, and its appearance may herald the beginning of the disease. It may be accompanied by a flulike syndrome with fever, fatigue, and polyarthralgia. In addition, it often exists in association with acute uveitis, an elevated sedimentation rate, and bilateral hilar adenopathy. As the lesions of erythema nodosum resolve, they become ecchymotic (erythema contusiformis) and can leave localized areas of hyperpigmentation. Biopsy specimens of erythema nodosum reveal a septal panniculitis. Erythema nodosum is not specific for sarcoidosis. The clinical picture and histology of erythema nodosum associated with sarcoidosis are indistinguishable from those of erythema nodosum associated with other diseases. However, the presence of erythema nodosum in sarcoidosis appears to have prognostic import. Patients presenting with erythema nodosum, polyarthralgias, and bilateral hilar adenopathy (Löfgren's syndrome) have a particularly favorable outcome, with at least 90% experiencing a spontaneous resolution of their disease within 6 to 12 months. In addition, in white patients, erythema nodosum alone may correlate with an improved prognosis.

Granulomatous skin lesions occur in 10%–35% of patients with sarcoidosis. In general, their presence confers an unfavorable prognosis, suggests a higher likelihood of extensive disease, and may warrant local or systemic treatment. Lupus pernio is a granulomatous lesion that is specific for sarcoidosis. It is a chronic, violaceous, nodular or plaquelike eruption on the nose, cheeks, and ears (Fig. 4) and can be associated with fusiform swelling and mutilation of the fingers. Its onset is usually insidious, its course is usually chronic, and it commonly results in significant scarring and deformity. It is most common in women between 40 and 60 years of age and is often associated with other manifestations of chronic sarcoidosis, such as pulmonary fibrosis, bone lesions, uveitis, and upper respiratory tract involvement. Granulomatous infiltration also may cause papules, plaques, nodules, ulcers, ichthyosiform lesions, psoriasis-like lesions, and scarring alopecia. Scarring is not a frequent outcome of these lesions, as it is in lupus pernio.

FIG. 4. Raised lesions of lupus pernio.

Neuroendocrine Involvement

Sarcoidosis causes clinically detectable nervous system disease in 10% of patients. Pathologic studies have shown that subclinical nervous system infiltration occurs in up to 15% of patients. Among patients with clinical neurosarcoidosis, 50%–75% have neurologic manifestations as their presenting feature. Multiple neurologic lesions are present in one third of such patients. Any structure in the central or peripheral nervous system may be involved, resulting in a wide spectrum of clinical disease.

Neurosarcoidosis may cause significant morbidity. It is also associated with a 10% mortality rate, which is approximately twice that of sarcoidosis in general.

A basal granulomatous meningitis is the most common pathologic lesion in the central nervous system of patients with sarcoidosis. It is clinically apparent in approximately two thirds and pathologically present in virtually all patients with central nervous system involvement. The basal predilection of these lesions explains the frequent involvement of the optic nerve, optic chiasm, pituitary, hypothalamus, and periventricular areas. This granulomatous meningitis also can extend along the perivascular space and disrupt the local parenchyma and vascular structures.

Cranial nerve involvement has been reported in 24%–73% of patients with neurosarcoidosis. Seventh (facial) nerve involvement is the most common neurologic manifestation of sarcoidosis. It usually presents as a unilateral peripheral lesion but may also occur bilaterally or in association with other cranial nerve abnormalities. The resulting palsy generally resolves spontaneously, but relapses can occur and result in sequelae such as spasms and contractions. The optic nerve is the next most frequently involved cranial nerve; symptoms and signs include decreased or blurred vision, papilledema, optic atrophy, visual field defects, and pupillary abnormalities. Visual evoked potentials may be abnormal in an asymptomatic patient with optic nerve involvement. Cranial nerves IX and X are the third most commonly involved cranial nerve complex in sarcoidosis; their involvement results in dysphagia, hoarseness, an absent gag reflex, an immobile soft palate, and vocal cord dysfunction. The eighth cranial nerve is the fourth most commonly affected; involvement results in deafness, vertigo, and a sensory-neural hearing loss.

Peripheral nerve involvement has been noted in 15%–18% of patients with sarcoidosis presenting as a mononeuropathy or polyneuropathy with sensory and/or motor abnormalities. As a result, pain, paresthesias, muscle weakness, and depression of tendon reflexes may be found. In one series, ulnar and peroneal nerves were the most frequently involved. A Guillain-Barré–like syndrome has also been described.

Meningeal involvement, with aseptic meningitis, has been reported to be present in 64% of patients with neurosarcoidosis, although most are asymptomatic. In these patients, examination of the cerebrospinal fluid generally shows hyperproteinorrachia, hypoglycorrhachia, and a lymphocytic pleocytosis. Cerebrospinal fluid levels of angiotensin-converting enzyme are elevated in 55% of patients. Cerebrospinal fluid levels of angiotensin-converting enzyme must be interpreted with caution, however, as similar elevations may be found in the setting of bacterial meningitis and tumors of the central nervous system. In patients with known systemic sarcoidosis and suspected neurosarcoidosis, an elevated level of angiotensin-converting enzyme in the cerebrospinal fluid may be helpful in following disease progression or response to therapy.

Hypothalamic-pituitary abnormalities have been noted in approximately 25% of patients with neurosarcoidosis. These patients manifest signs and symptoms caused by (1) anterior pituitary insufficiency, (2) abnormalities of water metabolism, and (3) compression or infiltration of the nearby optic chiasm. The pituitary and hypothalamus can be separately involved. Most studies show extensive infiltration and/or mass lesions in the hypothalamus, with a lesser degree of pituitary involvement. Central diabetes insipidus is the most common manifestation of hypothalamic sarcoidosis. Hypothalamic hyperphagia has also been described. Anterior pituitary insufficiency most commonly presents as gonadal dysfunction with decreased libido, impotence, or amenorrhea, and less commonly as hypothyroidism or adrenal insufficiency. A significant percentage of these patients have elevated prolactin levels and normal pituitary responses to hypothalamic releasing hormones, suggesting that the hypothalamus and hypothalamic stalk are the major sites of involvement.

The abnormal water metabolism that is found in most patients with hypothalamic-pituitary sarcoidosis appears to be of multifactorial origin. In some patients it is the result of partial or complete diabetes insipidus. Other patients appear to have primary abnormalities of thirst. Either or both these abnormalities may result in chronic hypernatremia.

Granulomatous masses may involve any part of the central nervous system. Whereas most of these are diffuse or infiltrating, some are manifested as space-occupying lesions. The clinical presentation of these lesions is not significantly different from that of mass lesions caused by other processes and can include headaches, seizures, localized neurologic dysfunction, papilledema, and uncal or cerebellar tonsillar herniation.

Intracranial hypertension can occur in sarcoidosis as a result of a number of mechanisms. Involvement of the ependyma and choroid plexus can alter cerebrospinal fluid dynamics. Chronic meningitis can cause obliteration of the subarachnoid space and aqueductal stenosis, and intraventricular granulomas can cause outlet obstruction of the fourth ventricle.

The symptoms that result from central nervous system lesions in sarcoidosis can vary depending on the anatomic site of the infiltrative process and the degree to which intracranial pressure is increased. Increased intracranial pressure can cause headache, nausea, vomiting, lethargy, and cranial nerve palsies. Cortical infiltration can mimic cerebrovascular accidents, and basal ganglion involvement can lead to a wide range of extrapyramidal manifestations, including choreiform movements, hemiballismus, and parkinsonism. Seizures occur in 5%–22% of patients with neurologic sarcoidosis. *Grand mal* seizures are most common, but partial, jacksonian, psychomotor, and myoclonic seizures can occur. The presence of seizures is generally associated with a poor prognosis. Patients may respond to corticosteroid therapy. Low-dose whole-brain radiation therapy has also been described as potentially beneficial.

Vascular compromise, manifested as strokes or transient ischemic attacks, rarely occurs in sarcoidosis. This is surprising, as perivascular and vascular infiltration of the meningeal and cerebral vessels, often with local infarction, is well described pathologically. Spinal cord involvement is also extremely rare in sarcoidosis; when present, it is caused by local meningeal involvement with extramedullary compression or intramedullary mass formation.

The diagnosis of neurosarcoidosis is generally facilitated by evidence of sarcoidosis in other organs. Compatible neurologic findings supported by CT, MRI, or cerebrospinal fluid data in the setting of histologic confirmation from other tissues may be adequate for diagnostic purposes. However, this may not obviate the need to examine neurologic tissue in situations in which other etiologies cannot adequately be ruled out.

The diagnosis of nervous system sarcoidosis in the absence of other manifestations of sarcoidosis may be extremely difficult. Biopsy of neurologic tissue or tissue from other, seemingly less involved organs (such as the lung or conjunctivae) may be necessary. Guidance for these biopsies may be provided by CT, MRI, pulmonary function tests, slit-lamp examination, or gallium scanning. The abnormalities noted with these studies are, however, often not specific for sarcoidosis.

Muscle

Skeletal muscle involvement in sarcoidosis can be documented in up to 80% of patients. In the vast majority, this involvement is asymptomatic. Symptomatic muscle disease may be manifested as nodules, myalgias, and frank myopathy. Acute myopathy, although rare, is more common in women. It presents as a polymyositis-like syndrome with muscle pain, weakness, and tenderness. Chronic myopathy is somewhat more common and generally poorly responsive to corticosteroids. It presents with the gradual onset of weakness and wasting and is associated with elevated levels of muscle enzymes and a myopathic electromyogram.

Liver

Although the liver is involved pathologically in 60%–90% of patients with sarcoidosis, clinically significant hepatic disease is infrequent. Small periportal granulomas are noted most commonly. A nonspecific mononuclear cell infiltrate with varying degrees of fibrosis can also be seen. The majority of patients are asymptomatic and have only low-grade increases in serum alkaline phosphatase, transaminases, or bilirubin levels. In some cases, modest hepatomegaly may be found. In a minority of patients, more serious involvement may take the form of chronic hepatocellular injury with secondary cirrhosis, hepatic encephalopathy, portal hypertension, or bleeding esophageal varices. Cases of Budd-Chiari syndrome have been reported. Sarcoidosis may also be associated with chronic intrahepatic cholestasis, which can be difficult to differentiate from primary biliary cirrhosis, and with extrahepatic biliary tract obstruction resulting from granulomatous involvement of the hepatic duct and surrounding lymph nodes.

Hepatic sarcoidosis may also be manifested as a fever of unknown origin (FUO). Patients with hepatic sarcoidosis presenting with FUO often also have abdominal organ, spleen, and lymph node involvement.

Spleen

Granulomatous infiltration of the spleen occurs in up to 60%–90% of patients with sarcoidosis; disease is usually clinically silent. Splenomegaly develops in 5%–15% of patients; in a minority of these, complications such as hypersplenism, splenic rupture, portal hypertension, and abdominal pain develop. Sarcoidosis is only one of many disorders that cause splenic granulomas. Thus, it is important to interpret splenic granulomas in the clinical context in which they are noted.

Heart

The most common cardiac abnormality in sarcoidosis is cor pulmonale, resulting from severe pulmonary disease. Primary cardiac involvement also occurs and is clinically recognizable in 3%–5% of patients. Granulomas, however, are found in up to 30% of patients with sarcoidosis at autopsy. No portion of the heart is immune to granulomatous infiltration. The myocardium is most frequently involved, with the left ventricular free wall being affected most commonly. Involvement of the ventricular

septum, the right ventricular free wall, and the atrial wall follow in order of decreasing frequency. When the left ventricle is involved, the granulomas are most commonly located in the papillary muscles and the free wall below the papillary muscles. The extent of infiltration and scarring and its proximity to vital structures such as the atrioventricular node and conduction pathways appear to be crucial determinants of the clinical import of cardiac involvement. The abnormalities that result from these lesions are quite varied, including arrhythmias, bundle branch blocks, congestive heart failure, mitral regurgitation, ventricular aneurysms, pericardial effusions, and sudden death.

Ventricular tachycardia is the most frequent major arrhythmia occurring in patients with cardiac sarcoidosis. Its appearance usually indicates extensive inflammatory scarring of the heart. Ventricular fibrillation and atrial arrhythmias are less commonly noted. When atrial arrhythmias exist, they are usually the result of atrial dilatation arising from left ventricular dysfunction and not the result of direct granulomatous infiltration. Complete heart block and bundle branch blocks also occur. They are usually caused by involvement of the cephalad portion of the intraventricular septum near the atrioventricular node and conduction bundles, respectively.

Valvular disease occurs in 3% of patients. Mitral regurgitation is well described and may be the result of papillary muscle dysfunction caused by infiltration of the papillary muscle or the left ventricular free wall below the papillary muscle. More often, the lesion is the result of altered papillary muscle dynamics resulting from left ventricular dilatation or dysfunction.

Extensive ventricular involvement can cause congestive heart failure. Ventricular aneurysms that exacerbate congestive failure and arrhythmias can also form. An association between long-term corticosteroid therapy and the development of aneurysms has been reported. However, definitive documentation that steroid therapy predisposes to aneurysm development is still lacking.

There are a number of reasons why establishing a clinical diagnosis of cardiac sarcoidosis may be problematic. First, the clinical manifestations of the disease—chest pain, palpitations, congestive heart failure, electrocardiographic changes, syncope, and light-headedness—are also manifestations of other, more common cardiac disorders. Second, when sarcoidosis causes cardiac dysfunction, it often does not cause dysfunction in other organ systems. Thus, the majority of patients with cardiac sarcoidosis do not have overt lung, eye, or skin involvement that might cause a physician to suspect this disorder.

As many as half of all patients with cardiac sarcoidosis may have electrocardiographic abnormalities. Ventricular arrhythmias are evident in up to 22% of patients. Because of this, Holter monitoring has been suggested as part of the routine evaluation of patients with sarcoid. Subclinical cardiac dysfunction can occasionally be detected by cardiopulmonary exercise testing. Endomyocardial biopsies are useful when they yield myocardial granulomas, but a nonspecific lymphocytic myocarditis is commonly encountered. In addition, the diagnostic sensitivity of endomyocardial biopsies is likely quite variable, given the patchy distribution of granulomatous changes in the heart and the inability of the procedure to obtain samples from the area of the heart that is likely involved. Lastly, a number of investigators have described a pattern of inhomogeneity of thallium uptake in the myocardium of patients with cardiac sarcoidosis. Involved areas are visualized as thallium defects at rest, which then disappear with exercise. This “reverse distribution” pattern is the opposite of that seen during thallium imaging in patients with ischemic coronary disease. The sensitivity and specificity of the “reverse distribution pattern” has not been defined. It is clear that the criteria for patient selection for exercise testing, endomyocardial biopsy, and thallium scanning are poorly defined, and the prognostic significance of cardiac abnormalities found are still unknown.

Electrolyte Abnormalities

Approximately 11% of patients with sarcoidosis are hypercalcemic. The hypercalcemia tends to be episodic in patients with acute sarcoidosis and persistent in patients with chronic disease. It can be mild or severe and life-threatening, and in some patients it is the sole reason for treatment with systemic steroids. Hypercalciuria occurs in 15%–60% of patients with sarcoidosis. When severe, it can cause nephrolithiasis, nephrocalcinosis, and renal insufficiency.

The hypercalcemia and hypercalciuria of sarcoidosis are at least partially a consequence of increased intestinal calcium absorption. This increased absorption is the result of elevated levels of 1,25-dihydroxyvitamin D caused by the accelerated conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. The increased 1-hydroxylation occurs in a parathyroid hormone-independent fashion in the macrophages of sarcoidal granulomas. Thus, sunlight exposure worsens the hypercalcemia seen in these patients.

Increased osteolysis also appears to play a role in the calcium disorder seen in some patients with sarcoidosis. This heightened resorption may may be a direct effect of osseous granulomas, or of bone-resorbing soluble factor(s) such as osteoclast-activating factor.

Kidney

Renal insufficiency in sarcoidosis is generally the result of hypercalcemia and/or hypercalciuria. Granulomatous changes are noted in the kidneys of 4%–40% of patients but rarely cause clinically significant renal dysfunction.

Granulomatous renal arteritis, glomerulonephritis, and altered renal tubular function have been rarely reported. Some investigators feel that sarcoid nephritis is a steroid-responsive disorder. Others believe that although steroid responses can be seen, relapses are common, and renal failure often occurs within 5 years of the clinical onset of the disease.

Joints

Joint signs and symptoms occur in approximately 10%–35% of patients with sarcoidosis. The major manifestations are an acute and chronic polyarthritis.

The acute polyarthritis is seen early in the course of the disease. It is usually a symmetric peripheral arthritis and periarthritis that most commonly involves the ankles and knees, and less commonly the elbows, wrists, and the small joints of hands and feet. Histologically, there is a nonspecific inflammatory synovitis. The clinical presentation includes pain, tenderness, restricted motion, soft-tissue swelling, and joint effusions that can be transient and occasionally precede other signs of the disease. This form of joint involvement is frequently seen in association with bilateral hilar adenopathy, fever, and erythema nodosum (Löfgren's syndrome), and is generally associated with a high rate of spontaneous remission. Erythrocyte sedimentation rates may be elevated. In the absence of bone involvement, radiographic studies are usually normal or reveal soft-tissue swelling. Rarely, periarticular osteoporosis is noted. Acute polyarthritis occurs more commonly in women than in men. It also is more likely to develop and be associated with uveitis, erythema nodosum, and spontaneous remission in individuals who are HLA-B8-positive.

A relapsing chronic polyarthritis develops in 3%–6% of patients with chronic sarcoidosis. Some of these patients have had a previous episode of acute sarcoid polyarthritis, but the majority have not. The shoulders, knees, wrists, ankles, and small articulations of the hands are most commonly involved. Erythema nodosum and fever are uncommon. This involvement can be asymmetric and is rarely monarticular. Radiographic studies reveal soft-tissue swelling, periarticular osteoporosis, mild narrowing of the joint space, and well-defined eccentric erosions. In addition, articular destruction and collapse may result from inflammatory extension into subchondral bone. Histologically, the process is characterized by a granulomatous inflammation of the synovium, articulations, and tendon sheaths. Synovial fluid analysis reveals increased protein, increased leukocytes, and occasionally a lymphocytosis of the joint fluid.

Bone

Osseous involvement occurs radiographically in 1%–13% of patients and is generally associated with chronic sarcoidosis. It is more common in blacks than in whites and is rarely seen without chronic cutaneous lesions (such as lupus pernio), ocular sarcoidosis, and overt lung involvement. Radiographically, sarcoidosis can affect the skeleton in a focal or generalized and usually asymmetric fashion and can cause osteolytic and, less commonly, osteosclerotic lesions. In all cases, these lesions are not specific for sarcoidosis, radiographically resembling the lesions of other diseases. Osteoporosis, cortical thinning, well-defined cysts, and rarefactions are the usual types of lytic lesions. They are encountered most frequently in the hands, with the wrists and feet being less commonly involved. When diffuse, they can cause a latticework or honeycomb pattern. In general, they are not associated with periosteal reactions or sinus tracts, and the joints are not involved except when bone adjacent to the joint is destroyed. Osseous sarcoidosis is generally asymptomatic except in cases in which soft-tissue swelling or bony deformity causes local symptoms. The prognosis for the small number of patients with progressive destructive bony changes is poor, as these lesions tend to be unresponsive to treatment.

Upper Respiratory Tract

Sarcoidosis involves the upper respiratory tract in approximately 2%–6% of patients. Although occasionally seen as an isolated lesion, it is most common in symptomatic patients with manifestations of chronic sarcoidosis, including lupus pernio. The nasal mucosa, pharynx, larynx, nasal bones, and palate can all be involved. Sarcoidosis causes the nasal mucosa to appear erythematous and granular. Epistaxis, stuffiness, crusting, and nasal discharge are common symptoms. In addition, adhesions, polypoid lesions, submucosal nodules, ulcerations, septal perforations, paranasal sinus extension, osteolytic destruction of the nasal bone, and saddle-nose deformities have all been described. Biopsies of the nasal turbinate may need to be performed to differentiate sarcoidosis from other nasal disorders.

Hematologic Manifestations

Hematologic manifestations of sarcoidosis include anemia, lymphopenia, eosinophilia, and thrombocytopenia. Of these, lymphopenia is the most common, occurring in more than half of patients with active disease. A low CD4 count is seen in the peripheral blood, although BAL often reveals an increased number of CD4 cells. Examination of the bone marrow may reveal granulomatous changes.

ESTABLISHING THE DIAGNOSIS

To establish the diagnosis of sarcoidosis, three criteria must be met: (1) The patient's clinical and radiographic presentation must be compatible with sarcoidosis, (2) a biopsy must demonstrate noncaseating epithelioid cell granulomas, and (3) other causes of granulomatous infiltration must be carefully excluded.

The first criterion for diagnosis is usually not difficult to meet, even though the clinical presentation of sarcoidosis varies widely depending on the type and extent of organ involvement. Tissue biopsy specimens can be obtained from a number of sites in the body. The sensitivity of some biopsy techniques for making the diagnosis of sarcoid are detailed in Table 3. The optimal site from which to take a specimen depends on the clinical manifestations, personal preferences, and the procedures that are performed proficiently at a given institution. The gold standard procedure is thoracotomy with open lung biopsy and lymph node sampling, which yields noncaseating granulomas in 90%–100% of patients with sarcoid. Muscle biopsy, scalene node biopsy, and mediastinoscopy also have high sensitivity. However, because of the invasive nature of these procedures and their small but definite incidence of serious complications, they are not the initial diagnostic procedure of choice. Thoracoscopic biopsy may also have a high yield. However, experience with this approach is still quite limited. At our institution, bronchoscopy with transbronchial biopsies is often the procedure of first choice. Because granulomas tend to congregate in the peribronchial area, the diagnostic yield of transbronchial biopsy is high. The procedure can be performed with topical anesthesia in an awake patient with minimal discomfort, and the risk for major complications (pneumothorax, bleeding, respiratory distress) is low. With bronchoscopy, granulomas are obtained in 70%–90% of patients with Stage I disease, 85%–95% of patients with Stage II disease, and 80%–90% of patients with Stage III disease. To achieve this level of sensitivity, it is recommended that at least 4–10 biopsies be obtained. 85%–95% of patients with stage II disease, and 80%–90% of patients with stage III disease. An added advantage of bronchoscopy is that it allows other specimens to be collected for cytologic and microbiologic examination to help rule out other conditions.

Site	Percentage of patients with sarcoidosis having a positive biopsy result	Comments
Skin	30–90	Biopsy of normal skin or erythema nodosum of little value
Liver	75	Large number of diseases cause hepatic granulomas; must be interpreted with caution
Muscle	50–85	Optimal sensitivity requires large biopsy specimen with extensive sectioning and pathologic examination
Conjunctiva	10–63	
Minor salivary gland	58	
Lacrimal gland	21	Higher sensitivity if only enlarged gland or glands that take up gallium 67 are sampled
Scalene lymph node	47–82	
Mediastinoscopy		
Stage I	90–95	
Stage II	90–95	
Stage III	50–63	
Bronchoscopy with transbronchial biopsy		Optimal sensitivity requires up to 4–10 biopsy specimens
Stage I	70–93

Open lung biopsy	90–100	

TABLE 3. *Selected biopsy sites in sarcoidosis*

Biopsy of the skin, conjunctivae, salivary glands, and lacrimal glands may also reveal the diagnosis. Skin biopsies are useful only when the skin is clinically involved by lesions other than erythema nodosum. Biopsies of normal skin and erythema nodosum lesions provide little help in establishing the diagnosis. For conjunctival biopsy to be optimally sensitive, biopsy of clinically involved conjunctivae is necessary, and the fixed tissue must be carefully sectioned and intensively examined. The utility of blind biopsies of normal conjunctivae is still controversial. Similarly, lacrimal biopsies are positive most frequently when the gland is enlarged or positive on gallium scan.

The third criterion for diagnosing sarcoidosis is the exclusion of other causes of tissue granulomatosis (Table 4). Mycobacterial infection, fungal infection, berylliosis, hypersensitivity pneumonitis, granulomatous vasculitis, foreign-body granulomas, and granulomatous reactions in lymph nodes draining malignancies all need to be considered. Mycobacterial and fungal infections can usually be excluded by appropriate staining and culturing of tissue and secretions. However, the proper use and utility of PCR are still being evaluated. In addition, although up to 50% of patients with sarcoidosis are anergic, they usually demonstrate cutaneous sensitivity to tuberculin when actively infected with *M. tuberculosis.* A thorough history may be all that is required to rule out berylliosis and hypersensitivity pneumonitis. When hypersensitivity pneumonitis needs to be considered in greater depth, IgG-precipitating antibodies to the suspected causal antigen should be sought. The beryllium-induced blast transformation assay may be used to make a diagnosis of berylliosis. Histologic examination alone may be adequate to rule out the granulomatous vasculitides, foreign-body granulomas, and concomitant malignancies. If uncertainty remains, a biopsy specimen from a second site may be required.

TABLE 4. *Differential diagnosis of noncaseating granulomas*

Clinical findings and liver biopsy may not allow the physician to differentiate with confidence chronic intrahepatic cholestasis caused by sarcoidosis from primary biliary cirrhosis. Assays for serum antimitochondrial antibodies can be helpful in these cases, because they are positive in 99% of patients with primary biliary cirrhosis and are usually negative in sarcoidosis. In addition, the demonstration of extrahepatic granulomas can be used to support a diagnosis of sarcoidosis.

Crohn's disease also can be difficult to differentiate from sarcoidosis. Both are characterized by the presence of noncaseating granulomas and may be associated with similar dermatologic, hepatic, and ocular lesions. In addition, patients with Crohn's disease may have abnormalities on pulmonary function tests and increased numbers of $OKT4^+$ lymphocytes on BAL. At present, these two diseases are probably best distinguished on the basis of clinical differences. Crohn's disease is usually localized to the digestive tract. In contrast, sarcoidosis is a systemic disease with prominent respiratory, ophthalmic, and cutaneous lesions.

Asymptomatic patients with normal physical examination findings and bilateral hilar adenopathy and patients with bilateral hilar adenopathy and erythema nodosum or uveitis have sarcoidosis with such a high frequency that biopsy confirmation of the diagnosis may not be necessary. This view, however, remains somewhat controversial. Many still feel that histologic confirmation of the diagnosis is essential, as infections, particularly tuberculosis and fungal infections, and neoplasms, particularly lymphomas and primary lung cancers, can cause asymptomatic hilar adenopathy.

Gallium 67 scanning, measurement of serum angiotensin-converting enzyme levels, and BAL with analysis of the recovered cell populations were felt to provide highly specific information allowing a diagnosis of sarcoidosis. However, all these tests are not sufficiently sensitive or specific to be used alone to establish the diagnosis. Gallium scans are positive in only two thirds of patients with sarcoidosis, and increased gallium uptake is seen in many other inflammatory lung disorders. Whereas gallium uptake in cranial, mediastinal, and hilar areas has been postulated to be helpful in diagnosing sarcoidosis, the specificity of these patterns is problematic. Serum levels of angiotensin-converting enzyme are elevated in only 50%–80% of patients with sarcoidosis. Although rare, angiotensin-converting enzyme levels can also be elevated in a wide spectrum of granulomatous and nongranulomatous disorders (Table 5). A predominantly lymphocytic BALF is also not specific for

sarcoidosis, being present in hypersensitivity pneumonitis, berylliosis, lymphomas, and tuberculosis.

TABLE 5. *Selected diseases in which elevated serum levels of angiotensin-converting enzyme have been reported*

A positive Kveim-Siltzbach test result has also been proposed as specific for sarcoidosis. The test is performed by injecting a sterile suspension of sarcoidal tissue intradermally. In patients who have a positive Kveim test result, a nodule will form at the site of the injection in 2 to 6 weeks. The test is then completed by taking a biopsy sample of the nodule and demonstrating that it contains noncaseating granulomas. Many investigators have reported that with properly standardized extract, the test is sensitive and specific for sarcoidosis. However, it is positive most often in patients with typical sarcoidosis. It is far less sensitive in patients with atypical presentations, in whom additional diagnostic studies must be performed. In addition, the test delays a diagnosis by 2 to 6 weeks. Kveim biopsy findings can be difficult to interpret, and patients cannot receive corticosteroid therapy until the test is completed. At present, the lack of readily available standardized antigen extract and the availability of other reliable diagnostic procedures has markedly reduced the use of the Kveim-Siltzbach test in the United States.

EVALUATING THE EXTENT AND SEVERITY OF ORGAN INVOLVEMENT

The extent and severity of organ involvement in sarcoidosis must be assessed when the disease is first diagnosed and periodically thereafter. Assessment must be tailored to the individual patient. There are, however, a number of tests that should be considered for all patients. A complete blood cell count and platelet count provide information about the patient's hematologic profile. Periodic chest x-ray studies and pulmonary function testing help to assess a patient's lung involvement. Initial pulmonary function testing should include spirometry, lung volumes, and diffusing capacity. Patients without obstructive physiology can then be followed with serial measurements of vital capacity and diffusing capacity. An electrocardiogram is adequate initial screening for cardiac involvement in patients without cardiac symptoms. Periodic slit-lamp examinations should be obtained regardless of whether ocular signs or symptoms are present. Liver function tests, including alkaline phosphatase levels, provide an indication of hepatic involvement. Serum calcium, blood urea nitrogen, and creatinine levels should be checked, and a 24-hour urine calcium collection should be performed. These tests may be repeated as necessary to assess therapeutic response.

PROGNOSIS

The majority of patients with sarcoidosis have a good prognosis. In approximately two thirds of patients, the disease resolves spontaneously with minor or no residua. In the other third of patients, the disease smolders or worsens. Overall, 15%–20% of patients suffer a permanent loss of lung function, and approximately 5% die of the disorder. These deaths are most commonly caused by respiratory failure with cor pulmonale and right-sided heart failure. Hemoptysis secondary to bronchiectasis or aspergillomas, arrhythmias resulting from cardiac involvement, nervous system involvement, and uremia are less common causes of death. A number of variables appear to have prognostic import. Those that correlate with a good prognosis include an acute disease presentation plus the presence of erythema nodosum (in whites), acute iritis, a stage I radiograph, and few manifestations of extrathoracic disease. Poor prognostic variables include an insidious disease presentation plus a stage III or IV chest radiograph, bone involvement, lupus pernio, chronic uveitis, upper respiratory tract involvement, bronchial involvement, cor pulmonale, nephrocalcinosis, and hepatomegaly. Genetic background also may have prognostic import. American blacks have a worse prognosis than American whites. In addition, HLA-B8 has been associated with spontaneous disease resolution, and HLA-B13 has been associated with a chronic, persistent form of the disorder.

A rough correlation exists between radiographic stage and the course of intrathoracic disease. Patients with stage I disease have the best prognosis, with approximately 50%–80% experiencing spontaneous radiographic resolution within 1 to 5 years. Approximately 10% of these patients maintain stage I radiographs for long periods of time, and 15%–30% progress to stage II to stage IV disease. Patients presenting with stage II radiographs have a somewhat less favorable prognosis. Approximately 40%–60% of these patients experience a spontaneous radiographic resolution or remission. The remainder have a chronic stage II radiograph or progress to stage III or stage IV disease. Patients with stage III radiographs have the worst prognosis, with spontaneous radiographic resolution occurring only 12%–35% of the time. The remaining patients usually maintain their stage III radiographs, with only 5%–10% progressing to stage IV disease.

ASSESSMENT OF DISEASE ACTIVITY

The signs and symptoms of sarcoidosis can be the result of inflammation or fibrosis. Inflammatory lesions are felt to be potentially reversible, whereas fibrotic lesions are not. Chronic inflammation in sarcoidosis has also been postulated to lead to tissue fibrosis. As a result, it has been assumed that treatment decisions might be made on a more rational basis and a patient's response to anti-inflammatory agents predicted more accurately if patients with active inflammation could be differentiated from those with largely fibrotic disease. This would allow the physician to identify and aggressively treat the patients who are at the greatest risk for development of tissue fibrosis and most likely to benefit from the therapeutic intervention. It would also allow the physician to avoid steroid-induced side effects in patients who are likely to improve spontaneously or not respond to steroid therapy. Clinical signs and symptoms and physiologic abnormalities provide some prognostic data. However, their utility in an individual patient is limited. As a result, a number of other assessment techniques have been employed. Gallium 67 radioisotope scanning, determination of serum angiotensin-converting enzyme activity, and evaluation of BALF have received the most attention.

Angiotensin-Converting Enzyme

Angiotensin-converting enzyme, a normal constituent of the endothelium, converts angiotensin I to angiotensin II. Leiberman et al. reported that in contrast to normal controls, 15 of 17 patients with clinically active sarcoidosis had increased levels of serum angiotensin-converting enzyme. Subsequent studies showed that angiotensin-converting enzyme was aberrantly produced in these patients by granulomatous tissue. Initial reports suggested that angiotensin-converting enzyme levels could be used for diagnosis and assessment of disease activity. Unfortunately, elevated serum levels of angiotensin-converting enzyme are found in only 50%–75% of patients with clinically active sarcoidosis, and the enzyme may be elevated in a number of other conditions, such as hepatic cirrhosis, hyperthyroidism, and diabetes mellitus (Table 5). When elevated, enzyme levels do seem to correlate with the clinical activity in some patients. However, subsequent studies have found angiotensin-converting enzyme determinations to be no more sensitive than chest radiographs in determining the need for treatment. In addition, it has been reported that steroid therapy may lower serum angiotensin-converting enzyme levels independently of changes in disease activity. Thus, the clinical utility of serum angiotensin-converting enzyme levels in staging sarcoidosis remains unsettled.

Gallium 67 Scanning

Another staging procedure, often used in conjunction with BAL, is radioisotope scanning with gallium 67. After intravenous injection, this isotope is actively taken up by inflammatory tissue and accumulates in the lungs and other involved organs of patients with clinically active sarcoidosis. Gallium 67 scanning may provide an index of macrophage activation in patients with sarcoidosis, because it appears that alveolar macrophages are the primary pulmonary inflammatory cells that incorporate gallium 67. As with BAL, the value of this technique in staging has been called into question. However, it may be useful in separating fibrotic from inflammatory disease, and in localizing extrapulmonary sites of disease activity. Gallium 67 scanning is relatively noninvasive and is easily performed serially. The disadvantages of this technique are that it is nonspecific, expensive, and difficult to quantitate, and it exposes the patient to radiation.

Bronchoalveolar Lavage

In the early 1980s, investigators defined two groups of patients with sarcoidosis based on the proportion of T lymphocytes in their BALF. Patients with 28% T lymphocytes in their BALF were said to have “high-intensity alveolitis,” and those with 28% BALF T lymphocytes had “low-intensity alveolitis.” It was proposed that patients with high BALF lymphocyte counts, particularly in association with positive gallium scans, are likely to deteriorate clinically. However, several studies have raised questions about the usefulness of BALF lymphocyte counts alone as a measure of disease activity, response to therapy, or prognosis. Two prospective studies

in patients with newly diagnosed, untreated sarcoidosis followed for long periods of time showed no correlation between BALF lymphocyte counts and initial radiographic findings, pulmonary function abnormalities, need for steroid treatment, and, importantly, long-term outcome. Foley and co-workers found that an increase in the BALF lymphocyte count and CD4/CD2 ratios were actually associated with an improved prognosis. The lack of correlation between BALF lymphocyte counts and disease activity and prognosis has also been noted by Ceuppens and co-workers. They did find, however, that a decrease in or return to normal of the T-cell helper-suppressor ratio accompanied or preceded clinical and radiologic improvement and response to corticosteroid therapy. Thus, quantification of lung T cells does not provide usable prognostic information. In addition, the utility of BALF histamine, angiotensin-converting enzyme, procollagen III aminopeptide, fibrinogen, and vitronectin levels in predicting disease chronicity or the development of fibrosis remains to be proved. Other soluble BALF components, including immunoglobulins, surfactant proteins, reactive oxygen species, and antiproteases, have also been evaluated. Correlation of their presence in lavage fluid with prognosis or disease progression remains an area of ongoing investigation.

BALF cytokine levels might provide prognostic information. Alveolar macrophages from patients with sarcoidosis have been demonstrated to express increased levels of mRNA for TNF-g, IL-6, IFN-g, GM-CSF, and IL-1. It has been suggested that increased levels of each of these cytokines as well as of interleukin-8 in BALF may parallel disease activity. Whether measurements of these and other cytokines in BALF will prove clinically useful in predicting the prognosis of sarcoidosis is unknown.

Measurement of potential serum markers of disease activity may also be useful in this regard. A soluble form of the IL-2 receptor (sIL-2R) is released by activated T cells in many granulomatous disorders. As sIL-2R is easily detectable in serum, several investigators have attempted to use sIL-2R levels to stage disease activity. These studies have found that the levels of sIL-2R are markedly increased in the serum of patients with active sarcoidosis, are significantly lower in patients with inactive disease, and fall with clinical improvement. Although the levels of serum sIL-2R correlate well with clinical parameters, their correlation with BALF T-cell counts, CD4/CD8 ratios, and BALF T-cell HLA-DR expression is poor. If these promising early reports are substantiated, the measurement of serum sIL-2R or BALF levels of sIL-2R may prove to be useful in predicting activity of sarcoidosis.

In summary, measurement of BAL cell profiles, soluble protein levels and cytokine levels, gallium scanning, and serum ACE levels have not been consistently shown to be good predictors of disease progression or response to therapy in patients with sarcoidosis. It is clear, however, that at some centers and in some patients, these assays, particularly if used in serial fashion, have been useful in prognosis and prediction of therapeutic response. At present, it is not clear if the conflicting reports in the literature reflect the true lack of utility of these assays or differences in the patient populations being studied. At present, these tests cannot be relied upon to the exclusion of clinical judgement in making decisions regarding patient management. Thus, until more information is available and newer assays are tested further, it seems most prudent to use traditional criteria, including clinical symptoms, pulmonary function tests, and chest radiographs, as well as indices of inflammation in assessing patients with sarcoidosis.

TREATMENT

It is not necessary to treat all patients with sarcoidosis. Decisions regarding treatment must be individualized, and are best based on individual manifestations of the disease and the clinical course of a given patient.

Extrapulmonary Disease

There is general agreement that systemic therapy with corticosteroids is indicated for any patient with life- or organ-threatening disease and for patients with refractory or progressive organ involvement (or symptoms) that have not responded to topical or symptomatic therapy. Some of the indications for systemic steroids in patients with extrapulmonary sarcoidosis are shown in Table 6. When systemic therapy is required for life-threatening disease, it is recommended that treatment be initiated with 40 to 60 mg of prednisone, given orally, once each day. After a clinical response has been achieved, the daily dose may be tapered by 5 to 10 mg/month. When the daily dose has been reduced to the equivalent of 20 mg of prednisone per day, a schedule of 40 mg on alternate days may be instituted. In patients without life-threatening complications, treatment may be initiated with 40 to 60 mg of prednisone on an alternate-day regimen. This dose is slowly tapered during the next 12 to 18 months, with the rate of taper and ultimate duration of therapy tailored to the clinical status of the patient. If disease reactivation occurs during dose reduction, the daily or alternate-day dose of prednisone should be increased by 10 mg and this dose administered for 2 to 3 months before tapering is attempted again. Some patients may require prolonged or even lifelong therapy.

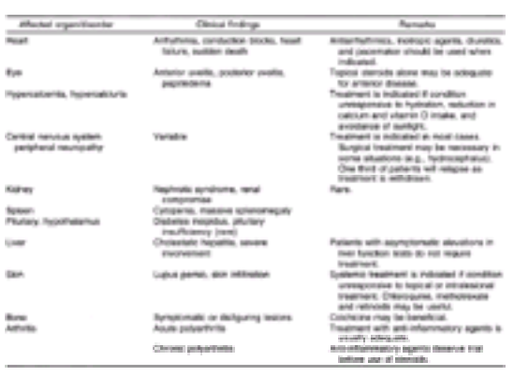

TABLE 6. *Extrapulmonary sarcoidosis: indications for systemic treatment*

It is important to realize that parenteral corticosteroid is not required for all extrapulmonary manifestations of sarcoidosis. Topical steroids are often effective in the treatment of anterior uveitis. Intradermal steroids, chloroquine, methotrexate, and retinoids may cause regression of sarcoid skin lesions, and nonsteroidal anti-inflammatory agents are useful in controlling joint pain and systemic manifestations of sarcoidosis. Colchicine is considered to be particularly effective in the treatment of the arthralgias and periarthritis of sarcoidosis, and mild hypercalcemia can occasionally be managed with hydration, a low-calcium diet, and avoidance of sunlight and vitamin D. Ketoconazole may also be useful in the treatment of hypercalcemia and hypercalcuria, as it decreases the synthesis of 1,25-dihydroxyvitamin D.

Pulmonary Disease

The present treatment of patients with pulmonary sarcoidosis remains a subject of considerable controversy. Given the variability in clinical course, the high rate of spontaneous remission, and the lack of reliable indicators of prognosis, the criteria for initiating and altering systemic treatment with corticosteroids remain ill-defined. This controversy is augmented by the realization that although steroids cause radiographic and functional improvement, their ability to alter the natural history of sarcoidosis is difficult to document.

Some authors advocate treatment of all patients with pulmonary sarcoidosis regardless of symptoms or physiologic abnormalities. Most, however, feel that only patients who are symptomatic or whose condition is deteriorating should be treated. An approach in accordance with this view is summarized below.

1. Patients with stage I disease are often asymptomatic and usually have normal or near normal pulmonary function. They should be carefully observed with serial chest radiographs and pulmonary function tests initially every 3 months. If disease progresses radiographically or if pulmonary function significantly declines (15% decrease in lung volumes or diffusing capacity), treatment with steroids should be initiated.

2. Patients with stage II or stage III disease with normal or near normal pulmonary function and minimal symptoms should be followed serially and treated if they progress as described for stage I patients. Patients presenting with significantly abnormal pulmonary function (lung volumes and/or diffusing capacity 65% of predicted) warrant an empiric trial of steroids. The indices of inflammation noted above are often helpful in defining parameters of disease activity that can be followed in these patients. Clinical status and pulmonary function should also be monitored and chest radiographs taken periodically.

3. Patients presenting with fibrobullous disease (advanced stage III or stage IV) also warrant an empiric trial of steroids. Although the likelihood of reversing fibrotic changes is small, patients with concomitant pulmonary inflammation may improve significantly with therapy.

4. Patients with severe, end-stage lung disease despite treatment may be candidates for single lung or heart-lung transplantation. Referral to an appropriate transplantation center should be made, preferably before the onset of cor pulmonale.

These recommendations parallel those recently made by Sharma in a commentary for the American Thoracic Society.

There is little agreement as to the amount of steroid necessary to adequately treat pulmonary sarcoidosis. Initial dosages, daily versus alternate day regimens, and schedules for tapering vary institutionally and among practitioners. The response (or lack thereof) of the individual patient will largely dictate his or her regimen. In severe cases of pulmonary sarcoidosis, up to 60 mg of prednisone daily may be used as an initial dose. In most other cases, a lower prednisone dose of 40–60 mg every other day can be used from the outset. The patient is then observed on therapy for up to several months.

In patients who appear to respond, the initial prednisone dose (40–60 mg/day) is maintained for 3 to 6 months and then reduced by 5 to 10 mg every 1 to 3 months. This usually results in a total duration of therapy of between 12 and 15 months. In patients who do not respond, steroids are tapered and discontinued more rapidly.

Relapses can occur during the treatment period. When a relapse occurs, the most recent effective dose should be reinstituted for 2 to 3 months and then tapering should be attempted. A few patients require lifelong steroid therapy, although usually at relatively low doses. Others have remissions, only to have reactivation of disease years later. For these reasons, most patients with sarcoidosis should remain under observation indefinitely and have their disease activity periodically reassessed.

Agents Other Than Steroids

The use of cytotoxic agents in the treatment of refractory sarcoidosis is based on uncontrolled studies that claim or refute therapeutic success with a variety of agents. Methotrexate has been used in uncontrolled trials in low doses (e.g., 10 mg/week) with some success, particularly in patients with severe skin involvement. Long-term therapy with methotrexate carries the risk for hepatotoxicity. Serial liver biopsies may be required to monitor this potential problem. Cyclophosphamide, azathioprine, and chlorambucil have also been used and appear to be of limited value. Cyclosporine has been reported in case studies to be of benefit in pulmonary sarcoidosis refractory to corticosteroids. Thalidomide has also been reported to be of benefit in one case of cutaneous and pulmonary sarcoidosis. There are no known advantages of any of these agents. The choice between these drugs is best dictated by the clinician's familiarity with each and the patient's clinical presentation. In cases in which active sarcoidosis is not adequately treated with high-dose steroids or in which the patient cannot tolerate steroids because of side effects, a trial of one of these agents may be warranted.

Transplantation

End-stage organ failure may develop in patients with severe sarcoidosis. In such situations, transplantation of solid organs, including lung, heart, liver, and kidney, has been successfully performed. It has been well documented that noncaseating granulomas can be seen in lung and heart allografts after transplantation. This finding appears to be specific for patients with sarcoidosis and is not observed in allografts of patients who have undergone transplantation for other diseases. Fortunately, clinical disease caused by recurrent sarcoidosis in the transplanted organ is uncommon. This may be in part a consequence of the uniform use of immunosuppressive agents to prevent transplant rejection. As sarcoid recurrence in allografts appears to be associated with little in the way of clinical symptoms or organ dysfunction, transplantation remains a viable option for patients with sarcoidosis-induced end-stage organ failure.

Interestingly, there have been case reports in which sarcoidosis appears to have been transmitted via organ donation. Experience is not yet broad enough to determine if subsequent clinical manifestations related to sarcoidosis will be severe enough to exclude persons with sarcoidosis from organ donation.

Lieberman J, Schleissner LA, Nosal A, Sastre A, and Mishkin FS. Clinical correlations of serum angiotensin-converting enzyme (ACE) in sarcoidosis: A longitudinal study of serum ACE, 67-gallium scans, chest roentgenograms, and pulmonary function. *Chest* 1983;84:522–528.

Liebow AA, The J. Burns Amberson Lecture—pulmonary angiitis and granulomatosis. *Am Rev Respir Dis* 1973;108:11–18. *Extensive classic clinicopathologic discussion of pulmonary angiitis and granulomatosis, including Liebow's original description of necrotizing sarcoid granulomatosis.*

Lohmann-Matthes M-L, Steinmuller C, Franke-Ullmann G. Pulmonary macrophages. *Eur Respir J* 1994;7:1678–1689. *Comprehensive review of pulmonary macrophages, covering cellular origin and localization, metabolic functions, surface markers, and cytokine production.*

Lower EE, Baughman RP. Prolonged use of methotrexate for sarcoidosis. *Arch Intern Med* 1995;155:846–851. *Nonrandomized trial evaluating the safety and efficacy of methotrexate in patients with sarcoidosis. Fifty patients who completed at least 2 years of methotrexate therapy were monitored.*

Mangiapan G, Hance AJ. Mycobacteria and sarcoidosis: an overview and summary of recent molecular biological data. *Sarcoidosis* 1995;12:20–37. *Extensive review taking a new look at the proposed relationship between sarcoidosis and mycobacterial infection using molecular techniques (polymerase chain reaction).*

Martinez EJ, Orens JB, Deeb M, Brunsting LA, Flint A, Lynch JP. Recurrence of sarcoidosis following bilateral allogeneic lung transplantation. *Chest* 1994;106:1597–1599. *One of several reports documenting recurrence of sarcoidosis after lung transplantation.*

Meyrier A, Valeyre D, Bouillon R, Paillard F, Battesti JP, Georges R. Different mechanisms of hypercalciuria in sarcoidosis. Correlations with disease extension and activity. *Ann N Y Acad Sci* 1986;465:575 (Johns C, ed. *Tenth International Conference on Sarcoidosis and Other Granulomatous Disorders*). *Good review of mechanisms of hypercalciuria in sarcoidosis.*

Muller-Quernheim J, Pfeifer S, Mannel D, Strausz J, Ferlinz R. Lung-restricted activation of the alveolar macrophage/monocyte system in pulmonary sarcoidosis. *Am Rev Respir Dis* 1992;145:187. *In this study, alveolar macrophages isolated from the lungs of patients with active sarcoidosis spontaneously released TNF-*a *and IL-1, whereas peripheral blood monocytes from these same patients did not. This observation supports the concept of compartmentalized activation of cells involved in the inflammatory process in sarcoidosis.*

Roberts WC, McAllister HA, Ferrans VJ. Sarcoidosis of the heart: a clinicopathologic study of 35 necropsy patients (group I) and review of 78 previously described necropsy patients (group II). *Am J Med* 1977;63:86. *Extensive study of the histopathology of cardiac sarcoidosis.*

Rochester CL, Elias JA. Cytokines and cytokine networking in the pathogenesis of interstitial and fibrotic lung disorders. *Semin Respir Med* 1993;14:389–415 (Rhagu G, ed. *Interstitial Pulmonary Disorders*). *Comprehensive review of cytokines and cytokine networking in interstitial lung diseases, including sarcoidosis.*

Satorre J, Antle CM, O'Sullivan R, White VA, Nugent RA, Rootman J. Orbital lesions with granulomatous inflammation. *Can J Ophthalmol* 1991;26:174. *Extensive review of causes of granulomatous inflammation of the orbit.*

Schauman J. *Sur le Lupus Pernio. Memoire Présenté en Novembre 1914 à la Société Française de Dermatologie et Syphilégraphic pour le Prix Zambaco.* Stockholm: PA Norsledt och Soness Furlag; 1934. *One of the original descriptions of lupus pernio.*

Scott TF. Neurosarcoidosis. *Neurology* 1993;43:8–12. *Review of neurosarcoidosis, including a brief summary of cerebrospinal fluid findings.*

Selroos O. Sarcoidosis and pregnancy: a review with results of a retrospective survey. *J Intern Med* 1990;227:221–224. *Interesting retrospective analysis of 38 pregnant women with sarcoidosis, including a literature review of the topic.*

Shammas RL, Movahed A. Sarcoidosis of the heart. *Clin Cardiol* 1993;16:462–472. *Review of cardiac sarcoidosis, including clinical manifestations, diagnostic techniques, treatment, and management.*

Sharma OP. Pulmonary sarcoidosis and corticosteroids. *Am Rev Respir Dis* 1993;147:1598–1600. *Commentary on the role of corticosteroids in the treatment of sarcoidosis, including recommendations for dosage and duration of therapy.*

Sharma OP. Myocardial sarcoidosis. A wolf in sheep's clothing. *Chest* 1994;106:988–990. *Commentary on diagnosis, evaluation, and treatment of cardiac sarcoidosis.*

Sharma OP, Sharma AM. Sarcoidosis of the nervous system. A clinical approach. *Arch Intern Med* 1991;151:1317. *Good review of neurosarcoidosis, with extensive bibliography.*

Shijubo N, Imai K, Shigehara K, Honda Y, Koba H, Tsujisaki M, Hinoda Y, Yachi A, Ohmichi M, Hiraga Y, Abe S. Soluble intercellular adhesion molecule-1 (ICAM-1) in sera and bronchoalveolar lavage fluid of patients with idiopathic pulmonary fibrosis and pulmonary sarcoidosis. *Clin Exp Immunol* 1994;95:156–161. *One of a number of studies demonstrating the compartmentalized immune response in sarcoidosis. In this study, patients with sarcoidosis were found to have normal levels of circulating ICAM-1 but had increased levels of ICAM-1 in BALF.*

Takemura T, Matsui Y, Oritsu M, Akiyama O, Hiraga Y, Omichi M, Hirasawa M, Saiki S, Tamura S, Mochizuki I, Mikami R. Pulmonary vascular involvement in sarcoidosis: granulomatous angiitis and microangiopathy in transbronchial lung biopsies. *Virchows Archiv A Pathol Anat* 1991;418:361. *Pathologic study of 174 cases of sarcoidosis showing a significant (53%) prevalence of granulomatous angiitis and microangiopathy.*

Tanoue LT, Elias JA. Cytokines and interstitial lung disease. In: Leff A, ed. *Pulmonary and Critical Care Pharmacology and Therapeutics.* New York: McGraw-Hill; 1996:275–284. *Overview of cytokines and cytokine interactions in interstitial lung disease, including sarcoidosis, with extensive bibliography.*

Teirstein AS, Lesser M. Worldwide distribution and epidemiology of sarcoidosis. In: Fanburg BL, ed. *Sarcoidosis and Other Granulomatous Diseases of the Lung.* New York: Marcel Dekker; 1983:101–134 (vol 20; chapter 4). *Description of the worldwide epidemiology of sarcoidosis, broken down by continent and country.*

Tenneson M. Lupus pernio. *Bull Soc Fr Dermatol Syphilol* 1892;3:417. *One of the original descriptions of sarcoidosis of the skin.*

Thomas PD, Hunninghake GW. Current concepts of the pathogenesis of sarcoidosis. *Am Rev Respir Dis* 1987;135:747–760. *Extensive, well-written review of sarcoidosis, including clinical manifestations, pathology, etiology, and immune pathogenesis.*

Vandenplas O, Depelchin S, Delaunois L, Delwiche JP, Sibille Y. Bronchoalveolar lavage immunoglobulin A and G and antiproteases correlate with changes in diffusion indices during the natural course of pulmonary sarcoidosis. *Eur Respir J* 1994;7:1856–1864. *An evaluation of BALF immunoglobulin and antiprotease levels and T4/T8 lymphocyte ratios as potential predictive markers for changes in diffusion indices in patients with sarcoidosis. The authors point out that duration of disease is important in the evaluation of potential parameters of disease activity.*

Verstraeten A, Demedts M, Verwilghen J, van den Eeckhout A, Marien G, Lacquet LM, Ceuppens JL. Predictive value of bronchoalveolar lavage in pulmonary sarcoidosis. *Chest* 1990;95:560. *One of multiple studies examining lymphocyte populations in BALF. As in other reports, a high ratio of T4 cells to T8 cells and a high lymphocyte count are consistent with an alveolitis, but do not predict course or prognosis of disease.*

Weissler JC. Southwestern Internal Medicine Conference. Sarcoidosis: immunology and clinical management. *Am J Med Sci* 1994;307:233–245. *Overview of immunopathogenesis of sarcoidosis with commentary on clinical management.*

Wilson JD, Castillo M. Magnetic resonance imaging of granulomatous inflammations: sarcoidosis and tuberculosis. *Top Magn Reson Imaging* 1994;6:32–40. *Discussion of the role of magnetic resonance imaging in the diagnosis of neurosarcoidosis.*

Winterbauer RH, Moores KD. A clinical interpretation of bilateral hilar adenopathy. *Ann Intern Med* 1973;78:65. *Sentinel article examining 100 patients with bilateral hilar adenopathy. Bilateral hilar adenopathy in patients without symptoms and with negative physical examination was felt always to be associated with sarcoidosis. The authors propose that biopsy confirmation in these cases is not necessary.*

Wollschlager C, Khan F. Aspergillomas complicating sarcoidosis. A prospective study in 100 patients. *Chest* 1984;86:585. *A comprehensive examination of aspergilloma complicating sarcoidosis.*
